  The Netsh commands for Interface Portproxy provide a command-line tool for administering servers that act as proxies between IPv4 and IPv6 networks and applications. For more information about how to use the Netsh Interface PortProxy commands, see the Netsh command-line help or see "Netsh commands for Interface PortProxy" in Help and Support Center for Windows Server 2003.

- Ipsec6.exe

  For experimenting with IPSec for IPv6, you can use the Ipsec6 tool to configure IPSec policies and security associations in

an IPv6 environment. For more information about Ipsec6, see "IPv6 utilities" in Help and Support Center for Windows Server 2003.

- Network Monitor (Netmon.exe)

  The Network Monitor tool (Netmon.exe) is a protocol analyzer that you can use to monitor a new network design. For more information about Netmon.exe, see "Network Monitor" in Help and Support Center for Windows Server 2003.

# Deploying DHCP

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Dynamic Host Configuration Protocol (DHCP) in the Microsoft® Windows® Server 2003 family of operating systems enables centralized automatic management of IP addresses and other TCP/IP settings for network clients. You can reduce administrative overhead in your organization by designing and implementing a reliable and scalable DHCP solution.

**In This Chapter**

Overview of DHCP Deployment

Creating Your DHCP Server Design

Integrating DHCP with Other Services

Defining Scopes

Implementing Your DHCP Solution

Example DHCP Implementation

Additional Resources for Deploying DHCP

**Related Information**

- For more information about Dynamic Host Configuration Protocol (DHCP), see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

- For more information about integrating DHCP with Domain Name System (DNS), see "Deploying Domain Name System (DNS)" in this book.

- For more information about integrating DHCP with Windows Internet Name Service (WINS), see "Deploying WINS" in this book.

# Overview of DHCP Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Valid IP addresses and other network options must be configured for all computers and other devices on the network, such as printers, in a corporate network. Manually configuring this information is a time-consuming process that adds significant costs to an organization and is susceptible to user error.

Windows Server 2003 Dynamic Host Configuration Protocol (DHCP) reduces the complexity and administrative overhead involved in managing network client IP addressing and configuration. DHCP allows you to assign IP addresses to network clients automatically and dynamically, as needed, and to automate, centralize, and simplify IP address and option configuration and distribution across your network. This protects against common configuration errors that occur when values are entered manually at each computer and helps to prevent address conflicts.

By using DHCP options, you can configure DHCP servers to supply a full range of configuration values when assigning a DHCP lease, allowing you to configure a large number of computers at one time, and to change configuration as necessary.

Different types of organizations can benefit from the automation and centralization that Windows Server 2003 DHCP provides, including:

- Organizations in which administrators are responsible for configuring IP addresses and options for a large number of devices.
- Organizations that include a large population of mobile users or network configurations that frequently change.
- Organizations that already use versions of DHCP earlier than Microsoft® Windows® 2000, which can benefit from the added functionality of Windows Server 2003 DHCP by upgrading their DHCP deployment.

If you are deploying DHCP in a new Windows Server 2003 environment, begin your deployment process by creating a design for your DHCP servers. When you have completed all of the design steps for your DHCP infrastructure, you can implement your DHCP solution by configuring your DHCP servers. If you are upgrading your existing DHCP infrastructure to Windows Server 2003, begin by reviewing your current DHCP design and modifying it if required, and then migrate your existing DHCP databases.

# DHCP Deployment Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Deploying or upgrading DHCP in your organization involves several important planning, design, and implementation steps. Figure 2.1 shows the process for deploying DHCP.

**Figure 2.1 Deploying DHCP**

# Creating Your DHCP Server Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is important to create a DHCP server design that meets the needs of your organization in terms of functionality, availability, interoperability, and total cost of ownership (TCO).

Figure 2.2 shows the process for creating a DHCP server design.

**Figure 2.2 Designing Your DHCP Server**

# Upgrading Your Existing DHCP Server Hardware

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Determine whether your current hardware and software, including routers, switches, and other servers and clients, support Windows Server 2003 DHCP. Windows Server 2003 DHCP servers support Windows DHCP clients and third-party operating systems that use DHCP and comply with RFC 2131. For more information about the operating systems that support DHCP, see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

If your current systems support Windows Server 2003, but are close to the end of their expected lifecycle, consider upgrading your hardware at the same time that you upgrade to Windows Server 2003. Upgrading DHCP servers running Microsoft® Windows NT® Server version 4.0 or earlier to Windows Server 2003 allows you take advantage of benefits related to the Active Directory directory service, such as integrated secure dynamic updates of the DNS database.

For information about hardware life expectancy, contact your hardware vendor or refer to any internal metrics that your organization might have developed. For information about hardware compatibility, see the Windows Catalog link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

For more information about performing a hardware inventory, see "Planning for Deployment" in *Planning, Testing, and Piloting Deployment Projects* of this kit.

# Determining DHCP Server Locations

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To determine where to locate your DHCP servers, consider whether you are deploying a distributed, centralized, or combined DHCP infrastructure.

For a distributed DHCP infrastructure, locate a DHCP server on each subnet. Because distributed infrastructures use a DHCP server on each subnet, they require a greater number of servers than centralized networks. For example, a network that includes 30 subnets and that is using a true distributed topology requires at least 30 DHCP servers, and possibly more to provide for redundancy.

In a centralized DHCP infrastructure, DHCP servers are placed in a central location. A centralized DHCP topology requires the deployment of DHCP/bootstrap protocol (BOOTP) relay agents. Additional hardware resources are not generally required for DHCP relay agents; in most cases, the routers that are positioned between each subnet can assume this role, as defined in RFC 1542. If the routers cannot relay DHCP messages, configure a computer running Windows Server 2003 to act as a DHCP/BOOTP relay agent. For more information about configuring relay agents, see "Enabling DHCP Support for Multiple Subnets" later in this chapter.

Combining both distributed and centralized DHCP infrastructures provides the maximum efficiency for your network. In a combined DHCP infrastructure, the locations for DHCP servers are based on the physical characteristics of the local area network (LAN) or wide area network (WAN) infrastructure, and not the logical groupings defined by the Active Directory logical structure. DHCP servers are not required for every subnet if the connecting routers support DHCP/BOOTP relay agents. You can administer Windows Server 2003 DHCP servers remotely from a computer running Windows Server 2003 and Microsoft Management Console (MMC) DHCP snap-in. You can also administer a DHCP server remotely at the command line by using Netsh commands for DHCP, or you can remotely administer a DHCP server from a computer running Microsoft® Windows® XP Professional that has the Windows Server 2003 Administration Tools Pack installed. You must have the correct level of security permissions in order to administer a DHCP server. For more information about using the Windows Server 2003 Administration Tools Pack, see "Windows Server 2003 Administration Tools PackWindows Server 2003 Administration Tools Pack" in Help and Support Center for Windows Server 2003.

# Optimizing DHCP Server Performance

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can optimize the performance of DHCP servers in your organization by doing the following:

- Extending the duration of the IP address lease.
- Improving DHCP server hardware, specifically upgrading to a faster hard drive or adding random access memory (RAM).

**Extending the IP Address Lease and Renewal Duration**

The volume of traffic on your network can have a negative impact on DHCP performance. For example, a subnet that relies on a DHCP server at a remote location on the WAN might experience poor performance at start of day, when users turn on computers and a large load of requests might be sent over the network.

DHCP traffic does not use significant network bandwidth during periods of normal usage; however, the following two phases of DHCP client configuration generate some network traffic load:

- IP address lease
- IP address renewal

When a DHCP client initializes TCP/IP or renews its address lease, it acquires an IP address from the DHCP server. This process results in an exchange between the DHCP client and the DHCP server, which typically consists of four packets, each containing a maximum of 4 kilobytes (KBs). For more information about the DHCP exchange, see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

You can reduce the amount of network traffic generated by DHCP IP address lease and IP address renewal by extending the lease duration. Before you extend the lease duration, you must take into consideration other factors in your network, such as ratio of clients to available IP addresses, or clients that frequently lease addresses on more than one subnet, such as laptops that move frequently. If you have a relatively stable network and many more available IP addresses than DHCP clients, increasing the lease duration reduces network traffic, because DHCP messages are sent less frequently. If, however, you have a limited number of IP addresses available to your DHCP clients, or a network that changes frequently, a longer lease duration might cause you to run out of IP addresses because IP addresses are not returned to the address pool and made available to other DHCP clients until the lease expires. For more information about extending the lease duration, see "Determining Lease Duration" later in this chapter.

**Improving DHCP Server Hardware**

You can optimize DHCP performance in your system by optimizing individual DHCP server performance. Windows Server 2003 includes performance monitoring tools that you can use to test and monitor your servers.

For more information about performance monitoring tools, see "Performance Monitoring Tools" in Help and Support Center for Windows Server 2003.

The primary factors that impact DHCP server performance include:

- The speed of the server disk drives.
- The amount of RAM installed in the DHCP server computer.

The greatest volume of disk usage occurs when the service is started and when the database is backed up. When planning your DHCP server hardware specifications, evaluate the average time required for disk access and for disk read/write operations. If necessary, maximize DHCP server performance by increasing RAM and purchasing high-speed disk drives for the servers.

# Enabling DHCP Support for Multiple Subnets

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you have multiple subnets in your network, and do not have a DHCP server on every subnet, determine whether your current routers relay DHCP/BOOTP messages.

If your routers cannot be used for DHCP/BOOTP relay, set up a DHCP/BOOTP relay agent on at least one computer running Windows Server 2003 on each subnet. The DHCP/BOOTP relay agent relays DHCP and BOOTP message traffic between the DHCP-enabled clients on the local network and a remote DHCP server located on another physical network by using the IP address of the remote DHCP server.

Figure 2.3 shows a simple, routed network in which the router acts as a DHCP relay agent.

**Figure 2.3 Subnets Configured to Use a DHCP Relay Agent**

If your routers cannot be used for DHCP/BOOTP relay and you choose not to configure DHCP/BOOTP relay agents, you must configure your network so that a DHCP server has a network adapter on each subnet it serves. You can accomplish this by either placing a DHCP server on each subnet, or by multihoming DHCP servers. This distributed configuration does not provide fault tolerance. If a DHCP server becomes unavailable, DHCP clients on the subnet cannot receive IP addresses and options.

**Note**

- The DHCP Relay Agent service is available only on computers running Windows Server 2003, Microsoft® Windows® 2000, or Windows NT 4.0. To use the DHCP Relay Agent routing protocol, the Routing and Remote Access service must be installed and enabled.

For more information about installing and configuring DHCP relay agents, see "Configure the DHCP Relay Agent" in Help and Support Center for Windows Server 2003. For more information about the DHCP Relay Agent service, see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit) or see Help and Support Center for Windows Server 2003.

# Determining How Many DHCP Servers to Deploy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A single DHCP server can serve an almost unlimited number of clients. However, factors such as the size and layout of your network, the IP address class selected for use, and the volume of traffic on your network often make this impractical. You can deploy multiple DHCP servers to reduce the volume of DHCP-related traffic across your network and create faster response times for DHCP messages. Deploying multiple DHCP servers also creates fault tolerance on your network. If you choose to deploy more than one DHCP server, it is important to weigh the benefits of increased response times against the costs required for additional hardware.

When deciding how many DHCP servers you need, consider:

- The location of DHCP-enabled clients on your network.

- The transmission speeds between the segments for which DHCP service is provided.

  If you have slower WAN or dial-up links, place a DHCP server on both sides of these links to improve DHCP response times for local clients.

- The network traffic that DHCP produces, as well as your current network traffic.

  If your current volume of network traffic is high, consider deploying multiple DHCP servers to reduce the volume of DHCP requests traveling across the network. Make sure to account for periods when network traffic is heaviest, such as the beginning of the day, when many users turn on their computers at the same time.

- Disk space requirements.

  It is important to consider the database size when choosing your hardware. Each lease requires approximately 600 bytes per lease for the database, plus 1200 bytes for backup (600 bytes for the backup and 600 bytes for the temporary directory). In addition, the audit logs require approximately 500 bytes per lease transaction and are stored for seven days.

  **Tip**

  - In general, allow at least 50-70 MB for the audit logs, however the number of lease transactions depends on the number of leases as well as the lease duration.

  To figure out how much hard disk space is required, first multiply the number of leases by 600 bytes, then multiply the estimated number of lease transactions by 500 bytes, and add these two results. The sum is the minimum amount of disk space required by the DHCP server.

  For example, a DHCP server with 10,000 leases and lease duration of one week requires approximately 18 MB to store the leases and the backup (6 MB for the database, 6 MB for the backup, and 6 MB for the temporary database). The audit logs would require an absolute minimum of 10 MB: 5 MB (500 bytes x 10,000 leases) for startup, and 5 MB when the leases renew halfway through the week. If the number of leases increases or if lease time is shortened, this requirement will increase. A company might allocate 100 MB for audit logs to allow for flexibility in adding leases or reducing lease duration, as well as dealing with any peak-load events.

# Optimizing DHCP Availability

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A highly available solution must account for all possible points of failure, including server failures, WAN link interruptions, and router failures. You can increase the fault tolerance and availability of your design by using one or more of the following, depending on your needs and hardware cost considerations:

- Split-scope configurations
- Clustered DHCP servers
- Using standby servers

# Using Split-Scope Configurations

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can increase fault tolerance by splitting DHCP scopes between multiple DHCP servers. With a split-scope configuration, if one server becomes unavailable, the other server can take its place and continue to lease new IP addresses or renew existing clients. Splitting DHCP scopes also helps to balance server loads.

When splitting the IP address pool of a scope between two servers, assign the same scope to both servers, and exclude opposite portions of the address range. You also need to make identical reservations at both DHCP servers, so that either server can assign the reserved IP address, ensuring that the intended device receives the address that is reserved for its use.

Figure 2.4 shows a network that is using a split-scope configuration.

**Figure 2.4 Split-Scope Configuration**

In Figure 2.4, DHCP Server 1 has 80 percent of the addresses in the scope and DHCP Server 2 has 20 percent of the addresses in the scope. Splitting a scope between servers in this way, which is commonly referred to as the "80/20 rule," often relies on the proximity of the DHCP servers to the clients it serves. For example, when a DHCP client that is on the same subnet as DHCP Server 1 sends out a DHCP Discover packet, it takes longer for DHCP messages from clients to reach the DHCP Server 2 than DHCP Server 1, because DHCP Server 2 is on the other side of a router from the DHCP client. You can also configure a delay on the DHCP relay agent to ensure the local DHCP server has adequate time to respond. Because DHCP clients always accept the lease from the DHCP server that sends the first response, clients normally obtain leases from DHCP Server 1. If DHCP Server 1 goes offline for any reason, clients accept leases from DHCP Server 2.

# Using Clustered DHCP Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 DHCP can use Windows Clustering, which allows two or more servers to be managed as a single system. You can increase DHCP (or multicast address dynamic client allocation protocol [MADCAP]) scalability, availability, and reliability by using the Cluster service to deploy a DHCP server cluster.

By using clustering support for DHCP, you can implement a local method of DHCP server failover. In this way, you can achieve greater fault tolerance and minimize disruptions and work stoppages. Windows Clustering can automatically detect the failure of an application or server and restart the application on or transfer the server role to an alternate server. Users experience only a brief break in service.

Windows Clustering creates a virtual DHCP server so that if one of the clustered nodes fails, the namespace and all of the services contained in that node are automatically transferred to a second node. No changes are visible to the client, which sees the same IP address for the clustered DHCP servers.

Use Windows Clustering alone to create a fault-tolerant design that makes efficient use of available IP addresses. To further enhance DHCP fault tolerance and availability, combine DHCP server clustering with a remote failover configuration — such as a split-scope configuration across different segments of your network. Although combining server clustering with a split-scope configuration increases DHCP availability, you must consider whether the benefits to your organization outweigh the hardware costs involved.

Figure 2.5 shows an example of clustered DHCP servers. DHCP Server 1 is the active DHCP server, and DHCP Server 2 is the backup DHCP server.

**Figure 2.5 Clustered DHCP Servers**

**Example: Using a Split-Scope Configuration in Combination with a DHCP Server Cluster to Enhance Availability and Fault Tolerance**
A company has its main corporate office in North America, and two European offices in Milan and Seville. The North American DHCP server cluster includes two servers, which are configured as nodes of the server cluster.

Twenty percent of the available IP leases for the Milan and Seville sites are configured on the North American server cluster. The remaining 80 percent of the available IP leases are configured on the local Milan and Seville DHCP servers.

This configuration provides the following levels of fault tolerance for the European sites:

1. Under normal circumstances clients in Milan and Seville request IP lease assignments from the local DHCP server, which contains 80 percent of the available IP addresses for the subnet.

2. If either the Milan or Seville DHCP server is slow or unavailable, European DHCP clients use the North American DHCP server, which contains 20 percent of the available IP addresses for the Milan and Seville subnets. The relay agent between the European offices and the North American office is configured to delay the DHCP messages from the European offices, allowing the local (Milan or Seville) DHCP server enough time to respond.

3. Because the North American DHCP server is configured as a server cluster, if one node of the cluster becomes unavailable, Windows Clustering automatically brings the other node online.

# Using Standby Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A standby server and its scopes are not activated for use under normal conditions, and are activated by the administrator only when needed, such as when a DHCP server fails or is taken offline for an extended period of time. Standby servers require manual administration to ensure failover transition, and therefore might not be as effective as other failover methods, such as split scopes and clustered servers.

To use a standby configuration, configure an additional DHCP server to server as a backup if the primary server goes offline. You can either configure the standby server to be identical to your primary DHCP server or configure the standby server with unused scopes to temporarily replace the primary DHCP server.

If you are configuring the standby server with the identical scope to your primary DHCP server, you must implement server-side address conflict detection to prevent the assigning of duplicate addresses.

**Important**

- Because server-side conflict detection uses Address Resolution Protocol (ARP) and Internet Control Message Protocol (ICMP) messages to detect conflicts, Internet Connection Firewall (ICF) or other firewalls that are installed on clients on your network might interfere with conflict detection.

For more information about backing up your DHCP servers, see "Backing up the DHCP databaseBacking up the DHCP database" or "Netsh commands for DHCP" in Help and Support Center for Windows Server 2003.

# Integrating DHCP with Other Services

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you use DHCP servers for Microsoft network clients, you must use a name resolution service. Networks that support clients running Windows 2000, Microsoft® Windows® XP Professional, and Windows Server 2003 use the DNS service to support name resolution. Networks that support clients running versions of the operating system earlier than Windows 2000 must use a form of NetBIOS name resolution, such as WINS. Networks that support both types of clients must implement both WINS and DNS servers.

Windows Server 2003 DHCP provides support for both DNS dynamic updates and secure DNS dynamic updates. DHCP and DNS work together to perform dynamic updates and work with Active Directory to perform secure DNS dynamic updates. DHCP also works with Active Directory to prevent unauthorized DHCP servers from running on the network.

Figure 2.6 shows the process for integrating DHCP with other services.

**Figure 2.6 Integrating DHCP with Other Services**

For detailed instructions on using this template, right click on the blank page with all objects de-selected. Choose the menu items you want to view information about listed at the bottom of the list of menu items.

# Configuring Dynamic Update and Secure Dynamic Update

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Windows Server 2003 DHCP Server service can be configured to perform DNS dynamic updates and secure DNS dynamic updates for DHCP clients, which eliminates the need for administrators to update DNS records manually when a client's IP address changes. Clients running Windows 2000, Windows XP, or Windows Server 2003 can also perform dynamic updates.

Clients running versions of Windows earlier than Windows 2000 do not support DNS dynamic update. To enable the DHCP server to perform DNS dynamic updates on behalf of these clients, use the default client preference settings. Clients using WINS for name resolution cannot make an explicit request for DNS dynamic update protocol preference. For these clients, the DHCP service can be configured to update both the PTR and the A resource records.

By itself, dynamic update is not secure; any client can modify DNS records. When secure dynamic update is configured, the authoritative name server accepts updates only from clients and servers that are authorized to make dynamic updates to the appropriate objects in Active Directory. Secure dynamic update is available only on Active Directory–integrated zones. To configure secure dynamic updates, you can use the Windows Server 2003 secure dynamic update feature.

Secure dynamic update protects zones and resource records from being modified by unauthorized users by enabling you to specify the users and groups that can modify zones and resource records. By default, Windows Server 2003, Windows XP Professional, and Windows 2000 clients attempt unsecured dynamic updates first. If that request fails, they attempt secure updates.

When using multiple DHCP servers and secure dynamic updates, add each of the DHCP servers as members of the DnsUpdateProxy global security group so that any DHCP server can perform a secure dynamic update for any record. Otherwise, when a DHCP server performs a secure dynamic update for a record, that DHCP server is the only computer that can update the record.

**To configure dynamic update for DHCP clients and servers**

1. In the DHCP snap-in, select and right-click the DHCP server you want to configure, and then click **Properties**.
2. In the *server name***Properties** dialog box, click the **DNS** tab.
3. On the **DNS** tab, select the **Enable DNS dynamic updates according to the settings below** check box.
4. On the **DNS** tab, select the dynamic update method you want: either always updating DNS A and PTR, or only updating the records when requested by the DHCP client.

Use the DNS snap-in to enable secure dynamic update. For more information about dynamic update and secure dynamic update, see "Deploying Domain Name System (DNS)" in this book and in Help and Support Center for Windows Server 2003.

**Important**

- If DHCP will perform DNS dynamic updates, do not install it on a domain controller. Instead, install DHCP on a member server. When DHCP is installed on a domain controller and is configured to perform dynamic updates on behalf of clients in DNS zones that are configured to allow only secure dynamic update, specify a user account to update the DNS records. For more information about installing DHCP, see "Checklist: Installing a DHCP server" in Help and Support Center for Windows Server 2003.

# Authorizing DHCP Servers in Active Directory

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An unauthorized DHCP server on a network can cause a variety of problems, such as the leasing of incorrect IP addresses and options. To protect against this type of problem, when a Windows 2000 or Windows Server 2003 domain member DHCP server attempts to start on the network, it first queries Active Directory. The DHCP server compares its IP address and server name to the list of authorized DHCP servers. If either the server name or IP address is found on the list of authorized DHCP servers, the server is authorized as a DHCP server. If no match is found, the server is not authorized in Active Directory and does not respond to DHCP traffic. The process of authorizing DHCP servers is useful for only Windows 2000–based or Windows Server 2003–based DHCP servers. This process cannot be used for DHCP servers running Windows NT Server, or servers running non-Windows-based DHCP services. Only a member of the Enterprise Admins group can authorize or unauthorize a DHCP server in Active Directory.

**Important**

- You must be logged in as an enterprise administrator to authorize a DHCP server.

**To authorize a DHCP server in Active Directory**

1. In the DHCP snap-in, right-click **DHCP**.
2. Select **Manage authorized servers**.
3. In the **Manage Authorized Servers** dialog box, click **Authorize**.
4. In the **Authorize DHCP Server** dialog box, type the name or IP address of the DHCP server, and then click **OK**.

**Note**

- Detection of unauthorized DHCP servers requires the deployment of Active Directory and the DHCP service running on Windows 2000 or Windows Server 2003. Other DHCP servers do not attempt to determine whether they are authorized by Active Directory before offering IP address leases.

# Defining Scopes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before DHCP clients can use a DHCP server for dynamic TCP/IP configuration, you must define and activate scopes for your DHCP clients. A *scope* is the full, consecutive range of possible IP addresses for a subnet. The IP addresses in a scope define a single subnet on which DHCP services are offered. DHCP servers use scopes to manage network IP address distribution and the configuration of DHCP options.

Figure 2.7 shows the process for defining scopes.

**Figure 2.7 Defining Scopes**

# Creating Scopes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You must create a DHCP scope for each subnet in your network. Each subnet has a DHCP scope, with a single continuous range of IP addresses.

Before you create scopes, you must install DHCP on your server. For more information about installing DHCP, see "Checklist: Installing a DHCP server" in Help and Support Center for Windows Server 2003.

You can use the DHCP MMC snap-in to create a new scope on your DHCP server.

**To create a DHCP scope**

1. In the DHCP snap-in, select the name of the DHCP server.

2. Select **Action**, andthen select **New Scope**. This opens the **New Scope Wizard**. Complete the New Scope Wizardby configuring the following properties:

    - A scope name and description of the scope.

    - A consecutive range of possible IP addresses.

    - A unique subnet mask. For more information about defining subnet masks, see "Designing a TCP/IP Network" in this book.

    - The IP addresses that are to be excluded from the scope.

    - Lease duration values.

    - Options.

For a worksheet to assist you in completing the New Scope Wizard, see the "Scope Data Collection Worksheet" (DNSDHC_1.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see the "Scope Data Collection Worksheet" on the Web at http://www.microsoft.com/reskit).

After you create the scope, you can set reservations and configure any additional DHCP options. For information about setting reservations, see "Creating Reservations" later in this chapter. For information about configuring additional DHCP options, see "Configuring DHCP Options" later in this chapter.

# Setting Exclusion Ranges

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To prevent address conflicts, the scopes that you define must exclude the IP addresses of devices that you statically configure, such as DHCP servers. By setting exclusion ranges, an administrator can exclude IP address ranges within a scope so that those addresses are not offered to DHCP clients. When you create a new scope, immediately exclude addresses of the existing statically configured computers. Excluded IP addresses can be active on your network, but only when these addresses are manually configured or distributed as reserved IP addresses. For more information about reservations, see "Creating Reservations" later in this chapter.

You can set exclusion ranges in the **Add Exclusions** page of the **New Scope Wizard**. For more information about using the New Scope Wizard, see "Creating Scopes" earlier in this chapter.

**To set an exclusion range after a scope is created**

1. In the DHCP snap-in, expand the scope you want to configure.
2. Select and right-click **Address Pool** under the appropriate scope.
3. Select **New Exclusion Range**.
4. In the **Add Exclusion** dialog box, type the starting and ending IP addresses of the exclusion range, and then click **Add**.

# Determining Lease Duration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When a scope is created, the default lease duration is set to eight days. However, because lease renewal is an ongoing process that can affect the performance of DHCP clients and your network, you can increase or decrease the lease duration to fit your specific needs. Determine what segments of your network have specific lease duration requirements, and decide how best to modify lease duration settings to improve DHCP performance on your network.

You can set the lease duration in the **Lease Duration** page of the **New Scope Wizard**. For more information about using the New Scope Wizard, see "Creating Scopes" earlier in this chapter.

**To set the lease duration after a scope is created**

1. In the **DHCP** snap-in, select and right-click the scope you want to configure.
2. Select **Properties**.
3. In the **Lease duration for DHCP clients** box, adjust the lease time for the scope.

**Increasing the Default Lease Duration**

You can increase the lease duration in a scope to reduce network traffic. Increase the lease duration only if that segment of your network has a large number of IP addresses available and a configuration that rarely changes. Increasing lease duration reduces the rate at which IP addresses are reclaimed when changes occur.

In a more stable environment, you can use a long lease, such as several months. This ensures both that addresses are ultimately recovered, and that DHCP-related network traffic is kept to a minimum.

**Caution**

- Use caution when configuring unlimited lease durations. Even stable environments have a certain amount of client turnover. At a minimum, roving computers might be added and removed, desktop computers might be moved from one office to another, and network adapters might be replaced. If a client with an infinite lease is removed from the network, the DHCP server is not notified, and the IP address cannot be reused.

**Reducing the Default Lease Duration**

Reduce the lease duration for segments of your network that have any of the following:

- A limited number of IP addresses available.
- Client configurations that change frequently.
- Clients that relocate often; for example, because they connect to conference rooms or wireless networks.

Although reducing the lease duration creates more DHCP-related network traffic, it increases the rate at which addresses are returned to the available address pool for reassignment. With an average volume of DHCP request traffic, Windows Server 2003 DHCP has a four-hour default grace period after which an expired lease can be reused. This means that an address is marked for deletion four hours after the lease expires, regardless of lease duration. When the volume of DHCP-related traffic is heavy and no leases are available to service lease requests, DHCP immediately instantiates a cleanup cycle, which reclaims any leases marked for deletion. By default, the cleanup cycle occurs every 60 minutes. You can adjust the duration of the default grace period after which an expired lease is marked for deletion by editing the following key in the registry:

```
HKLM\System\CurrentControlSet\Services\DHCPServer\Parameters\LeaseExtension
```

**Caution**

- Do not edit the registry unless you have no alternative. The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up

first.

# Configuring DHCP Options

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

DHCP uses options to pass additional IP settings to DHCP clients on a network. Examples of DHCP options include:

- The default gateway IP address
- The DNS server IP address
- The DNS domain name

You can configure DHCP options for specific values and enable them for assignment and distribution to DHCP clients based on server, scope, class, or reserved client levels. For example, you can enable the vendor class option Release on Shutdown for any laptops on your network to allow IP addresses assigned to mobile clients to be reincorporated into the address pool more quickly.

You can configure options for an entire server, a scope, or for a single reserved client. The most specific options (reserved client) take precedence over the least specific options (server). Values configured manually on a client override any DHCP options of any type and of any level.

Using the **New Scope Wizard**, you can configure some scope-level options, including router (default gateway), domain name, DNS servers, and WINS servers. You can also configure options at the server, scope, and reserved-client levels in the DHCP snap-in.

**To configure server-level options**

1. In the DHCP snap-in, expand the server for which you want to configure options.
2. Right-click **Server Options**, and then click **ConfigureOptions**.
3. In the **Server Options** dialog box, select the options you want to configure.
4. In the **Data Entry** section of the **Server Options** dialog box, type the option parameters, and then click **OK**.

**To configure scope-level options**

1. In the DHCP snap-in, expand the scope for which you want to configure options.
2. Right-click **Scope Options**, and then click **Configure Options**.
3. In the **Scope Options** dialog box, select the options you want to configure.
4. In the **Data Entry** section of the **Scope Options** dialog box, type the option parameters, and then click **OK**.

**To configure options for a reserved client**

1. In the DHCP snap-in, expand the scope that holds the reservation for which you want to configure options, and then expand **Reservations**.
2. Right-click the reservation for which you want to configure options, and then click **Configure Options**.
3. In the **Reservation Options** dialog box, select the options you want to configure.
4. In the **Data Entry** section of the **Reservation Options** dialog box, type the option parameters, and then click **OK**.

For more information about configuring reservations, see "Creating Reservations" later in this chapter.

Many option types are predefined in Windows Server 2003 DHCP. Other standard DHCP option types can be added as needed to support DHCP client software that recognizes or requires them. Windows Server 2003 DHCP supports all DHCP options, including those defined in RFC 2132, although most DHCP clients use or support only a small subset of the available option types.

In general, use the following guidelines when configuring DHCP options for clients on your network:

- Add or define new, custom option types only if you have new software or applications that require a nonstandard DHCP option.
- If your network is large, be conservative and selective when assigning global options. These options apply to all clients of a DHCP server, unless more specific options are specified.
- Use scope-level options for most options that clients are assigned. Setting options at the scope level allows you to take scope-related differences into account, such as different client needs or the use of a different DNS server from other scopes in the network.
- Use class-level options if you have a large network or diverse groups of clients that are able to support membership in option classes.
- Use reserved client options only for clients that have special requirements, for example, if your intranet has a DNS server that performs forwarding for resolving Internet DNS names not authoritatively managed on your network. In this case, you need to add the IP address of an external DNS server on your DNS server computer. You can configure your DNS server as a reserved client in DHCP and set this address as another reserved client option.

# Configuring Option Classes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 DHCP includes vendor-defined and user-defined option classes. Use DHCP option classes to configure the parameters necessary for network clients to meet the special requirements of custom applications. Equipment from multiple vendors on a network can also use different option numbers for different functions. The option types used to support vendor-defined classes — the vendor class identifier and the vendor-specific option — are defined in the Internet DHCP options standard reference, RFC 2132.

You can add and configure vendor-defined classes for submanaging DHCP options that are assigned to clients identified by vendor type. You can also add and configure user-defined classes for submanaging DHCP options that are assigned to clients identified by a common need for a similar DHCP option configuration.

After you configure specific user-defined and vendor-defined options classes, you must configure scopes to assign the option classes to clients.

**Vendor-Defined Classes**
DHCP clients can use vendor-defined classes to identify the client's vendor type and configuration to the DHCP server when obtaining a lease. For a client to identify its vendor class during the lease process, the client needs to include the vendor class ID option (option code 60) when it requests or selects a lease from a DHCP server.

When vendor options are specified, the server performs the following additional steps to provide a lease to the client:

1. The server checks to see that the vendor class identified by the client request is a recognized class defined on the server.

2. If the vendor class is recognized, the server checks to see whether any additional DHCP options are configured for this class in the active scope.

3. If the vendor class is not recognized, the server ignores the vendor class identified in the client request, and returns options allocated to the default vendor class (includes all DHCP Standard Options).

4. If the scope contains options configured specifically for use with clients in this vendor-defined class, the server returns those options and uses the vendor-specific option type (option code 43) as part of its acknowledgment message.

In most cases, the default vendor class — DHCP Standard Options — provides a default grouping for any Windows Server 2003 DHCP clients or other DHCP clients that do not specify a vendor class ID. In some cases, you might define additional vendor classes for other DHCP clients, such as printers or some types of UNIX clients. When you add other vendor classes for these purposes, be sure that the vendor class identifier that you use to configure the class at the server matches the identifier used by clients for your third-party vendor.

**User-Defined Classes**
User-defined classes allow DHCP clients to specify what type of client they are, such as a remote access client or a desktop computer. For Windows Server 2003 clients, you can define specific user class identifiers to relate information about a client's software configuration, its physical location in a building, or its user preferences. If user-defined option classes are not specified, default settings are assigned.

# Configuring DHCP Option Parameters

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When a DHCP server actively provides option parameters, clients receive and use the associated values in their local TCP/IP configurations for the period of leased configuration.

By default, Microsoft-based DHCP clients can recognize and use two categories of option parameters: information options and protocol options.

**Information Options**
Use the MMC DHCP snap-in to *explicitly* configure information options and any associated values provided to clients. These options are not required and can be assigned at your discretion. Use information options to assign values, such as DNS servers, WINS servers, and domain name.

**Windows Server 2003 Protocol Options**
You *implicitly* configure values for protocol options based on properties configured at either the applicable server or one of its scopes. These options are always included in DHCP client/server messages, as they are a required part of protocol design. For example, Lease Duration/Time is a protocol option.

In most cases, the actual values included in these protocol options are provided to clients based on property settings for the applicable DHCP server. Depending on the needs of your clients, you can also use the DHCP snap-in to configure these options individually for defined scopes, identifying members of a specified user or vendor class, or for a single reserved client.

# Creating Reservations

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For clients that require a constant IP address, you can either manually configure a static IP address, or assign a reservation on the DHCP server. *Reservations* are permanent lease assignments that are used to ensure that a specified client on a subnet can always use the same IP address. You can use DHCP reservations for hosts that require a consistent IP address, but do not need to be statically configured. Reserved IP addresses differ from statically configured IP addresses in one significant manner: when network parameters are changed at the DHCP server, the device configured with a reserved IP address receives the new network parameters when the device requests renewal of its lease. To change network parameters on a device configured with a static IP address, the changes must be made manually to the device.

Determine the clients for which you need to manually configure an IP address — such as DHCP server, DNS servers, WINS servers, routers, and domain controllers — and which clients can receive addresses from DHCP. Keep in mind that for clients for which you manually configure static IP addresses, you must insert all configuration parameters that the client requires in order to interact with the network. This includes IP addresses, DNS and WINS parameters, and default gateway information. Clients that have reserved IP addresses always have the same IP address, but still receive updated configuration information from the DHCP server.

You might want to assign network printers and certain servers DHCP reservations to ensure that they always have the same IP address, but continue to receive updated configuration information from the DHCP server. For example, create reservations for servers that must always have the same IP address, such as:

- Windows Internet Name Service (WINS) and Domain Name System (DNS) servers
- Print servers that use TCP/IP print services
- Firewalls
- Routers

DHCP-enabled clients receive any available options, such as DNS server or router (default gateway), from the DHCP server when they renew their leases. If these devices are manually configured, an administrator must reconfigure each device individually when a change occurs.

**To create a reservation**

1. In the DHCP snap-in, expand the scope for which you want to create a reservation.
2. Select and right-click **Reservations**, and then click **New Reservation**.
3. In the **NewReservation** dialog box, enter the **Reservation name**, **IP address**, **MAC address**, and **Description** of the reservation.
4. Select the appropriate **Supported types**: DHCP only, BOOTP only, or Both.
5. Click **Add**.

# Creating Superscopes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A *superscope* is an administrative grouping of scopes that can support multiple logical IP subnets on the same physical subnet. Superscopes contain a list of member scopes that can be activated together. You cannot configure scope-level properties on superscopes; you must configure these on the member scopes. A superscope allows a DHCP server to provide leases from more than one scope to clients on a single physical network.

You can use superscopes to resolve DHCP service issues for the following situations:

- DHCP clients are located on a single physical network segment that includes multiple logical IP subnets.
- Multiple DHCP servers manage separate logical subnets on the same physical subnet.
- The available address pool for an active scope is nearly depleted and more computers must be added to the physical network segment.
- Clients are migrating to a new scope.
- You need to support DHCP clients on a network that has multiple logical subnets in one physical subnet on the other side of a BOOTP/DHCP relay agent.

Before you create a superscope, you must use the DHCP MMC snap-in to define at least one scope to be included in the superscope. Scopes added to a superscope are called *member scopes*. You can add additional member scopes either from the superscope menu, or from the individual scope menus.

**To create a new superscope**

1. In the DHCP snap-in, create at least one scope to be included in the superscope. For information about creating scopes, see "Creating Scopes" earlier in this chapter.
2. Select and right-click the DHCP server, and then select **New Superscope**. This opens the **New Superscope Wizard**.
3. On the **Superscope Name** page of the **New Superscope Wizard**, type a name for the superscope.
4. On the **Select Scopes** page of the **New Superscope Wizard**, inthe **Available Scopes** list, select one or more scopes to include in the superscope.

**To add scopes to an existing superscope**

1. In the DHCP snap-in, select and right-click the superscope, and then select **New Scope**. This opens the **New Scope Wizard**.
2. Complete the **New Scope Wizard**. For information about creating scopes, see "Creating Scopes" earlier in this chapter.

   –or–

3. Create a new scope, right-click the new scope, and then select **Add to Superscope**.
4. In the **Add Scope** *name* **to a Superscope** dialog box, in the **Available superscopes** list, select the superscope.

**Note**

- Deleting the superscope does not delete the member scopes.

# Configuring Multicast Scopes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 DHCP service offers MADCAP support in the form of multicast scopes. MADCAP supports dynamic assignment and configuration of IP multicast addresses on TCP/IP-based networks. Multicast scopes provide ranges of Class D IP addresses, which are reserved for multicast operation, by using directed transmission from one point to multiple points. With the exception of DHCP-assignable options, which multicast scopes do not support, you can configure a multicast scope in the same way that you configure a regular DHCP scope.

Multicast IP addresses allow multiple clients to receive data that a server sends to a single IP address, enabling point-to-multipoint communication. This type of transmission is often used for streaming media transmissions, such as video conferencing.

**Important**

- In all TCP/IP networks, each computer requires a unique primary computer IP address from one of the standard address classes used for building the network (Class A, B, or C range). You must assign this required primary computer IP address before you can configure a computer to support and use secondary IP addresses such as multicast IP addresses.

Although the Windows Server 2003 DHCP service supports both DHCP and MADCAP, the services function independently; clients that do not obtain IP addresses from the DHCP service can still obtain MADCAP addresses from the DHCP service. DHCP scopes are used to allocate IP address ranges from Class A, B, or C addressing schemes, which enable unicast for point-to-point communication between networked computers. MADCAP scopes allocate Class D IP addresses to enable point-to-multipoint communication.

**To configure a MADCAP scope**

1. In the DHCP snap-in, select and right-click the DHCP server you want to configure. The **New Multicast Scope Wizard** appears.

2. In the **New Multicast Scope Wizard**, type a name and description for this multicast scope.

3. Set the multicast IP address range and Time to Live (TTL).

4. Add any exclusion ranges and the lease duration, then activate the multicast scope.

**Tip**

- Clients that use MADCAP must be configured to use the MADCAP API. For more information about writing or programming applications that use the MADCAP API, see the MSDN Online link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Removing DHCP Scopes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Remove DHCP scopes when a subnet is no longer in use or when you need to renumber your network to use a different IP address range.

Do not remove a scope while it has active leases. Before you remove a scope, deactivate the scope until all client leases expire or all lease renewal requests are denied. When you have confirmed that the scope no longer contains active leases, you can remove it by using the DHCP snap-in. For more information about deactivating scopes, see "Deactivate a scope"Deactivate a scope in Help and Support Center for Windows Server 2003.

# Implementing Your DHCP Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you have planned your DHCP solution and made the necessary configurations, you must implement your new or updated DHCP solution in your production environment. The DHCP implementation process involves the following steps:

- Configuring your DHCP clients.
- Migrating existing DHCP servers, if necessary.
- Testing your DHCP solution.

Figure 2.8 shows the process for implementing your DHCP solution.

**Figure 2.8 Implementing Your DHCP Solution**

# Installing DHCP on Your Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Install DHCP on your server either by using Manage Your Server or by adding DHCP from Add/Remove Windows Components. If you are migrating an existing DHCP server to a new Windows Server 2003–based server, install DHCP on the Windows Server 2003–based server before continuing with your migration. For more information about installing DHCP on your server, see "DHCP server role: Configuring a DHCP server," "Installing a DHCP serverInstalling a DHCP server," and "Checklist: Installing a DHCP server" in Help and Support Center for Windows Server 2003.

# Migrating Existing DHCP Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you already have a working DHCP infrastructure on your network, you can migrate your DHCP database and server configuration from your existing servers to new Windows Server 2003–based servers. Migrating can save you time because you do not need to reconfigure the scope, lease, and option information on the new server.

Before migrating the database, create a backup of your working configuration, and test the migration procedures in a lab environment.

The following procedures migrate lease, scope, and option information, including reservations and exclusions. If you have changed any registry settings from their defaults on the existing server, you must manually make these changes on the new Windows Server 2003–based server for them to take effect.

**Caution**

- The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Windows Server 2003 Resource Kit Registry Referenceon the *Windows Server 2003 Deployment Kit* companion CD or at http://www.microsoft.com/reskit.

# Exporting DHCP Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When migrating from an existing DHCP server running Windows NT 4.0 or Windows 2000 Server, the first step is to export the current DHCP settings. Use the following procedure to export the DHCP database from an existing Windows NT 4.0–based server or a Windows 2000–based server.

**To export the DHCP server settings from a Windows NT 4.0–based server or Windows 2000–based server**

1. Run DHCPExim.exe. This opens the **DhcpExim** dialog box.

   To download and install DHCPExim.exe, see the Resource Kit Tools link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

2. In the **DhcpExim** dialog box, select **Export configuration of the local service to a file**.

3. In the **DHCPEXIM Export To File** dialog box, enter a file name and location to save the file, and then click **OK**.

   The target location the file is shown in the **DhcpExim Export** dialog box.

4. In the **DhcpExim Export** dialog box, select all of the scopes on the list to migrate all settings on the server. Alternatively, you can only the specific scopes you want to export if you are not migrating the entire server. Select the **Disable the selected scopes on local machine before export** check box to disable the scopes on this server before exporting, and then click **Export**.

   **Tip**

   - This step might take several minutes to complete, and there is no dialog box to indicate the progress of the export. You can view the process running on the **Processes** tab of the **Windows Task Manager**.

5. Click **OK** when a message appears that says "The operation was completed successfully."

6. Copy the exported file to a location where you can access it from the new Windows Server 2003–based server.

# Importing DHCP Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After exporting the DHCP settings and moving the exported file to a location where you can access it, you are ready to use the Netsh command-line tool to import the DHCP settings to the new DHCP server running Windows Server 2003. You might want to configure the new DHCP server to use the IP address that was formerly used on the old DHCP server. Before you do this, make sure to disconnect the old server from the network in order to avoid any IP address conflicts.

**To import the DHCP server settings to Windows Server 2003–based DHCP server**

1. Install DHCP on the Windows Server 2003–based server. DHCP must be installed before you can import the file.

2. At the command prompt, type:

   ```
   netsh DHCP server import <path of export file> all
   ```

   This imports the configurations of all scopes that you exported from the server running Windows NT 4.0 or Windows 2000.

For more information about the Netsh command-line tool, see "Netsh" in Help and Support Center for Windows Server 2003.

# Configuring DHCP Clients

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When configuring your DHCP clients, it is important to consider the types of computers on each subnet of the network. For example, you might configure one subnet with a shorter lease duration for portable computer users. To configure a Windows client to obtain an IP address from the DHCP server, select **Obtain an IP address automatically** from the **Internet Protocol (TCP/IP) Properties** window.

In addition to Windows-based clients, you can configure DHCP for UNIX, Linux, or Macintosh clients. Refer to the documentation for these operating systems to configure the clients for DHCP.

**Note**

- You can override DHCP information by configuring the individual client. Any information entered manually into a client's TCP/IP configuration overrides dynamic settings.

# Providing Support for Remote Access Clients

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The remote access server can be configured to use DHCP to lease IP addresses in blocks of 10 from the DHCP server and store them in the registry. The remote access server leases additional addresses in blocks of 10 as needed.

When passing the leases on to remote access clients, the remote access server discards the options configured for the scope. However, remote access clients receive WINS or DNS entries from the remote access server. This information is not taken from the DHCP options of the lease that the remote access client is using; it is taken directly from the settings of the remote access server.

You can use a DHCP relay agent to provide DHCP scope options to remote access clients. In this situation, the remote access client continues to receive an IP address from the remote access server, but uses DHCPInform packets to obtain WINS addresses, DNS addresses, domain names, or other DHCP options.

**Note**

- DNS and WINS addresses obtained from DHCPInform packets override DNS and WINS addresses obtained from the remote access server.

For more information about using DHCP for remote access clients, see "Using Routing and Remote Access servers with DHCP" in Help and Support Center for Windows Server 2003 and article Q216805, "RAS Server Behavior When Configured to Use DHCP to Assign IP Addresses," in the Microsoft Knowledge Base. For more information about configuring a DHCP relay agent to provide DHCP options to remote access clients, see article Q232703, "How to Use DHCP to Provide RAS Clients with DHCP Options," in the Microsoft Knowledge Base. To find these articles, see the Microsoft Knowledge Base link on the Web Resources page at www.microsoft.com/windows/reskits/webresources.

# Configuring Support for BOOTP Clients

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 provides support for dynamic BOOTP, which allows you to provide BOOTP support without making a reservation for each BOOTP client.

You can use DHCP to configure and support BOOTP clients. BOOTP clients can be configured to receive boot file information, or IP address information. You can also use DHCP to configure options for your BOOTP clients.

**Configuring DHCP to Provide Boot File Information**
To configure the DHCP service to provide boot file information to BOOTP clients, create BOOTP entries for each client-specific platform in the BOOTP table on the DHCP server.

Information stored in the BOOTP table is returned to any BOOTP clients on the network that broadcast a BOOTP request message. If the BOOTP table includes at least one BOOTP entry, the DHCP service replies to BOOTP client requests. If no BOOTP entries are configured, the BOOTP client gets a lease, but no options or other information are passed to the BOOTP client.

The reply message returned by the DHCP service indicates the name of a Trivial File Transfer Protocol (TFTP) server on the network and the location of the boot file. The client then contacts the TFTP server to retrieve the boot image file.

BOOTP clients download the image file from a TFTP server. Because Windows Server 2003 does not provide a full TFTP file service, you might need to use a third-party TFTP server to support BOOTP clients that must start from an image file (usually diskless workstations).

**Configuring DHCP to Provide IP Address Information**
Windows Server 2003 allows you to designate a pool of addresses from which IP addresses for BOOTP clients are dynamically assigned, similar to the way that a scope is used for DHCP clients. After verifying that a specified lease time has elapsed and that the BOOTP client IP address is not still in use, the DHCP service can reclaim addresses used in the dynamic BOOTP address pool.

To include BOOTP client support in your DHCP scope design, designate the DHCP scope as a BOOTP address pool or as both a DHCP and BOOTP address pool on the **Advanced** tab of the **Scope Properties** window in the DHCP snap-in. For more information about configuring a BOOTP address pool, see "Add dynamic BOOTP client support to a scope" in Help and Support Center for Windows Server 2003.

**Configuring Options for BOOTP Clients**
To retrieve all options, the client must specify option 55 (the Options Request List parameter) in the BOOTP request. Windows Server 2003 DHCP servers return as many options to BOOTP clients as can fit in a single datagram response. Because BOOTP only allocates 300 bytes for options, any options that exceed the 300 bytes are not sent. Therefore, when configuring options on a server that will service BOOTP clients, be aware of the size limitations for BOOTP response packets.

For more information about BOOTP options, see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

### Important

- DHCP options can apply to both DHCP and BOOTP clients. Therefore, you must configure your scopes to ensure that DHCP options are applied correctly.

# Testing Your DHCP Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The ideal environment for validating a deployment plan is a test laboratory that is constructed to simulate your production environment. If you do not have a DHCP infrastructure in place, create a new DHCP infrastructure in the pilot lab. If you already have a DHCP infrastructure in place, recreate your existing infrastructure in the pilot lab and then test your migration and your updated solution.

Use the following guidelines when testing your DHCP solution in the pilot lab:

- Ensure that your test servers come from the same vendor and are configured in the same way as the servers that exist in your production environment. Represent all client computers that use DHCP in your organization in your pilot lab.

- Duplicate the network configuration of your organization in the pilot lab. If the network uses both Ethernet and Token Ring, you need to include both configurations in the test lab. If possible, set up a separate Windows Server 2003 domain for the lab so that you can monitor the performance of the domain controllers without interference from other network activity. If you are planning to deploy DHCP on a WAN, include routers in your lab design and use a link simulator to simulate network latency.

- Deploy a typical set of applications that run together in your production environment on the test server. This allows you to identify any interoperability issues that might arise when users run different applications simultaneously.

- Test your DHCP solution in burst traffic conditions. Make sure that all services on your servers continue to be available during burst traffic conditions, such as following a large-scale power outage, when many clients might restart simultaneously.

For more information about testing your design, see "Designing a Test Environment" in *Planning, Testing, and Piloting Deployment Projects* of this kit.

Testing your DHCP solution in a pilot lab allows you to identify problems with your infrastructure, system configuration, or software. After you have tested your configuration thoroughly in a pilot lab, you can roll out your DHCP solution in your production environment.

# Example DHCP Implementation

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This DHCP example implementation depicts how a fictional company uses the Windows Server 2003–based DHCP servers to streamline and automate administration and assignment of IP addresses and other client configuration information. Though your network configuration might differ from this example, you can apply the basic concepts.

The company has two offices, a main administrative office, and branch offices 25 miles away. The company employs 600 people, many of whom travel frequently between the two offices with portable computers.

The main office is housed on two floors, with 75 desktop computer users per floor. Because many of these employees also have portable computers, conference rooms are configured with wireless networking. Wireless networking also provides ease of network connectivity to employees from the branch offices who are attending meetings at the main office.

**Connectivity and Routing**

A digital subscriber line (DSL) account at a rate of 1.1 megabits per second (Mbps) is established for each of the two company sites, providing a dedicated connection to the Internet through a DSL modem. Additional network adapters are installed on the server computers at both sites, one network adapter per subnet.

The DSL-connected server in the main office has two additional network adapters, one for Subnet A and one for Subnet B. On Subnet A, network cable runs from the network adapter to a hub. On wireless Subnet B, media network cable runs from the network adapter to a hub, then to wireless access points stationed in conference rooms.

The DSL-connected server computer in the branch office has four additional network adapters, one each for subnets C through F. On wireless subnet C, network cable runs from the network adapter to a hub, then to wireless access points stationed in conference rooms. On subnets D, E, and F, network cable runs from the network adapters to hubs that extend to each individual subnet.

To provide secure, private, encrypted communication between the two sites over DSL, both DSL-connected servers are also configured as virtual private network (VPN) servers.

To allow messages from both DHCP servers and DHCP clients to cross from site to site and between subnets at each site, the Routing and Remote Access service on the DSL-connected servers have the DHCP relay agent routing protocol installed and configured.

For more information about connecting remote sites, see "Connecting Remote Sites" in this book.

**Transmission Security Between Sites**

Because the company wants the highest level of security available for the VPN connection that allows the two sites to communicate using their 1.1 Mbps DSL connections over the Internet, they install a Windows Server 2003 certification authority (CA) and establish a Layer Two Tunneling Protocol (L2TP) connection, relying on Internet Protocol security (IPSec) for encryption services. The combination of L2TP and IPSec is known as L2TP/IPSec. With certificate-based authentication and an L2TP/IPSec connection, the company is using the strongest form of authentication in Windows Server 2003. For more information about using a certification authority, see "Designing an Authentication Strategy" in the *Designing and Deploying Directory and Security Services* book of this kit. For more information about using IPSec, see "Deploying IPSec" in this book.

**Active Directory Domain Structure**

The company uses Active Directory to list IP addresses of DHCP servers authorized for operation on the network. If an unauthorized DHCP server running Windows 2000 or Windows Server 2003 is started on the network, it determines its authorization status from the directory service. If the server determines that it is not authorized, it stops functioning in the domain as a DHCP server, and cannot be used to provide IP address leases to clients. There are two sites to define in Active Directory, one at the main administrative site and one at the branch office site. Creating two sites optimizes the exchange of directory information and facilitates administration by centralizing resources such as configuration information.

# Subnets and IP Addressing

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Although the company employs approximately 600 people, most employees use both a desktop computer and a portable computer. Because the portable computers function primarily via wireless connections to the network, one subnet at each of the two company sites is configured as a wireless subnet.

In all, there are six subnets on the company network, with 600 desktop clients and approximately 425 portable clients divided among the subnets as shown in Table 2.1. All subnets on the network are configured with the subnet mask 255.255.255.0. All six subnets are serviced by DHCP, with one DHCP server located at each site.

The main office houses 150 employees dispersed over two floors of the building. All users also have portable computers that they frequently take to meetings in conference rooms. All of conference rooms are configured for wireless networking.

The company has divided the main office into two Class C subnets:

- Subnet A — Floors 1 and 2
- Subnet B — Wireless subnet with wireless access points installed in conference rooms

The branch office houses 450 employees, dispersed throughout a three-story building. Over 200 users also have portable computers that they frequently take to meetings in conference rooms, all of which are configured for wireless networking.

The company has divided the branch office into four Class C subnets:

- Subnet C — Wireless subnet for conference rooms
- Subnet D — Floor 3
- Subnet E — Floor 2
- Subnet F — Floor 1

**Table 2.1 Address Range and Clients per Subnet**

| Subnet | Address Range | Approximate Number of Clients |
|---|---|---|
| A | 192.168.0.1/24 to 192.168.0.254/24 | 150 |
| B | 192.168.1.1/24 to 192.168.1.254/24 | Up to 225 |
| C | 192.168.2.1/24 to 192.168.2.254/24 | Up to 225 |
| D | 192.168.3.1/24 to 192.168.3.254/24 | 150 |
| E | 192.168.4.1/24 to 192.168.4.254/24 | 150 |
| F | 192.168.5.1/24 to 192.168.5.254/24 | 150 |

Before creating and activating scopes on the DHCP server, the company plans IP address ranges, exclusion ranges, and reservations (where applicable) for each subnet. The company uses Class C IP address ranges on every subnet, as each Class C address range provides 254 IP addresses when the subnet mask is defined as 255.255.255.0.

Because the client count per non-wireless subnet is 150 or fewer clients, 254 IP addresses per subnet allow the company to provide static address assignments for any servers that require them, and dynamic assignments to all clients on the network — with plenty of IP addresses remaining to provide for future network expansion.

The wireless subnets are configured with a lease duration of 15 minutes. Because of the short lease time, 254 IP addresses per subnet is a sufficient amount for the wireless subnets, even though these subnets experience substantial traffic, with portable computers joining and leaving the subnet at high volume during a typical day. These short leases expire soon after the portable computer is disconnected from the network, and the IP address used by that computer becomes available for lease to other DHCP clients as they connect to the wireless subnet.

# Exclusion Ranges

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Some network devices need to use statically assigned IP addresses rather than addresses dynamically assigned through DHCP. For example, DHCP servers must have statically configured IP addresses. Also, some devices (such as legacy network printers) do not support DHCP.

For the devices that need static IP assignments, the company creates an exclusion range from each IP address range. Creating one or more exclusion ranges prevents the DHCP server from assigning a client lease with any address in the exclusion range, thereby protecting it for use as a static IP address and preventing address conflicts between statically configured devices and dynamically configured devices.

Although any addresses in the address range can be excluded, the company chooses to exclude the first 20 addresses from each address range for non-wireless subnets, and the first five IP addresses from each address range for wireless subnets. The company uses additional exclusion ranges to configure load balancing and fault tolerance using the 80/20 rule. For more information about DHCP scopes, see "Scope Configuration" later in this chapter.

# Address Pools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After the address range and exclusion ranges are defined, the remaining addresses form the available address pool within the scope. These addresses are eligible for dynamic assignment by the server to DHCP clients on the network. Table 2.2 shows the address pool for each subnet prior to adding the exclusion ranges used to apply the 80/20 rule.

**Table 2.2 DHCP Address Pools per Subnet**

| Subnet | Address Pool |
|---|---|
| A | 192.168.0.21/24 to 192.168.0.254/24 |
| B (wireless) | 192.168.1.6/24 to 192.168.1.254/24 |
| C (wireless) | 192.168.2.6/24 to 192.168.2.254/24 |
| D | 192.168.3.21/24 to 192.168.3.254/24 |
| E | 192.168.4.21/24 to 192.168.4.254/24 |
| F | 192.168.5.21/24 to 192.168.5.254/24 |

For more information about DHCP scopes and the 80/20 rule, see "Scope Configuration" later in this chapter.

# Reservations

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The company uses IP address reservations for file and print servers on their network. Reservations are used to create a permanent IP address lease assignment by the DHCP server. Reservations ensure that a specified hardware device on the subnet can always use the same IP address.

When using the 80/20 rule and splitting a scope's IP address pool between two servers for load balancing and fault tolerance, identical reservations must be made at both DHCP servers. When reservations are made at both servers, neither server assigns the reserved IP address to another client, assuring that the intended device receives the address reserved for its use.

Table 2.3 shows two example address reservations. For more information about the 80/20 rule and for an example of how these reservations are created in specific scopes at each DHCP server, see "Scope Configuration" later in this chapter.

**Table 2.3 Example Address Reservations**

| Device | Subnet | Reserved IP Address |
|---|---|---|
| Application server | A | 192.168.0.21/24 |
| File server | D | 192.168.3.68/24 |

**Note**

- Reservations can be created using any IP address in the scope's address range, even if the IP address is also within an exclusion range. Because of this design, when the 80/20 rule is implemented and some addresses in the scope are excluded (80 percent at one server, 20 percent at the other), reservations still function properly.

# Message Routing

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The company uses DHCP relay agents to relay DHCP messages between subnets and sites. To support and use DHCP across multiple subnets, routers connecting each subnet should comply with DHCP/BOOTP relay agent capabilities described in RFC 1542. To cut the cost of expensive network hardware such as routers, the company uses the Windows Server 2003 Routing and Remote Access service including, DHCP relay agents, to forward DHCP/BOOTP messages between subnets. Because the VPN servers act as routers for network traffic, the DHCP relay agents are configured on the VPN servers.

For more information about installing and configuring DHCP relay agents, see "Configure the DHCP Relay Agent" in Help and Support Center for Windows Server 2003.

# Installing DHCP and Authorizing Servers in Active Directory

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The company completes the following steps at both sites:

1. Configures the servers.
2. Installs the DHCP Server service.
3. Opens the DHCP snap-in from the MMC.
4. Authorizes the DHCP server in Active Directory.
5. Adds DHCP administrators to the DHCP Administrators group or the DHCP Users group, depending on their user rights.
6. Creates, configures, and activates one scope for each subnet.

After creating scopes at the DHCP servers, the company defines a site in Active Directory for the branch office. Each of the six subnets is then associated with the appropriate site. When configuring your network, however, you can configure all sites in Active Directory before creating DHCP scopes.

# Scope Configuration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

By using the 80/20 split-scope configuration for fault tolerance and availability, scopes for all six subnets on the company network are defined on both DHCP servers. Exclusion ranges are used to allocate available addresses per scope, per server, as follows:

- The main office DHCP server is configured with 80 percent of the IP addresses available for lease to clients in each scope serving subnets A and B and 20 percent of the IP addresses available for lease to clients located at the branch office (subnets C through F).

- The branch office DHCP server has 80 percent of all addresses in all scopes available for lease to clients in the branch office (subnets C through F) and 20 percent of all addresses in all scopes available for lease to clients located in the main office (subnets A and B).

Thus, if either server suffers a hard-disk failure or other failure, the alternate server is available to assign and renew leases on all subnets.

To achieve the 80/20 rule, each Class C IP address range of 254 IP addresses available in each non-wireless scope is divided in the following manner:

- 20 IP addresses for static assignments.

- 187 IP addresses, or 80 percent of the addresses for lease, in the address pool of the DHCP server at the same site.

- 47 IP addresses, or 20 percent of the addresses for lease, in the address pool of the DHCP server at the other site.

The wireless scopes are divided in the following manner:

- 5 IP addresses for static assignments.

- 203 IP addresses, or 80 percent of the addresses for lease, in the address pool of the DHCP server at the same site.

- 51 IP addresses, or 20 percent of the addresses for lease, in the address pool of the DHCP server at the other site.

Table 2.4 shows the address pools and exclusion ranges configured on the main office DHCP server.

**Table 2.4 Scope Configurations on the DHCP Server at the Main Office**

| Scope Name | Address Range | Exclusion Ranges | Address Pool |
|---|---|---|---|
| A | 192.168.0.1 to 192.168.0.254 | 192.168.0.1 to 192.168.0.20, 192.168.0.21 to 192.168.0.67 | 192.168.0.68 to 192.168.0.254 |
| B (wireless) | 192.168.1.1 to 192.168.1.254 | 192.168.1.1 to 192.168.1.5, 192.168.1.204 to 192.168.1.254 | 192.168.1.6 to 192.168.1.203 |
| C (wireless) | 192.168.2.1 to 192.168.2.254 | 192.168.2.1 to 192.168.2.203 | 192.168.2.204 to 192.168.2.254 |
| D | 192.168.3.1 to 192.168.3.254 | 192.168.3.1 to 192.168.3.20, 192.168.3.68 to 192.168.3.254 | 192.168.3.21 to 192.168.3.67 |

| | | | |
|---|---|---|---|
| E | 192.168.4.1 to 192.168.4.254 | 192.168.4.1 to 192.168.4.20, 192.168.4.68 to 192.168.4.254 | 192.168.4.21 to 192.168.4.67 |
| F | 192.168.5.1 to 192.168.5.254 | 192.168.5.1 to 192.168.5.20, 192.168.5.68 to 192.168.5.254 | 192.168.5.21 to 192.168.5.67 |

Table 2.5 shows the address pools and exclusion ranges configured on the branch office DHCP server.

**Table 2.5 Scope Configurations on the DHCP Server at the Branch Office**

| Scope Name | Address Range | Exclusion Ranges | Address Pool |
|---|---|---|---|
| A | 192.168.0.1 to 192.168.0.254 | 192.168.0.1 to 192.168.0.20, 192.168.0.68 to 192.168.0.254 | 192.168.0.21 to 192.168.0.67 |
| B (wireless) | 192.168.1.1 to 192.168.1.254 | 192.168.1.1 to 192.168.1.203 | 192.168.1.204 to 192.168.1.254 |
| C (wireless) | 192.168.2.1 to 192.168.2.254 | 192.168.2.1 to 192.168.2.5, 192.168.2.204 to 192.168.2.254 | 192.168.2.6 to 192.168.2.203 |
| D | 192.168.3.1 to 192.168.3.254 | 192.168.3.1 to 192.168.3.20, 192.168.3.21 to 192.168.3.67 | 192.168.3.68 to 192.168.3.254 |
| E | 192.168.4.1 to 192.168.4.254 | 192.168.4.1 to 192.168.4.20, 192.168.4.21 to 192.168.4.67 | 192.168.4.68 to 192.168.4.254 |
| F | 192.168.5.1 to 192.168.5.254 | 192.168.5.1 to 192.168.5.20, 192.168.5.21 to 192.168.5.67 | 192.168.5.68 to 192.168.5.254 |

**Lease Duration**

Subnet B in the main office and Subnet C in the branch office are both wireless subnets. Because wireless clients (portable computers and other portable devices) are connected to and disconnected from the network in large numbers and for short intervals throughout the average day, lease duration on these two subnets is set for 15 minutes. These short lease times help to ensure that the maximum number of IP addresses are available in the scope as clients connect to the network.

Lease time for all other (nonwireless) subnets is eight days.

**Scope Options**

Each scope is configured with option 249, classless static routes. Using classless static routes, each DHCP client can be easily configured with the route to any destination on the network, and the subnet mask can be specified. Because each scope represents a physical subnet, the scope can be viewed as the start location for any message that is to be sent by a client to another subnet. The parameters used to configure option 249 are Destination, Mask, and Router. One or more static routes can be configured with option 249; the company provides all DHCP enabled clients on the network with routes to all other subnets using option 249.

This option is not configured as a server option because it maps routes between subnets, so no one set of values for the required parameters of Destination, Mask, and Router is always correct. For example, subnets A and D each use a router (that is, a VPN server configured with the Routing and Remote Access service and DHCP Relay Agent service enabled) to communicate with each other. Of course, the routers they use are different, and the destination is different in each case.

**Server Options**

The DHCP standard options shown in Table 2.6 are configured as server options at the main office DHCP server.

**Table 2.6 Example DHCP Options**

| Option Number | Description | Value |
|---|---|---|

| | | |
|---|---|---|
| 006 | DNS servers | 192.168.0.3, 192.168.3.3 |
| 044 | WINS/NBNS servers | 192.168.0.4, 192.168.3.4 |
| 132 | Enable NBT hostname resolution | Byte: 0x1 (1=on) |
| 133 | Enable gethostbyname() WINS resolution | Byte: 0x1 (1=on) |

**Other Settings**

Scopes on both DHCP servers are configured with the same reservations, lease durations, scope options, and server options.

# Additional Resources for Deploying DHCP

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

# Deploying Domain Name System (DNS)

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Microsoft® Windows® Server 2003 Domain Name System (DNS) provides efficient name resolution and interoperability with standards-based technologies. Deploying DNS in your client/server infrastructure enables resources on a TCP/IP network to locate other resources on the network by using host name-to-IP address resolution and IP address-to-host name resolution. The Active Directory® directory service requires DNS for locating network resources.

**In This Chapter**

Overview of DNS Deployment

**Related Information**

- For more information about DNS, the Windows Server 2003 DNS Server service, and Windows Server 2003 DNS Client service, see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

# Overview of DNS Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

DNS is the primary method for name resolution in the Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; and Windows® Server 2003, Datacenter Edition operating systems (collectively referred to as "Windows Server 2003" in this chapter). DNS is also a requirement for deploying Active Directory, but Active Directory is not a requirement for deploying DNS. However, integrating DNS with Active Directory enables DNS servers to take advantage of the security, performance, and fault tolerance capabilities of Active Directory.

If you are planning to deploy DNS to support Active Directory, plan your DNS namespace in conjunction with planning your Active Directory logical structure. For more information about designing the Active Directory logical structure, see "Designing the Active Directory Logical Structure" in *Designing and Deploying Directory and Security Services* of this kit.

# Process for Deploying DNS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Deploying DNS involves planning and designing your DNS infrastructure, including the DNS namespace, DNS server placement, DNS zones, and DNS client configuration. In addition, if you are integrating DNS with Active Directory, you must plan the level of integration and identify your security, scalability, and performance requirements. Figure 3.1 shows the DNS deployment process.

**Figure 3.1 Deploying DNS**

# Concepts about DNS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 DNS is based on Requests For Comments (RFCs) standards developed by the Internet Engineering Task Force (IETF) and is therefore interoperable with other standards-compliant DNS implementations. DNS uses a distributed database that implements a hierarchical naming system. This naming system enables an organization to expand its presence on the Internet and enables the creation of names that are unique both on the Internet and on private TCP/IP-based intranets.

By using DNS, any computer on the Internet can look up the name of any other computer in the Internet namespace. Computers running Windows Server 2003 and Microsoft® Windows® 2000 also use DNS to locate domain controllers and other servers running Active Directory.

**DNS Roles**

Deploying a DNS infrastructure involves design, implementation, and maintenance tasks. The individuals who are responsible for these tasks include DNS designers and the DNS administrators. Before you begin designing your DNS deployment, it is helpful to identify the individuals in your organization who are responsible for these roles. Table 3.1 lists the responsibilities of the DNS designer and DNS administrator roles.

**Table 3.1 DNS Roles**

| Role | Responsibility |
|---|---|
| DNS designer | • Designing the DNS namespace<br>• Placing DNS servers and zones within the DNS namespace<br>• Creating a secure DNS infrastructure<br>• Designing DNS integration with Active Directory |
| DNS administrator | • Deploying, configuring, and managing the DNS infrastructure<br>• Managing Active Directory integration |

**DNS designer role**

If you are deploying DNS to support Active Directory in an environment that does not already have a DNS infrastructure, the DNS designer is responsible for the DNS integration with the entire Active Directory forest. The DNS designer works closely with the DNS administrator for Active Directory.

If you are deploying DNS to support Active Directory in an environment that has an existing DNS infrastructure, the DNS designer works with the DNS administrator for Active Directory to delegate the forest root DNS name to Active Directory. The Active Directory forest administrator delegates management of DNS to a DNS administrator.

**DNS administrator role**

DNS administrators manage and maintain the DNS namespace, DNS servers, DNS clients, DNS zones, and zone propagation. DNS administrators are also responsible for maintaining network security by anticipating and mitigating new security threats. In addition, DNS administrators are responsible for DNS integration with other Windows Server 2003 services.

**New in Windows Server 2003**

Windows Server 2003 DNS includes several new features, including:

- **Conditional forwarding.** Conditional forwarding enables a DNS server to forward DNS queries based on the DNS domain name in the query. For more information about conditional forwarding, see Help and Support Center for Windows Server 2003.

- **DNS application directory partitions.** DNS application directory partitions enable you to set the replication scope for Active Directory–integrated DNS data. By limiting the scope of replication traffic to a subset of the servers running Active

Directory in your forest, you can reduce replication traffic.

- **DNSSEC.** DNS provides basic support for the DNS Security Extensions (DNSSEC) protocol as defined in RFC 2535: *Domain Name System Security Extensions*. For more information about DNSSEC, see Help and Support Center for Windows Server 2003.

- **EDNS0.** Extension Mechanisms for DNS (EDNS0) enable DNS requestors to advertise the size of their UDP packets and facilitate the transfer of packets larger than 512 octets, the original DNS limit for UDP packet size. For more information about EDNS0, see Help and Support Center for Windows Server 2003.

**Tools for Deploying DNS**

Windows Server 2003 includes a number of tools to assist you in deploying a DNS infrastructure.

**Netdiag.exe**

The Netdiag.exe tool assists you in isolating networking and connectivity problems. Netdiag.exe performs a series of tests that you can use to determine the state of your network client. For more information about Netdiag.exe, in Help and Support Center for Windows Server 2003, click **Tools**, and then click Windows Support Tools.

**Nslookup.exe**

You can use the Nslookup.exe command-line tool to perform query testing of the DNS domain namespace and to diagnose problems with DNS servers.

**Dnscmd.exe**

You can use the Dnscmd.exe command-line tool to perform administrative tasks on the DNS server the same as you can by using the DNS Microsoft Management Console (MMC) snap-in.

**DNSLint**

DNSLint is a command-line tool that you can use to address some common DNS name resolution issues, such as lame delegation and DNS record verification. DNSLint is in the Support.cab file in the \Support\Tools folder on the Windows Server 2003 operating system CD. You can install DNSLint by running Suptools.msi.

**Terms and Definitions**

The following are some important DNS-related terms.

**Authoritative DNS server** A DNS server that hosts a primary or secondary copy of zone data. Each zone has at least one authoritative DNS server.

**Conditional forwarding** A DNS query setting that enables a DNS server to route a request for a particular name to another DNS server by specifying a name and IP address. For example, a DNS server in contoso.com can be configured to forward queries for names in treyresearch.com to a DNS server hosting the treyresearch.com zone.

**Delegation** The process of using resource records to provide pointers from parent zones to child zones in a namespace hierarchy. This enable DNS servers in a parent zone to route queries to DNS servers in a child zone for names within their branch of the DNS namespace. Each delegation corresponds to at least one zone.

**DNS client resolver** A service that runs on client computers and sends DNS queries to a DNS server. Some resolvers use a cache to improve name resolution performance.

**DNS namespace** The hierarchical naming structure of the domain tree. Each domain label that is used in a fully qualified domain name (FQDN) indicates a node or branch in the domain tree. For example, host1.contoso.com is an FQDN that represents the node host1, under the node Contoso, under the node com, under the DNS root.

**DNS server** A computer that hosts DNS zone data, resolves DNS queries, and caches the query responses.

**Domain tree** In DNS, the inverted hierarchical tree structure that is used to index domain names within a namespace. Domain trees are similar in purpose and concept to the directory trees used by computer filing systems for disk storage.

**Public namespace** A namespace on the Internet, such as www.microsoft.com, that can be accessed by any connected device. Beneath the top-level domains, the Internet Corporation for Assigned Names and Numbers (ICANN), the Internet Assigned Numbers Authority (IANA), and other Internet naming authorities delegate domains to organizations such as Internet Service Providers (ISPs), which in turn delegate subdomains to their customers or host zones for their customers. For more information about public namespaces, see the Internet Assigned Numbers Authority (IANA) link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Forward lookup zone** An authoritative DNS zone that is primarily used to resolve network resource names to IP addresses.

**Fully qualified domain name (FQDN)** A DNS name that uniquely identifies a node in a DNS namespace. The FQDN of a computer is a concatenation of the computer name (for example, client1) and the primary DNS suffix of the computer (for example, contoso.com), and a terminating dot (for example, contoso.com.).

**Internal namespace** A namespace internal to an organization to which it can control access. Organizations can use the internal namespace to shield the names and IP addresses of its internal computers from the Internet. A single organization might have multiple internal namespaces. Organizations can create their own root servers and any subdomains as needed. The internal namespace can coexist with an external namespace.

**Iterative query** A query made by a client to a DNS server for an authoritative answer that can be provided by the server without generating additional server-side queries to other DNS servers.

**Primary DNS server** A DNS server that hosts read-write copies of zone data, has a DNS database of resource records, and resolves DNS queries.

**Secondary DNS server** A DNS server that hosts a read-only copy of zone data. A secondary DNS server periodically checks for changes made to the zone on its configured primary DNS server, and performs full or incremental zone transfers, as needed.

**Recursive query** A query made by either a client or a DNS server on behalf of a client, the response to which can be an authoritative answer or a referral to another server. Recursive queries continue until the DNS server receives an authoritative answer for the queried name. By default, recursion is enabled for Windows Server 2003 DNS.

**Resource record (RR)** A DNS database structure containing name information for a particular zone. For example, an address (A) resource record can map the IP address 172.16.10.10 to the name DNSserverone.contoso.com or a namespace (NS) resource record can map the name contoso.com to the server name DNS1.contoso.com. Most of the basic RR types are defined in RFC 1035: *Domain Names — Implementation and Specification*, but additional RR types are defined in other RFCs.

**Reverse lookup zone** An authoritative DNS zone that is primarily used to resolve IP addresses to network resource names.

**Stub zone** A partial copy of a zone that can be hosted by a DNS server and used to resolve recursive or iterative queries. Stub zones contain the Start of Authority (SOA) resource records of the zone, the DNS resource records that list the zone's authoritative servers, and the glue address (A) resource records that are required for contacting the zone's authoritative servers. Stub zones are used to reduce the number of DNS queries on a network, and to decrease the network load on the primary DNS servers hosting a particular name.

**Zone** In a DNS database, a contiguous portion of the domain tree that is administered as a single separate entity by a DNS server. The zone contains resource records for all of the names within the zone.

**Zone file** A file that consists of the DNS database resource records that define the zone. DNS data that is Active Directory–integrated is not stored in zone files because the data is stored in Active Directory. However, DNS data that is not Active Directory–integrated is stored in zone files.

**Zone transfer** The process of copying the contents of the zone file located on a primary DNS server to a secondary DNS server. Using zone transfer provides fault tolerance by synchronizing the zone file in a primary DNS server with the zone file in a secondary DNS server. The secondary DNS server can continue performing name resolution if the primary DNS server fails.

# Examining Your Current Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you deploy Windows Server 2003 DNS, you must assess your current environment to determine the DNS needs and constraints of your organization. After that, create a Windows Server 2003 DNS deployment plan to match those needs and constraints. Figure 3.2 shows the process for examining your current environment.

**Figure 3.2 Examining Your Current Environment**

# Determining Internet Status

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you want devices outside your private network to be able to resolve names belonging to your internal namespace, your IP addresses and DNS domain names must be registered with an Internet registration authority (Internet registrar). Internet registrars are organizations that are responsible for:

- Assigning IP addresses.
- Registering DNS domain names.
- Keeping public records of registered IP addresses and domain names.

If your network is currently or will be connected to the Internet, you must ensure that the domain name of your organization is valid and registered to you.

# Identifying the DNS Data Host

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Determine who will host your DNS data. You can either host your DNS data on your own DNS servers or you can have an external ISP host your DNS data. By hosting your own DNS data, you have complete control of network resource allocation and security. Use an ISP if you have a small network that will not be expanding rapidly in the near future.

If you decide to use an ISP to host your DNS data, ensure that the DNS infrastructure of the ISP can support your DNS deployment.

Even if you decide to host your own DNS data, you might consider using an ISP to resolve names outside your private network. For example, the company contoso.com might decide to host all names belonging to the internal namespace corp.contoso.com on its own DNS servers while using an ISP to enable its employees to resolve external Web addresses such as www.microsoft.com.

# Analyzing Your Network Topology

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Analyze your existing network topology and plan your DNS namespace while accounting for the service and administrative goals of your organization.

Allow for anticipated expansion of the number of nodes in your DNS hierarchy by including domain name placeholders between the domain names that you are initially deploying. Adding domain name placeholders enables you to avoid having to redesign your DNS infrastructure to accommodate additional domain names.

Anticipate the possibility of changes to your business model by assigning domain names that can be used in a modified context. For example, instead of using the domain name *accounting.contoso.com*, you might use *finance.contoso.com*, in anticipation of the possibility of expanding into additional financial services beyond accounting.

**Diagram Your Existing DNS Infrastructure**

If you are upgrading to Windows Server 2003, rolling out a new DNS deployment, or integrating Windows Server 2003 DNS with Active Directory, you might not need to make any changes to your existing DNS infrastructure. However, if you are migrating from a third-party DNS infrastructure or integrating Windows Server 2003 DNS with an existing third-party DNS infrastructure, create a diagram of your existing DNS infrastructure, including domains, servers, and clients. Use this diagram to assist you in deciding whether to make changes to your current DNS infrastructure when you deploy Windows Server 2003 DNS.

**Identify Your Security Policies**

Identify and document your organization's security policies before you begin to design and deploy your DNS infrastructure. In this way, you can ensure that your DNS servers, zones, and resource records support these policies. For more information about security policies, see "Deploying Security Policy" in *Designing a Managed Environment* of this kit.

# Designing a DNS Namespace

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you deploy a DNS infrastructure, the DNS designer in your organization must design a DNS namespace. You can design an external namespace that is visible to Internet users and computers, or you can design an internal namespace that is accessible only to users and computers that are within the internal network. After your DNS namespace has been deployed, DNS administrators are responsible for managing and maintaining the DNS namespace. Figure 3.3 shows the process for designing a DNS namespace.

**Figure 3.3 Designing a DNS Namespace**

# Identifying Your DNS Namespace Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The first step in designing a DNS namespace is to determine whether you need a new namespace for your organization, or whether you can retain an existing Windows or third-party DNS namespace.

**Important**

- You must plan your DNS namespace in conjunction with planning your Active Directory logical structure. For more information about designing the Active Directory logical structure, see "Designing the Active Directory Logical Structure" in *Designing and Deploying Directory and Security Services* of this kit.

Table 3.2 summarizes the DNS namespace design requirements for each possible scenario.

**Table 3.2 DNS Namespace Design Requirements**

| Scenario | Design Requirements |
|---|---|
| You are upgrading an existing DNS infrastructure from a version of Windows earlier than Windows Server 2003. | DNS namespace design can remain the same. |
| You are upgrading from a third-party DNS infrastructure that uses DNS software that adheres to standard DNS domain naming guidelines. | DNS namespace design can remain the same. |
| Your existing DNS software does not conform to standard DNS domain naming guidelines. | Bring your existing DNS namespace design into compliance with DNS domain naming guidelines before deploying a Windows Server 2003 DNS namespace. |
| You are integrating Windows Server 2003 DNS into an existing third-party DNS software that adheres to standard DNS domain naming guidelines. | Integrate Windows Server 2003 DNS with your current DNS infrastructure. You do not need to change the namespace design of the third-party DNS infrastructure or your existing namespace. |
| You are deploying a new Windows Server 2003 DNS infrastructure. | Design a logical naming convention for your DNS namespace based on DNS domain naming guidelines. |
| You are deploying Windows Server 2003 DNS to support Active Directory. | Create a DNS namespace design that is based on your Active Directory naming convention. |
| You are modifying your existing DNS namespace to support Active Directory, but you do not want to redesign your DNS namespace. | Ensure that Active Directory domain names match your existing DNS names. This enables you to deploy the highest level of security by using the simplest management techniques. |

# Creating Internal and External Domains

Updated: September 14, 2007

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Organizations that require an Internet presence as well as an internal namespace must deploy both an internal and an external DNS namespace and manage each namespace separately. You can create a mixed internal and external DNS namespace in one of two ways:

- By making the internal domain a subdomain of the external domain.
- By using different names for the internal and external domains.

| **Note** |
| --- |
| You can also use the same name for the internal domain and the external domain. However, this method is not recommended. It creates name resolution problems because it introduces DNS names that are not unique. This method requires additional configuration to enable optimized performance. |

Select the configuration design option that best meets the needs of your organization. Table 3.3 lists the design options for deploying a mixed internal and external namespace and the level of management complexity for each option, along with an example to illustrate each option.

**Table 3.3 Mixed Internal and External DNS Namespace Design Options**

| Design Option | Management Complexity | Example |
| --- | --- | --- |
| The internal domain is a subdomain of the external domain. Microsoft strongly recommends this option. For more information, see Using an Internal Subdomain. | Easy to deploy and administer. | An organization with an external namespace contoso.com uses the internal namespace corp.contoso.com. |
| The internal and external domain names are different from each other. For more information, see Using Different Internal and External Domain Names. | More complicated than previous option. | An organization uses contoso.com for its external namespace, and corp.internal for its internal namespace. |

# Using an Internal Subdomain

Updated: September 14, 2007

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The recommended configuration option for a mixed internal and external DNS namespace is to make your internal domain a subdomain of your external domain. For example, an organization that has an external namespace domain name of contoso.com might use the internal namespace domain name corp.contoso.com. Using an internal domain that is a subdomain of an external domain:

- Requires you to register only one name with an Internet name authority even if you later decide to make part of your internal namespace publicly accessible.
- Ensures that all of your internal domain names are globally unique.
- Simplifies administration by enabling you to administer internal and external domains separately.

You can use your internal subdomain as a parent for additional child domains that you create to manage divisions within your company.

For example, to implement an internal subdomain of the external domain contoso.com:

1. Configure the external DNS server with the namespace contoso.com. This server contains a static zone with only records for servers that are to be available publicly on the Internet. These records would typically include such servers as www.contoso.com, ftp.contoso.com, and so on.
2. Configure the internal DNS server with the namespace corp.contoso.com. Note that while the internal namespace is a subdomain of the external namespace, the internal zone is not delegated from the external zone. That is, the external server does not have a delegation record.
3. Register all hosts in the organization's internal network in the corp.contoso.com namespace, either in the corp.contso.com domain or in child domains within that namespace. For example, a server for the sales department might have the fully qualified domain name of salesvr1.sales.corp.contoso.com.
4. Disable dynamic updates on the external server because no computers in the company's internal network should be registered in the external namespace.
5. Configure the internal DNS server to forward Internet queries to enable internal hosts to resolve external (Internet) names. You can do this in one of two ways:

   - Configure the internal DNS server to forward to the external server, which enables recursion on the external server. In addition, you can configure the internal server as a secondary server to the external server. This enhances the security of the internal network by ensuring that the internal server never makes a query directly on the Internet.
   - Configure the internal DNS server to forward queries to the Internet service provider's DNS server. This method enhances security on the external server because it makes it possible to disable recursion on the external server.

   Instead of using forwarders, the internal DNS server may be configured simply to use the standard Internet root hints to resolve Internet names. The DNS server is configured with the list of standard root hints when the DNS server role is installed. This option is the least secure, however, because it requires the internal DNS server to be able to access DNS servers on the Internet.

# Using Different Internal and External Domain Names

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If it is not possible for you to configure your internal domain as a subdomain of your external domain, use a stand-alone internal domain. This way, your internal and external domain names are unrelated. For example, an organization that uses the domain name contoso.com for their external namespace uses the name corp.internal for their internal namespace.

The advantage to this approach is that it provides you with a unique internal domain name. The disadvantage is that this configuration requires you to manage two separate namespaces. Also, using a stand-alone internal domain that is unrelated to your external domain might create confusion for users because the namespaces do not reflect a relationship between resources within and outside of your network. In addition, you might have to register two DNS names with an Internet name authority if you want to make the internal domain publicly accessible.

# Deciding Whether to Deploy an Internal DNS Root

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you have a large distributed network and a complex DNS namespace, it is best to use an internal DNS root that is isolated from public networks. Using an internal DNS root streamlines the administration of your DNS namespace by enabling you to administer your DNS infrastructure as if the entire namespace consists of the DNS data within your network.

If you use an internal DNS root, a private DNS root zone is hosted on a DNS server on your internal network. This private DNS root zone is not exposed to the Internet. Just as the DNS root zone contains delegations to all of the top-level domain names on the Internet, such as .com, .net, and .org, a private root zone contains delegations to all of the top-level domain names on your network. The DNS server that hosts the private root zone in your namespace is considered to be authoritative for all of the names in the internal DNS namespace.

Using an internal DNS root provides the following benefits:

- **Simplicity.** If your network spans multiple locations, an internal DNS root might be the best method for administering DNS data in a network.

- **Secure name resolution.** With an internal DNS root, DNS clients and servers on your network never contact the Internet to resolve internal names. In this way, the DNS data for your network is not broadcast over the Internet. You can enable name resolution for any name in another namespace by adding a delegation from your root zone. For example, if your computers need access to resources in a partner organization, you can add a delegation from your root zone to the top level of the DNS namespace of the partner organization.

**Important**

- Do not reuse names that exist on the Internet in your internal namespace. If you repeat Internet DNS names on your intranet, it can result in name resolution errors.

If name resolution is required by computers that do not support software proxy, or by computers that support only LATs, then you cannot use an internal root for your DNS namespace. In this case, you must configure one or more internal DNS servers to forward queries that cannot be resolved locally to the Internet.

Table 3.4 lists the types of client proxy capabilities and whether you can use an internal DNS root for each type.

**Table 3.4 Client Proxy Capabilities**

| Proxy Capability | Microsoft Software with Corresponding Proxy Capabilities | Forwards Queries | Can You Use an Internal Root? |
|---|---|---|---|
| No Proxy | Generic Telnet | ● | |
| Local Address Table (LAT) | Winsock Proxy (WSP) 1.*x* and later<br>Microsoft® Internet Security and Acceleration (ISA) Server 2000 and later | ● | |
| Name Exclusion List | WSP 1.*x* and later<br>Internet Security and Acceleration (ISA) Server 2000 and later, and all versions of Microsoft® Internet Explorer | ● | ● |
| Proxy Auto-configuration (PAC) File | WSP 2.*x*, Internet Security and Acceleration Server (ISA) Server 2000 and later, Internet Explorer 3.01 and later | ● | ● |

# Configuring Name Resolution for Disjointed Namespaces

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you need to create or merge two DNS namespaces when you deploy Windows Server 2003 DNS, this can result in *disjointed namespaces* — a DNS infrastructure that includes two or more top-level DNS domain names. To configure internal name resolution for multiple DNS top-level domains, you must do one of the following:

- If you have an internal DNS root, add delegations for each top-level DNS zone to the internal DNS root zone.
- If you want to reduce cross-domain DNS query traffic, configure the DNS servers that host the DNS zones in the first and second namespaces to host secondary zones for the DNS zones in each other's namespaces. In this configuration, the DNS servers that host the DNS zones in each namespace are aware of the DNS servers in the other namespace. This solution requires increased storage space for hosting secondary copies of zones in different namespaces, and generates increased zone transfer traffic.
- If storage capacity on DNS servers is a consideration, configure the DNS servers that host the DNS zones in one namespace to forward name resolution queries in a second namespace to the DNS servers that are hosting the DNS zones for the second namespace. Then configure the DNS servers that host the DNS zones in the second namespace to forward name resolution queries in the first namespace to the DNS servers that are hosting the DNS zones for the first namespace. You can use Windows Server 2003 DNS conditional forwarders for this configuration.

You can also use Windows Server 2003 DNS stub zones to facilitate DNS data distribution between separate namespaces. For more information about conditional forwarders and stub zones, see Help and Support Center for Windows Server 2003 and the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

# Integrating a Windows Server 2003 DNS Infrastructure Into an Existing DNS Namespace

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 DNS is standards-compliant and interoperates with other implementations of DNS, including Microsoft® Windows NT® version 4.0, BIND 9.1.0, BIND 8.2, BIND 8.1.2, and BIND 4.9.7. The complexity of your integration process depends, in part, on the DNS features that you need to support. If the computers in your DNS infrastructure are running versions of DNS that support the same features, then integrating the Windows Server 2003 DNS infrastructure is a simple process. If the computers in your DNS infrastructure are running versions of DNS that do not support the same DNS features, then the integration process is more complex.

Table 3.5 compares feature support in Windows Server 2003 DNS and other implementations of DNS.

**Table 3.5 Feature Support in Different Implementations of DNS**

| Feature | Windows Server 2003 | Windows 2000 | Windows NT 4.0 | BIND 9 | BIND 8.2 | BIND 8.1.2 | BIND 4.9.7 |
|---|---|---|---|---|---|---|---|
| Supports RFC 2782: *A DNS RR for specifying the location of services (DNS SRV)* | ● | ● | ● | ● | ● | ● | ● |
| Dynamic update | ● | ● | | ● | ● | ● | |
| Secure dynamic update based on the GSS-Transaction signature (TSIG) algorithm | ● | ● | | | | | |
| WINS and WINS-R records | ● | ● | ● | | | | |
| Incremental zone transfer | ● | ● | | ● | ● | | |
| UTF-8 character encoding | ● | ● | | | | | |
| DNS MMC snap-in | ● | ● | | | | | |
| Dnscmd.exe | ● | ● | | | | | |
| Active Directory–integrated zones | ● | ● | | | | | |

| Aging and scavenging of obsolete records | ● | ● | | | | | |
| Stub zones | ● | ● | | ● | | | |
| Conditional forwarding | ● | | | ● | | | |

# Creating DNS Domain Names and Computer Names

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you deploy your Windows Server 2003 DNS infrastructure, you must create a naming convention for your DNS Internet and internal domains and the DNS computers on your network. To create a DNS naming convention, you must establish the following:

- An Internet DNS domain name, if your organization is connected to the Internet.
- An internal DNS domain name for your organization.
- A DNS resource naming convention.

In addition, you must determine whether you need to support NetBIOS names in your organization.

# Creating an Internet DNS Domain Name

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you are deploying a new Windows Server 2003 DNS infrastructure that is connected to the Internet, you must create an Internet DNS domain name for your organization. Because all of the nodes in your network that require name resolution are assigned a DNS name that includes the Internet DNS domain name for your organization, it is important to select an Internet DNS domain name that is short and easy to remember. Because DNS is hierarchical, DNS domain names grow when you add subdomains to your organization. Short domain names result in computer names that are easy to remember, facilitating resource access.

A DNS namespace that is connected to the Internet must be a subdomain of a top-level or second-level domain of the Internet DNS namespace. If you are deploying a new Windows Server 2003 DNS namespace, you must select a top-level Internet DNS domain in which to register your Internet DNS domain name. For example, you can register your domain as a subdomain of .com, .org, or .net, or as a subdomain of the domain name that is assigned to your country/region, such as .au (Australia), .fr (France) or .ca (Canada).

When you have selected your Internet DNS domain name and identified the top-level domain for which your DNS domain is a subdomain, complete the following steps to register your DNS domain name:

1. Search the Internet to confirm that the DNS domain name that you selected for your organization is not registered to another organization. If the DNS domain name that you selected is owned by another organization, you can attempt to buy it from that organization, or select a different DNS domain name.

2. Configure at least one authoritative DNS server to host the DNS zone for your domain name. This DNS server might be located on your network or on the network of your ISP.

3. Register your DNS domain name with an Internet registrar, and supply the registrar with the DNS name and IP address of at least one DNS server that is authoritative for your DNS domain name. For a list of Internet registrars, see the ICANN link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

The Internet domain name registration process varies according to the design of your DNS namespace. Table 3.6 lists the domain names that you need to register for each type of DNS namespace design.

**Table 3.6 Internet DNS Domain Name Registration**

| Namespace Design | Domain Name Registration | Example |
|---|---|---|
| The internal domain name is a subdomain of the external domain. | Register only the external domain name. | The domain name contoso.com is used for the external namespace.<br>The domain name corp.contoso.com is used for the internal namespace. |
| The internal and external domain names are different from each other. | Register the external domain name, and then, if you want the internal domain to be publicly accessible, also register the internal domain name. | The domain name contoso.com is used for the external namespace.<br>The domain name corp.contoso.com is used for the internal namespace. |

When you register your DNS domain name, the Internet registrar creates a delegation in the DNS zone that is authoritative for the top-level domain that you selected. This is the top-level domain for the DNS servers that are authoritative for your organization's Internet DNS domain name.

**Note**

- If a domain name that you want to register is not available in one top-level domain, such as .com, and you register the same domain name in another top-level domain, such as .net, then people who are searching for your domain name on the Internet might assume that computers and services in the wrong top-level domain belong to your company.

# Creating Internal DNS Domain Names

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When creating names for your internal domains, use the following guidelines:

- If your organization has an Internet presence, use names relative to your registered Internet DNS domain name. For example, if you have registered the Internet DNS domain name contoso.com for your organization, use a DNS domain name such as corp.contoso.com for your intranet domain name.
- Do not use the name of an existing corporation or product as your domain name.
- Do not use top-level Internet domain names, such as .com, .net, .org, .us, .fr, .gr, on your intranet. Using top-level Internet domain names on your intranet can result in name resolution errors for computers on your network that are connected to the Internet.
- Do not use acronyms or abbreviations for domain names. The business units that these acronyms represent can be difficult for users to recognize.
- Do not use business unit or division names for domain names. Business units and other divisions change periodically and the domain names can become obsolete or misleading.
- Do not use geographic names that are difficult to spell and remember.
- Avoid extending your DNS domain name hierarchy more than five levels from the internal or DNS root domain. Limiting the extent of the domain name hierarchy reduces administrative costs.

If you are deploying DNS in a private network and do not plan to create an external namespace, it is recommended that you register the DNS domain name that you create for your internal domain. If you do not register the name and later attempt to use it on the Internet, or connect to a network that is connected to the Internet, you might find that the name is unavailable.

# Creating DNS Computer Names

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is important to develop a practical DNS computer naming convention for your network. This enables users to remember the names of computers on public and private networks easily, and therefore facilitates access to resources on your network.

The DNS computer name creation process varies according to whether you are creating a new DNS infrastructure, integrating your DNS infrastructure with an existing third-party infrastructure, or upgrading an existing DNS infrastructure.

**Creating Computer Names in a New Windows Server 2003 DNS Infrastructure**
Use the following guidelines when creating names for the DNS computers in your new Windows Server 2003 DNS infrastructure:

- Select computer names that are easy for users to remember.
- Identify the owner of a computer in the computer name. For example, john-doe-1 indicates that John Doe uses the computer.
- Select names that describe the purpose of the computer. For example, a file server named past-accounts-1 indicates that the file server stores information related to past accounts.
- Do not use character case to convey the owner or purpose of a computer. DNS is not case-sensitive.
- If you are deploying DNS to support Active Directory, match the Active Directory domain name to the primary DNS suffix of the computer name. For more information about designing the Active Directory logical structure, see "Designing the Active Directory Logical Structure" in *Designing and Deploying Directory and Security Services* of this kit.
- Use unique names for all computers in your organization. Do not assign the same computer name to different computers in different DNS domains.
- Use ASCII characters to ensure interoperability with computers running versions of Windows earlier than Windows 2000. For DNS computer names, use only the characters listed in RFC 1123:*Requirements for Internet Hosts — Application and Support*, which include A–Z, a–z, 0–9, and the hyphen (-). Windows Server 2003 DNS supports almost any UTF-8 character in a name; however, do not use extended ASCII or UTF-8 characters unless all of the DNS servers in your environment support them.

**Note**

- Windows Server 2003 DNS is configured to use UTF-8 name checking by default.

**Creating Computer Names in an Integrated DNS Infrastructure**
If you are integrating Windows Server 2003 DNS with an existing third-party DNS infrastructure, you do not need to make any changes to your third-party DNS host names. If you are migrating to Windows Server 2003 DNS from a third-party DNS infrastructure, you must ensure that the host names that are used in the third-party DNS infrastructure conform to the DNS Internet naming standards.

If you are integrating or migrating an existing public DNS infrastructure that is connected to the Internet into your existing DNS infrastructure, you do not need to make any changes to the DNS domain names of your infrastructure.

**Creating Computer Names When Upgrading a DNS Infrastructure**
If you are upgrading to Windows Server 2003 DNS from Windows NT 4.0, you do not need to change your DNS host names; however, you might need to convert any NetBIOS names to DNS names. DNS names must conform to the DNS standard defined by RFC 1123.

Table 3.7 lists the different character sets that are supported by standard DNS, Windows Server 2003 DNS, and NetBIOS.

**Table 3.7 Character Set Restrictions**

| Character Set Restriction | Standard DNS (Including Windows NT 4.0) | DNS in Windows 2000 and Windows Server 2003 | NetBIOS |
|---|---|---|---|
| Characters permitted | Supports RFC 1123, which permits A–Z, a–z, 0–9, and the hyphen (-). | Supports RFC 1123 and UTF-8. On a per-server basis, You can configure the Windows 2000 DNS Server service to allow or disallow the use of UTF-8 characters on your DNS server. | Not allowed: Unicode characters, numbers, white space, symbols: / \ [ ] : \| < > + = ; , ? and *) |
| Maximum host name and FQDN length. | 63 octets per label.<br>255 bytes per FQDN (254 bytes for the FQDN plus one byte for the terminating dot). | The same as standard DNS with the addition of UTF-8 support. Character count is insufficient to determine size because some UTF-8 characters exceed one octet in length. Domain controllers are limited to 155 bytes for an FQDN. | 16 bytes in length. |

**Important**

- Names encoded in UTF-8 format must not exceed the limits defined in RFC 2181: *Clarifications to the DNS Specification*, which specifies a maximum of 63 octets per label and 255 octets per name.

# Determining if You Need to Support NetBIOS Names

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

During a domain upgrade to Windows Server 2003, you might need to support NetBIOS on your network if your domain includes clients that are running versions of Windows earlier than Windows 2000. For example, if your network is multi-segmented, WINS is required to create the NetBIOS browse list. Without WINS, the network must rely on Active Directory for browsing resources. This can have a significant impact on clients that are running applications that require NetBIOS support, even if the client operating system does not require NetBIOS support. When WINS is installed, performance monitor counters for WINS are also installed. Use these WINS performance monitor counters to determine how many queries WINS is receiving, and how many names WINS is resolving. This information will help you to determine whether it is necessary to support NetBIOS names on the network.

Windows Server 2003 DNS is compatible with WINS; therefore, in a mixed networking environment, you can use a combination of DNS and WINS. Windows NT 4.0–based clients can register in both Windows 2000 WINS and Windows Server 2003 WINS. Also, computers running either the Microsoft® Windows® 2000 Professional or Windows® XP Professional operating systems can register in Windows NT 4.0 WINS. To maintain backward compatibility, each computer is given a NetBIOS name that must be unique in the domain to which the computer belongs.

Preserving existing NetBIOS names can be difficult because NetBIOS names have a broader character set than DNS names. One solution is to replace NetBIOS names with DNS names to ensure that the names adhere to existing DNS naming standards. This is not possible for organizations that support computers running versions of Windows earlier than Windows 2000.

RFC 2181: *Clarifications to the DNS Specification* expands the character set that is allowed in DNS names to include any binary string. The binary strings do not have to be interpreted as ASCII. Windows 2000 and Windows Server 2003 support UTF-8 character encoding (RFC 2044). UTF-8 is a superset of ASCII and a translation of the UCS-2 (or Unicode) character encoding. The UTF-8 character set enables you to transition from Windows NT 4.0 NetBIOS names to Windows 2000 and Windows Server 2003 DNS names

By default, multibyte UTF-8 name checking is used. This provides the greatest tolerance when the DNS service processes characters. This is the preferred name-checking method for most DNS servers that are not providing name resolution services for Internet hosts.

**Important**

- Windows Server 2003 and Windows 2000 DNS support NetBIOS and UTF-8 characters for computer names. Other versions of DNS only support the characters permitted in RFC 1123. Therefore, only use NetBIOS and UTF-8 character sets when you are certain that Windows Server 2003 or Windows 2000 DNS is the method used for name resolution. Names that are intended to be visible on the Internet must contain ASCII-only characters, as recommended in RFC 1123.

# Creating Subdomains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you are deploying DNS on a large enterprise network, or if you expect your network to expand to include additional subnets and sites, consider distributing the management of portions of your DNS namespace to the administrators for the different subnets and sites in your network. To distribute the management of your DNS namespace, create subdomains of your initial DNS domain and delegate the authority for these subdomains to DNS servers located on different subnets or sites. In this way, you can create any number of separate and autonomous entities within a DNS namespace, each of which is authoritative for a portion of the overall namespace.

# Example: Merging DNS Namespaces

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Contoso Corporation merged with Trey Research Corporation. Before the merger, each corporation used internal domains that were subdomains of their external domains. The Contoso Corporation used a private root to simplify their DNS server administration. The Trey Research Corporation forwarded queries to the Internet, rather than using a private root.

The external namespace of the newly merged corporation contains the zones contoso.com and treyresearch.com. Each zone in the external namespace contains the DNS resource records that the companies want to expose to the Internet. The internal namespace contains the internal zones, *corp.contoso.com* and *corp.treyresearch.com*.

The Contoso division and the Trey Research division each use a different method to support name resolution for names in their namespace. The Contoso division uses the name contoso.com externally and corp.contoso.com internally. The internal root servers host the root zone. Internal servers also host the zone, corp.contoso.com. The name contoso.com is registered with an Internet name authority.

To ensure that every client within the organization can resolve every name in the newly merged organization, the private root zone contains a delegation to the zone for the top level of the merged organization's internal namespace, corp.treyresearch.com.

To resolve internal and external names, every DNS client must submit all queries to either the internal DNS servers or to a proxy server. Figure 3.4 shows this configuration.

**Figure 3.4 Name Resolution in the Contoso Division**

Based on this configuration, internal clients can query for names in the following ways:

- **Query internal DNS servers for internal names.** The internal DNS servers resolve the query. If a DNS server that receives a query does not contain the requested data in its zones or cache, it uses root hints to contact the internal root DNS servers.

- **Query a proxy server for names on the Internet.** The proxy server forwards the query to DNS servers on the Internet. The DNS servers on the Internet resolve the query.

- **Query internal DNS servers for names in the Trey Research division.** Because the root servers contain a delegation to the top level of the DNS namespace of the Trey Research division, the internal DNS servers recursively resolve the query by contacting the DNS servers in the Trey Research division.

External clients:

- **Cannot query for internal names.** This limitation helps secure the internal network.

- **Query DNS servers on the Internet for names in the contoso.com external namespace.** The DNS servers on the Internet resolve the query.

The Trey Research division uses the name treyresearch.com externally and the name corp.treyresearch.com internally. The server InternalDNS.treyresearch.com hosts the corp.treyresearch.com zone. The Trey Research division does not have a private root.

To simplify management of clients and DNS servers, Trey Research division administrators decided to use conditional forwarding. Administrators configured the DNS server InternalDNS.treyresearch.com to forward queries in the following manner:

- The server forwards all queries destined for the Contoso division to a DNS server for the Contoso division. For example, the server forwards queries destined for corp.contoso.com to InternalDNS.contoso.com.

- At the same time, the server forwards all other queries destined for contoso.com to a DNS server on the Internet.

Figure 3.5 shows this configuration.

**Figure 3.5 Conditional Forwarding in the Trey Research Division**

# Designing a DNS Server Infrastructure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

DNS servers store information about the DNS namespace and use the information to answer queries from DNS clients. The size of the DNS zone data, how many DNS clients you have, and where these clients are physically located all impact your DNS server topology.

The DNS designer in your organization designs DNS servers that enable you to create an effective DNS data distribution and update topology while minimizing query and zone transfer network traffic. The DNS administrators in your organization manage and maintain your DNS servers. Figure 3.6 shows the process for designing DNS servers.

**Figure 3.6 Designing a DNS Server Infrastructure**

# Allocating Hardware Resources

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A typical recommendation for DNS server hardware includes the following:

- Single-processor computers with 400 megahertz (MHz) Pentium II CPUs.
- 256 megabytes (MB) of RAM for each processor.
- At least 4 gigabytes (GB) of available hard disk space.
- A network adapter.

Using faster CPUs, more RAM, and larger hard drives improves the scalability and performance of your DNS servers. DNS servers use approximately 100 bytes of RAM for each resource record. Using this figure, you can calculate how much memory you need.

# Determining the Number of Required DNS Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To reduce administrative overhead, use the minimum number of DNS servers required. Be sure to make at least two DNS servers authoritative for each zone to enable fault tolerance and load sharing.

Add additional DNS servers in order to:

- Provide redundancy when your namespace design requires greater DNS availability.
- Improve query response time when better DNS performance is required.
- Reduce WAN traffic for remote locations.

Use the following guidelines to determine the number of DNS servers that you need to deploy:

- If the ratio of DNS servers to clients is very low and you are experiencing significant name resolution delays, add additional DNS servers to host secondary or Active Directory–integrated zones. Use your anticipated number of queries and dynamic updates per second to determine the number of DNS servers that you need. The Windows Server 2003 DNS Server service is capable of responding to more than 10,000 queries per second on a Pentium III microprocessor running at 700 MHz.

  For information about capacity planning, see "Allocating Hardware Resources" earlier in this chapter.

- If you delegate zones, add additional DNS servers to handle the delegated zones. Note that you do not need to delegate zones when you have multiple zones. You can host all zones on the same server or servers. One DNS server running Windows Server 2003 can host 20,000 small zones.
- If you plan to host Active Directory–integrated zones, you must place these zones on Windows 2000–based or Windows Server 2003–based domain controller.
- If high-volume traffic is a consideration in your environment, add additional DNS servers to balance the workload. Although DNS helps reduce broadcast traffic between local subnets, it does create some traffic between servers and clients, particularly in complex routed environments. In addition, although the DNS service supports incremental zone transfers (IXFRs) and clients and servers can cache recently used names, traffic considerations can still remain an issue, depending on available bandwidth. This is especially true when using short Dynamic Host Configuration Protocol (DHCP) leases, which require more frequent dynamic updates.
- If you have a high number of client nodes on a single subnet, placing more than one DNS server on the subnet allows for backup and failover in the event that the primary DNS server stops responding.

If your DNS design includes primary and secondary zones and you run a large number of secondary servers for a zone, the primary DNS server can become overloaded when the secondary servers poll to ensure that their zone data is current. You can solve this problem in one of three ways:

- Use some of the secondary DNS servers as primary servers for the zone. Other secondary servers can poll and request zone updates from these primary servers.
- Increase the refresh interval so that the secondary servers poll less frequently. Note, however, that a longer refresh interval might cause your secondary zones to be outdated more often.

# Determining DNS Server Placement

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The placement of your DNS servers and the number of DNS servers that you deploy affects the availability of DNS. It is important to ensure that you plan the placement of your DNS servers to allow for DNS availability and Active Directory availability.

**Placing DNS Servers for Availability**
To ensure that DNS is always available, make sure that your DNS infrastructure does not include any single points of failure. To improve fault tolerance and load sharing have clients point to a primary and alternate DNS server. In a LAN configuration, place the pair of authoritative DNS servers on separate subnets. In a WAN configuration, place the pair of authoritative DNS servers on different networks, and then ensure that at least one DNS server is available for each network. This configuration removes routers as potential points of failure. Whenever possible, distribute your DNS servers across different geographic locations to enable communications to continue in the event of a natural disaster.

If you identify single points of failure in your network, determine whether they affect only DNS or all network services. If a router goes down and your clients cannot access any network services, then DNS failure is not an issue. If a router goes down and local DNS servers are unavailable but other network services are available, then your clients cannot access required network resources because they cannot look up DNS names.

If you have an Internet presence, DNS must be working properly for Internet clients to access your Web servers, send mail, and locate other services; therefore, it is recommended that you run a secondary DNS server offsite. If you have a business relationship with an organization on the Internet, either business partners or ISPs, they might agree to run a secondary server for you; however, ensure that the data on the organization's server is secured against Internet attackers.

To ensure that DNS is available if your offsite primary DNS servers are down, consider deploying a secondary DNS server offsite.

For more information about how to place DNS servers to maximize Active Directory availability, see "Designing the Active Directory Logical Structure" in *Designing and Deploying Directory and Security Services* of this kit.

# Using Forwarding

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If a DNS server does not have the data to resolve a query in its cache or in its zone data, it forwards the query to another DNS server, known as a *forwarder*. Forwarders are ordinary DNS servers and require no special configuration; a DNS server is called a forwarder because it is the recipient of a query forwarded by another DNS server.

Use forwarding for off-site or Internet traffic. For example, a branch office DNS server can forward all off-site traffic to a forwarder at the company headquarters, and an internal DNS server can forward all Internet traffic to a forwarder on the external network. To ensure fault tolerance, forward queries to more than one forwarder.

Forwarders can increase network security by minimizing the list of DNS servers that communicate across a firewall.

You can use conditional forwarding to more precisely control the name resolution process. Conditional forwarding enables you to designate specific forwarders for specific DNS names. You can use conditional forwarding to resolve the following:

- Queries for names in off-site internal domains
- Queries for names in other namespaces

**Using Conditional Forwarding to Query for Names in Off-Site Internal Domains**

In Windows Server 2003 DNS, non-root servers resolve names for which they are not authoritative, do not have a delegation, and do not have in their cache by doing one of the following:

- Querying a root server.
- Forwarding queries to a forwarder.

Both of these methods generate additional network traffic. For example, a non-root server in Site A is configured to forward queries to a forwarder in Site B, and it must resolve a name in a zone hosted by a server in Site C. Because the non-root server can forward queries only to Site B, it cannot directly query the server in Site C. Instead, it forwards the query to the forwarder in Site B, and the forwarder queries the server in Site C.

When you use conditional forwarding, you can configure your DNS servers to forward queries to different servers based on the domain name specified in the query. This eliminates steps in the forwarding chain and reduces network traffic. When conditional forwarding is applied, the server in Site A can forward queries to forwarders in Site B or Site C, as appropriate.

For example, the computers in the Seville site need to query computers in the Hong Kong site. Both sites use a common DNS root server, DNS3.corp.fabrikam.com, located in Seville.

Before the Contoso Corporation upgraded to Windows Server 2003, the server in Seville forwarded all queries that it could not resolve to its parent server, DNS1.corp.contoso.com, in Seattle. When the server in Seville queried for names in the Hong Kong site, the server in Seville first forwarded those queries to Seattle.

After upgrading to Windows Server 2003, administrators configured the DNS server in Seville to forward queries destined for the Hong Kong site directly to a server in that site, instead of first detouring to Seattle, as shown in Figure 3.7.

**Figure 3.7 Conditional Forwarding to an Off-Site Server**

Administrators configured DNS3.corp.fabrikam.com to forward any queries for corp.treyresearch.com to DNS5.corp.treyresearch.com or DNS6.corp.treyresearch.com. DNS3.corp.fabrikam.com forwards all other queries to DNS1.corp.contoso.com or DNS2.corp.contoso.com.

For more information about conditional forwarding in Windows Server 2003 DNS, see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

**Using Conditional Forwarding to Query for Names in Other Namespaces**

If your internal network does not have a private root and your users need access to other namespaces, such as a network belonging to a partner company, use conditional forwarding to enable servers to query for names in other namespaces. Conditional forwarding in Windows Server 2003 DNS eliminates the need for secondary zones by configuring DNS servers to forward queries to different servers based on the domain name.

For example, the Contoso Corporation includes two namespaces: Contoso and Trey Research. Computers in each division need access to the other namespace. In addition, computers in both divisions need access to computers in the Supplier private namespace.

Before upgrading to Windows Server 2003, the Trey Research division created secondary zones to ensure that computers in both the Contoso and Trey Research namespace can resolve names in the Contoso, Trey Research, and Supplier namespaces. After upgrading to Windows Server 2003, the Trey Research division deleted its secondary zones and configured conditional forwarding instead.

# Upgrading DNS Servers to Windows Server 2003 DNS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The procedure you need to follow to upgrade DNS servers to Windows Server 2003 depends on whether you want to support Active Directory or not. If you are upgrading to Windows Server 2003 DNS and might not support Active Directory, for information about upgrading your existing DNS servers or migrating third-party DNS servers, see "Migrating servers" in Help and Support Center for Windows Server 2003. Migration involves the following:

- Plan your migration schedule to ensure that your DNS clients have access to a DNS server at all times.
- Back up your existing configuration.
- Migrate data from existing DNS servers to Windows Server 2003 DNS.

If you are upgrading your DNS servers to support Active Directory, see "Designing the Active Directory Logical Structure" in *Designing and Deploying Directory and Security Services* of this kit.

After you have upgraded or migrated your servers, test them to ensure that they are resolving correctly. For more information about DNS troubleshooting and testing DNS server performance, see "Monitor Servers" in Help and Support Center for Windows Server 2003, and the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

# Designing DNS Zones

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Each zone type that is available in Windows Server 2003 DNS has a specific purpose. The DNS designer in your organization selects the type of zones to deploy based on the practical purpose of each zone. The DNS administrators in your organization manage and maintain your DNS zones. Figure 3.8 shows the process for designing DNS zones.

**Figure 3.8 Designing DNS Zones**

# Choosing a Zone Type

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Design zones to correspond to your network administration infrastructure. If a site in your network is administered locally, deploy a zone for the subdomain. If a department has a subdomain, but no administrator, keep the subdomain in the parent zone. Decide whether or not to store your zones in Active Directory. Active Directory distributes data using a multimaster replication model that provides more security than standard DNS. With the exception of secondary zones, you can store all zone types in Active Directory because all other zones are considered primary zones. When designing DNS zones, host each zone on more than one DNS server.

Decide which type of zone to use, based on your domain structure. For each zone type, with the exception of secondary zones, decide whether to deploy file-based zones or Active Directory–integrated zones.

**Primary Zones**
Deploy primary zones that correspond to your planned DNS domain names. You cannot store both an Active Directory–integrated and a file-based primary copy of the same zone on the same DNS server.

**Secondary Zones**
Add secondary zones if you do not have an Active Directory infrastructure. If you do have an Active Directory infrastructure, use secondary zones on DNS servers that are not serving as domain controllers. A secondary zone contains a complete copy of a zone. Therefore, use secondary zones to improve zone availability at remote sites if you do not want zone data propagated across a WAN link by means of Active Directory replication.

**Stub Zones**
A *stub zone* is a copy of a zone that contains only the original zone's start of authority (SOA) resource record, the name server (NS) resource records listing the authoritative servers for the zone, and the glue address (A) resource records that are needed to identify these authoritative servers.

A DNS server that is hosting a stub zone is configured with the IP address of the authoritative server from which it loads. DNS servers can use stub zones for both iterative and recursive queries. When a DNS server hosting a stub zone receives a recursive query for a computer name in the zone to which the stub zone refers, the DNS server uses the IP address to query the authoritative server, or, if the query is iterative, returns a referral to the DNS servers listed in the stub zone.

Stub zones are updated at regular intervals, determined by the refresh interval of the SOA resource record for the stub zone. When a DNS server loads a stub zone, it queries the zone's primary servers for SOA resource records, NS resource records at the zone's root, and glue address (A) resource records. The DNS server attempts to update its resource records at the end of the SOA resource record's refresh interval. To update its records, the DNS server queries the primary servers for the resource records listed earlier.

You can use stub zones to ensure that the DNS server that is authoritative for a parent zone automatically receives updates about the DNS servers that are authoritative for a child zone. To do this, add the stub zone to the server that is hosting the parent zone. Stub zones can be either file-based or Active Directory–integrated. If you use Active Directory–integrated stub zones, you can configure them on one computer and let Active Directory replication propagate them to other DNS servers running on domain controllers.

Although conditional forwarding is the recommended method for making your servers aware of other namespaces, you can also use stub zones for this. For more information about using stub zones, see Help and Support Center for Windows Server 2003.

### Note

- Only DNS servers running Windows Server 2003 and BIND 9 support stub zones.

**Stub Zones and Conditional Forwarding**
Stub zones and conditional forwarding are Windows Server 2003 DNS features that enable you to control the routing of DNS traffic over a network. These features enable a DNS server to respond to a query by doing one of the following:

- Providing a referral to another DNS server.
- Forwarding the query to another DNS server.

A stub zone enables a DNS server that is hosting a parent zone to be aware of the names and IP addresses of DNS servers that are authoritative for a child zone, even if the DNS server does not have a complete copy of the child zone. In addition, when a stub zone is used, the DNS server does not have to send queries to the DNS root servers. If the stub zone for a child zone is hosted on the same DNS server as the parent zone, the DNS server that is hosting the stub zone receives a list of all new authoritative DNS servers for the child zone when it requests an update from the stub zone's primary server. In this way, the DNS server that is hosting the parent zone maintains a current list of the authoritative DNS servers for the child zone as the authoritative DNS servers are added and removed.

Use conditional forwarding if you want DNS servers in one network to perform name resolution for DNS clients in another network. You can configure DNS servers in separate networks to forward queries to each other without querying DNS servers on the Internet. If DNS servers in separate networks forward DNS client names to each other, the DNS servers cache this information. This enables you to create a direct point of contact between DNS servers in each network and reduces the need for recursion.

If you are using a stub zone and you have a firewall between DNS servers in the networks, then DNS servers on the query/resolution path must have port 53 open. However, if you are using conditional forwarding and you have a firewall between DNS servers in each of the networks, the requirement to have port 53 open only applies to the two DNS servers on either side of the firewall.

**Active Directory–Integrated Zones**
If your DNS topology includes Active Directory, use Active Directory–integrated zones. Active Directory–integrated zones enable you to store zone data in the Active Directory database. Zone information about any primary DNS server within an Active Directory–integrated zone is always replicated.

Because DNS replication is single-master, a primary DNS server in a standard primary DNS zone can be a single point of failure. In an Active Directory–integrated zone, a primary DNS server cannot be a single point of failure because Active Directory uses multimaster replication. Updates that are made to any domain controller are replicated to all domain controllers and the zone information about any primary DNS server within an Active Directory–integrated zone is always replicated. Active Directory–integrated zones:

- Enable you to secure zones by using secure dynamic update.
- Provide increased fault tolerance. Every Active Directory–integrated zone can be replicated to all domain controllers within the Active Directory domain or forest. All DNS servers running on these domain controllers can act as primary servers for the zone and accept dynamic updates.
- Enable replication that propagates changed data only, compresses replicated data, and reduces network traffic.

If you have an Active Directory infrastructure, you can only use Active Directory–integrated zones on Active Directory domain controllers. If you are using Active Directory–integrated zones, you must decide whether or not to store Active Directory–integrated zones in the application directory partition.

You can combine Active Directory–integrated zones and file-based zones in the same design. For example, if the DNS server that is authoritative for the private root zone is running on an operating system other than Windows Server 2003 or Windows 2000, it cannot act as an Active Directory domain controller. Therefore, you must use file-based zones on that server. However, you can delegate this zone to any domain controller running either Windows Server 2003 or Windows 2000.

**Storing Active Directory–Integrated Zones in Application Directory Partitions**
Windows Server 2003 Active Directory enables you to configure an application directory partition that limits the scope of replication. Data stored in an application directory partition is replicated to a subset of domain controllers. This subset is determined by the replication scope of the data. In the default configuration of Windows Server 2003 Active Directory, DNS application directory partitions are present only on the domain controllers that run the DNS Server service. By storing Active Directory–integrated zones in an application directory partition, you can reduce the number of objects that are stored in the global catalog, and you can reduce the amount of replication traffic within a domain.

In contrast, Active Directory–integrated zones that are stored in domain directory partitions are replicated to all domain controllers in the domain. Storing Active Directory–integrated zones in an application directory partition allows replication of DNS data to domain controllers anywhere in the same Active Directory forest.

When you are setting up your Active Directory environment and installing the first Windows Server 2003 domain controller in the forest, if you install DNS, two Windows Server 2003 DNS application directory partitions are created by default. A forest-

wide DNS application directory partition called **ForestDNSZones** will be created, and for each domain in the forest, a domain-wide DNS application directory partition called **DomainDNS Zones** will be created.

# Choosing a Propagation Method

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you decide which zone each DNS server hosts, decide how to propagate the zones among the servers. Propagated zones provide higher availability, improve query response time, and reduce network traffic produced by name queries. However, propagated zones require storage space and increase network traffic. If your network is distributed and managed at different sites, use subdomains for these sites. If you do not have a distributed network, avoid using subdomains when possible.

In Windows Server 2003, zones are propagated by means of file-based zone transfer or Active Directory replication. If you use file-based zones, file-based zone transfer is the method of propagation. If you have Windows Server 2003 and Windows 2000 Active Directory–integrated zones, use Active Directory replication.

**File-Based Zone Transfer**
Windows Server 2003 and Windows 2000 DNS support both incremental and full zone transfer of file-based zones. Incremental zone transfer is the default method, but if this method is not supported by a third-party DNS server that is involved in the transfer, DNS servers running Windows Server 2003 and Windows 2000 transfer the full zone.

Incremental zone transfer, described in RFC 1995:*Incremental Zone Transfer in DNS*, provides better use of available network bandwidth. Rather than sending the entire contents of the zone file, the primary server only transfers the incremental changes in the zone. This reduces the impact of DNS zone transfers on network traffic. Without incremental zone transfers, the primary server transfers the entire zone file to the secondary server every time a DNS zone is updated.

Windows Server 2003 DNS uses full zone transfer when zones must be transferred to DNS servers that do not support incremental zone transfer, such as DNS servers running on Windows NT 4.0 or earlier versions of BIND 8.

**Active Directory Replication**
Active Directory replication propagates zone changes between domain controllers. Replication processing differs from DNS full zone transfers, in which the DNS server transfers the entire zone. Replication processing also differs from incremental zone transfers, in which the server transfers all changes made since the last change.

Active Directory zone replication provides the following additional benefits:

- Network traffic is reduced because the domain controllers only send the final result of all changes.
- When a zone is stored in Active Directory, replication occurs automatically. No additional configuration is required.
- When Active Directory zone replication occurs between sites, zone data that is greater than the default transfer size is automatically compressed before it is transferred. This compression decreases the network traffic load.

After careful analysis, you can partition and delegate your DNS zones based on what is required for providing efficient and fault-tolerant name service to each location or site.

If you are using Active Directory–integrated zones in a Windows Server 2003 domain, you must select an Active Directory–integrated zone replication scope. When selecting a replication scope, note that network traffic increases as you broaden the replication scope. For example, if you choose to replicate Active Directory–integrated DNS zone data to all DNS servers in the forest, this produces greater network traffic than replicating the DNS zone data to all DNS servers in a single Active Directory domain in that forest. Balance your need to minimize replication traffic against your need to minimize zone query traffic. The DNS administrators in your organization are responsible for managing zone replication.

Table 3.8 lists the replication options for Active Directory–integrated zone data.

**Table 3.8 Replication Options for Active Directory–Integrated Zone Data**

| Option | Description | When to Use |
|---|---|---|

| | | |
|---|---|---|
| All DNS servers in the Active Directory forest | The zone data replicates to all the DNS servers running on Windows Server 2003–based domain controllers in all domains of the Active Directory forest. | You want the broadest scope of replication. This option generally produces the most zone replication traffic. Note that you can choose this option only if all DNS servers hosting an Active Directory–integrated copy of this zone run Windows Server 2003. |
| All DNS servers in a specified Active Directory domain | The zone data replicates to all DNS servers running on Windows Server 2003–based domain controllers in the specified Active Directory domain. This option is the default setting for Active Directory–integrated DNS zone replication.<br><br>(The specified Active Directory domain is the domain hosted by the domain controller on which the DNS server hosting the zone is running.) | You do not need the zone to be replicated throughout the forest and you want to limit zone replication traffic. This option produces less zone replication traffic than replicating the zone to all DNS servers in the forest or to all domain controllers in the domain. If you choose this option, the zone data does not replicate to DNS servers running on Windows 2000–based domain controllers. |
| All domain controllers in the Active Directory domain | The zone data replicates to all domain controllers in the specified Active Directory domain, whether or not the DNS Server service runs on the domain controllers in the domain. | You host an Active Directory–integrated copy of this zone on a DNS server running on a Windows 2000–based domain controller. |
| All domain controllers specified in the replication scope of a DNS application directory partition | The zone data replicates to all the domain controllers specified in the replication scope of the DNS application directory partition. | You want to customize zone replication scope for your organization. With this option, you can minimize zone replication traffic while maximizing functionality. However, this option requires more administrative overhead. You can choose this option only if all DNS servers hosting an Active Directory–integrated copy of this zone run Windows Server 2003. |

# Migrating Zones to Windows Server 2003 DNS Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can migrate zones to DNS servers running Windows Server 2003 in one of two ways:

- By using zone transfer.
- By copying the zone files.

If you copy the zone files, you must manually verify the integrity of the zones. Regardless of the method that you use to migrate zones, you must decide whether to take the original DNS server offline, or to use it as a secondary server. If you determine that the original third-party DNS server causes interoperability problems on your network, or if you need to use that server hardware for another purpose, take the server offline. Otherwise, keep the server on you network to provide backup for your primary DNS server running Windows Server 2003.

For more information about using zone transfer, see "Initiate a zone transfer at a secondary server" in Help and Support Center for Windows Server 2003.

# Configuring and Managing DNS Clients

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you configure DNS clients, you must specify a list of DNS servers for clients to use when resolving DNS names. You can also specify a DNS suffix search list to be used by the clients when performing DNS query searches for short, unqualified domain names.

Figure 3.9 shows the process for configuring and managing DNS clients.

**Figure 3.9 Configuring and Managing DNS Clients**

# Configuring Client DNS Server Lists and Suffix Search Lists

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Configure your clients' DNS server lists and suffix search list by including at least two DNS server IP addresses on the clients and domain controllers: the IP address for a preferred server and the IP address for an alternate server. Use a server running in the local site for the preferred server. The alternate server can be running in either a local or a remote site.

The DNS suffix search list is populated based on the primary DNS suffix of the client and any connection-specific DNS suffixes. The client uses these suffixes to try to resolve unqualified names. You can modify the DNS suffix search list manually, or by using Group Policy. Limit the size of your suffix search list if you can, because a large suffix search list increases network traffic.

# Using Group Policy to Simplify Client Configuration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 includes a new set of Group Policy settings to simplify the rollout of Windows Server 2003 DNS clients. You can use them to set your suffix search lists, dynamic update configuration, and many other settings. As with all Group Policy settings, you can specify different settings based on site, domain, or OU.

For more information about these Group Policy settings, see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

# Securing Your DNS Infrastructure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Because DNS was designed to be an open protocol, DNS data can be vulnerable to security attacks. Windows Server 2003 DNS provides improved security features to decrease this security issue. The DNS designer in your organization is responsible for creating a secure DNS infrastructure. The DNS administrators in your organization are responsible for maintaining network security by anticipating and mitigating new security threats.

Figure 3.10 shows the process for securing your DNS infrastructure.

**Figure 3.10 Securing Your DNS Infrastructure**

# Identifying DNS Security Threats

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A DNS infrastructure is vulnerable to a number of types of security threats.

**Footprinting** The process of building a diagram, or footprint, of a DNS infrastructure by capturing DNS zone data such as domain names, computer names, and IP addresses for sensitive network resources. DNS domain and computer names often indicate the function or location of domains and computers.

**Denial-of-service attack** An attack in which the attacker attempts to deny the availability of network services by flooding one or more DNS servers in the network with recursive queries. When a DNS server is flooded with queries, its CPU usage eventually reaches its maximum and the DNS Server service becomes unavailable. Without a fully operating DNS server on the network, network services that use DNS are unavailable to network users.

**Data modification** The use of valid IP addresses in IP packets that an attacker has created to destroy data or conduct other attacks. Data modification is typically attempted on a DNS infrastructure that has already been foot printed. If the attack is successful, the packets appear to be coming from a valid IP address on the network. This is commonly called IP spoofing. With a valid IP address (an IP address within the IP address range of a subnet), an attacker can gain access to the network.

**Redirection** An attack in which an attacker is able to redirect queries for DNS names to servers that are under the control of the attacker. One method of redirection involves the attempt to pollute the DNS cache of a DNS server with erroneous DNS data that might direct future queries to servers that are under the control of an attacker. For example, if a query is made to example.contoso.com and a referral answer provides a record for a name that is outside of the contoso.com domain, the DNS server uses the cached data to resolve a query for the external name. Redirection can be accomplished when an attacker has writable access to DNS data, such as with non-secure dynamic updates.

For more information about common types of attacks, developing a security policy, and evaluating your level of risk, see "Designing an Authentication Strategy" and "Designing a Resource Authorization Strategy" in *Designing and Deploying Directory and Security Services* of this kit.

# Developing a DNS Security Policy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If your DNS data is compromised, attackers can gain information about your network that can be used to compromise other services. For example, attackers can harm your organization in the following ways:

- By using zone transfer, attackers can retrieve a list of all the hosts and their IP addresses in your network.
- By using denial-of-service attacks, attackers can prevent e-mail from being delivered to and from your network, and they can prevent your Web server from being visible.
- If attackers can change your zone data, they can set up fake Web servers, or cause e-mail to be redirected to their servers.

Your risk of attack varies depending on your exposure to the Internet. For a DNS server in a private network that uses a private namespace, a private addressing scheme, and an effective firewall, the risk of attack is lower and the possibility of discovering the intruder is greater. For a DNS server that is exposed to the Internet, the risk is higher.

Developing a DNS security policy involves:

- Deciding what access your clients need, what tradeoffs you want to make between security and performance, and what data you most want to protect.
- Familiarizing yourself with the security issues common to internal and external DNS servers.
- Studying your name resolution traffic to see which clients can query which servers.

You can choose to adopt a low-level, mid-level, or high-level DNS security policy.

**Low-Level DNS Security Policy**

Low-level security does not require any additional configuration of your DNS deployment. Use this level of DNS security in a network environment in which you are not concerned about the integrity of your DNS data, or in a private network in which no external connectivity is possible. A low-level security policy includes the following characteristics:

- All DNS servers in your network perform standard DNS resolution.
- All DNS servers are configured with root hints that point to the root servers for the Internet.
- All DNS servers permit zone transfers to any server.
- All DNS servers are configured to listen on all of their IP addresses.
- **Secure cache against pollution** is disabled on all DNS servers.
- Dynamic update is allowed for all DNS zones.
- User Datagram Protocol (UDP) and TCP/IP port 53 is open on the firewall for your network for both source and destination addresses.

**Mid-Level DNS Security Policy**

Mid-level DNS security consists of the DNS security features that are available without running DNS servers on domain controllers and storing DNS zones in Active Directory. A mid-level security policy includes the following characteristics:

- The DNS infrastructure of your organization has limited exposure to the Internet.

- All DNS servers are configured to use forwarders to point to a specific list of internal DNS servers when they cannot resolve names locally.
- All DNS servers limit zone transfers to servers listed in the NS records in their zones.
- DNS servers are configured to listen on specified IP addresses.
- **Secure cache against pollution** is enabled on all DNS servers.
- Secure dynamic update is allowed for all DNS zones.
- Internal DNS servers communicate with external DNS servers through the firewall with a limited list of allowed source and destination addresses.
- External DNS servers in front of your firewall are configured with root hints pointing to the root servers for the Internet.
- All Internet name resolution is performed by using proxy servers and gateways.

**High-Level DNS Security Policy**

High-level DNS security uses the same configuration as mid-level security and also uses the security features available when the DNS Server service is running on a domain controller and DNS zones are stored in Active Directory. Also, high-level security completely eliminates DNS communication with the Internet. This is not a typical configuration, but it is recommended whenever Internet connectivity is not required. High-level security policy includes the following characteristics:

- The DNS infrastructure of your organization has no Internet communication by means of internal DNS servers.
- Your network uses an internal DNS root and namespace, where all authority for DNS zones is internal.
- DNS servers that are configured with forwarders use internal DNS server IP addresses only.
- All DNS servers limit zone transfers to specified IP addresses.
- DNS servers are configured to listen on specified IP addresses.
- **Secure cache against pollution** is enabled on all DNS servers.
- Internal DNS servers are configured with root hints that point to the internal DNS servers hosting the root zone for your internal namespace.
- Secure dynamic update is configured for all DNS zones except for the top-level and root zones, which do not allow dynamic updates at all.
- All DNS servers are running on domain controllers. An access control list (ACL) is configured on the DNS Server service to allow only specific individuals to perform administrative tasks on DNS servers.
- All DNS zones are stored in Active Directory. An ACL is configured to allow only specific individuals to create, delete, or modify DNS zones.
- ACLs are configured on DNS resource records to allow only specific individuals to create, delete, or modify DNS data.

**Note**

- Windows Server 2003 DNS does not support the use of DACLs on zones to control which clients or users can send queries to the DNS server.

**Cache Pollution Protection**

When cache pollution protection is enabled, the DNS server disregards DNS resource records that originate from DNS servers that are not authoritative for the resource records. Cache pollution protection is a significant security enhancement; however, when cache pollution protection is enabled, the number of DNS queries can increase.

In Windows Server 2003 DNS, cache pollution protection is enabled by default. You can disable cache pollution protection to reduce the number of DNS queries; however, to ensure the security of your system, it is strongly recommended that you leave cache pollution protection enabled on your DNS servers.

For information about cache pollution protection, see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

# Securing DNS Servers That Are Exposed to the Internet

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

DNS servers that are exposed to the Internet are especially vulnerable to attack. You can secure your DNS servers that are exposed to the Internet by doing the following:

- Place the DNS server on a perimeter network instead of your internal network.

  For more information about perimeter networks, see "Deploying ISA Server" in this book.

  Use one DNS server for publicly accessed services inside your perimeter network and a separate DNS server for your private internal network. This reduces the risk of exposing your private namespace, which can expose sensitive names and IP addresses to Internet-based users. It also increases performance because it decreases the number of resource records on the DNS server.

- Add a secondary server on another subnet or network, or on an ISP. This protects you against denial-of-service attacks.

- Eliminate single points of failure by securing your routers and DNS servers, and distributing your DNS servers geographically. Add secondary copies of your zones to at least one offsite DNS server.

- Encrypt zone replication traffic by using Internet Protocol security (IPSec) or virtual private network (VPN) tunnels to hide the names and IP addresses from Internet-based users.

- Configure firewalls to enforce packet filtering for UDP and TCP port 53.

- Restrict the list of DNS servers that are allowed to initiate a zone transfer on the DNS server. Do this for each zone in your network.

- Monitor the DNS logs and monitor your external DNS servers by using Event Viewer.

# Securing Internal DNS Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Internal DNS servers are less vulnerable to attack than external DNS servers, but you still need to protect them. To secure your internal DNS servers:

- Eliminate any single point of failure. Note, however, that DNS redundancy cannot help you if your clients cannot access any network services. Think about where the clients of each DNS zone are located, and how they resolve names if the DNS server is compromised and unable to answer queries.
- Prevent unauthorized access to your servers. Allow only secure dynamic update for your zones and limit the list of DNS servers that are allowed to obtain a zone transfer.
- Monitor the DNS logs and monitor your internal DNS servers by using Event Viewer. Monitoring your logs and your server can help you detect unauthorized modifications to your DNS server or zone files.
- Implement Active Directory–integrated zones with secure dynamic update.

# Securing Dynamically Updated DNS Zones

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Use Active Directory–integrated zones and configure them for secure dynamic update. Secure dynamic update resolves the security risks associated with using dynamic update. Because dynamic update allows any computer to modify any record, an attacker can modify zone data, then impersonate existing servers.

For example, if you install the Web server, web.contoso.com, and it registers its IP address in DNS by using dynamic update, an attacker can install a second Web server, also name it web.contoso.com, and use dynamic update to modify the corresponding IP address in the DNS record. In this way, the attacker can impersonate the original Web server and capture secure information.

To prevent server impersonation, implement secure dynamic update. By using secure dynamic update, only the computers and users specified in an access control list (ACL) can modify objects within a zone.

If your security policy demands stricter security, modify these settings to further restrict access. Restrict access by computer, group, or user account, and assign permissions for the entire DNS zone and for the individual DNS names within the zone.

For more information about securing dynamically updated DNS zones, see the *Networking Guide* of the *Windows Server 2003 Resource Kit* (or see the Networking Guide on the Web at http://www.microsoft.com/reskit).

# Securing DNS Zone Replication

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Zone replication can occur either by means of zone transfer or as part of Active Directory replication. If you do not secure zone replication, you run the risk of exposing the names and IP addresses of your computers to attackers. You can secure DNS zone replication by doing the following:

- Using Active Directory replication.
- Encrypting zone replication sent over public networks such as the Internet.
- Restricting zone transfer to authorized servers.

**Using Active Directory Replication**

Replicating zones as part of Active Directory replication provides the following security benefits:

- Active Directory replication traffic is encrypted; therefore zone replication traffic is encrypted automatically.
- The Active Directory domain controllers that perform replication are mutually authenticated, and impersonation is not possible.

**Note**

- Use Active Directory–integrated zones whenever possible, because they are replicated as part of Active Directory replication, which is more secure than file-based zone transfer.

**Encrypting Replication Traffic Sent Over Public Networks**

Encrypt all replication traffic sent over public networks by using IPSec or VPN tunnels. When encrypting replication traffic sent over public networks:

- Use the strongest level of encryption or VPN tunnel authentication that your servers can support.
- Use the Windows Server 2003 Routing and Remote Access service to create the IPSec or VPN tunnel.

**Restricting Zone Transfer to Authorized Servers**

If you have secondary servers and you replicate your zone data by using zone transfer, configure your DNS servers to specify the secondary servers that are authorized to receive zone transfers. This prevents an attacker from using zone transfer to download zone data. If you are using Active Directory–integrated zones instead, configure your servers to disallow zone transfer.

# Integrating DNS with Other Windows Server 2003 Services

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you deploy Windows Server 2003 DNS, it is important to integrate the DNS service with other Windows Server 2003 services, such as DHCP and WINS. DNS administrators are responsible for integrating DNS with WINS and DHCP. Figure 3.11 shows the process for integrating Windows Server 2003 DNS with other Windows Server 2003 services.

**Figure 3.11 Integrating DNS with Other Windows Server 2003 Services**

# Integrating DNS with DHCP

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 DNS supports DHCP by means of the dynamic update of DNS zones. By integrating DHCP and DNS in a DNS deployment, you can provide your network resources with dynamic addressing information stored in DNS. To enable this integration, you can use the Windows Server 2003 DHCP service.

The dynamic update standard, specified in RFC 2136: *Dynamic Updates in the Domain Name System (DNS UPDATE)*, automatically updates DNS records. Both Windows Server 2003 and Windows 2000 support dynamic update, and both clients and DHCP servers can send dynamic updates when their IP addresses change.

Dynamic update enables a DHCP server to register address (A) and pointer (PTR) resource records on behalf of a DHCP client by using DHCP Client FQDN option 81. Option 81 enables the DHCP client to provide its FQDN to the DHCP server. The DHCP client also provides instructions to the DHCP server describing how to process DNS dynamic updates on behalf of the DHCP client.

The DHCP server can dynamically update DNS A and PTR records on behalf of DHCP clients that are not capable of sending option 81 to the DHCP server. You can also configure the DHCP server to discard client A and PTR records when the DHCP client lease is deleted. This reduces the time needed to manage these records manually and provides support for DHCP clients that cannot perform dynamic updates. In addition, dynamic update simplifies the setup of Active Directory by enabling domain controllers to dynamically register SRV resource records.

If the DHCP server is configured to perform DNS dynamic updates, it performs one of the following actions:

- The DHCP server updates resource records at the request of the client. The client requests the DHCP server to update the DNS PTR record on behalf of the client, and the client registers A.

- The DHCP server updates DNS A and PTR records regardless of whether the client requests this action or not.

By itself, dynamic update is not secure because any client can modify DNS records. To secure dynamic updates, you can use the secure dynamic update feature provided in Windows Server 2003. To delete outdated records, you can use the DNS server aging and scavenging feature.

# Integrating DNS with WINS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you upgrade to Windows Server 2003 DNS from an earlier version of Windows, you might need to continue support an existing WINS infrastructure. Windows Server 2003 DNS enables you to support an existing WINS deployment by allowing you to configure a DNS server to query a WINS server as a DNS zone setting.

WINS provides dynamic NetBIOS name resolution. If your organization supports clients and applications that use WINS for NetBIOS name resolution, you need to continue to support WINS. If some of your clients are registered in WINS and other clients need to resolve their names but are not capable of NetBIOS name resolution, you can use WINS lookup to enable your DNS server to look up names in the WINS namespace.

This feature is particularly useful if some of your clients that require NetBIOS name resolution cannot use WINS or if some of your clients cannot register with DNS (for example, clients that run the Microsoft® Windows® 95 or Windows® 98 operating system). Use WINS referral if some of your DNS servers do not support the resource records used for WINS lookup and WINS reverse lookup.

**WINS Lookup and WINS Reverse Lookup**

By configuring your DNS server for WINS lookup, you can direct DNS to query WINS for name resolution, so that DNS clients can look up the names and IP addresses of WINS clients. To direct DNS to query WINS for name resolution, add a WINS lookup record to the authoritative zone. An authoritative DNS server checks that zone when it receives a query for a name. If the DNS server does not find the name in the authoritative zone, but the zone contains a WINS lookup record, the DNS server queries the WINS server. If the name is registered with WINS, the WINS server returns the associated record to the DNS server.

The DNS server then compiles and returns the corresponding DNS record in response to the original DNS request. DNS clients do not need to know whether a client is registered with WINS or DNS, and they do not need to query the WINS server.

You can also configure your DNS server for WINS reverse lookups. Reverse lookups work slightly differently. When an authoritative DNS server is queried for a nonexistent PTR record, and the authoritative zone contains the WINS-R record, the DNS server uses a NetBIOS node adapter status lookup.

**Note**

- For fault tolerance, you can specify multiple WINS servers in the WINS lookup record. The server that is running the Windows 2000 or Windows Server 2003 DNS Server service tries to locate the name by searching the WINS servers in the order specified by the list.

**Configuring WINS Referral**

Computers that are running third-party implementations of DNS do not support the records used for WINS lookup and WINS reverse lookup. If you attempt to use a combination of Microsoft and third-party DNS servers to host a zone containing these records, the mixture can cause data errors or failed zone transfers at the third-party DNS servers.

If you have such a combination, you can use WINS referral to create and delegate a special WINS zone that refers DNS lookups to WINS. This zone does not perform any registrations or updates. Next, you configure all DNS clients to append the WINS referral zone name to unqualified queries. That way, the client can query both DNS and WINS at the same time, using a DNS query. To simplify administration, you can use DHCP or Group Policy to configure the clients to perform the configuration. Deploying this configuration overrides the default DNS client resolver behavior, requiring you to finish populating the suffix search order with combinations of suffixes, such as the primary DNS suffix, the primary DNS suffix devolved, and connection specific suffixes.

For more information about DHCP, see "Deploying DHCP" in this book. For more information about Group Policy, see "Designing a Group Policy Infrastructure" in *Designing a Managed Environment* of this kit.

**Note**

- The WINS zone must be hosted on a DNS server that is running Windows Server 2003 or Windows 2000 and must not be propagated to third-party DNS servers. Third-party DNS servers do not support WINS resource records and might not be able to host the zone.

# Implementing Windows Server 2003 DNS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you have tested your configuration in a pilot lab, you can implement your changes in your production environment. Figure 3.12 shows the process for implementing Windows Server 2003 DNS.

**Figure 3.12 Implementing Windows Server 2003 DNS**

# Preparing to Deploy Windows Server 2003 DNS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Prepare your environment for Windows Server 2003 DNS deployment by ensuring that you have reliable backups of anything that you plan to change, including servers and zones. Test your backups before you proceed with your deployment. In addition, create a recovery plan for contingencies such as data loss, server failure, and failure of network connections.

Before implementing your DNS deployment, ensure that routing links between the servers that you plan to deploy are in place and are working correctly. Depending on how your DNS infrastructure is configured, your DNS servers might need to query the following:

- Root servers.
- Forwarders.
- Servers hosting parent zones.
- Servers hosting child zones.
- Servers on an external network or the Internet.

If you expect clients to query for names on the Internet and you plan to use a proxy server, ensure that the proxy server is in place and that a proxy-client/firewall-client is installed on the client. In addition, ensure that the Web client configuration is set in a Conseil Européen pour la Recherche Nucléaire (CERN)–compliant Internet browser. Microsoft Internet Explorer is an example of a CERN–compliant Internet browser.

# Setting up the DNS Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you install DNS, ensure that your computer is named correctly and that you can ping other computers in the network that your DNS servers might need to query. Because clients locate DNS servers by IP address, assign a static IP address to each DNS server.

You can set up your DNS server in one of four ways:

- Install DNS on a server by using the Active Directory Installation Wizard to install Active Directory.

  The Active Directory Installation Wizard automatically creates an Active Directory–integrated copy of the forward lookup zone that corresponds to the name of the Active Directory domain, and configures the zone for secure dynamic update. In addition, the wizard creates the standard reverse lookup zones recommended by the DNS RFCs.

  You can start the Active Directory Installation Wizard by running **dcpromo.exe** at a command prompt. For more information about Active Directory installation and removal, see the *Active Directory Collection* of the *Windows Server 2003 Technical Reference* (or see the Active Directory Collection on the Web at http://www.microsoft.com/reskit).

- Before or after you install Active Directory on the server, you can use the Add or Remove Programs tool to install the DNS Server service and then run the Configure DNS Server Wizard to configure your zones. As with the Active Directory Installation Wizard, the Configure DNS Server Wizard creates the standard reverse lookup zones recommended by the DNS RFCs, and either configures the server as a root server or initializes the root hints.

- You can use the command-line tool Dnscmd.exe to configure the DNS server.

- You can use Microsoft® Visual Basic® Scripting Edition (VBScript) or other scripting languages through the Windows Management Instrumentation (WMI) provider packaged with Windows Server 2003.

For more information about these setup options and for information about Windows Server 2003 DNS, including how the Active Directory Installation Wizard and the Configure DNS Server Wizard determine whether or not to initialize the root hints, see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at www.microsoft.com/reskit).

# Setting up Zones

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you install DNS by using the Active Directory Installation Wizard, the wizard creates DNS zones that correspond to the Active Directory domains that you specify. If the zones that you specified during the zone planning phase of your deployment do not already exist, create them now. Note that the default DNS installation by the Active Directory Installation Wizard includes secure dynamic update and an Active Directory–integrated zone. If this is not the configuration you want to deploy, change the default settings.

If the zone that the wizard creates is not the type of zone that you want, change it now.

**Note**

- Converting any zone to an Active Directory–integrated zone can increase the use of DNS server resources and network resources. This is because converting a zone can trigger Active Directory replication.

If you want to push updates to secondary DNS servers for a zone, configure **DNS notify** at the primary DNS server.

For more information about how to add and remove zones, see Help and Support Center for Windows Server 2003.

# Configuring Forwarding

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If any of your servers need to forward queries to any other server, configure forwarding on the servers that must forward queries. If you want your server to forward queries to different servers depending on the DNS suffix specified in the query, configure conditional forwarding appropriately.

For more information about conditional forwarding, see "Using Forwarding" earlier in this chapter, and see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

# Configuring the DNS Server for Dynamic Update

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Depending on how you deploy your server and zones, your zones might already be configured for dynamic update or secure dynamic update. If the zones are not configured as you intend, make any necessary changes. You can configure your zones to perform dynamic updates, secure dynamic updates, or no updates. However, configuring your zones to perform unsecured dynamic updates is a security risk and is not recommended.

For information about how to configure dynamic updates, see "Dynamic update" in Help and Support Center for Windows Server 2003. For information about how to allow only secure dynamic updates, see "Allow only secure dynamic updates" in Help and Support Center for Windows Server 2003.

# Configuring Aging and Scavenging

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

With dynamic update, whenever a computer joins the network and registers with DHCP, the DNS server automatically adds resource records to the zone. However, in some cases, the DNS server does not automatically delete them, and they can become outdated. Outdated resource records use disk space on the server, and a server might use an outdated resource record to answer a query. As a result, DNS server performance suffers. To solve these problems, the Windows Server 2003 DNS Server service can scavenge outdated records by searching the database for records that are obsolete and deleting them.

You can configure aging and scavenging from DNS Manager or by using **Dnscmd.exe**.

For more information about configuring aging and scavenging in Windows Server 2003 DNS, see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

# Configuring Zone Transfer and Replication Scope

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you use file-based primary or secondary zones, configure each primary server for a zone to allow zone transfers to each secondary server for a zone. Next, configure each secondary server for a zone with a list of primary servers for that zone.

If you use Active Directory replication in a Windows Server 2003 domain, configure the zone replication scope as described in Table 3.8.

If the DNS server is a domain controller, you can change the zone type to Active Directory–integrated. However, if the DNS server is not a domain controller, this option is not available. Active Directory–integrated zone data is stored and replicated as part of the Active Directory database.

For more information about DNS zone storage and replication in Active Directory, enlisting a DNS server in a DNS application directory partition, removing a DNS server from a DNS application directory partition, or changing zone replication scope, click the **Index** button in Help and Support for Windows Server 2003, and then in the keyword box, type **DNS zones**.

# Verifying that the DNS Server is Operating Correctly

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you install and configure the DNS server, verify that it is operating correctly. Use the monitoring features of the DNS MMC snap-in, such as simple or recursive query testing. You can also examine the event log or use the DNSLint Windows Server 2003 command-line support tool to test DNS servers for problems with delegations and missing Active Directory replication records. In addition, you can use the Nslookup.exe command-line tool to attempt queries. To access the monitoring features of the DNS MMC snap-in, click **Properties** on the **Action** menu, and then click the **Monitoring** tab.

For more information about DNS troubleshooting and verifying DNS server operation, see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

# Setting Up DNS Clients

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Set up each DNS client with the following:

- Host name and DNS suffix.
- Preferred and alternate DNS servers.
- Optionally, Proxy Auto-Configuration file or name exclusion list (if a proxy client).

You can use any of the following methods to set up your DNS clients:

- Use the TCP/IP settings of the client.
- Use Group Policy to configure groups of clients.
- Use the DHCP Server service to configure some client settings automatically.

For more information about how to install and configure DNS clients, see "Configuring DNS client settings" in Help and Support Center for Windows Server 2003.

# Using Command-Line Tools to Deploy DNS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use the command-line tool Dnscmd.exe to perform most of the tasks that you can perform from the DNS MMC snap-in. By using Dnscmd.exe, you can create, delete, and view zones and records and reset server and zone properties. You can also perform routine administration operations, such as creating or updating a zone, reloading the zone, refreshing the zone, writing the zone back to a file or Active Directory, pausing and resuming the zone, clearing the cache, adding records to root hints, stopping and starting the DNS service, and viewing statistics.

You can also use Dnscmd.exe to write batch file scripts and for remote administration. For more information about Dnscmd.exe, in Help and Support Center for Windows Server 2003, click **Tools**, and then click **Windows Support Tools**. For information about installing and using the Windows Server 2003 Support Tools and Support Tools Help, see the Sreadme.doc file in the \Support\Tools folder on the Windows Server 2003 operating system CD.

You can use the Nslookup.exe command-line tool to perform query testing of the DNS domain namespace and to display configuration information.

# Additional Resources for Deploying DNS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information and tools related to this chapter.

# Deploying WINS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Internet Name Service (WINS) in the Microsoft® Windows® Server 2003 operating system allows large organizations to accomplish NetBIOS name resolution with high availability, security, and performance. The following sections describe the WINS deployment process, including how to design and customize a secure replication strategy. WINS migration information and examples are also provided.

**In This Chapter**

Overview of WINS Deployment

Building Your WINS Server Strategy

Designing Your WINS Replication Strategy

Securing Your WINS Solution

Integrating WINS with Other Services

Implementing Your WINS Solution

Additional Resources for Deploying WINS

**Related Information**

- For more information about Windows Internet Name Service (WINS), see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

- For more information about planning and designing your Domain Name System (DNS) network, see "Deploying Domain Name System (DNS)" in this book.

# Overview of WINS Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

WINS provides a dynamic solution for network basic input/output system (NetBIOS) name resolution in enterprise networks. Although most large networks currently have a WINS infrastructure, some still rely on other methods of NetBIOS name resolution, such as the Lmhosts file. If your organization does not currently use WINS, and intends to continue operating with Microsoft® Windows® 95, Windows 98, Windows Millennium Edition, or Microsoft® Windows NT® version 4.0, consider implementing WINS when you deploy Windows Server 2003 in order to automate NetBIOS name resolution. Certain applications, such as Microsoft® Exchange Server, also rely on NetBIOS name resolution. Therefore, even if all of your computers are running Microsoft® Windows® 2000, Windows XP, or Windows Server 2003, you might still require NetBIOS name resolution based on the applications running in your environment.

If you are upgrading your current WINS servers to Windows Server 2003, determine if your existing hardware is compatible with Windows Server 2003, then migrate your WINS solution to Windows Server 2003.

By deploying WINS, you provide NetBIOS name resolution for clients on your network. WINS implements a distributed database for NetBIOS names and their corresponding addresses. WINS clients register their names at a local WINS server, and the WINS servers replicate the entries to the other WINS servers. This ensures the uniqueness of NetBIOS names and makes local name resolution possible.

# WINS Deployment Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Deploying WINS involves building a server strategy, designing a replication strategy, securing your WINS solution, integrating WINS with other services, and implementing your WINS solution. Figure 4.1 shows the general WINS deployment process.

**Figure 4.1 Deploying WINS**

# WINS Technology Background

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Smaller, non-routed networks can be configured as broadcast nodes, also known as B-nodes, accomplishing NetBIOS name registration and resolution by using broadcast packets. A non-WINS solution is viable where the broadcast domain is small and the resulting broadcast traffic is low. However, the traffic generated by broadcasts can overload a large network. In addition, some routers do not allow broadcast messages to pass through, so this method of name resolution is not an option for most enterprise networks. Although you can also use the static Lmhosts file for NetBIOS name resolution, manually editing the file with each name or IP address change can be time-consuming and prone to administrative error. Also, it is not a viable solution in a Dynamic Host Configuration Protocol (DHCP) environment. These more complex environments require a non-broadcast-based solution, which WINS provides by using unicast NetBIOS name registration and resolution.

WINS client support allows you to specify up to 12 WINS servers for redundancy. Different configurations, or node types, are available through WINS. The node type determines the method or methods that are used for NetBIOS name resolution. WINS supports the following node types, as shown in Table 4.1.

**Table 4.1 NetBIOS Node Types**

| Node Type | Resolution Method |
|---|---|
| B-node | IP broadcast messages register and resolve NetBIOS names to IP addresses. Windows 2000–based and Microsoft® Windows® XP–based computers use modified B-node name resolution. If the broadcast fails to resolve the name, an lmhosts file is used. |
| P-node | Point-to-point communication with a NetBIOS name server, such as WINS, to register and resolve computer names to IP addresses. |
| M-node | A mix of B-node and P-node communication to register and resolve NetBIOS names. M-node first uses broadcast resolution, and then attempts a server query if necessary. |
| H-node | A hybrid of B-node and P-node. An H-node computer attempts to query a server first and uses broadcasts only if direct queries fail. Windows 2000 and Windows XP–based computers are configured to use H-node by default. |

**New Features for Windows Server 2003**

The following improvements to the Windows Internet Name Service (WINS) have been made in the Windows Server 2003 family:

**Filtering records**

Improved filtering and new search functions help you locate records by showing only those records that fit the criteria you specify. These functions are particularly useful in analyzing very large WINS databases. You can use multiple criteria to perform advanced searches for WINS database records. This improved filtering capability allows you to combine filters for customized and precise query results. Available filters include: record owner, record type, NetBIOS name, and IP address with or without subnet mask.

Because you can now store query results in the cache of the memory on your local computer, the performance of subsequent queries is increased, and network traffic is reduced.

**Accepting replication partners**

When determining a replication strategy for your organization, you can define a list that controls the source of incoming name records during pull replication between WINS servers. In addition to blocking name records from specific replication partners, you can also choose to accept only name records owned by specific WINS servers during replication, excluding the name records of all servers that are not on the list.

# Building Your WINS Server Strategy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When building your WINS server strategy, account for any existing hardware that you might need to upgrade, how many WINS servers are needed for your design, and how your server strategy increases WINS availability and optimizes WINS performance. Figure 4.2 shows the process for building your WINS server strategy.

**Figure 4.2 Building Your WINS Server Strategy**

# Reviewing WINS Hardware

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Determine whether your current WINS server hardware is sufficient to upgrade to Windows Server 2003. You might need to upgrade your server hardware for optimal WINS performance. A dual-processor WINS server increases performance about 25 percent, and a dedicated disk drive measurably improves WINS server name replication response time.

When selecting your hardware, consider the following performance guidelines:

- 67Use high-performance disk hardware. WINS causes frequent and intense activity on server hard disks.
- Consider using a redundant array of independent disks (RAID)-based solution, which improves disk access time.
- When evaluating the performance of a server, include WINS to ensure the server can handle its demanding use of central processing unit (CPU), memory, and disk input/output (I/O). Monitor server usage to determine whether WINS server hardware needs to be upgraded.

For a current list of compatible hardware, see the Hardware Compatibility List (HCL) link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

For more information about determining hardware compatibility, see "Planning for Deployment" in *Planning, Testing, and Piloting Deployment Projects* of this kit.

# Determining How Many WINS Servers to Deploy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The number of WINS servers needed and the locations of each server depend on the number of WINS clients per server and the network topology.

The number of users each server can support depends on usage patterns, data storage, and the processing capabilities of the server. A WINS server can typically register 1,500 names per minute or answer 4,500 queries per minute. This means that a single WINS server can adequately service up to 10,000 clients.

You might install additional WINS servers in locations separated by slow, or pay-by-usage wide area network (WAN) links. Set conservative client counts for a WINS server to minimize client query response times. Allow room in your design for peak-load conditions, such as large-scale power outages that force many computers to restart simultaneously, thereby bombarding the WINS servers with registration requests.

# Designing WINS for High Availability

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Any design that requires high availability must include more than one WINS server. Consider all possible points of failure, including servers, WAN links, and routers. These factors, along with the business goals of the organization, determine the required level of WINS redundancy and fault tolerance.

To ensure that you are planning a fault-tolerant WINS design, ask the following question for each server on your network: What happens to WINS if this server shuts down or if clients cannot reach it?

To help answer the question, consider two common situations in which a WINS server might fail to perform its role on a network:

- A hardware or power failure requires downtime for server repair or maintenance.
- A network link or router failure isolates a WINS server from clients.

To prepare for both of these situations:

- Consider the length of time a WINS server might be out of service on your network, factoring in both planned and unplanned outages.
- Consider what happens to your WINS clients if their primary WINS server shuts down. By maintaining and assigning secondary WINS servers for clients, you can reduce the impact of a single WINS server being offline.

For each client, specify the servers for WINS lookup and the node type. When designing your WINS client support strategy for maximum availability, do the following:

- Specify multiple WINS servers for clients to provide server redundancy.
- For fault tolerance in the case of link failure, point clients to a local WINS server as their primary WINS server, and a remote WINS hub as their secondary WINS server. Ideally, the secondary WINS server is located in a separate building and on a separate power grid from the primary WINS server.
- Consider using an Lmhosts file to provide secondary name resolution in the event of a WINS failure.

  While Lmhosts files are not a recommended solution, in rare circumstances they can provide an effective temporary solution. Lmhosts files must be tightly managed because changes in the NetBIOS environment do not automatically update in static name files.

  For more information about the Lmhosts file, see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

# Using Multiple Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To provide additional fault tolerance, configure a secondary (or backup) WINS server. Although WINS replication architecture benefits from employing a minimum number of WINS servers, employing a secondary WINS server improves the availability of your design. This solution balances performance and availability against cost and manageability.

When using two WINS servers to provide redundancy and load balancing, configure the replication relationship between these servers as a pull or push partnership. When you use replication, both servers contain the same WINS database information.

When a WINS server is configured as a pull partner, it periodically queries the partner server to determine if any updates are available. Use pull partnerships:

- Over lower-speed WAN or congested local area network (LAN) connections.
- To reduce replication traffic by consolidating WINS database updates.
- To perform WINS database updates at scheduled intervals.

When a WINS server is configured as a push partner, the WINS server notifies the partner server that updates are available for replication. Use push partnerships:

- Over LAN or higher-speed WAN connections.
- When the network traffic created by frequent WINS replication updates is not a consideration.
- To ensure WINS database updates are received as soon as possible.

The availability that is provided by WINS replication is appropriate for solving availability issues at local and remote locations. Adding a WINS server to a remote location ensures WINS availability in the event that a WAN link or router fails. For more information about replication strategies, see "Designing Your WINS Replication Strategy" later in this chapter.

# Using Windows Clustering

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Clustering provides a higher level of fault tolerance but consumes additional system resources. If your business goals require a WINS design that provides the highest availability, use server clusters as provided by Windows Clustering. By configuring WINS on multiple servers belonging to the same cluster, you:

- Share a common WINS database.
- Provide immediate failover in the event of failure.
- Restore failed servers sooner, because database resynchronization is not required between the cluster nodes.

**Note**

- If you choose to cluster your WINS servers, be sure to equip the servers with a hard disk containing high-speed I/O that is dedicated to WINS. This can speed up the database response and ensure clustering efficiency.

**Example: A Company Uses a Cluster to Simplify their WINS Design**

A large corporation uses a server cluster to provide infrastructure services, including WINS. Prior to implementing the server cluster, the company had a large and complicated Windows NT 4.0–based WINS replication topology. To maintain consistency and provide accurate information to clients, WINS client records were replicated to all WINS servers.

To simplify the replication matrix, provide redundancy, and more efficiently manage the WINS traffic load, a server cluster is used as the WINS replication hub. Applications and services running on nodes in the cluster are exposed to users and workstations as virtual servers. Figure 4.3 shows the replication matrix before the WINS cluster implementation.

**Figure 4.3 WINS Topology Pre-Clustering**

Figure 4.4 shows the new simplified replication matrix using a server cluster.

**Figure 4.4 WINS Topology Post-Clustering**

Windows Clustering only solves local availability issues. Windows Server 2003–based servers that belong to the same cluster require persistent, high-speed connections between all servers in the cluster.

**Note**

- Before adding WINS to a set of clustered servers, be sure to consider both the advantages and disadvantages of doing so. In many cases, the overall number of WINS servers is small, so clustering WINS is not necessary — replication makes WINS fault tolerant. Instead, configure your WINS clients with the address of a secondary WINS server to ensure uninterrupted service.

For more information about server clusters, see "Designing and Deploying Server Clusters" in *Planning Server Deployments* of this kit.

**Caution**

- WINS does not support rolling upgrades from Windows 2000 to Windows Server 2003 in a server cluster. You can upgrade and failover to Windows Server 2003. However, when WINS is brought online on Windows Server 2003, it cannot fail back to the Windows 2000 node.

# Optimizing WINS Performance

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Although WINS is designed to help reduce broadcast traffic between local subnets, it creates some traffic between servers and clients. This is particularly important if you use WINS on routed TCP/IP networks.

To optimize performance, begin by estimating the amount of network traffic between WINS clients and WINS servers under normal conditions. Estimate and monitor the following:

- NetBIOS names commonly registered by WINS clients.
- WINS registration and renewal caused by daily startup of clients.
- Mobile users and their effect when moving within a routed network.
- The effects of slower links, such as WAN links and their effect on replication performance and convergence.

**Reducing Response Time**

Reducing the response time of WINS improves performance, with the greatest visibility to users and management. As a result, a design that reduces the response time of WINS is highly successful.

The performance of your WINS design largely depends on other network traffic. For example, a subnet that relies on a WINS server elsewhere on the WAN might experience poor performance during peak hours when network usage is high. Increase the NetBIOS name registration renewal period, which defaults at six days, to reduce client-to-server renewal traffic. This setting must be changed on the WINS server.

Obtain reliable figures on the number of locations and hosts that your WINS design must support. When planning for WINS client traffic on large, routed networks, estimate and monitor the effect of name query, registration, and response traffic routed between subnets. Name requests and responses that occur at the daily startup of computers must pass through the traffic queues on the routers and might cause delays at peak times.

**Consolidating Multiple Subnets**

When you have multiple subnets in a small remote office, consider consolidating the office to one subnet address.

You can do this using asynchronous transfer mode (ATM) switching or a virtual private network (VPN) configuration. By consolidating to one subnet address, you can configure clients to use local broadcasts to resolve names before attempting to contact a WINS server across the WAN. Changing the client to M-node allows it to broadcast locally for resources before contacting a WINS server for NetBIOS name resolution. This can help to reduce the overall amount of WINS-associated traffic, especially WAN traffic.

Use DHCP scope option 046, WINS/NBT Node Type, to configure your WINS clients as M-node clients. For more information about configuring DHCP options at the DHCP server, see "Assign a scope-based optionAssign a scope-based option" in Help and Support Center for Windows Server 2003.

**Configuring Burst Handling**

Burst handling supports a high volume of WINS client name registration. When a large number of WINS clients simultaneously try to register their NetBIOS names, the WINS server can become saturated. In burst handling mode, the WINS server responds positively to clients that submit a registration request before the WINS server has processed and entered these updates in the WINS server database. The WINS server immediately sends a relatively short, random Time to Live (TTL) lease length to all WINS clients. The short TTL lease length forces WINS clients to reregister after the excessive WINS registration traffic subsides, therefore decreasing the load on the network and varying the delay interval to distribute the load over time.

Using the WINS MMC snap-in, you can configure the level of burst handling for the server, which modifies the size of the burst queue.

**To configure burst handling**

1. In the WINS MMC snap-in, right-click the appropriate WINS server.

2. Select the **Advanced** tab from the *server name* properties dialog box.

3. In **Enable Burst Handling**, select **Low (300)**, **Medium (500)**, **High (1000)**, or **Custom (50-5000)** as the burst queue size.

**Load Balancing with Redundant WINS Databases**

A WINS implementation design provides higher performance by specifying that multiple WINS servers contain replicas of WINS databases. These redundant servers improve performance by providing load balancing.

Use load balancing with redundant WINS databases when:

- The length of time to perform WINS functions is unacceptably long.
- The connections between the WINS servers support the additional WINS replication traffic.
- The traffic generated by WINS clients accessing a WINS server in another location saturates a WAN link.
- The cost of adding a server is not prohibitive.

# Designing Your WINS Replication Strategy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A good replication design is essential to your WINS availability and performance. Designs encompassing multiple WINS servers distribute NetBIOS name resolution across LAN and WAN environments, confining WINS client traffic to localized areas. To ensure consistent, network-wide name resolution, WINS servers must replicate their local entries to other servers. For more information about a WINS replication strategy, see the examples later in this section.

Figure 4.5 shows the process for designing your WINS replication strategy.

**Figure 4.5 Designing Your WINS Replication Strategy**

Before configuring replication, carefully design and review your WINS replication topology. For WANs, this planning can be critical to the success of your deployment and use of WINS.

WINS provides the following choices when you are configuring replication:

- You can manually configure WINS replication for a WAN environment.
- For larger networks, you can configure WINS to replicate within a LAN environment.
- In smaller or bounded LAN installations, consider enabling and using WINS automatic partner configuration for simplified setup of WINS replication.
- In larger or global installations, you might have to configure WINS across untrusted Windows NT domains.

If your network uses only two WINS servers, configure them as push/pull replication partners to each other. When configuring replication partners, avoid push-only or pull-only servers except where necessary to accommodate slow links. In general, push/pull replication is the most simple and effective way to ensure full WINS replication between partners. This also ensures that the primary and secondary WINS servers for any particular WINS client are push/pull partners of each other, a requirement for proper WINS functioning in the event of a failure of the primary server of the client.

In most cases, the hub-and-spoke model provides a simple and effective design for organizations that require complete

convergence with minimal administrative intervention. For example, this model works well for organizations with centralized headquarters or a corporate data center (the hub) and several branch offices (the spokes). Also, a second or redundant hub (that is, a second WINS server in the central location) can increase the fault tolerance for WINS.

In some large enterprise WINS networks, limited replication partnering can effectively support replication over slow network links. However, when you plan limited WINS replication, ensure that each server has at least one replication partner. Furthermore, balance each slow link that employs a unidirectional link by a unidirectional link elsewhere in the network that carries updated entries in the opposite direction.

# Specifying Automatic Partner Configuration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can configure a WINS server to automatically configure other WINS server computers as replication partners. By using this automatic partner configuration, other WINS servers are discovered when they join the network and are added as replication partners.

When using automatic partner configuration, each WINS server announces its presence on the network by using periodic multicasts. These announcements are sent as Internet Group Management Protocol (IGMP) messages for the multicast group address of 224.0.1.24, which is reserved for WINS server use.

Automatic partner configuration is typically useful in small networks, such as single subnet LAN environments. However, you can use automatic partner configuration in routed networks. For WINS multicast support in routed networks, the forwarding of multicast traffic is made possible by configuring routers for each subnet to forward traffic to the WINS multicast group address of. 224.0.1.24.

Because periodic multicast announcements between WINS servers can add traffic to your network, automatic partner configuration is recommended only if you have a small number of installed WINS servers (typically, three or fewer).

Automatic partner configuration monitors multicast announcements from other WINS servers, and performs the following configuration steps:

- Adds the IP addresses for the discovered servers to its list of replication partner servers.
- Configures the discovered servers as push/pull partners.
- Configures pull replication at two-hour intervals with the discovered servers.

If a remote server is discovered and added as a partner by means of multicasting, it is removed as a replication partner when WINS shuts down properly. To have automatic partner information persist when WINS restarts, you must manually configure the partners.

To manually configure replication with other WINS servers, use the WINS Microsoft Management Console (MMC) snap-in or the Netsh command-line tool to specify roles for each partner and any related information.

For more information about the Netsh command-line tool, see "Netsh" and "Netsh commands for WINS" in Help and Support Center for Windows Server 2003.

# Determining Replication Partners

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Choosing whether to configure a WINS server as a push partner, pull partner, or push/pull partner depends on several considerations, including the specific configuration of servers at your site, whether the partner is across a WAN, and how important it is to distribute changes immediately throughout the network.

In the hub-and-spoke configuration, you can configure one WINS server as the central server and all other WINS servers as push/pull partners of this central server. Such a configuration ensures that the WINS database on each server contains addresses for every node on the WAN. Figure 4.6 shows replication using a hub-and-spoke topology.

**Figure 4.6 WINS Replication in a Hub-and-Spoke Topology**

You can select other configurations for replication partner configurations to meet the particular needs of your site. For example, Figure 4.7 shows replication in a T network topology, in which Server1 has only Server2 as a partner, but Server2 has three partners. So Server1 gets all the replicated information from Server2, but Server2 gets information from Server1, Server3, and Server4.

**Figure 4.7 Replication in a T Network Topology**

If Server2 needs to perform pull replications with Server3, make sure it is a push partner of Server3. If Server2 needs to push replications to Server3, configure it as a pull partner of Server3. Determine whether to configure WINS servers as either pull or push partners, and set partner preferences for each server.

# Determining Convergence Time

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The time needed to replicate a new entry in a WINS database, from the WINS server that owns the entry to all other WINS servers on the network is defined as *convergence time*. When planning for WINS servers, you must decide what is acceptable as the convergence time for your network; the longer the replication path, the longer the convergence time.

Name query requests can succeed before the convergence time elapses, resulting in earlier replication of the new entry. This happens when:

- The entries replicate over a shorter path than the worst-case path.
- **The Number of changes in version ID before replication** threshold expires in the push replication settings before the **Replication Interval** expires in the pull replication settings in the **Replication Partners Properties** dialog box in the WINS snap-in.

# Configuring Replication Across WANs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When configuring WINS replication across WANs, the two most important issues are:

- Whether your WINS replication occurs over slower WAN links.
- The length of time required for all replicated changes in the WINS database to converge and achieve consistency on the network.

The frequency of WINS database replication between WINS servers is a major design issue. The WINS server database must be replicated frequently enough to prevent the downtime of a single WINS server from affecting the reliability of the mapping information in other WINS servers. However, the time interval between replications cannot be so small that it interferes with network throughput.

Network topology can influence your decision on replication frequency. For example, if your network has multiple hubs connected by relatively slow WAN links, you can configure WINS database replication between WINS servers on the slow links to occur less frequently than replication on the LAN or on fast WAN links. This reduces traffic across the slow link and reduces contention between replication traffic and WINS client name queries.

After determining the replication strategy that works best for your organization, map the strategy to your physical network. For example, if you have chosen a hub-and-spoke strategy, indicate on your network topology map which sites have the "hub" server, and which have the "spoke" servers. Also indicate whether the replication is push/pull, push-only, or pull-only.

Document the configurations of each WINS server, including the hardware configuration, IP address, replication configuration, and replication partners.

For more information about WIN configuration across WANs, see "Configuring WINS replication" in Help and Support Center for Windows Server 2003.

# Configuring Replication Across LANs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When configuring WINS replication across LANs, the issues are similar to those that occur in WAN environments, although less critical.

Because the data throughput of the underlying network links for LANs is much greater than for WANs, it might be acceptable to increase the frequency of WINS database replication by specifying push and pull parameters for LAN-based replication partners. For push/pull partners, you can do this by decreasing the **Number of changes in version ID before replication** and **Replication interval** settings from what you use for WAN-based partners on slower links.

For example, between LAN-based replication partners it often works to enable WINS to use a persistent connection between the servers. Without a persistent connection, the normal update count threshold defaults to a minimum of 20. You can specify a smaller update count with a persistent connection.

Next, you can specify a much smaller number, such as a value of one to three in the **Number of changes in version ID before replication** setting before WINS sends a push replication trigger to the other partner. For pull partners, you might also consider setting the **Replication interval** setting to a value in minutes, instead of hours.

As in WAN replication planning, the WINS server database must replicate frequently enough to prevent the downtime of a single WINS server from affecting the reliability of the mapping information in other WINS servers. However, the time interval between replications cannot be so small that it interferes with network throughput.

In environments with a large amount of network traffic it is a good idea to use a network monitoring tool, such as Network Monitor, to help measure and determine how to optimize your WINS replication strategy.

For more information about WINS configuration across LANs, see "Configuring WINS replication" in Help and Support Center for Windows Server 2003. For more information about the Network Monitor tool, see "Network Monitor" in Help and Support Center for Windows Server 2003.

# Configuring Replication Between Untrusted Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is possible to set up WINS replication between one or more WINS servers in domains that do not have a trust relationship. You can do this without a valid user account in the untrusting domain. To configure replication, an administrator for each WINS server must use the WINS snap-in or Netsh commands to manually configure each server to permit this replication.

**Important**

- If you require replication across a firewall, keep in mind that WINS replication occurs over TCP port 42. Therefore, this port must not be blocked on any network device between two WINS replication partners.

For more information about WINS configuration across domains that do not have trust relationships, see "Configuring WINS replication" in Help and Support Center for Windows Server 2003. For more information about domain trusts, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

# Mapping the Replication Architecture to the Physical Network

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After determining the replication strategy that works best for your organization, map the strategy to your physical network. For example, if you have chosen a hub-and-spoke strategy, indicate on your network topology map which sites will have the "hub" server, and which will have the "spoke" servers. Also indicate whether the replication is push/pull, push-only, or pull-only.

Document the configurations of each WINS server, including the hardware configuration, IP address, replication configuration, and replication partners.

The convergence time for the system is the sum of the two longest convergence times to the hub. For example, in an organization that has five WINS servers (WINS-A through WINS-E), if WINS-B and WINS-D replicate with WINS-A (the hub) every 30 minutes, and WINS-C and WINS-E replicate with the hub every 4 hours, the convergence time is 8 hours.

The following examples show three different types of replication.

**Example 1: Deploying WINS Over a Large Number of Branch Offices**

In this example, a medium-sized company has two main sites: a New York and a Los Angeles office with 500 computers in each office, connected through high-speed links. The company also has more than 160 small branch offices, including local sales offices. To save on the costs of the links, some branches act as concentrators for a region. Figure 4.8 shows a WINS server placement strategy for an organization with many small branch offices.

**Figure 4.8 Deploying WINS Over a Large Number of Branch Offices**

In most cases, the branches do not have local WINS servers — there is simply no need for a separate server for each branch. Instead, the company adds regional WINS servers when the costs of registration and query traffic increase above the cost of deploying the additional server. When the link to a regional WINS server fails, local names can still be resolved by the broadcast mechanism.

The regional WINS servers are not required for this configuration to function correctly, but they do provide a cost optimization. The company's network administrators avoid deploying the regional servers whenever possible because the added servers increase the convergence time. Administrators configure regional WINS servers as replication partners of the WINS servers in the main sites.

Clients in the main site are configured with the IP address of their local WINS server as primary, and the IP address of the WINS server in the other main site as secondary. Clients in the regional branches are configured with the IP address of the regional WINS server as primary, and the address of the closest main site WINS server as secondary. The replication interval is set to 15 minutes between sites; therefore, all computers are reachable within 15 minutes of an address registration or change.

**Example 2: Deploying WINS with a Concentrated User Base**

Figure 4.9 shows the network configuration of another example company that is very different. The network serves a larger company with three sites, Philadelphia, Seattle, and Houston, each with 5,000 users. The number of users justifies two WINS servers at each site.

**Figure 4.9 Deploying WINS Over a Few Large Sites**

The clients are configured with a local primary and secondary WINS server. Half of the clients have one local WINS server as primary and the other as secondary. The other half has exactly the opposite configuration. This balances the registration and query load over both WINS servers, and it provides a backup for maintenance purposes and in case of a server failure.

The local WINS servers use a very short replication interval of 10 minutes; therefore, all computers within the same site are reachable within 10 minutes of an address registration or change. The replication interval between the sites can be longer — about 30 minutes — because most users work with resources within their site.

**Example 3: A Large Hub-and-Spoke Design**

Figure 4.10 shows an extremely large WINS implementation, serving more than 100,000 nodes. In a configuration with so many WINS servers, a common error is to create many push/pull relationships for redundancy. This can lead to a system that, while functional, is overly complex and difficult to understand and troubleshoot.

**Figure 4.10 Large-Scale WINS Deployment Using Hub Topology**

Four major hubs are located in Seattle, San Francisco, Chicago, and Los Angeles. These hubs serve as secondary WINS servers for their regions while connecting the four geographic locations. All primary WINS servers are configured as push/pull partners with their hubs, and the hubs are configured as push/pull partners with other hubs.

The primary WINS servers replicate with the hubs every 15 minutes, and the hub-to-hub replication interval is 30 minutes. The convergence time of the WINS system is the time it takes for a client registration to be replicated to all WINS servers.

In this case the longest convergence time would be 1.5 hours from a Seattle primary server to a Chicago primary server. The total convergence time can be calculated by adding up the maximum time between:

- Seattle primary to Seattle secondary, 15 minutes
- Seattle secondary to San Francisco secondary, 30 minutes
- San Francisco secondary to Chicago secondary, 30 minutes
- Chicago secondary to Chicago primary, 15 minutes

However, the convergence time might be longer for WINS servers connected across slow links. It is probably not necessary for the servers in Paris or Berlin to replicate every 15 minutes. You might configure them to replicate every two hours or even every 24 hours, depending on the volatility of names in the WINS system.

This network contains low redundancy. If the link between Seattle and Los Angeles is down, replication still occurs through San Francisco. If, for example, the Seattle hub fails, the Seattle area can no longer replicate with the rest of the WINS system. Network connectivity, however, is still functional — all WINS servers contain the entire WINS database, and name resolution functions normally. All that is lost are changes to the WINS system that occurred since the Seattle hub failed. A Seattle user cannot resolve the name of a file server in Chicago that comes online after the Seattle hub fails. When the hub returns to service, all changes to the WINS database are replicated normally.

# Securing Your WINS Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In many WINS implementations, WINS replication occurs across public networks, such as the Internet. Replicating the NetBIOS names and IP addresses of all hosts within the organization over these public networks creates a security risk, which you can mitigate by using VPN tunnels or placing servers within a perimeter network. Figure 4.11 shows where you perform this step in the process of deploying your WINS solution.

**Figure 4.11 Securing WINS During the Deployment Process**

# Securing WINS Traffic with Tunnels

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

All WINS replication traffic sent over public networks should be encrypted. Encrypt the replication traffic by using Internet Protocol security (IPSec) or VPN tunnels. When choosing to encrypt replication traffic by using IPSec or VPN tunnels, do the following to further increase security:

- Use the strongest level of encryption.
- Use the Routing and Remote Access service to provide the IPSec or VPN tunnel.
- Use Kerberos V5 or other certificate-based authentication for secure communication channels.

For more information about deploying IPSec, see "Deploying IPSec" in this book. For more information about virtual private networks and the Routing and Remote Access service, see "Deploying Dial-up and VPN Remote Access Servers" in this book. For more information about enabling Kerberos V5 authentication, see "Enabling Kerberos V5 authentication" in Help and Support Center for Windows Server 2003.

# Running WINS on a Perimeter Network

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Place WINS servers in a perimeter network when you must send WINS traffic over a public network to avoid exposing intranet NetBIOS names and WINS data. This placement protects corporate resources while providing NetBIOS name resolution to external clients that need access to these resources.

**Caution**

- If you require replication from the WINS server in the perimeter network to a WINS server within the intranet, in the WINS snap-in, select **Replicate Only with Partners** in the **Replication Partners Properties** dialog box on both the WINS servers. Also consider using only pull replication from the intranet servers. To maintain security, encrypt all replication traffic across the inner firewall using IPSec or VPN tunnels.

# Integrating WINS with Other Services

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Most network administrators deploying WINS also plan a strategy for DNS and DHCP servers, because WINS is so closely linked to DNS and DHCP. Figure 4.12 shows when you perform this step in the process of deploying your WINS solution.

**Figure 4.12 Integrating WINS During the Deployment Process**

# Integrating WINS with DNS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If most of your clients use NetBIOS and your servers are running Windows 2000 or Windows Server 2003 DNS, enable WINS lookup on your DNS servers. When WINS lookup is enabled on DNS servers, WINS resolves any names that DNS resolution does not find. DNS does not support the WINS forward lookup and WINS-R reverse lookup records in versions of Windows earlier than Windows 2000. For information about enabling WINS lookup, see "Deploying Domain Name System (DNS)" in this book.

**Note**

- For a smooth integration with DNS, do not use extended characters in NetBIOS names, especially the underscore (_) and the period (**.**). Consult with your DNS administrator when determining NetBIOS naming standards.

If all of your network computers are running Windows 2000, Windows XP, or Windows Server 2003 and you are not supporting any applications that require NetBIOS names, you might consider establishing DNS as your only method of name resolution. However, before you consider decommissioning your WINS servers, identify any computers or applications that rely on NetBIOS, and determine the impact of removing NetBIOS. You might find that a critical application relies on NetBIOS (with no alternative currently available) in which case, you must continue to use WINS. For example, certain applications, such as Microsoft® Systems Management Server (SMS) and Microsoft® BackOffice® client/server mail configurations using Exchange Server, might require NetBIOS naming.

For more information about DNS, see "Deploying Domain Name System (DNS)" in this book or see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

# Integrating WINS with DHCP

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When using DHCP and WINS together on your network, use additional DHCP scope options to assign WINS node types and to identify WINS primary and secondary servers for DHCP clients.

Computers with static IP addresses can be problematic and their initial registration record in WINS becomes tombstoned if they are not periodically stopped and restarted. You can have a more reliable and manageable network by creating DHCP reservations for these computers. These reservations ensure that the computer gets the same IP address from the DHCP server for each request.

When you configure a network to use both DHCP and WINS, set the DHCP lease period to be equal to or greater than the WINS renewal period. This prevents a situation in which the WINS server fails to notice that a DHCP client has released a DHCP-assigned IP address. Specifically, the client cannot send a WINS renewal request because it did not renew its IP address. If another computer is assigned that IP address before the WINS server notes the change, the WINS server mistakenly directs requests for the address to the new client. This is significant only if you do not use the default lease lengths for both services, and lease durations were changed for either DHCP or WINS individually.

For more information about deploying DHCP, see "Deploying DHCP" in this book.

# Implementing Your WINS Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For best performance, avoid deploying WINS on heavily loaded servers, or on servers that perform other tasks that might reduce performance of the hard disk, memory, and processors. If you do host more than one service on a WINS server, consider how each service might impact the others. For example, hosting two name services (such as WINS and DNS) on the same server can result in slow performance for each service due to intensive hard disk access. Or a WINS server hosting a print service might be slow to register names if it is handling several large print jobs simultaneously. It might be appropriate to run multiple services on the same computer in a branch office because servers in branch offices are usually not under heavy use.

Figure 4.13 shows the process for implementing your WINS solution.

**Figure 4.13 Implementing Your WINS Solution**

# Migrating WINS to Windows Server 2003

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

1. Before migrating from legacy WINS servers, make sure your existing WINS infrastructure is appropriate for your current needs. For example, if you have recently upgraded most desktop computers in your organization to Windows 2000 or Windows XP, or if you have recently stopped using an application that relies heavily on WINS, your current WINS structure might be too robust for your current needs, and might not be structured in the most efficient way possible. In a case such as this, start the deployment from the design phase, rather than migrating the existing database to new servers.

2. Follow these steps when migrating your WINS database from Windows NT 4.0 or Windows 2000 to Windows Server 2003:

3. Install the WINS service.

   This can be installed either during or after installing Windows Server 2003.

4. Configure the WINS service.

   Verify that the server is pointing to itself for WINS. You can do this by viewing the TCP/IP properties of your network adapter.

5. Convert the WINS database for use on the Windows Server 2003–based server.

   This conversion might occur automatically from existing Windows NT 4.0–based or Windows 2000–based servers. If not, follow these steps:

   a. At the command prompt, type **net stop wins** on both the existing and new servers.

   b. Copy the contents of the %SystemRoot%\System32\Wins folder from the existing server to the new Windows Server 2003–based server.

   c. At the command prompt, type **net start wins** on both servers.

   **Note**

This process can take 30 minutes or more to complete depending on the size of the database. Do not stop the process until it is finished. It is normal for Jetconv.exe to require heavy CPU usage during the conversion.

During the conversion process, you might be prompted for additional files from the Windows Server 2003 operating system CD.

**To access WINS conversion files**

1. Copy the Edb500.dl_ file from the I386 folder on the CD-ROM to the %SystemRoot%\System32 folder on the server.

2. At the command prompt, type **expand edb500.dl_ edb500.dll** to expand the Edb500.dl_ file on the server.

3. At the command prompt, type **net start wins** to finish the conversion process.

4. Verify that the WINS database is shown in the WINS snap-in on the server.

# Testing Your WINS Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After completing your WINS design, test it in a lab to find potential problems before implementing your design on your production network. As you roll out your design, test your network to ensure it is working as expected.

The best time to discover potential problems with your design is in a test lab prior to your full implementation. When preparing your test lab, be sure to:

- Use a server computer from the same vendor and with the same configuration as the servers that will be used for the actual WINS servers. Set up a representative sample of the computers in your organization to be tested as WINS clients.
- If you are planning to deploy WINS over a WAN, design your lab with routers and use a link simulator to simulate network latency.
- Deploy a typical set of applications together on the WINS test server. This step is vital in determining any compatibility issues that might arise when users run different applications simultaneously.

For more information about planning a test environment, see "Designing a Test Environment" in *Planning, Testing, and Piloting Deployment Projects* of this kit.

# Evaluating the Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After implementing your WINS design, evaluate your deployment to ensure that it complies with your design and meets your organization's business goals.

**To assess the availability of your design** Stage a simulated failure to ensure that functionality, security, and performance are maintained.

**To evaluate WINS service availability** Disable or disconnect each WINS server that is a part of a redundant WINS design. Provide procedures detailing how to restore synchronization of WINS databases after a failed server is reactivated or repaired.

**To evaluate WINS security** Initiate WINS replication, and examine the data transmissions between the locations to ensure that the WINS replication traffic is encrypted.

# Additional Resources for Deploying WINS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For more information about WINS, refer to the following sources:

# Deploying ISA Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Microsoft® Internet Security and Acceleration (ISA) Server is an integrated firewall and Internet caching server. Deploying ISA Server saves network bandwidth by providing faster Web access for users. ISA Server secures your network, allowing you to implement your business security policy by configuring a broad set of rules that specify which sites, protocols, and content can be passed through the firewall.

**In This Chapter**

Overview of ISA Server

Determining the Role of ISA Server

Evaluating Interoperability Issues

Designing for High Availability

Securing the Design

Implementing Your ISA Server Solution

Additional Resources for Deploying ISA Server

**Related Information**

- For more information about creating a virtual private network (VPN), see "Deploying Dial-up and VPN Remote Access Servers" in this book.

# Overview of ISA Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

ISA Server offers a complete Internet connectivity deployment solution as a firewall and a Web caching server.

**Important**

- ISA Server (the successor to Proxy Server 2.0) is a separate product from the Microsoft® Windows® Server 2003 operating system. You must install ISA Server Service Pack (SP1) for ISA Server immediately after installing ISA Server for it to be interoperable with Windows Server 2003.

ISA Server monitors requests and responses between the Internet and internal client computers; ISA Server also controls which computers on the Internet the internal clients can access.

ISA Server offers many security and caching options, including:

- **Enhanced security with multilayer firewall and integrated intrusion detection**.

  ISA is a complete firewall product that provides packet filtering, stateful packet inspection and application-level awareness for many common protocols, such as Simple Mail Transfer Protocol (SMTP) and Domain Name System (DNS). You can create access policies based on user-level information, IP addresses, or Web content.

- **Secure publishing**.

  You can use ISA Server as a reverse cache server to define a secure publishing policy. This protects internal publishing servers and makes them safely accessible to Internet clients.

- **ISA Server can cache Web content, potentially reducing your external bandwidth requirements**.

  You can configure the cache to contain content that your organization uses frequently or that your Internet clients access.

- **ISA Server is extensible**.

  You can program the COM interface in ISA Server using high-level programming languages or scripting languages. Developers can implement application and web filters to extend the core firewall functionality. You can use the ISA Server management interface to develop additional administration tools and management scripts.

# ISA Server Deployment Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The process for deploying ISA Server includes determining the deployment mode (cache, firewall, or integrated) you need to use, examining the integration between ISA Server and other components in your network, and choosing the best method for securing your network design.

Figure 5.1 shows the process for deploying ISA Server.

**Figure 5.1 Deploying Your ISA Server**

# Determining the Role of ISA Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

ISA Server can act as a firewall, a Web caching server, or both in your network. Figure 5.2 shows the process for determining the role of your ISA server.

**Figure 5.2 Determining the Role of ISA Server**

You can install ISA Server in firewall, cache, or integrated mode.

- In **firewall mode**, you can secure network communication by configuring rules and access policies that control communication between your internal network and the Internet. You can also publish internal servers.

- In **cache mode**, you can improve network performance and save bandwidth by storing frequently accessed content closer to the user. You can also route requests from internal users to the appropriate Web server and publish Web servers in cache mode.

- In **integrated mode**, all cache and firewall features are available. You can configure a policy to meet both cache performance and security requirements.

Use Table 5.1 to determine which mode of ISA Server installation is most appropriate in your network.

**Table 5.1 Determining the ISA Server Installation Mode**

| Goal | Mode |
|---|---|
| Secure your connection to the Internet, connect remote offices, or implement secure extranets. | Firewall |
| Increase performance of your Internet connection. | Cache |
| Secure your connection to the Internet and increase the performance of your Internet connection. | Integrated |

# Implementing ISA Server in Firewall Mode

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

ISA Server in *firewall mode* acts as a secure gateway between the Internet and internal clients. By configuring the access policies, you can prevent unauthorized access and malicious content from entering the network, as well as restrict outbound traffic.

In Figure 5.3, ISA Server is deployed in firewall mode and as a publisher of internal services, including e-mail and Web services.

**Figure 5.3 ISA Server in Firewall Mode**

All inbound traffic requiring access to the Web or e-mail servers must pass through the firewall first. Likewise, ISA Server can also limit Internet access to specified clients. In this example, ISA Server is acting as a dedicated firewall controlling access to the internal network.

# Implementing ISA Server in Cache Mode

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

ISA Server in *cache mode* accelerates Web access performance by caching Internet content locally. ISA can provide access control for Web content, both in forward cache mode and reverse cache mode.

**Forward Cache Mode**

When a client in the internal network requests a Web page, ISA Server in *forward cache mode* checks if the content is cached locally. If so, the request is not forwarded to the Internet, and the forward cache server returns the Web pages to the client. If the Web page is not stored locally, ISA Server (acting on behalf of the client) retrieves the Web page from the Internet. ISA Server then saves that Web page in the local cache. The next time a client requests that page, ISA Server can fulfill the request without going to the Internet to retrieve the page. This results in using less bandwidth on the Internet connection. Figure 5.4 illustrates a forward cache mode configuration.

**Figure 5.4 ISA Server in Forward Cache Mode**

**Reverse Cache (Web Publishing) Mode**

You can also configure ISA Server in reverse cache mode. ISA Server in *reverse cache mode* caches content provided to the Internet from the Web server. When an Internet client requests a Web page, the request is sent to the ISA Server–based computer first. If the page is stored there locally, there is no need to retrieve the page from the Web server. This increases performance for Internet clients accessing the Web site from the Internet, as well as increasing security for the server. Figure 5.5 illustrates a reverse cache mode configuration.

**Figure 5.5 ISA Server in Reverse Cache Mode**

# Implementing ISA Server in Integrated Mode

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

ISA Server in *integrated mode* provides a firewall solution and acts as a Web cache server simultaneously by allowing both services to coexist on the same server.

Before implementing both the firewall and Web cache on the same server, consider the following points:

- Purchasing less equipment can minimize costs.
- Centralizing the management of both resources on a single computer can simplify administration.
- Implementing both services on a single computer presents a single point of failure for both services. If that computer goes offline, multiple services are taken offline.

# Determining Client Types

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

ISA Server supports the following types of clients.

**Web Proxy client**
Makes all Internet requests to the ISA Server "Outgoing Web Requests" listener. Most often, this is a Web browser that is either configured manually by the user, or is configured automatically by using Group Policy or a configuration script. ISA restricts user-based Web access controls to Web Proxy clients only.

**SecureNAT client**
Provides IP-based security, but does not allow for user-level authentication. To configure a SecureNAT client, you only have to set the default route between the client and the ISA Server default internal IP address. Because a SecureNAT client uses no other configuration, any computer that uses TCP/IP can be a SecureNAT client.

**Firewall client**
Restricts access on a per-user, per-application basis for outbound access for requests that use Transmission Control Protocol (TCP) and User Datagram Protocol (UDP). To configure a firewall client, you must install the Firewall Client software on each client computer. You can install the Firewall Client software from the shared folder *ISA Server Name*\mspclnt on the ISA Server–based computer.

You can only install the Firewall Client software on computers running Microsoft® Windows® 95 Service Release 2, Windows NT 4.0, Windows® 98, Windows® Millennium Edition, Windows® 2000 Professional, Windows XP Professional, Windows® XP 64-Bit Edition, or the Windows Server 2003 family.

Before you deploy or configure client software assess your organizational needs, determine which applications and services your internal clients require, and assess how you plan to publish servers. Finally, map these needs to the client types supported by ISA Server.

Use Table 5.2 to determine which clients to deploy on your network.

**Table 5.2 Determining Which Clients to Deploy**

| Goal | Client | Reason |
|---|---|---|
| Improve the performance of Web requests for internal clients.<br><br>Combine user-level and content controls to Web access. | Web Proxy | Web Proxy clients do not require any software to be installed but does require specific configuration. |
| Avoid deploying client software or configuring client computers. | SecureNAT | SecureNAT clients do not require any software or specific configuration. |
| Improve Web performance in an environment with non-Microsoft operating systems. | SecureNAT | SecureNAT client requests pass transparently to the ISA Server firewall service and then to the caching service. |
| Publish servers that are located on your internal network. | SecureNAT | You can publish Internal servers as SecureNAT clients, which eliminates the need for creating special configuration settings on the publishing server. |
| Allow Internet access only for authenticated users. | Firewall or Web Proxy | You can configure user-based access policy rules for firewall clients. There is also an option to require authentication with Web Proxy clients. |

# Evaluating Interoperability Issues

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you can make ISA Server interoperable with other network services and computers, you need to evaluate possible implementation and integration issues within your configuration, as shown in Figure 5.6.

**Figure 5.6 Evaluating Interoperability Issues**

# Running Other Services with ISA Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can run ISA Server on a computer with other services running already, such as e-mail or Web servers. However, it is not recommended to place other services on the firewall. For improved security and protection, place services behind the firewall, as shown in Figure 5.7. For example, if your organization needs to deploy ISA Server to connect branch offices to the Internet in integrated mode, ISA Server can be installed on existing e-mail or Web servers to simplify deployment and minimize the cost.

**Figure 5.7 Running Other Services with ISA Server**

# Implementing ISA Server in a Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

ISA Server with ISA Server SP1 can be installed as a stand-alone server or as a member of an array in a Microsoft® Windows® 2000 Server or Windows Server 2003 domain. When you install ISA Server as a stand-alone server, the configuration information is saved to the local registry. When you install ISA Server as a member of an array in a Windows 2000 or Windows Server 2003 domain, the ISA Server schema is installed into the Active Directory® directory service. You need to install Active Directory on the ISA Server domain to use ISA Server arrays.

ISA Server can be installed as a stand-alone server in a Windows NT Server 4.0 domain. No special configuration is required. You can use arrays of ISA Server computers to connect and secure Windows NT 4.0 domain users and clients to the Internet. However, the array must be set up on a separate Windows 2000 or Windows Server 2003 domain. Then you can establish a trust relationship from the domain containing the ISA Server computer to the Windows NT 4.0 domain.

# Using ISA Server with Other Network Services

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You might have run the Routing and Remote Access service in Windows 2000 or Windows Server 2003 to make network services and computers available to remote clients. ISA Server enables remote connectivity and extends routing and remote access functionality by providing additional security features. ISA Server packet filtering replaces the packet filtering functionality in the Routing and Remote Access service. In addition, ISA Server uses the dial-up connections that you previously configured for routing and remote access.

Similarly, you might have used Internet Connection Sharing (ICS) or network address translation (NAT) to access the Internet. ISA Server provides the connectivity enabled by NAT or ICS, while adding sophisticated security and caching features.

**Caution**

- You cannot combine ICS or the NAT that is included with the Routing and Remote Access service for Windows Server 2003 with ISA Server or else you will lose firewall functionality. Also, IIS cannot run on the same computer as ISA Server without special configuration. For more information about configuring IIS for use with ISA Server, see the ISA Server link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources, and then search for the keyword *socket pooling*.

# Designing for High Availability

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before deploying ISA Server, estimate your Internet connectivity requirements. Use the following sections as guidelines for planning the size and type of your servers, and whether to deploy them as an array. Figure 5.8 shows the process for designing for high availability.

**Figure 5.8 Designing for High Availability**

# Performing Capacity Planning

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The flowchart in Figure 5.9 outlines the capacity planning process for ISA Server.

**Figure 5.9 ISA Server Capacity Planning Process**

Use the following guidelines for capacity planning:

- Ensure the minimum hardware requirements deploying ISA Server are met.
- Decide whether to install ISA Server as a firewall. If yes, ensure that the minimum firewall requirements are met.
- Decide whether or not to install ISA Server as a Web cache server. If yes, ensure that the minimum hardware requirements are met.

The following list describes the minimum hardware requirements for installing ISA Server:

- A computer with a 300 megahertz (MHz) or higher Pentium II-compatible CPU.
- The computer must be running either a member of the Windows 2000 Server family, or a member of the Windows Server 2003 family. If you are installing ISA Server on a computer running Windows Server 2003, you must also install ISA Server SP1.

  **Note**

  - Using the latest service pack is always recommended.
- 256 megabytes (MB) of memory.
- 20 MB of available hard disk space.
- A network adapter to communicate with the internal network.
- One local hard disk partition that is formatted with the NTFS file system.
- To implement the array and enterprise-level policy configuration, you must also run Active Directory.
- If you are using ISA Server in firewall or integrated mode, two network adapters are required.
- If your ISA Server is also supporting other services, such as e-mail or Web services, additional resources might be

required.

Use Table 5.3 to determine the type of computers to use and whether you require an array.

**Table 5.3 Hardware Requirements for Different Network Loads**

| Hits per Second | Minimum Hardware Required | RAM |
|---|---|---|
| Less than 500 | One computer, Pentium II, 300 MHz processor | 256 MB |
| 500 to 900 | One computer, Pentium III, 550 MHz processor | 256 MB |
| More than 900 | One computer, Pentium III, 550 MHz processor, for each 800 hits per second increment | 256 MB per server |

**Note**

- You can also use Performance Monitor to identify bottlenecks and determine whether to add more servers.

If multiple computers are required to handle the network load, consider setting up an array of ISA Server–based computers. Arrays allow Web cache routing across a group of ISA Server–based computers. For more information, see "Configuring ISA Server in an Array" later in this chapter.

**Firewall Requirements**

Table 5.4 lists hardware requirements and network connections based on expected throughput for firewall clients accessing content on the Internet.

**Table 5.4 Hardware Requirements for Firewall**

| Throughput Requirements | Minimum Hardware Required | Internet Connection Type |
|---|---|---|
| 36 Kilobits per second (Kbps) to 1 Megabits per second (Mbps) | One computer, Pentium II, 300 MHz processor | POTS modem, cable modem, or xDSL |
| 384 Kbps to 1.5 Megabits per second (Mbps) | One computer, Pentium II, 300 MHz processor | T1 |
| 3 Mbps - 44 Mbps | One computer, Pentium III, 550 MHz processor | T3 or faster |
| More than 44 Mbps | One computer, Pentium III, 550 MHz, for each 50 MB/second required | OC3 or faster |

**Forward Caching Requirements**

You can deploy ISA Server as a *forward-caching server*, which maintains a centralized cache of frequently-requested Internet content. In this case, consider how many users might access the Internet.

Table 5.5 lists the hardware requirements for using ISA Server in forward cache mode.

**Table 5.5 Hardware Requirements for Forward Caching**

| Internet Users | Minimum Hardware Required | RAM | Disk Space for Caching |
|---|---|---|---|
| Up to 500 | One computer, Pentium II, 300 MHz processor | 256 MB | 2–4 Gigabytes (GB) |
| 500 -1,000 | One computer, two Pentium III, 550 MHz processors | 256 MB | 10 GB |
| More than 1,000 | Two computers, Pentium III, 550 MHz processors | 256 MB for each server | 10 GB for each server |

If your user-base exceeds 1,000 users, you can use hardware with faster processors and more memory, or you can add more ISA Server installations.

**Reverse Caching Requirements**

You can deploy ISA Server as a *reverse-caching server* to fulfill Web requests from the Internet to your network. For example,

you might place an ISA Server computer between the Internet and an organization's Web server that is hosting a commercial Web business or providing access to business partners. In that case, you need to consider how often external clients might request content from the publishing servers.

Table 5.6 lists hardware requirements for ISA Server in reverse cache mode, based on the number of hits per second from Internet users.

**Table 5.6 Hardware Requirements for Reverse Caching**

| Hits Per Second | Minimum Hardware Required |
|---|---|
| Fewer than 100 | One computer, Pentium II, 300 MHz processor |
| 101 to 250 | One computer, Pentium III, 450 MHz processor |
| More than 250 | One computer, Pentium III, 550 MHz processor for each 250 hits per second. You can use Performance Monitor to determine bottlenecks, and then add more servers or more powerful hardware, as necessary. |

Memory requirements depend on the size of the cacheable content that you are publishing, and the working set of the content. Ideally, all cacheable content should fit into the available memory. By default, the ISA Web Proxy service uses half of the available server memory for RAM caching. For example, if the Web site you are publishing has 250 MB of cacheable content, then your ISA server computer should have at least twice this much available RAM before the Web Proxy service starts.

**Adding Computers**

In some cases, you need to decide whether to add an additional ISA Server–based computer or to improve the performance of the existing computer by adding an additional processor. Each option has different advantages.

When you add a new computer and create an array of ISA Server–based computers, you set up a fault-tolerant system. If one computer fails, the other continues to function. On the other hand, adding a computer means that you have to purchase and manage additional hardware and any software that is installed on the computer.

# Designing for Scalability

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When designing for scalability, consider differences between Microsoft® Internet Security and Acceleration (ISA) Server Standard Edition and Microsoft® Internet Security and Acceleration (ISA) Server Enterprise Edition, such as:

- ISA Server Standard Edition supports only a single computer configuration, and therefore, cannot be used in an array.
- ISA Server Enterprise Edition can be configured either in a single computer configuration or in an array.

# Configuring ISA Server in an Array

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Computers running ISA Server Enterprise Edition can be grouped together in arrays. An *array* is a group of ISA Server–based computers used to perform Web cache routing. Arrays allow a group of ISA Server–based computers to be treated and managed as a single, logical entity. An array installation also provides increased performance and bandwidth savings. Grouping your ISA Server–based computers in an array allows your client requests to be distributed among multiple servers, thereby improving response time for clients.

All the servers in an array share a common configuration. This saves management time because the array is configured once and the configuration is applied to all the servers in the array. Furthermore, you can apply an enterprise policy to an array. This allows centralized management for all the arrays in the enterprise. A unique array policy can be applied to each array in the enterprise.

It is recommended that you consider installing ISA Server as an array even if there is only one server. The advantages to this include the ability to easily add an additional server to the array in the future and the ability to use the advanced array management features.

**Note**

- All array members must be in the same domain and in the same site.

Table 5.7 compares ISA Server features as a stand-alone server and in an array configuration.

**Table 5.7 Comparing Features of ISA Server as a Stand-Alone Server or as an Array**

| ISA Server Stand-Alone Server | ISA Server Array |
|---|---|
| Can be installed in a Windows NT 4.0 domain. | Requires Active Directory. |
| Cannot use array or enterprise policies. | Uses both enterprise- and array-level policies. |
| Installs from either ISA Server Standard or ISA Server Enterprise Edition. | Installs from ISA Server Enterprise Edition only. |

# ISA Server and DNS Round Robin

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Firewall and Web proxy clients can achieve fault tolerance when two or more computers running ISA Server are used together with a Domain Name System (DNS) server.

You can use DNS to assign the same name to all the ISA Server–based computers in a cluster. With this configuration, when a client requests an object from the ISA Server–based computer specifying the DNS name, the DNS server resolves the name to one of the computers running ISA Server in the array in a round robin fashion. This increases fault tolerance through redundancy and improves performance through the use of multiple computers answering client requests.

**Note**

- For DNS round robin to work for an ISA array, the duplicated resource records must all use the array name.

Figure 5.10 shows the DNS server receiving a request from the clients and forwarding the request to the computers running ISA Server in a round-robin configuration.

**Figure 5.10 DNS Round Robin**

# Securing the Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

ISA Server secures your connection to the Internet or to remote sites and extranets. Security decisions for implementing ISA Server are discussed in the following sections. Figure 5.11 shows the process for securing the design.

**Figure 5.11 Securing the Design**

# Connecting Remote Sites Using ISA Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Using ISA Server to connect remote offices includes the following benefits:

- The ability to connect remote offices together through the Internet using a virtual private network (VPN).
- Hierarchical caching can also be implemented across the wide area network (WAN) on ISA Server–based computers.

# Securing Network Perimeters with ISA Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A perimeter network, also known as a screened subnet, is a network that is set up separately from an organization's private network and the Internet. The perimeter network allows external users access to the specific servers located in the perimeter network, while preventing access to the internal network. In addition, an organization might allow very limited access from computers in the perimeter networks to computers in the internal network.

A perimeter network is commonly used for deploying the e-mail and Web servers. The perimeter network can be set up using either of the following configurations:

- Back-to-back perimeter network configuration with two ISA Server–based computers on either side of the perimeter network.

- Three-homed ISA Server–based computer with both the perimeter and internal network protected by the same computer.

# Designing a Back-to-Back Perimeter Network

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In a back-to-back perimeter network configuration, two ISA Server–based computers are located on either side of the perimeter network. Figure 5.12 shows a back-to-back perimeter network configuration.

**Figure 5.12 Back-to-Back Perimeter Network**

Both ISA Server–based computers are set up in integrated or firewall mode. This configuration reduces the risk of compromise by requiring anyone attempting to access the internal network from the Internet to access both systems to reach the internal network.

Perform the following steps to make the servers on the perimeter network available to Internet clients:

1. Configure the local address table (LAT) on the ISA Server–based computer that is connected to the internal network to include the IP addresses of the computers in the internal network.

2. Configure the LAT on the ISA Server–based computer connected to the Internet to include the IP address of the ISA Server–based computer connected to the internal network, and the IP addresses of all the publishing servers in the perimeter network.

3. Create a Web publishing rule on the ISA Server–based computer connected to the Internet to publish the Web server.

4. Create a server publishing rule on the ISA Server–based computer connected to the Internet to publish the e-mail server. Configure the server publishing rule to apply to the e-mail server.

5. Create a Web publishing rule to publish the Web server, and configure the rule to redirect requests to the hosted site.

6. With this back-to-back perimeter network design, selected traffic can access the e-mail or Web server without accessing the internal network. This example publishes the e-mail and the Web servers without exposing the internal network to the Internet.

# Designing a Three-Homed Perimeter Network

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In a three-homed perimeter network, a single ISA Server–based computer is set up with three network adapters:

- The first network adapter connects to clients on the internal network.
- The second network adapter connects to the servers located in the perimeter network.
- The third network adapter connects to the Internet.

Figure 5.13 illustrates the three-homed perimeter network configuration.

**Figure 5.13 Three-Homed Perimeter Network**

Perform the following configuration steps for the three-homed ISA Server perimeter network:

- Configure the LAT to include all of the addresses on the internal network. The LAT should not include the addresses on the perimeter network.
- Enable packet filtering and IP routing.
- Create IP packet filters for each of the servers in the perimeter network. For each IP packet filter, the local computer should be specified as the IP address of the server on the perimeter network.

# Using ISA Server in Extranets

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An extranet is a private network that is configured for use outside your internal network. The extranet is installed to support selected partners who require access to your network. ISA Server supports the installation of extranets through the built-in capability of VPNs. Figure 5.14 shows ISA Server within an extranet design.

**Figure 5.14 ISA Server in Extranets**

# Implementing Your ISA Server Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After determining the roles you want for ISA Server and completing your ISA Server design, you will implement your ISA Server solution. Figure 5.15 shows when to implement your ISA Server solution.

**Figure 5.15 Implementing Your ISA Server Solution**

Figure 5.16 shows the process for implementing the ISA Server solution in your network.

**Figure 5.16 Details of Implementing Your ISA Server Solution**

Use the following steps to deploy ISA Server in your network:

1. Ensure that you are running either Windows 2000 Server or the Windows Server 2003 family. If necessary, upgrade the operating system before continuing with the deployment.

2. Ensure that the latest service pack in installed. If necessary, install the service pack before proceeding with the deployment.

3. Ensure that the network adapters are installed and working correctly; make sure you have a valid connection to the Internet.

    - You can choose to connect your network to the Internet through either a persistent connection (T1, T3, xDSL, or cable modem) or a dial-up connection. If you choose a direct connection, you need to set up a network adapter that connects the ISA Server–based computer to the Internet.

    - When you set TCP/IP properties for the external network adapter, consult with your ISP for the correct settings. Specifically, you need the IP address, subnet mask, default gateway, and IP addresses for the DNS servers to use in DNS name searches. In some cases, your ISP might be using Dynamic Host Configuration Protocol (DHCP) or bootstrap protocol (BOOTP) for dynamic assignment of client addresses.

    - Typically, ISA Server has only one IP default gateway. You should configure the IP address of the default gateway on the external — not internal — network adapter. Leave the **Default Gateway** setting for the internal network adapter blank.

    - When setting TCP/IP properties for any internal network adapter, you should enter a permanently reserved IP address for the ISA Server–based computer and an appropriate subnet mask for your internal network. Addressing that is assigned by DHCP should not be used for the internal network adapter, because DHCP might reset the default gateway you selected for the ISA Server–based computer. The external network adapter can be DHCP-enabled, including the default gateway and DNS settings, or these settings can be statically defined.

4. If you are installing ISA Server Enterprise Edition you need to initialize the enterprise. You can run the Enterprise Initialization Tool in ISA Server startup.

    - If this is the first time you are installing ISA Server as an array member, you should run the ISA Server Enterprise Initialization Tool.

    - If you are installing a stand-alone server, or if you have previously installed ISA Server in your enterprise as an array member, you do not need to run the Enterprise Initialization Tool, and you can select **Install ISA Server**.

    **Important**

    - In order to install the ISA Server schema to Active Directory, you must be a member of both the Enterprise Administrators and Schema Administrators groups.

5. Install ISA Server. Setup asks for the following information:

    - **Installation options**.

      You can select a **Typical** installation, **Full** installation, or **Custom** installation.

    - **Array selection**.

      If you previously initialized the enterprise, you can select which array to join. If you did not initialize the enterprise, then ISA Server is installed as a stand-alone server.

    - **Mode**.

      You can install ISA Server in firewall mode, integrated mode, or cache mode.

    - **Cache configuration**.

If you install ISA Server in integrated or cache mode, you need to configure which cache drives to use and the size of the cache.

- **LAT configuration**.

  If you install ISA Server in integrated or firewall mode, you need to configure the address ranges to include in the LAT.

6. Before building your LAT, ensure that you enter all subnets correctly.

   - The LAT is automatically constructed from the Windows Server 2003 routing table. If the computer is connected to a routed internal network and you are unsure of the routing topology of your network or how to add static routes, you can manually construct the LAT to contain the range(s) of IP addresses that your internal clients use.

   - Because a default gateway cannot be set on the internal interface of the ISA Server–based computer, you need to create static routes for your internal network at a later time to achieve full connectivity. You can do this using the **route** command from the command prompt.

   - A LAT that is configured correctly ensures that ISA Server can determine which network adapter to use, in order to access different portions of your internal network. If the LAT is not configured correctly, a client request for an internal IP address might be incorrectly routed to the Internet or redirected through the firewall service.

7. After installation, ISA Server effectively blocks all communication between your internal network and the Internet. No communication can occur until you configure an access policy with the protocol, site, and content rules specifically allowing access. Similarly, you must configure publishing rules if you want to allow Internet clients access to computers on your internal network.

   If you installed ISA Server as an array member, then an enterprise policy might be applied to the array. In this case, ISA Server might allow communication if the enterprise policy is configured appropriately.

8. Install the latest service pack for ISA Server.

# Additional Resources for Deploying ISA Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information and tools related to this chapter.

# Deploying IPSec

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Internet Protocol security (IPSec) in the Microsoft® Windows® Server 2003 operating system protects networks from active and passive attacks by securing IP packets through the use of packet filtering, cryptography, and the enforcement of trusted communication. IPSec is useful in host-to-host, virtual private network (VPN), site-to-site (also known as gateway-to-gateway or router-to-router), and secure server scenarios, and can be managed by using Group Policy or scripted by using command-line tools.

# Overview of IPSec Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Private networks face various external and internal threats. You can use specific tools to counter specific threats. For example, antivirus systems can protect desktops and servers to a limited extent against known attacks.

IPSec can be used to secure all communications between parties — for example, by using authentication and encryption — without requiring any further modifications to applications or protocols. If you need to ensure that messages are not modified in transit or that they are unreadable to network intruders, IPSec provides a solution you can use to achieve these ends. Although IPSec can be applied to a variety of situations, this chapter describes solutions that are useful for most, but not all environments.

Although businesses typically separate their internal network from the Internet by using firewalls that block traffic sent to specified ports and protocols, internal corporate networks have become so complex that it is difficult to protect all mission-critical data at all times from attackers. Yet business applications fully depend on network access, so using a firewall to block incoming traffic by port is not always practical; it is difficult to know which ports require protection and which ports carry essential communication. IPSec provides a much stronger access model based on enforcing trusted communication.

Designed by the Internet Engineering Task Force (IETF), Internet Protocol security (IPSec) is a framework of open standards for ensuring private, secure communications over Internet Protocol (IP) networks, through the use of cryptographic security services.

IPSec is not a full-featured host firewall. However, it does provide the ability to centrally manage policies that can permit, block, or negotiate security for unicast IP traffic, based on specific addresses, protocols, and ports. Microsoft Internet Connection Firewall (ICF) is designed as a locally managed basic host firewall. The primary difference between IPSec and ICF is that IPSec provides complex static filtering based on IP addresses, while ICF provides stateful filtering for all addresses on a network interface. It is recommended that you use ICF when you want to implement a firewall for a network interface that can be accessed through the Internet. It is recommended that you use IPSec when you want to secure traffic on the wire, or when you need to allow access only to a group of trusted computers.

IPSec is included in Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; Windows® Server 2003, Datacenter Edition; Windows® Server 2003, Web Edition operating systems; and the 64-bit editions of Windows Server 2003. Portions of IPSec and related services in these platforms were jointly developed by Microsoft and Cisco Systems, Inc. This chapter primarily focuses on design decisions and planning required to use IPSec for end-to-end secure networking scenarios for Windows Server 2003 and Microsoft® Windows® XP operating systems.

To best deploy IPSec in a typical network environment, you also need Active Directory® directory service domains and Group Policy in place.

Focus on the following areas when planning an IPSec deployment:

- Deciding where and how you must secure computers on your network by grouping computers in Active Directory organizational units (OUs).

- Deciding how tight to make the security by what policy you assign.

# IPSec Deployment Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before deploying IPSec on your network, make decisions about which computers to secure, where the security should be implemented, and how tight the security must be. Then test your deployment plan in a lab, and finally deploy IPSec on your network.

Use the steps shown in Figure 6.1 to design the deployment process of IPSec on your network.

**Figure 6.1 Deploying IPSec**

# Windows Server 2003 IPSec Concepts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use the Windows Server 2003 implementation of IPSec to compensate for the limited protections provided by applications for network traffic, or as a network-layer foundation of a defense-in-depth strategy. Do not use IPSec as a replacement for other user and application security controls, because it cannot protect against attacks from within established and trusted communication paths. Your authentication strategy must be well defined and implemented for the potential security provided by IPSec to be realized, because authentication verifies the identity and trust of the computer at the other end of the connection. For example, if IPSec is required to encrypt all traffic only to trusted domain member computers, but there are weak controls on how computers can join the domain, the IPSec-protected traffic might be exposed to a trusted man-in-the-middle attack. Similarly, if attackers can join their computers to the domain, they might obtain trusted, encrypted access to IPSec-protected servers. If computers cannot be properly authenticated, IPSec does not provide security.

Table 6.1 outlines the specific security needs that IPSec addresses.

**Table 6.1 IPSec Security Solutions**

| Security Concern | IPSec Solution |
|---|---|
| Network attacks using specific protocols or ports. | Two methods:<br>• IPSec traffic blocking, to block specified traffic.<br>• IPSec policy filter lists can allow traffic from only trusted senders over particular protocols to particular addresses and ports. |
| Eavesdropping. Also known as *sniffing*. Eavesdropping occurs when an attacker uses a frame capture program (also known as a sniffer) to view the data that is placed on the network. | IPSec uses the Encapsulating Security Payload (ESP) protocol to encrypt data by using Triple Data Encryption Standard (3DES) or Data Encryption Standard (DES) so that IP packets cannot be read if intercepted in transit. |
| Data modification. If an intruder can access the information, they might be able to change it in such a way that the recipients cannot detect that any change has occurred. | IPSec uses a cryptographic checksum that incorporates a secret key to provide data integrity. Although a packet can be modified, the checksum cannot be updated for the proper value without knowledge of the secret key. An invalid checksum indicates to the receiving computer that the packet was modified in transit. |
| Identity spoofing. Intruders falsely using an IP address to compromise packet filter security. | IPSec uses Kerberos, public key certificates, or preshared key authentication to verify the identity of computer systems before the application level communication can take place. |
| Denial-of-service attack. By flooding a computer or network with malicious, malformed, or useless information, an attacker can disrupt normal operations. | IPSec uses IP packet filtering to determine whether communication is allowed, secured, or blocked, according to specified IP address ranges, protocols, or TCP or User Datagram Protocol (UDP) ports. IPSec cannot be targeted by denial-of-service attacks. |

When communication is secured between computers, IPSec authenticates computer identities and negotiates security options. Security options include aspects such as encryption strength or acceptable authentication methods. Negotiating security options ensures that communication partners agree how to secure the connection. By requiring IPSec for all network access to a server, you can ensure that only trusted computers can access the server. Active Directory can be used to deliver Group Policy security settings for all clients in a domain, as well as for groups of servers in an OU. Thus you can create, distribute, and enforce access rules for groups of computers for any of the following:

- Computers that are members of a specific domain

- A specific group of computers with common needs or roles in an OU
- A specific computer

**Compatibility**

Operating systems older than Microsoft® Windows® 2000 do not provide built-in support for IPSec. These include Microsoft® Windows® 98, Windows® Millennium Edition, and Microsoft® Windows NT®. If you have computers running these operating systems in your environment, make sure they are not required to use IPSec because the enforcement of IPSec-secured communications denies them access to resources.

Several features in the Windows Server 2003 implementation of IPSec are not provided in Windows 2000 or in Microsoft® Windows® XP Professional. If you plan to apply IPSec policies that use any of the new features that are available only in the Windows Server 2003 implementation of IPSec, do not use the Windows XP or Windows 2000 IP Security Policy Management snap-ins to manage these policies. Using those operating systems to manage Windows Server 2003 policies will result in the new features in the Windows Server 2003 policies being lost. IPSec policies that do not use the new Windows Server 2003 features, however, can be applied to computers running any of the three operating systems.

Remote management and monitoring of IPSec is only supported between computers running the same version of the Windows operating system. For remote management and monitoring of IPSec, it is recommended that you use Remote Desktop Connection.

For central management of IPSec policy on computers running Windows XP, Windows 2000, and Windows Server 2003, use Active Directory.

The IPSec internal infrastructure components were significantly modified for Windows Server 2003. Policies created on computers running Windows XP, Windows 2000, and Windows Server 2003 can be shared between any of those operating systems, but many tools have changed for creating and managing those policies and some tools are not installed by default. In Windows Server 2003, use the IP Security Policy Management snap-in, the Netsh IPSec context, and the Resultant Set of Policy (RSoP) snap-in for management and the IP Security Monitor snap-in for monitoring. Netdiag.exe, which is included in the Support Tools folder of the Windows Server 2003 operating system CD, no longer includes IPSec functionality. IPSecmon.exe, which was included in Windows 2000, is not included with Windows Server 2003 (it has been replaced by the new IP Security Monitor snap-in). IPSecpol.exe, which was included with the *Microsoft® Windows® 2000 Server Resource Kit*, is not included with Windows Server 2003. IPSeccmd.exe, which was included in the Support Tools folder of the Windows XP operating system CD, is not included with Windows Server 2003. For Windows Server 2003, the Netsh IPSec context replaces and enhances the functionality provided by Netdiag.exe and IPSeccmd.exe.

**New in Windows Server 2003**

IPSec provides new features that enhance security, scalability, availability, ease of deployment, and administration. Although the additions to Windows Server 2003 provide greater security, they are not always compatible with earlier versions of Windows. Ensure that you understand which technologies work with clients in your environment, and then determine whether to upgrade clients, postpone the use of specific IPSec technologies, or a mix of both. Then test your plan in a lab before deploying it in your production environment.

The new technologies highlighted in this section focus on those pertinent to deployment.

**Filters update IP configuration of IPSec partners** You can use the IP Security Policy Management snap-in or Netsh to configure the source or the destination address fields that the target computer interprets as the addresses for the Dynamic Host Configuration Protocol (DHCP) server, the Domain Name System (DNS) servers, the Windows Internet Name Service (WINS) servers, and the default gateway. As a result, IPSec policies can now automatically accommodate changes in the IP configuration of the source or destination, by using either DHCP or static IP configurations. Enhanced subnet definitions are also supported by Windows Server 2003 IPSec.

**NAT traversal support has been added** Windows Server 2003 IPSec meets new Internet Engineering Task Force (IETF) draft version 2 specifications, "UDP Encapsulation of IPSec Packets" and "Negotiation of NAT-Traversal in the IKE," which describe methods by which ESP-protected IPSec traffic can pass through a network address translator (also known as a NAT). However, some applications might not work when their traffic is first protected with IPSec ESP and then passed through a network address translator. The Internet Key Exchange (IKE) protocol automatically detects network address translators and uses UDP ESP encapsulation to send all user data by using UDP port 4500. Using the Authentication Header (AH) protocol across network address translators is not supported by IPSec NAT traversal (NAT-T).

**Netsh enables command-line support for IPSec** Replacing IPSecpol.exe and IPSeccmd.exe, the new IPSec context of the Netsh command-line tool can be used to automate IPSec configuration, deploy IPSec remotely or across many computers, and perform other tasks. For example, domain logon scripts, startup scripts, and other files can be used to configure IPSec policy.

For more information, see "Netsh commands for Internet Protocol Security (IPSec)" in Help and Support Center for Windows Server 2003.

**Default exemptions have been removed** IPSec provides greater protection because filtering exemptions that existed in Windows XP and Windows 2000 have been removed from Windows Server 2003. In Windows XP and Windows 2000, all broadcast, multicast, Internet Security Association and Key Management Protocol (ISAKMP), Kerberos, and Resource Reservation Protocol (RSVP) traffic was exempt from IPSec filtering. In Windows Server 2003, only ISAKMP traffic is exempt from IPSec filtering. Exemptions can be added by using the IP Security Policy Management snap-in or the Netsh IPSec context. The Kerberos protocol is no longer a default exemption; if you want to enable Kerberos authentication, you must create filters in the IPSec policy that explicitly allow all traffic to each domain controller IP address in the domain member's domain. If you created policies for Windows XP or Windows 2000, you might need to configure explicit permit filters to maintain the expected behaviors of the IPSec policy on servers running Windows Server 2003. For more information, see "Understanding IP Filters, Filter Actions, and Filter Lists" later in this chapter.

**RSoP support has been added** RSoP provides information that can help assess and resolve unexpected IPSec behavior resulting from Group Policy conflicts. For more information, see "Using RSoPd to Analyze IPsec Policy Assignments" later in this chapter.

Other improvements that enhance security and IPSec policy management include:

- 2048-bit Diffie-Hellman keys, which provide very strong cryptographic key generation to maximize 3DES encryption strength.
- Persistent IPSec policy, which enhances security during computer startup. Additionally, persistent IPSec policy provides a method for local administrators to force local IPSec policy settings to be applied when Active Directory-based policy is assigned. For more information about persistent IPSec policy, see "Assigning IPSec Policies Locally" later in this chapter.
- Stateful filtering of network traffic during computer startup, which permits only the following traffic during computer startup: the outbound traffic that the computer initiates during startup, the inbound traffic that is sent in response to the outbound traffic, and DHCP traffic.
- The IP Security Monitor snap-in, which displays more details about IPSec communication than IPsecmon.exe (used for monitoring IPSec in Windows 2000). These additional details and performance enhancements enable effective monitoring of IPSec-secured servers.

For more information about new features of Windows Server 2003, see "New features for IPSec" in Help and Support Center for Windows Server 2003.

#### Terms and Definitions

This section provides brief definitions of core IPSec and IPSec-related terms. For more information, see the sources mentioned in "Additional Resources for Deploying IPSec" later in this chapter, or Help and Support Center for Windows Server 2003.

**Authentication** The process for verifying that a peer or object is who or what it claims to be. Examples include confirming the source of information, such as verifying a digital signature, or verifying the identity of a computer.

**Authentication Header (AH)** An IPSec protocol that provides data origin authentication, data integrity, and anti-replay for the entire packet (the IP header and the data payload carried in the packet, except fields in the IP header that are allowed to change in transit). AH can be used alone, in combination with ESP, or in IPSec tunnel mode. Windows AH functionality complies with RFC 2402.

**Cryptography** The process of keeping messages and data secure. Cryptography enables and ensures data confidentiality, data integrity, authentication (peer and data origin), and nonrepudiation.

**Default response** An IPSec rule that is used to ensure that the computer responds to requests for secure communication. If an active policy does not have a rule defined for a computer that is requesting secure communication, the default response rule is applied and security is negotiated. The default response rule cannot be deleted, but it can be deactivated. It is activated by default for all policies.

**Encapsulating Security Payload (ESP)** An IPSec protocol that provides data confidentiality, data origin authentication, data integrity, and anti-replay for the ESP payload. ESP can be used alone, in combination with AH, or in IPSec tunnel mode. Windows ESP functionality complies with RFC 2406.

**Filter action** The part of an IPSec rule that defines the security requirements for the data transmission. A filter action can be

configured to permit traffic, block traffic, or negotiate secure communications with IPSec. If security negotiation is selected, you must also configure security methods and their order, whether to accept initial incoming unsecured traffic, whether to allow unsecured communication with computers that do not support IPSec, and whether to use perfect forward secrecy (PFS).

**Group Policy** The infrastructure within Active Directory that enables directory-based change and configuration management of user and computer settings, including security and user data. You use Group Policy to define configurations for groups of users and computers. The Group Policy settings that you create are contained in a Group Policy object (GPO). By associating a GPO with selected Active Directory system containers — domains, sites, and OUs — you can assign the GPO's policy settings to the users and computers in those Active Directory containers. Although Group Policy applies to both users and computers, IPSec policy is a computer configuration Group Policy setting that is only applied to computers.

**Group Policy Object (GPO)** A collection of Group Policy settings that are stored at the domain level that affect users and computers contained in domains, sites, and OUs. In addition, each computer has one local GPO. To create an individual GPO, use the Group Policy Object Editor snap-in. Although GPOs can apply to both users and computers, IPSec policy objects can only be applied to computers.

**IPSec authentication** The process of verifying trust in an identity. IKE uses mutual authentication between computers to establish trusted communications, and requires the use of one of the following authentication methods: Kerberos V5, a computer X.509 v3 public key infrastructure (PKI) certificate, or a preshared key. The two communication endpoints must have at least one common authentication method, or communication fails.

**IPSec filter** A specification in an IPSec rule that is used to match IP packets to filter actions (permit, block, or negotiate security). An IP filter list contains one or multiple filters, and it can be shared among different IPSec policies. For example, one filter list can contain the list of each domain controller IP address in a domain.

**IPSec policy** A collection of one or more IPSec rules that determine IPSec behavior.

**IPSec rule** A statement in an IPSec policy that associates a filter list with a filter action, an authentication method, and an IPSec mode. An IPSec rule is typically configured for a specific purpose (for example, "Block all inbound traffic from the Internet to TCP port 135"). Many IPSec rules can be defined in a single IPSec policy.

**IPSec transport mode** A mode of IPSec that is used to protect host-to-host communications. Transport mode provides security between computers that are on the same local area network (LAN) or connected by private wide area network (WAN) links.

**IPSec tunnel mode** A mode of IPSec that is used to protect site-to-site (gateway-to-gateway) traffic between networks, such as site-to-site networking through the Internet. The sending gateway encapsulates the entire IP datagram by creating a new IP packet that is then protected by one of the IPSec protocols. Windows Server 2003 supports IPSec tunnel mode for configurations where Layer Two Tunneling Protocol (L2TP) cannot be used. For more information about recommended uses of tunnel mode, see "Using IPSec in Tunnel Mode" later in this chapter.

**Netsh** A command-line scripting tool for configuring networking components on the local computer or on remote computers running Windows 2000, Windows XP Professional, or Windows Server 2003. The Netsh IPSec context is only available on Windows Server 2003, although policies created with Netsh can be used for computers running other versions of Windows that support IPSec.

**Perfect forward secrecy (PFS)** A mechanism that determines whether the existing keying material for a master key can be used to derive a new session key. Session key PFS performs a new Diffie-Hellman key exchange to generate new master key keying material instead of using master key keying material to derive more than one session key.

**Tunnel endpoint** The tunneling computer that is closest to the IP traffic destination, as specified by the associated IP filter list. Two rules are required to describe an IPSec tunnel. For the outbound traffic rule, the tunnel endpoint is the IP address or subnet of the IPSec peer on the other end of the tunnel. For the inbound traffic rule, the tunnel endpoint is an IP address or subnet configured on the local computer.

# Determining Your IPSec Needs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The first step in deploying IPSec on your network is to determine which computers need to be secured. Some data on your network might need higher levels of security than others. Although adding IPSec can protect your network and data, it can also reduce performance, and some computers might not support IPSec. As shown in Figure 6.2, you must decide which data and which computers on your network you need to secure and at what level of security.

**Figure 6.2 Determining Your IPSec Needs**

When beginning your design process, make sure to have specifications about your current network environment available for use. Your hardware and software inventory and a map of network topology are essential tools for the design phase. Because IPSec policies are based on which computers and data you want to secure, where that data is stored within the network, and the operating systems you need to support, this information lets you know where you can deploy IPSec. For more information about creating those documents, see "Planning for Deployment" in *Planning, Testing, and Piloting Deployment Projects* of this kit.

Some network environments are well suited to IPSec as a security solution and others are not. This section lists some common examples.

**Recommended IPSec Uses**

IPSec is recommended for the following uses:

- **Packet filtering.** IPSec provides limited firewall capabilities for end systems. You can use IPSec with the NAT/Basic Firewall component of the Routing and Remote Access service to permit or block inbound or outbound traffic. You can also use IPSec with ICF, which provides stateful filtering. However, to ensure proper IKE management of IPSec security associations (SAs), you must configure ICF to permit ISAKMP UDP port 500 traffic.

- **Securing host-to-host traffic on specific paths.** You can use IPSec to provide protection for traffic between servers or other static IP addresses or subnets. For example, IPSec can secure traffic between domain controllers in different sites or between Web servers and database servers.

- **Securing traffic to servers.** You can require IPSec protection for all client computers that access a server. In addition, you can set restrictions on which computers are allowed to connect to a server running Windows Server 2003.

- **L2TP/IPSec for VPN connections.** You can use the combination of the L2TP and IPSec (L2TP/IPSec) for all VPN scenarios. This does not require the configuration and deployment of IPSec policies.

- **Site-to-site (gateway-to-gateway) tunneling.** You can use IPSec in tunnel mode for site-to-site (gateway-to-gateway) tunnels when you need interoperability with third-party routers, gateways, or end systems that do not support L2TP/IPSec or Point-to-Point Tunneling Protocol (PPTP) connections.

**Note**

- Because IPSec depends on IP addresses for establishing secure connections, you cannot specify dynamic IP addresses. It is often necessary for a server to have a static IP address in IPSec policy filters. In large network deployments and in some mobile user cases, using dynamic IP addresses at both ends of the connection can increase the complexity of IPSec policy design.

**IPSec Uses That Are Not Recommended**

IPSec can reduce processing performance and increase network bandwidth consumption. Additionally, IPSec policies can be quite complex to configure and manage. Finally, the use of IPSec can introduce application compatibility issues. For these reasons, IPSec is not recommended for the following uses:

- **Securing communication between domain members and their domain controllers.** In addition to reduced network performance, using IPSec for this scenario is not recommended because of the complexity of the IPSec policy configuration and management required.

- **Securing all traffic in a network.** In addition to reduced network performance, using IPSec for this scenario is not recommended because:

    - IPSec cannot negotiate security for multicast and broadcast traffic.

    - Traffic from real-time communications, applications that require Internet Control Message Protocol (ICMP), and peer-to-peer applications might be incompatible with IPSec.

    - Network management functions that must inspect the TCP, UDP, and protocol headers are less effective or cannot function at all, due to IPSec encapsulation or encryption of IP payloads.

Additionally, the IPSec protocol and implementation have characteristics that require special consideration in the following scenarios:

- **Securing traffic over wireless 802.11 networks.** You can use IPSec transport mode to protect traffic sent over 802.11 networks. However, IPSec is not the recommended solution for providing security for corporate 802.11 wireless LAN networks. Instead, it is recommended that you use 802.11 Wired Equivalent Privacy (WEP) encryption and IEEE 802.1X authentication. Support for IPSec, configuration management, and trust are required on client computers and servers. Because many computers on a network do not support IPSec or are not managed, it is not appropriate to use IPSec alone to protect all 802.11 corporate wireless LAN traffic. Additionally, IPSec tunnel mode policies are not optimized for mobile clients with dynamic IP addresses, nor does IPSec tunnel mode support dynamic address assignment or user authentication, which is needed for remote access VPN scenarios. To secure remote access traffic to organization networks when that traffic is sent over public wireless networks that are connected to the Internet, use L2TP/IPSec VPN connections.

- **Using IPSec in tunnel mode for remote access VPN connections.** Using IPSec in tunnel mode is not recommended for remote access VPN scenarios. Instead, use L2TP/IPSec or PPTP for remote access VPN connections.

# Using IPSec in Transport Mode

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Table 6.2 provides a summary of when IPSec transport mode is appropriate to use.

**Table 6.2 IPSec Transport Mode Uses**

| IPSec Scenario | IPSec Transport Mode Usage |
|---|---|
| Require packet filtering | Although IPSec does not provide full firewall functionality, it can be used to statically permit or block traffic based on source and destination address combinations, and based on the IP protocol and TCP and UDP ports. Some of the functions found in standard firewalls that IPSec does not provide include stateful inspection, application protocol awareness, intrusion inspection, and packet logging. Although IPSec lacks some features of firewalls, the packet blocking and filtering it provides can be effective in limiting the spread of viruses or in thwarting specific attacks known to use specific ports. It can also be used to prevent specific applications and services from being used on the network. |
| Require end-to-end security | This is the easiest way to secure traffic with IPSec, typically between servers or clients and servers. End-to-end security creates a secure channel for trustworthy communication. |

You can also combine these two IPSec methods to enhance the network-level security of your infrastructure. Both methods are detailed later in this chapter.

# IPSec Packet Filtering

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use Windows Server 2003 IPSec to secure specific servers in your enterprise. IPSec can be configured to permit or block specific types of traffic based on source and destination address combinations and specific protocols and specific ports. You can use this feature of IPSec to block well-known ports of software so that even if a server is infected, it cannot be used to infect other computers or allow access via the well-known port.

For example, nearly all the systems illustrated in Figure 6.3 can benefit from packet filtering to restrict communication to only specific addresses and ports.

**Figure 6.3 Filtering Packets by Using IPSec**

By blocking communication to specific ports of a server, it is more difficult for an intruder to access the server or for the server to be used to attack other computers. You can strengthen security by using IPSec filtering to control exactly the type of communication that is allowed between systems. For example, as illustrated in Figure 6.3:

- The internal network domain administrator can assign a domain-based IPSec policy to block all traffic from the perimeter network.
- A perimeter network domain administrator can assign a domain-based IPSec policy to block all traffic to the internal network.
- The administrator of the computer running Microsoft® SQL Server™ on the internal network can create an exception to the domain-based IPSec policy to permit SQL protocol traffic to the Web application server on the perimeter network.
- The administrator of the Web application server on the perimeter network can create an exception to the domain-based policy to permit SQL traffic to the computer running SQL Server on the internal network.
- The administrator of the Web application server on the perimeter network can also block all traffic from the Internet, except requests to TCP port 80 (HTTP) and TCP port 443 (SSL), which are used by Web services. This provides additional security against traffic allowed in from the Internet in case the firewall was mis-configured or compromised by an attacker.
- The domain administrator can block all traffic to the management computer, but allow traffic to the perimeter network.

You can also use IPSec with the NAT/Basic Firewall component of the Routing and Remote Access service or IP packet filtering to enhance IPSec permit or block filtering of inbound or outbound traffic.

# End-to-End Security

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

IPSec end-to-end security establishes trust and security from a unicast source IP address to a unicast destination IP address (peer-to-peer). You can use this IPSec capability for secured server scenarios in which only trusted computers are allowed access to a server. In secured server scenarios, you can use IPSec to control access to all applications and services running on the server, and then either encrypt or only simply authenticate all application network traffic. The computers (IPSec peers) are authenticated through the use of Kerberos V5, certificate-based public key authentication, or — only if necessary — preshared key authentication.

**Peer-to-Peer Communication**

As shown in Figure 6.4, only the sending and receiving computers need to be aware of IPSec. Each handles security at its respective end and assumes that the medium over which the communication takes place is not secure. The two computers can be located near each other, as on a single network segment, or across the Internet. Computers or network elements that route data from source to destination are not required to support IPSec. A firewall between IPSec peers must be configured to forward IPSec traffic on UDP source and destination port 500, IP protocol 50 (ESP), or IP protocol 51 (AH). If network address translation is taking place between two computers, they must both support IETF IPSec NAT-T specification draft version 2. A firewall must be configured to forward traffic on UDP source and destination port 4500.

**Figure 6.4 Peer-to-Peer Security in IPSec**

End-to-end security is typically used to secure data sent over connections that transmit sensitive data or that might be susceptible to eavesdropping, such as:

- Servers within a corporate network.
- Servers over the Internet. For example, end-to-end security can secure traffic used by business-to-business application systems, protect file and database content as it is distributed to your business partners, or encrypt Remote Authentication Dial-In User Service (RADIUS) traffic between RADIUS clients, proxies, and servers.
- Front-end servers in a data center or perimeter network and servers inside the corporate internal network. There are two methods for securing data in this scenario:
    - End-to-end IPSec transport protection of traffic between the servers. Use IPSec to guarantee authenticity and unmodified traffic between servers, other computers using static IP addresses, or subnets. For example, IPSec can secure traffic between domain controllers, between routers connecting remote sites or forests, or between Web servers and database servers. You can use encryption if the traffic does not require inspection by an intrusion detection system between the servers.
    - End-to-gateway IPSec protection of traffic, so that the traffic is secured with IPSec, but can be fully inspected or modified by a firewall. Depending on the gateway, you can use IPSec transport mode or IPSec tunnel mode.

For any VPN scenarios, you can use the combination of L2TP and IPSec (L2TP/IPSec). For compatibility with other routers and gateways, or end-systems that do not support L2TP/IPSec or PPTP connections, you can use IPSec in tunnel mode for site-to-site (gateway-to-gateway) tunnels.

**Securing an Application Server**

Figure 6.5 shows end-to-end IPSec in transport mode securing an application server.

**Figure 6.5 Using IPSec to Secure an Application Server**

In this scenario, an application server in an internal corporate network must communicate with clients running Windows 2000 or Windows XP Professional; a WINS server, DNS server, and DHCP server; Active Directory domain controllers; and a third-party data backup server. Typically, an administrator uses Group Policy to configure and assign an Active Directory-based IPSec policy to an application server. In this scenario, the IPSec policy specifies that traffic is secured or permitted for different data paths, as described below.

**Secured traffic**

The users on the client computers are company employees who access the application server to view their personal payroll information and performance review scores. Because the traffic between these clients and the application server involves highly sensitive data, and because the administrator wants the server to only communicate with other domain members, he or she uses an IPSec policy that requires ESP encryption and communication only with trusted computers in the Active Directory domain.

Additionally, in Windows Server 2003, a specific group of computers can be authorized to use IPSec when either Kerberos V5 or certificates are used for IKE authentication. This capability is known as *certificate-to-account mapping*. When IPSec certificate-to-account mapping is used, an administrator can control which computers are authorized to use IPSec by configuring Group Policy security settings and assigning either the **Access this computer from the network** or the **Deny access to this computer from the network** logon right to individual or multiple computers, as needed. For more information, see "Public Key Certificate" later in this chapter.

**Permitted traffic**

Traffic is permitted for the following data paths:

- Traffic between the WINS server, DNS server, DHCP server, and the application server is permitted because WINS servers, DNS servers, and DHCP servers must typically communicate with computers that run on a wide range of operating systems, some of which might not support IPSec.

- Traffic between Active Directory domain controllers and the application server is permitted, because using IPSec to secure communication between domain members and their domain controllers is not a recommended usage due to the complexity of the IPSec policy configuration and management required in Active Directory.

- Traffic between the third-party data backup server and the application server is permitted because the third-party backup server does not support IPSec.

**Example: Contoso's Use of End-to-End Security**

The fictitious Contoso Corporation implemented a mix of IPSec solutions to meet its end-to-end security needs. Using IPSec end-to-end security makes sense for Contoso because it has branches throughout the world that need to securely exchange data; messages need to pass securely and smoothly across the Internet. Also, Contoso might need to prevent network access to its servers from attackers who might penetrate their network, either through the perimeter network or by directly using a network port in any Contoso office.

Contoso considered using IPSec end-to-end security on all communications, but quickly realized that this was unnecessary and

instead chose to authenticate network access to a select set of computers, and to encrypt only its most sensitive communications. Contoso uses IPSec on traffic sent between the following computers or locations:

- Servers within their network, such as between their Distributed File System (DFS) shares and all clients. Contoso used Kerberos authentication for these connections.

- Contoso headquarters servers and partner sites at which Contoso products are manufactured. In the case of the partner connections, Contoso also restricted which partner computers can connect to their corporate network. In this case, Contoso used public key certificate authentication because they shared common root certification authorities (CAs) with their partners. Their partners obtained computer certificates from third-party PKI providers. Contoso allowed only IPSec traffic to pass through the firewall when communicating with partner networks. Contoso mapped computer certificates for partner networks to a shadow computer account in Active Directory, and specified that only computer accounts from the partner networks were allowed IPSec access to their servers. To do this, they configured the **Access this computer from the network** logon right on each of their servers and assigned this right to computer accounts in the partner networks.

- Web server access to the data center database on cluster servers. Contoso used certificate authentication to enable IPSec-protected connections because the Web servers did not have a security domain trust with the data center cluster servers. The IPSec policy on the data center servers allowed only inbound SQL traffic from the Web servers. To allow IPSec-protected access to Web servers that are managed by a contractor and that do not run the Windows operating system, Contoso used preshared key authentication.

By protecting these connections, Contoso protected high-value communications that were critical to their business success. If they had failed to properly protect order information, competitors might have gained valuable data, or orders might have been canceled or modified by attackers.

# Using IPSec in Tunnel Mode

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Tunnel mode is primarily used for interoperability with gateways or end systems that do not support L2TP/IPSec or PPTP VPN site-to-site connections. Table 6.3 provides a summary of scenarios in which IPSec tunnel mode is appropriate to use.

**Table 6.3 IPSec Tunnel Mode Usage**

| IPSec Scenario | IPSec Tunnel Mode Usage |
|---|---|
| Establish gateway-to-gateway tunnels between sites, when the gateways or end systems do not support L2TP/IPSec VPN connections. | Use only when necessary for interoperability with gateways or end systems that do not support L2TP/IPSec VPN connections. When L2TP/IPSec VPN connections are supported, use L2TP/IPSec (IPSec transport mode) instead. When IPSec in tunnel mode is used for gateway-to-gateway tunnels, static IP addresses are required for the IPSec tunnel endpoints.<br><br>For an illustration of this scenario, see Figure 6.6. |
| Protect traffic end-to-end, but one endpoint of the communication does not support IPSec. | Use an IPSec tunnel from one endpoint to a firewall or IPSec-enabled router nearest to the endpoint that does not support IPSec. This scenario requires static IP addresses for both tunnel endpoints.<br><br>For an illustration of this scenario, see Figure 6.7. |
| Encrypt traffic end-to-end between two computers, but a third-party firewall or network intrusion detection system requires that traffic be decrypted. | Use one IPSec tunnel to reach the third-party firewall or the network intrusion detection system. Use another tunnel from the third-party firewall or network intrusion detection system to reach the destination. This scenario requires static IP addresses for all four tunnel endpoints.<br><br>For an illustration of this scenario, see Figure 6.8. |

**Gateway-to-Gateway Traffic Must be Secured**

In this scenario, traffic is being sent between a client computer in a vendor site (Site A) and a File Transfer Protocol (FTP) server at the corporate headquarters site (Site B). Although an FTP server is used for this scenario, the traffic can be any unicast IP traffic. The vendor uses a third-party gateway, while corporate headquarters uses a gateway running Windows Server 2003. An IPSec tunnel is used to secure traffic between the third-party gateway and the gateway running Windows Server 2003. Figure 6.6 shows IPSec in tunnel mode for gateway-to-gateway tunneling between sites.

**Figure 6.6 Gateway-to-Gateway Tunneling Between Sites**

**Note**

- For ease of deployment, it is recommended that the gateway running Windows Server 2003 be a stand-alone computer and that you remotely manage this computer by using Remote Desktop Connection. If this computer is joined to a domain, the computer must be able to access Active Directory locally, not through an IPSec tunnel.

**One Endpoint Does Not Support IPSec**

In this scenario, an IPSec tunnel is used to secure traffic between a computer running Windows Server 2003 in a perimeter network and an IPSec-enabled router (for example, a Cisco IOS router). Traffic on the path between the router and the third-party server in the internal corporate network is not secured, because the third-party server does not support IPSec. Note that this is not a VPN remote access scenario, because there is no dynamic address assignment, nor is user authentication used to establish the tunnel. The tunnel rules can be defined to protect traffic between the computer running Windows Server 2003 and either the internal network subnet or the specific IP address of the third-party server. Figure 6.7 shows IPSec in tunnel mode to provide end-to-end security of traffic when one endpoint of the communication does not support IPSec.

**Figure 6.7 One Endpoint Does Not Support IPSec**

**Traffic Must Be Decrypted for Third-Party Firewall Inspection**

In many cases, IPSec transport mode can provide secure end-to-end communication through firewalls. If traffic must be inspected at the firewall, you can use IPSec AH or ESP with null encryption in transport mode to maintain end-to-end security. However, if the traffic must be encrypted and inspected, you can use IPSec tunnel mode to secure traffic to the inspection point.

Figure 6.8 shows IPSec in tunnel mode encrypting traffic end-to-end between two computers: a line of business (LOB) application server running Windows Server 2003 in a perimeter network, and a computer running SQL Server that functions as a data store for the application server in an internal corporate network.

**Figure 6.8 Traffic Must Be Decrypted for Third-Party Firewall Inspection**

In this scenario, IPSec tunnels are used to secure traffic between the application server and the third-party firewall's external interface and between the third-party firewall's internal interface and the computer running SQL Server. Traffic is decrypted for firewall inspection and then reencrypted when it is forwarded to the IPSec peer. The tunnel rules can be defined to protect traffic between the application server and either the internal network subnet or the specific IP address of the computer running SQL Server.

**Note**

- This scenario cannot work if a computer running Microsoft® Internet Security and Acceleration (ISA) Server is used as the firewall. Use IPsec transport mode on the side where the ISA interface IP address is being used as the source or destination IP address.

For more information about using IPSec in tunnel mode, including detailed configuration procedures, see article Q252735, "How to Configure IPSec Tunneling in Windows 2000," in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Weighing IPSec Tradeoffs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Whether you use packet filtering or end-to-end security, deploying IPSec provides greater security at the expense of network and processing performance and compatibility with other services, tools, and features. Use the information in this section to determine the impact on your environment before deploying IPSec.

For example, you might decide that information sent between some departments, such as Accounting and Legal, require higher security than information sent to or from other departments, such as Production. You might also decide that all private information transmitted across the Internet must be secured. Finally, you might decide that you only want trusted computers to have network access to your servers. When planning your deployment, be aware that deploying IPSec on your network increases the overall cost of network and system administration. The exact cost cannot be predicted because it depends on many factors, including the level of application traffic. However, if you stage IPSec deployment in a lab, you can arrive at a good estimate. Do not deploy IPSec if the security it provides is not required. Consider whether the added cost is worth the added protection.

**Slower connection establishment**
IPSec is not recommended for scenarios in which clients make infrequent, short-lived connections. IPSec increases the time required to initially establish authenticated connections. Depending on policy design, network roundtrip time, and the load on the systems required to establish the connection, negotiating security initially using IKE typically increases connection time by one to three seconds. Make sure that you want to trade the one- to three-second increase in connection time for the added security. Typically, after IPSec SAs are established, no further delays occur. Because IPSec is not integrated with TCP, TCP connections can be established and ended rapidly after IPSec SAs are established.

**Reduced computing performance**
Although the Windows Server 2003 IPSec filtering engine is enhanced to provide significantly faster packet processing, filtering and encryption of each packet consumes computing power. As the volume of IPSec traffic — including policies, rules, and filters — increases, the load placed on the network and on computer CPUs increases also. For example, policies with 1,000 or more filters can cause a small load increase. Filters with specific source and destination IP addresses can be processed much more quickly than filters that specify a subnet or **Any IP Address**. IPSec implements a cache algorithm that can accelerate the processing of packets that match a filter. Packets that do not match any filter require the greatest amount of time to process.

If your systems already have high loads on their CPUs, consider adding more computers or using IPSec offload network adapters before deploying IPSec. IPSec offload network adapters accelerate cryptographic operations used to secure IPSec packets. However, these adapters do not accelerate filter processing time. IPSec-enabled network adapters can be used with Windows 2000, Windows XP, and Windows Server 2003. Such network adapters typically complete IPSec operations at such a high rate that there is minimal change in transmission speeds, resulting in minimal performance degradation. However, such adapters generally have a maximum number of SAs that they can support, after which additional SAs are processed by the Windows IPSec components.

**Thwarting some networking inspection technologies**
ESP and AH encapsulate IP payloads by adding a security header to every packet. Existing network management and diagnostic tools typically cannot interpret IPSec-protected packets. The tools that might be impacted include:

- Router-based access control lists.
- Firewall access controls.
- Network traffic analysis and reporting tools.
- Quality of Service (QoS).
- Third-party load balancing devices. Windows Server 2003 IPSec supports the Windows Server 2003 Network Load Balancing service for host-based load balancing, which might provide an alternate solution.
- Network address translation. Windows Server 2003 supports IPSec NAT-T, which is used to allow IPSec ESP-protected traffic to traverse one or more network address translators.

- Stateful filtering controls on the direction of traffic flow. IKE and IPSec communication typically function best when traffic flows in both directions. IPSec does not easily allow for connections in only one direction.

- Network-based intrusion detection.

These functions require that network packets be inspected, modified, or both. If IPSec protocols are not used to encrypt packets, these functions can be enhanced to inspect inside the IPSec protocol header. If IPSec encryption is required for security, however, it might be difficult to maintain full network management functionality.

**Increased packet size reduces throughput, increases network utilization**
IPSec protection adds overhead to IP packets, reducing effective throughput and increasing network utilization. Although the IETF design and Microsoft implementation of IPSec attempt to minimize both impacts, existing networks and servers might be operating at maximum capacity without IPSec. Before deploying IPSec, test several different IPSec policy configurations, because each policy configuration is likely to result in different performance impacts on clients and servers. It might be necessary to increase the available network bandwidth or CPU power, or install IPSec offload adapters to compensate for the increased overhead of IPSec.

**Application incompatibility with IPSec NAT-T**
Windows Server 2003 supports IPSec NAT-T as described by version 2 of the IPSec NAT-T Internet drafts, but some applications might not work when their traffic is first protected with IPSec and then passed through a network address translator. Test how your planned implementation of IPSec interacts with network address translators in a lab before deploying IPSec in your environment.

**Loss of connectivity during cluster node addition or removal**
IPSec establishes and maintains cryptographic state between computers. Many clustering and load-balancing services use the same IP address for all nodes in a cluster, which creates incompatibilities with IPSec. Windows Server 2003 IPSec has proprietary extensions that allow it to work with the Windows Server 2003 Network Load Balancing service and Windows Cluster Service. However, support for these extensions does not exist in the current Windows 2000 and Windows XP IPSec client implementations, so you might experience some loss of connectivity when you add or remove cluster nodes.

**Requiring IPSec for communication between Active Directory domain members and domain controllers might block connections**
IPSec is based on the authentication of computers on a network; therefore, before a computer can send IPSec-protected data, it must be authenticated. The Active Directory security domain provides this authentication using the Kerberos protocol. Accordingly, when IKE uses Kerberos to authenticate, the Kerberos protocol and other dependent protocols (DNS, UDP LDAP and ICMP) are used for communication with domain controllers. Additionally, Active Directory–based IPSec policy settings are typically applied to domain members through Group Policy. As a result, if IPSec is required from domain members to the domain controllers, authentication traffic will be blocked and IPSec communications will fail. In addition, no other authenticated connections can be made using other protocols, and no IPSec other policy settings can be applied to that domain member through Group Policy. For these reasons, using IPSec for communications between domain members and domain controllers is not supported.

**ICMP-based functionality might fail**
When designing an IPSec policy to secure or block ICMP traffic, keep in mind that such a policy might cause services and tools that rely on ICMP to measure network response times to produce misleading results. For example, Windows 2000 and Windows XP domain members have an IP/DNS-compatible locator, which measures ICMP response times for domain controller load balancing within a site. Also, Group Policy measures ICMP response times to determine if the connection to the domain controller is a slow link. Also, tools that depend on ICMP, such as Tracert, might not work when ICMP traffic is protected by IPSec.

**Multicast and broadcast traffic might fail**
In Windows Server 2003, you can configure IPSec filters to block multicast and broadcast traffic. Therefore, any application that uses multicast or broadcast might fail if the computer has an IPSec policy that blocks such traffic.

# Examples: IPSec in a Corporate Network

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The fictitious Contoso Corporation evaluated their security needs when considering whether to implement IPSec. Although there are many tools to counter threats in a computing environment, this example focuses on security concerns and solutions that relate to IPSec. To begin this process, administrators created a map of the hardware and software in their environment. Notable aspects of an environment include domain membership, operating system versions, computer roles, and the location of computers on the network.

Some computers have relatively low security needs or are very difficult to manage. Although it might be advantageous to secure all data, using IPSec demands administrative resources on both the client side and the server side of the communication. Accordingly, using ICF and anti-virus tools protects computers that are difficult to manage or that have relatively low security needs. Contoso relied on firewall functionality provided by a perimeter network, and a proxy server for Internet access from their internal network. Contoso specified a default client configuration consisting of computers running Windows 2000 and Windows XP. Client computers are configured as follows:

- The client computers and users have accounts in the corporate Active Directory security domain. An enterprise CA is installed on a server running Windows Server 2003, to provide automatic certificate enrollment for user and computers.
- An antivirus program is used to examine all incoming and outgoing files and e-mail.
- Encrypting File System (EFS) encrypts sensitive documents on the client computers' hard disk.
- Services and applications use Kerberos authentication when it is available.
- All domain members are assigned Group Policy settings that do the following:
    - Automatically enroll with the CA to obtain a computer certificate. This certificate can be used to gain remote access to the corporate network when the computer is connected to the Internet for L2TP/IPsec client VPN connections. It is also used for IPSec when Kerberos authentication is not available.
    - ICF is enabled by default for all network connections on portable computers running Windows XP. However, domain administrators disable ICF on portable computers when those computers are connected to the corporate network. ICF is disabled so that users on can share files and allow inbound access to other applications on their desktop.
    - Enforce an IPSec policy to negotiate security with specific IPSec-protected servers and to block ports that are used by known viruses and prohibited applications.

Three examples of how Contoso used IPSec on their servers are as follows:

- The Contoso IT group used a set of servers to receive order information from customers, and decided that they needed to ensure that the orders were received only from their partners and were not modified in transit. Because data authenticity and integrity were important, but confidentiality was not, they required AH protection for customers to connect with these computers. IPSec ESP with null encryption was allowed for customers that must traverse a network address translator to make the IPSec-protected connection to Contoso. Contoso allowed customers to use certificates from a specific list of third-party PKI providers (public PKI root CAs).
- The Contoso Human Resources department stored information about employee salaries and medical claims. The department carefully controlled access with user security settings. But it was also necessary to meet health care regulations to maintain the privacy of this traffic as it flowed over the network. Further, Contoso wanted a defense-in-depth strategy to protect against attackers who might gain remote access to their servers over the network, through the use of compromised employee user IDs and passwords. IPSec allows Contoso to restrict client network access only to computers that are members of the domain. If necessary, access can be further restricted to a specific group of computers in the domain. Accordingly, to secure their servers, Contoso used an IPSec policy to require ESP encryption for

domain members to connect.

Because Windows Server 2003 IPSec can detect the presence of network address translators and automatically use UDP headers to allow IPSec traffic to traverse the network address translators, Contoso was able to discontinue using PPTP for remote access VPN connections. For enhanced security, administrators switched all remote users to L2TP/IPSec VPN connections using L2TP/IPSec NAT-T-capable clients, newly available from Microsoft. For more information, see the Virtual Private Networks link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.Use the job aid "Designing an IPSec Policy" (DNSIPS_1.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Designing an IPSec Policy" on the Web at http://www.microsoft.com/reskit) to record information about your environment. Use a separate copy of the worksheet for each policy you create to meet the security needs of each group of servers.

# Designing an IPSec Policy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You need to create a set of IPSec policies that matches the needs of your environment. Organizations that have consistent security needs and a more simple network structure can create fewer and less complex policies to meet their goals. Other organizations with more stringent security needs and more complex environments require a greater number of policies and potentially more rules in their policies.

Use the steps shown in Figure 6.9 to help you decide how restrictively secure you want to make your IPSec policies.

**Figure 6.9 Designing IPSec Policies**

When designing an IPSec policy, you need to decide whether to apply an IPSec policy to protect traffic just for specific paths (between specific IP addresses) or to provide general protection for all traffic sent to and from a specific computer. If you want to use IPSec to provide general protection for all traffic sent to and from a specific computer, configure a policy that is based on blocking all traffic and then permitting exceptions, or permitting all traffic and then blocking particular ports. Blocking all traffic provides greater security, but this approach also requires a detailed analysis of the computer's communications, to ensure that required traffic is not blocked.

Consider a simple scenario that requires a simple IPSec policy strategy. All computers belong to a single Active Directory domain. The environment is composed entirely of servers running Windows Server 2003 and clients running Windows XP. All servers (except domain controllers) request confidentiality by using ESP, and all clients support IPSec. In such a case, only two policies are required: one for clients, and one for member servers. These policies can be applied by using Group Policy at the OU level in Active Directory. Because a different IPSec policy is applied to servers, the server computer accounts are grouped into their own OU. A GPO is created for the OU, and then the IPSec server policy is assigned to that GPO.

Because of the operating systems that the computers run and because all of the computers are domain members, both the IPSec server and client policies require that Kerberos be used for mutual authentication. To ensure that domain controllers do not receive any IPSec policy, the predefined domain security group for domain controllers is denied Read access to the GPO that assigns IPSec client policy at the domain level.

Conversely, many more policies can be required in a more complicated scenario. A single IPSec policy can contain many rules, each rule tailored for a specific type of traffic. Many different IPSec policies might need to be designed, to meet the security requirements different computers. Factors that can increase the number of policies required in your environment include:

- **Computer roles.** Different servers performing in different roles require different types of security, including some combination of packet filtering, confidentiality, integrity, and tunneling. Meeting the security needs of an environment that includes many servers with different roles and requirements can require hundreds of different configurations per server. Furthermore, servers might serve multiple roles, which complicates role-based configurations.

- **Sensitivity of data sent over the network.** Different levels of encryption are required to accommodate different security needs. For example, 3DES, which provides greater security than DES, can be used to protect transmission of personnel files stored on a file server.

- **Computer operating systems.** Some operating systems automatically support IPSec transport mode, but some require special client software to be installed. Depending on their operating system, computers might receive IPSec policy through different means: some by Group Policy, others only through locally installed policies. Additionally, Windows Server 2003 IPSec includes several new features that are not supported by Windows 2000 or Windows XP.

- **Domain memberships.** Some clients and servers belong to domains in different forests, some to UNIX realms, and some are members of workgroups. The trusts and authentication methods in place between such forests, realms, and workgroups affect which IPSec configurations are available.

- **Domain relationships.** As above, what IPSec configurations are available and what authentication is possible depends on whether domains are in the same forest or different forests, and on whether those forests trust each other.

If you have a complex environment, use IPSec only where it is truly needed. Although you want to provide an appropriate level of security, use as few policies as possible to minimize the complexity of your system. A simpler system is less likely to produce problems and is also easier to troubleshoot if it does.

After identifying what network segments, communications, and computers you want to secure by using IPSec, you need to specify the settings and rules that make up an IPSec policy. The settings and rules you specify also determine how strictly security is enforced by your IPSec policies. Not only must you put policies in place to meet your security requirements, but you must also ensure that computers on your network have compatible policies that can allow them to negotiate SAs.

#### General IPSec Policy Settings

General IPSec policy settings must be specified whether you want the policy to provide packet filtering or end-to-end security. Make sure to manage all IPSec policies in a controlled way from design, through testing, and into production. To ensure proper management, include version numbers in policy names. General IPSec policy settings are shown in Table 6.4.

**Table 6.4 General IPSec Policy Settings**

| Setting | Description | Example | For More Information |
|---|---|---|---|
| Name | The name and version number of the policy.<br><br>If the policy will be imported into a Windows 2000 Active Directory store or a local policy store, limit the name to 62 characters. | ContosoDefDomain v1.23 | "Add, edit, or remove IPSec policies" in Help and Support Center for Windows Server 2003 |
| Description | Optional text that describes the policy, includes the name of its administrative owner, and that can aid in management of this system. | *Administrative owner_name*. This policy blocks certain ports and requests integrity to specific server IP addresses. | "Add, edit, or remove IPSec policies" in Help and Support Center for Windows Server 2003 |
| Policy change poll interval | Specifies the period of time in minutes between polling by the IPSec Policy Agent for changes to existing applied policies.<br><br>IPSec polling does not detect changes made to domain or OU membership or the assigning or unassigning of policies in a GPO. These changes are detected by the Winlogon service every 90 minutes, by default. | Default of 180 minutes accepted | "Add, edit, or remove IPSec policies" in Help and Support Center for Windows Server 2003 |
| Key exchange settings | Determines how keys are created, and how frequently (in seconds) IKE negotiates an ISAKMP SA.<br><br>In the IP Security Monitor snap-in, relevant statistics are displayed under **Main Mode\IKE Policies**. | Default settings accepted | "Configure key exchange settings" in Help and Support Center for Windows Server 2003 |

| | | | |
|---|---|---|---|
| Key exchange methods | Determines how identities are protected when keys are exchanged.<br><br>You can specify which algorithms are used, including Message Digest 5 (MD5) and Secure Hash Algorithm (SHA1) for integrity, DES and 3DES for confidentiality, and the length of the master key. An ordered list of security settings is also specified, so that several settings can be offered during negotiation with the IPSec peer. | Default methods accepted | "Create key exchange security methods" in Help and Support Center for Windows Server 2003 |

**Note**

- Computers running Windows Server 2003 and Windows XP support the 3DES and DES algorithms and do not require installation of any additional components. However, computers running Windows 2000 must have the High Encryption Pack or Service Pack 2 (or later) installed in order to use 3DES. If a computer running Windows 2000 is assigned a policy that uses 3DES encryption, but does not have the High Encryption Pack or Service Pack 2 (or later) installed, the security method defaults to the weaker DES algorithm. To ensure at least some level of privacy for communication, make sure to allow DES as a fallback option whenever a 3DES setting is applied to a group of computers in case some of them cannot support 3DES.

**IPSec Rules**

IPSec rules determine which traffic is affected by an IPSec policy and which actions take place when that type of traffic is encountered. Table 6.5 describes the contents of IPSec rules that two computers use to establish a secure, authenticated channel.

**Table 6.5 Settings of IPSec Rules**

| Setting | Description | Setting Example | For More Information |
|---|---|---|---|
| Filter list | Specifies a named list of filters. Each filter in the filter list specifies the types of traffic to which the filter action is applied. Filters can be defined to match specific IP protocols, source and destination TCP and UDP ports, and source and destination IP addresses.<br><br>The filter list name might include the version number, the last update time, and the administrative owner. Each computer discards the filter list name during policy processing.<br><br>The description or name for each filter is maintained on each computer during policy processing. Make sure to name each filter. | Source Address: My IP Address<br><br>Destination Address: 172.16.0.4<br><br>Protocol: TCP<br><br>Source Port: Any<br><br>Dest Port: 1434<br><br>Mirrored: Yes<br><br>Name: Me to sqlsvr3 TCP * 1434 | "Filter list" in Help and Support Center for Windows Server 2003 |
| Filter action | Specifies whether a packet is permitted, blocked, or secured. If packets are to be secured, specifies how they are secured. A list of security methods specifies the security protocol, cryptographic algorithm, and session key regeneration frequency. | Request Security | "Filter action" in Help and Support Center for Windows Server 2003 |
| Authentication methods | One or more authentication methods, which are specified in order of preference. Available options are Kerberos V5, certificate, or preshared key. | Kerberos V5 | "Authentication methods" in Help and Support Center for Windows Server 2003 |

| | | | |
|---|---|---|---|
| Tunnel endpoint | Specifies whether to use tunnel mode and, if so, the tunnel's endpoint. | 172.16.0.5 | "Tunnel endpoint" in Help and Support Center for Windows Server 2003 |
| Connection type | Specifies whether the rule applies to LAN connections, remote access connections, or both. | LAN | "Connection type" in Help and Support Center for Windows Server 2003 |

For more information about IPSec policy rules, see "IPSec Policy Rules" in Help and Support Center for Windows Server 2003.

# Understanding Default IPSec Policies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 includes three default IPSec policies that are provided as examples only. Do not use any part of the examples as templates to edit or change when creating your own IPSec policies. Instead, design new custom IPSec policies for operational use. The example policies will be overwritten during operating system upgrades and when IPSec policies are imported (when the import files contain other definitions of the same example policies). The three default IPSec policies are as follows:

- **Client (Respond Only).** This default policy contains one rule, the default response rule. The default response rule secures communication only upon request by another computer. This policy does not attempt to negotiate security for any other traffic.

- **Server (Request Security).** This default policy contains two rules: the default response rule and a second rule that allows initial incoming communication to be unsecured. The second rule then negotiates security for all outbound unicast IP traffic (security is not negotiated for multicast or broadcast traffic). The filter action for the second rule allows IKE to fall back to unsecured communication when required. This policy can be combined with the Client (Respond Only) policy when you want traffic secured by IPSec when possible, yet allow unsecured communication with computers that are not IPSec-enabled. If IKE receives a response from an IPSec-enabled client, but the IKE security negotiation fails, the communication is blocked. In this case, IKE cannot fall back to unsecured communication.

- **Secure Server (Require Security).** This default policy has two rules: the default response rule and a rule that allows the initial inbound communication request to be unsecured, but requires that all outbound communication be secured. The filter action for the second rule does not allow IKE to fall back to unsecured communication. If the IKE security negotiation fails, the outbound traffic is discarded and the communication is blocked. This policy requires that all connections be secured with IPSec. Any clients that are not IPSec-enabled cannot establish connections.

Both the Server (Request Security) and Secure Server (Require Security) default policies allow inbound unsecured communication, so that they can be used with the Client (Respond Only) policy. IPSec policies that are designed for operational use are typically customized to combine these behaviors as needed for a specific computer or network environment. The most secure IPSec configuration is not be represented by the default policies.

The most secure configuration is one that negotiates security and neither receives unsecured traffic nor allows communication with non-IPSec-aware computers. In such a configuration, the client computer policy must have a filter in a rule to initiate secured communication when applications on the client computer attempt outbound connections to the server.

**Predefined Filter Lists**

There are two predefined example filter lists included with Windows Server 2003:

- **All ICMP Traffic.** This filter affects any ICMP traffic (IP protocol 1) that is sent and received by using the unicast IP address of any network interface on a computer and all other computers. In Windows Server 2003, this filter matches outbound IP broadcast and multicast traffic when that traffic also uses the ICMP protocol.

- **All IP Traffic.** This filter affects all IP traffic that is sent and received using the unicast IP address of any network interface on the computer to any destination IP address. Because inbound broadcast and multicast traffic use a multicast or broadcast type for the destination address, the inbound traffic is exempt. All ISAKMP traffic sent over UDP port 500, which is required for establishing IPSec-secured communication, is also exempted from IPSec filtering. For more information, see "Understanding IP Filters, Filter Actions, and Filter Lists" later in this chapter.

**Predefined Filter Actions**

There are three predefined example filter actions included with Windows Server 2003:

- **Permit.** All traffic that matches the associated filters in the filter list is permitted. This permit behavior is static, not stateful.

- **Request Security.** All inbound traffic that matches the associated filters in the filter list is allowed unsecured. All

outbound traffic that matches the associated filters in the filter list negotiates security. Traffic is secured if the computer at the other end of the connection supports IPSec with a complementary filter action and filter in its policy. If security negotiation fails to elicit a response from the peer within three seconds, a security association for plaintext traffic is created (this association is known as a *soft SA*). If the peer responds within three seconds and the security negotiation fails, the communication is blocked. After IPSec SAs are established, all traffic that matches the associated filters is secured in both directions between the two computer IP addresses. This behavior is designed so that servers can request security for all clients, but fall back to unsecured communication with computers that are not IPSec-enabled.

- **Require Security.** As with the Request Security filter action, all inbound traffic that matches the associated filters in the filter list is allowed unsecured, and all outbound traffic that matches the associated filters in the filter list negotiates security. Unlike Request Security, if IKE fails to receive a response and the security negotiation fails, the communication is blocked. After IPSec SAs are established, all traffic that matches the associated filters is secured in both directions between the two computer IP addresses.

Each of these three filter actions allows inbound unsecured communication. This is not the most secure behavior, nor can it be used to initiate secured communication in some trust environments. These filter actions allow the Server (Request Security) and Secure Server (Require Security) example policies to be used with the Client (Respond Only) example policy. If Kerberos authentication is used, this behavior is appropriate for servers that only communicate with clients in mutually trusted domains. For servers that are in one-way domain trust environments, the client computer policy must have a filter in a rule to initiate secured communication with the server.

It is not appropriate to allow inbound unsecured communication for servers that have an Internet interface, because it can make the servers vulnerable to a denial-of-service attack. Internet attackers can easily spoof IP packets to flood the server, causing a denial of service as the server attempts many IKE negotiations with non-existent source IP addresses. The most secure filter action is one that requires security for all inbound and outbound traffic. To create this filter action, verify that the **Accept unsecured communication, but always respond using IPsec** and **Allow unsecured communication with non-IPsec aware computers** check boxes are cleared.

# Understanding IP Filters, Filter Actions, and Filter Lists

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

IP filters are used to specify the type of traffic that is permitted, blocked, or secured by an IPSec policy. For more information about specifying IP filter lists, see "Add, edit, or remove IP filter lists" in Help and Support Center for Windows Server 2003.

# Specifying Default Exemptions to IPSec Filtering

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

By default in Windows 2000 and Windows XP, broadcast, multicast, Kerberos, RSVP, and ISAKMP traffic is exempt from IPSec filtering. In Windows Server 2003, the default filtering exemptions have been removed for Kerberos, RSVP, and multicast and broadcast traffic, but remain for ISAKMP traffic, and inbound multicast and broadcast traffic.

To modify the default filtering behavior for Windows Server 2003 IPSec, you can use the Netsh IPSec context or modify the registry.

To modify the default filtering behavior by using the Netsh IPSec context, use the following command:

**netsh ipsec dynamic set config ipsecexempt value={0|1|2|3}**

Depending on which exemptions you want, specify the values as follows:

- A value of **0** specifies that multicast, broadcast, RSVP, Kerberos, and ISAKMP traffic are exempt from IPSec filtering. This is the default filtering behavior for Windows 2000 and Windows XP.

  Use this setting only if required for compatibility with Windows 2000 and Windows XP. However, if Kerberos traffic is exempted from filtering, an attacker can bypass other IPSec filters by using either UDP or TCP source port 88 to access any open port. Many port scan tools will not detect this because these tools do not allow setting the source port to 88 when checking for open ports.

- A value of **1** specifies that Kerberos and RSVP traffic are not exempt from IPSec filtering (multicast, broadcast, and ISAKMP traffic are exempt).

- A value of **2**specifies that multicast and broadcast traffic are not exempt from IPSec filtering (RSVP, Kerberos, and ISAKMP traffic are exempt).

- A value of **3** specifies that only ISAKMP traffic is exempt from IPSec filtering. This is the default filtering behavior for Windows Server 2003.

If you change the value for this setting, you must restart the computer for the new value to take effect.

To modify the default filtering behavior by using the registry, do the following:

1. Under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\IPSEC**, add a new DWORD entry named **NoDefaultExempt**.

2. Assign this entry any value from **0**through **3**.

3. Restart the computer.

The filtering behaviors for each value are equivalent to those noted above for the **netsh ipsec dynamic set config ipsecexempt value=***x* command.

| ⚠**Caution** |
| --- |
| Do not edit the registry unless you have no alternative. The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Registry Reference at http://go.microsoft.com/fwlink/?LinkID=33702. |

The following table summarizes the equivalent filters that are implemented if all default exemptions to IPSec filtering are enabled (that is, if **NoDefaultExempt** is **0**). When the IP address is specified, the subnet mask is 255.255.255.255. When the IP address is **Any**, the subnet mask is 0.0.0.0.

**Table 6.6 Equivalent Filters for NoDefaultExempt=0**

| Source Address | Destination Address | Protocol | Source Port | Destination Port | Filter Action |
|---|---|---|---|---|---|
| My IP Address | Any IP Address | UDP | Any | 88 | Permit |
| Any IP Address | My IP Address | UDP | 88 | Any | Permit |
| Any IP Address | My IP Address | UDP | Any | 88 | Permit |
| My IP Address | Any IP Address | UDP | 88 | Any | Permit |
| My IP Address | Any IP Address | TCP | Any | 88 | Permit |
| Any IP Address | My IP Address | TCP | 88 | Any | Permit |
| Any IP Address | My IP Address | TCP | Any | 88 | Permit |
| My IP Address | Any IP Address | TCP | 88 | Any | Permit |
| My IP Address | Any IP Address | UDP | 500 | 500 (1) | Permit |
| Any IP Address | My IP Address | UDP | 500 | 500 | Permit |
| My IP Address | Peer IP Address | UDP | 4500 | 4500 (2) | Permit |
| Peer IP Address | My IP Address | UDP | 4500 | 4500 | Permit |
| My IP Address | Any | 46 (RSVP) | | | Permit |
| Any IP Address | My IP Address | 46 (RSVP) | | | Permit |
| Any IP Address | <multicast> (3) | | | | Permit |
| My IP Address | <multicast> | | | | Permit |
| Any IP Address | <broadcast> (4) | | | | Permit |
| My IP Address | <broadcast> | | | | Permit |
| <All IPv6 protocol traffic> (5) | | | | Permit | |

(1) In order for IPSec transport mode to be negotiated through an IPSec tunnel mode SA, ISAKMP traffic is not exempted if it needs to pass through the IPSec tunnel first.

(2) When IPSec NAT-T is performed, the filter exemption for UDP port 4500 is automatically generated, based on the source and destination IP addresses used during the initial part of the IKE negotiation on UDP port 500. This dynamic permit filter for port 4500 is displayed in the IP Security Monitor snap-in, under **Quick Mode\Specific Filters**, and in the output for the **netsh ipsec dynamic show qmfilter** command.

(3) Multicast traffic is defined as the class D range, with a destination address range of 224.0.0.0 with a 240.0.0.0 subnet mask, which corresponds to the range of addresses from 224.0.0.0 to 239.255.255.255.

(4) Broadcast traffic is defined as a destination address of 255.255.255.255 (the limited broadcast address), or as having the host ID portion of the IP address set to all 1's (the subnet broadcast address).

(5) IPSec does not support filtering for IP version 6 (IPv6) packets, except when IPv6 packets are encapsulated with an IPv4 header.

Windows Server 2003 IPSec does not support specific filters for broadcast protocols or ports, nor does it support multicast

groups, protocols, or ports. Because IPSec does not negotiate security for multicast and broadcast traffic, these types of traffic are dropped if they match a filter with a corresponding filter action to negotiate security. A filter with a source address of **Any IP Address** and a destination address of **Any IP Address** can block or permit all multicast and broadcast traffic. By default (and if the **NoDefaultExempt** registry key is set to a value of **2** or **3**), outbound multicast or broadcast traffic will be matched against a filter with a source address of **My IP Address** and a destination address of **Any IP Address**. More specific unicast IP address filters that block, permit, or negotiate security for unicast IP traffic should be configured in the same IPSec policy to achieve appropriate security.

For more information about viewing or modifying filter settings, see "Add, edit, or remove filter actions" and "Select a filter action for a rule" in Help and Support Center for Windows Server 2003.

# Linking Filter Actions and Filter Lists

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Filter lists and filter actions are linked together to form a rule in an IPSec policy. Although filter lists can be reused in different policies, they cannot be reused in the same policy. Filter actions can be reused by rules in the same policy, and they can be shared among different policies.

You can manage IPSec policy in one of two ways:

- Create a new policy and define the set of rules for the policy, adding filter lists and filter actions as required.

  In this method, you create an IPSec policy first and then add and configure rules. Filter lists (specifying traffic types) and filter actions (specifying how the traffic is treated) are added during rule creation.

- Create the set of filter lists and filter actions, and then create the policies and add rules that combine the filter lists with filter actions.

  In this method, you configure the filter lists and the filter actions. Next, you create IPSec policies and add rules that combine the appropriate filter list with the appropriate filter action. Additionally, you specify authentication methods, connection types, and tunnel settings.

# Configuring Firewalls

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The most secure firewall configuration is one in which the firewall permits only IKE and IPSec traffic to flow between the specific IP addresses of the peers. However, if these addresses are not static, or if there are many addresses, a less secure configuration might be required to permit IPSec and IKE traffic to flow between subnets.

When a firewall or filtering router exists between IPSec peers, it must be configured to forward IPSec traffic on UDP source and destination port 500, IP protocol 50 (ESP), or IP protocol 51 (AH). If you are using IPSec NAT-T, the firewall or filtering router must also be configured to forward IPSec traffic on UDP source and destination port 4500.

First, to permit IPSec traffic on UDP source and destination port 500, use the following settings to create a firewall filter called **Permit ISAKMP traffic on UDP port 500**:

- Source address = *Specific_IP_address*
- Destination address = *Specific_IP_address*
- Protocol = **UDP**
- Source port = **500**
- Destination port = **500**

If you are using IPSec NAT-T, to permit traffic on UDP source and destination port 4500, use the following settings to create a firewall filter called **Permit ISAKMP traffic on UDP port 4500**:

- Source address = *Specific_IP_address*
- Destination address = *Specific_IP_address*
- Protocol = **UDP**
- Source port = **4500**
- Destination port = **4500**

The firewall filter must also permit or track fragments for ISAKMP. IKE with certificate or Kerberos authentication requires ISAKMP packets to be fragmented because the IKE protocol uses UDP. ISAKMP messages that are larger than the local interface MTU are automatically fragmented by IP. If only certificate authentication is used, Windows Server 2003 implements a method to avoid IKE message fragmentation. When certificate authentication is used for communication between computers running Windows Server 2003 IPSec and Windows XP IPSec or Windows 2000 IPSec, fragmentation is required.

You must also allow IKE to be initiated from either a source or destination IP address. RFC 2408, *Internet Security Association and Key Management Protocol (ISAKMP)*, specifies that the IKE protocol must be able to negotiate security in either direction. Stateful filtering that allows only one computer to initiate IKE to a responder typically times out and deletes the stateful inbound filter in the firewall. As a result, IKE cannot rekey IPSec security associations, and IPSec connectivity is lost.

During the security negotiation, IKE detects whether IPSec NAT-T is required, and, if so, IKE automatically uses UDP port 4500 as the source and destination port. However, the exact firewall configuration that is required to permit this traffic depends on the location of the network address translator relative to the firewall. Typically, the network address translator modifies the source address and the source port of the IKE UDP header.

To permit IPSec traffic on IP protocol 50 (ESP) or IP protocol 51 (AH), use the following setting to create a firewall filter called **Permit IPSec traffic on ESP or AH protocol (50 or 51)**:

- Source address = *Specific_IP_address*

- Destination address = *Specific_IP_address*

- Protocol = **50** or **51**

When TCP traffic is protected by IPSec transport mode or tunnel mode, it should not require fragmentation. But UDP traffic that is protected by IPSec might require fragmentation. Therefore, you might need to enable fragment tracking for protocol 50 (ESP) or protocol 51 (AH).

- ESP and AH traffic should be allowed to flow in either direction. The upper layer protocols such as TCP will determine when IPSec packets are generated. However, ESP fully encapsulates the TCP header, so stateful filters might not be able to inspect the TCP header to track the TCP connection state and determine when to close the hole. IPSec SA state is controlled by IKE in the encrypted quick mode negotiation. Accordingly, IPSec SA creation and deletion can occur in either direction and cannot be detected by inspection of the IKE negotiation packets. Stateful filtering on the IPSec protocols might impact connectivity. To assess the possible impact, ensure that you test how effectively IPSec protects your application traffic with the appropriate firewall or filtering router.

After the firewall is opened to allow the IKE and IPSec protocols, the firewall might not be able to inspect packets to control which traffic is secured by IPSec. IPSec policy filters determine which traffic IPSec can secure, so if you want only a specific protocol to flow between two peers, you must create IPSec filters that enforce this behavior. Port-specific filters can control the direction in which connections are made. Therefore, if a computer is in a more trusted network (inside the firewall) and you want IPSec to secure traffic only over certain protocols and ports on that computer, do not enable the default response rule in the IPSec policy for that computer. If the default response rule is enabled and an attacker compromises the remote computer, the attacker might be able to modify the IPSec policy to negotiate security for all traffic through the firewall.

# Choosing the IPSec Protocol

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 IPSec protects data sent across the network by encapsulating the original payload with either an IPSec header (ESP or AH) for transport mode or an IPSec header and an additional IP header for tunnel mode. An IPSec protocol is often used to convert many different TCP and UDP ports used by applications and system services into one stream of secure traffic for the purpose of traversing an unsecured network. IPSec policy filters can control what protocols and ports are protected by IPSec.

Depending on which protocol is used, the entire original packet can be encrypted, encapsulated, or both. There are two IPSec protocols, Authentication Header (AH) and Encapsulating Security Payload (ESP).

**AH**

AH provides data origin authentication, data integrity, and anti-replay protection for the entire packet (both the IP header and the data payload carried in the packet), except for the fields in the IP header that are allowed to change in transit. It does not provide data confidentiality, which means that it does not encrypt the data. The data is readable, but protected from modification.

**ESP**

ESP provides data origin authentication, data integrity, anti-replay protection, and the option of confidentiality for the IP payload only. ESP in transport mode does not protect the entire packet with a cryptographic checksum. The IP header is not protected. ESP in tunnel mode encapsulates and secures the entire original packet, including the IP header (but not the outer IP header). Windows Server 2003 supports IPSec NAT-T, and ESP is the only protocol that can be used to traverse network address translators. The IKE protocol automatically detects the presence of a network address translator and proposes UDP-ESP encapsulation, rather than ESP, to allow IPSec traffic to pass through the network address translator. If only AH is specified as a security method in the filter action, the security negotiation will fail. ESP supports the option of null encryption when network address translator traversal, and not encryption, is needed.

Use Table 6.7 to choose which protocol to use.

**Table 6.7 Choosing IPSec Protocol Types**

| Protocol | Requirement | Usage |
|---|---|---|
| AH | The data and the header need to be protected from modification and authenticated, but remain readable. | Use for data integrity in situations where data is not secret but must be authenticated — for example, where access is enforced by IPSec to trusted computers only, or where network intrusion detection, QoS, or firewall filtering requires traffic inspection. |
| ESP | Only the data needs to be protected by encryption so it is unreadable, but the IP addressing can be left unprotected. | Use when data must be kept secret, such as file sharing, database traffic, RADIUS protocol data, or internal Web applications that have not been adequately secured by SSL. |
| Both AH and ESP | The header and data, respectively, need to be protected while data is encrypted. | Use for the highest security. However, there are very few circumstances in which the packet must be so strongly protected. When possible, use ESP alone instead. |

Using both AH and ESP is the only way to both protect the IP header and encrypt the data. However, this level of protection is rarely used because of the increased overhead that AH would incur for packets that are already adequately protected by ESP. ESP protects everything but the IP header, and modifying the IP header does not provide a valuable target for attackers. Generally, the only valuable information in the header is the addresses, and these cannot be spoofed effectively because ESP guarantees data origin authentication for the packets. In addition, some IPSec hardware offload adapters do not support the use of AH and ESP on the same packet. Hardware offload network adapters can accelerate IPSec processing by performing hardware offload of IPSec cryptographic functions. If you are using such offload adapters, determine the protocol support that they provide before selecting an IPSec protocol to use.

# Selecting IPSec Authentication Methods

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Peer authentication is the process of ensuring that an IPSec peer is who it claims to be. By using peer authentication, IPSec can determine whether or not to communicate with another computer before the communication begins. Windows Server 2003 IPSec performs peer authentication, but requires only mutual trust of the identities exchanged. It does not verify that the identity that is received is authorized to use a particular IP address.

Table 6.8 describes the uses of the authentication methods.

**Table 6.8 Choosing Authentication Methods**

| Security Requirement | Authentication Method | Examples |
|---|---|---|
| Communication within a Windows Server 2003 or Windows 2000 domain, or between trusted Windows Server 2003 or Windows 2000 domains. | Kerberos V5 | Clients accessing a Human Resources database<br>A Web server in a perimeter network connecting to a computer running SQL Server on an internal network |
| Communication outside of your domain or across the Internet where Kerberos V5 is not available but access to a CA is available. | Public key certificate | Partner organizations using a Web-based CA to access resources on your private network |
| Communication with systems that do not support the Kerberos V5 protocol and do not have access to a CA. | Preshared key | Windows 98 or Macintosh clients using third-party IPSec implementations<br>UNIX servers on a Windows network |

Windows Server 2003 IPSec supports three methods of peer authentication so that computers running different operating systems or that exist in different environments can find a common method when negotiating communication with a peer. An IPSec policy rule associates each IP address in a filter with an authentication method list, so that IKE can determine which authentication method list to use with each IP address. During IKE negotiation, the IKE initiator proposes a list of authentication methods to the IKE responder. The responder must use the source IP address of the initiator to identify which filter controls the IKE negotiation. The authentication method list that corresponds to the filter in the responder's IPSec policy is used to select one authentication method from the initiator's list. The responder then replies to inform the initiator of the agreed upon authentication method. If the selected authentication method fails, IKE does not provide a method for retrying a different authentication method.

# Kerberos Authentication

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Kerberos V5 is the default authentication standard in Windows Server 2003 and Windows 2000 domains. This method of authentication can be used by any computer in the domain or a trusted domain. Also, because the Kerberos protocol is no longer a default exemption, if you want to enable Kerberos authentication, you must create filters in the IPSec policy that explicitly allow all traffic to your domain controllers.

For IKE Kerberos authentication to be used successfully in Windows 2000 and Windows Server 2003 cross-forest trust configurations, you must use FQDNs when configuring external trusts. In addition, you must configure the IPSec policy on both computers to allow an IKE initiator to communicate to any domain controller in the forest domain hierarchy, so that the initiator can obtain a ticket from a domain controller in the responder's domain.

It is recommended that you use Kerberos authentication in a two-way (mutual) domain and forest trust environment. Although one-way domain and forest trusts are supported, it is not recommended to use Kerberos in this type of trust environment. If you do, you must design the IPSec policy to ensure that the IKE initiator can obtain a ticket from a domain controller in the responder's domain. Also, traffic might be lost if IKE fails to rekey main mode negotiations in the opposite direction. Because an IKE main mode negotiation is performed on demand when quick mode negotiations are rekeyed, when configuring lifetimes in kilobytes (KBs) for the associated filter action, use as high a value as possible to minimize rekey authentication failures. If you are using ESP DES or 3DES for encryption, you can set the lifetime value to as high as 200,000 KB (200 megabytes). If you set a higher value, however, the risk of a sophisticated attacker gaining knowledge of the 56-bit encryption keys increases. If you are using ESP or AH for integrity and authenticity, you can set the value to as high as 2 gigabytes because the key sizes are much larger for MD5 (128-bit) and SHA1 (160-bit).

By default, when Kerberos authentication is used, the **Access this computer from the network** or **Deny this computer access from the network**logon right (defined in Group Policy) is evaluated. This evaluation is only performed by the IKE main mode responder (the computer that receives the ticket and must determine whether accept it). Typically, clients obtain Kerberos tickets to access a server. Likewise, the IPSec policy must contain filters that will trigger the IKE negotiation from the IKE initiator, the client that is requesting IPSec access to the server. The server can then use these logon rights to restrict access to certain client computer security groups. However, if IKE rekeys main mode negotiations, the server does not evaluate these rights.

# Public Key Certificate

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In Windows 2000 and Windows Server 2003, you can use Certificate Services to automatically manage computer certificates for IPSec throughout the certificate lifecycle. Certificate Services is integrated with Active Directory and Group Policy, and it simplifies certificate deployment by enabling certificate auto-enrollment and renewal and by providing configurable certificate templates. In addition, by publishing the computer certificate as an attribute of the domain computer account, Certificate Services allows you to use IPSec to restrict network access to a server.

Use a public key certificate in situations that include access to corporate resources, external business partner communications, or computers that do not run the Kerberos V5 authentication protocol. This requires that at least one trusted root CA is configured on your network and that client computers have an associated computer certificate.

IPSec supports the use of a variety of third-party X.509 public key infrastructure (PKI) systems, in addition to Windows 2000 Server or Windows Server 2003 Certificate Services. Windows Server 2003 IKE has basic compatibility with several certificate systems, including those offered by Microsoft, Entrust, VeriSign, and Netscape. If you are using a third-party PKI system, the PKI system must be able to issue certificates to computers and store their certificates in the Windows Cryptographic Application Programming Interface (CryptoAPI) computer certificate store.

**Note**

- Certificates obtained from Certificate Services with the advanced option set for **Enable strong private key protection** do not work for IKE authentication because a personal identification number (PIN) cannot be entered to access the private key during IKE negotiation.

**General certificate authentication considerations**

IKE's use of certificate authentication is compatible with many different PKI architectures, and IKE places relatively few requirements on the contents of a certificate. Typically, computers that have a common trusted root, or whose certificates can chain through a cross-certification trust relationship, can successfully use IKE authentication. To use certificates for IKE authentication, you define an ordered list of acceptable root CA names in the authentication method. This list controls the certificates that IKE can select and the certificates that IKE will select. If IKE authentication fails, you cannot retry the authentication using a different method. For this reason, before you apply an IPSec policy that can use certificates for authentication, make sure that all target computers have the correct root CA certificates and relevant cross-certificates in the CryptoAPI PKI stores, as well as valid computer certificates. Additionally, to ensure that certificate authentication works as intended, test your PKI infrastructure with various IPSec policy configurations before deployment.

The following sections describe the IKE certificate selection and acceptance process. If you decide to use certificates for IKE authentication, understanding this process and its requirements is integral to ensuring proper deployment.

**IKE certificate selection process**

When IKE negotiates to use certificates for authentication, the following process is used to select a computer certificate:

1. The list of trusted roots is prepared. This list is the list of the CA root names provided by the peer in the Certificate Request Payloads (CRPs), and it matches the CA root names configured in the list of trusted roots in the appropriate authentication method of the IPSec policy. If there are no matching CA root names, all trusted CA root names from the appropriate authentication method are used.

2. IKE searches the computer store for an IPSec certificate that chains to any of the trusted CA roots identified in step 1. An IPSec certificate contains an Enhanced Key Usage (EKU) attribute with a value equal to the IP security IKE intermediate object identifier (OID) 1.3.6.1.5.5.8.2.2.

3. For each certificate chain found, the following checks are performed to verify that:

    - The certificate chain does not have any trust errors.

    - The certificate chain is not a root-only chain.

- The computer certificate has a private key.
- The computer certificate has an RSA type public/private key pair.
- The computer certificate has a public key length that is greater than 512 bits.
- The computer certificate has a Digital Signature key usage.
- The computer certificate is not a CA signing certificate that is used to issue certificates.
- The certificate chain passes certificate revocation list (CRL) checking, which is performed by default or if the value of the **StrongCrlCheck** registry key is set to **1** or **2**. For more information about CRL checking, see "CRL Checking" later in this chapter.

If all of these checks succeed, IKE selects the certificate chain to be sent to the IPSec peer. If any of these checks fails, IKE continues to search for another IPSec type certificate, using the same list of root CA names.

4. If a valid computer certificate chain is not located, IKE retries the process, from step 2. Although the same list of root CA names is used, IKE does not search for an IPSec type certificate.

5. If a valid computer certificate chain is still not found and if the list of root CA names in step 1 is a subset of the names allowed by the local IPSec policy, IKE retries, from step 2. This time, IKE uses the entire list of root CA names allowed by the local authentication method.

   This step is required for successful authentication when cross-certificates are used to establish trust relationships.

6. After IKE selects a computer certificate, it includes all intermediate certificates in the chain up to the root, except for the root CA certificate. A certificate chain in PKCS#7 format is then sent to the IPSec peer. If there are no intermediate CAs, only the computer certificate is sent.

   If a computer certificate cannot be selected, the authentication fails.

### Note

- If IKE negotiates with another computer running Windows Server 2003, or with other Microsoft IKE implementations that use IPSec NAT-T (such as Microsoft L2TP/IPsec VPN Client), a special method to avoid fragmentation of ISAKMP UDP packets might be implemented. Otherwise, the ISAKMP message that contains the certificate chain will likely be fragmented as the packet is transmitted.

#### IKE certificate acceptance process

1. IKE receives the peer's certificates or certificate chains and verifies that the peer's certificates chain up to any of the root CAs in the appropriate authentication method of the local IPSec policy.

2. For each peer certificate chain, the following checks are performed to verify that:

   - The computer certificate Subject Name or Subject AltName is consistent with the peer's ID field passed in the IKE negotiation.
   - The computer certificate chain does not have any trust errors. If there is a trust error, the peer authentication fails.

3. If the two checks in step 2 succeed, the following checks are performed for the peer certificate chain to verify that:

   - The certificate chain passes CRL checking, which is performed by default or if the value of the **StrongCrlCheck**

registry key is set to **1** or **2**.

- The computer certificate has an RSA type public/private key pair.
- The computer certificate has a public key length that is greater than 512 bits.
- The computer certificate has a Digital Signature key usage.

If any of these checks fails, the peer authentication fails.

4. If certificate-to-account mapping is enabled in the IPSec policy for the certificate root CA of the peer, IKE calls the Windows secure channel (Schannel) APIs to perform the mapping. Schannel completes the mapping and builds an access token for the computer account. This access token is automatically evaluated against the **Access this computer from the network** or the **Deny this computer access from the network** logon right defined in Group Policy Security settings.

   If the logon right evaluation fails, the peer authentication fails.

**Editing Default Certificate Templates to Include the Subject Name**

The IP Security Monitor snap-in, Event Viewer, and most IPSec diagnostics report the Subject Name attribute of the IPSec peer certificate. In Windows Server 2003 Certificate Services, the default version 2 certificate template for IPSec certificates does not include the computer name in the **Subject Name** field (the version 1 certificate templates cannot be modified). To aid in deployment and troubleshooting, edit the default IPSec certificate template to include either the FQDN or the common name of the computer in the **Subject Name** field. To do this, use the following procedure (note that you must be logged on as a member of the Enterprise Admins group or the root domain's Domain Admins group in Active Directory):

**To edit the default IPSec certificate template**

1. Open the Certificate Templates snap-in (Certtmp.msc).
2. Right-click the certificate template that you want to modify, and then click **Properties**.
3. On the **Subject Name** tab, click **Build from this Active Directory Information**, and then click **Common Name** or **Fully Distinguished Name**.
4. Enter the common name or FQDN as required.

If you choose to enter the common name of the computer, the name in the **Subject Name** field of the certificate will appear as CN=< FQDN>. If any FQDN is greater than 64 characters, select **Fully Distinguished Name**, not **Common Name**. After you complete this procedure, all subsequently issued computer certificates will contain the FQDN in the **Subject Name** field of the certificate. If you have already completed enrollment for computer certificates by using the default certificate template, create a new certificate template and configure it to supersede the existing template. Doing this will automatically update all computer certificates so that the blank name in the **Subject Name** field is replaced with the FQDN of the computer. If the existing certificate template is not superseded, each computer will have two computer certificates that can be used for IKE authentication. IKE can choose either one.

**Auditing IKE Negotiation Successes and Failures**

You can view the success or failure of IKE negotiations in the Event Viewer security log. To view these events, enable success or failure auditing for the **Audit logon events** audit policy for your domain or local computer. If auditing is enabled for IKE events, and IKE authentication fails, event 547 is recorded. If IKE authentication succeeds, event 541 is recorded.

When you enable success or failure auditing for the **Audit logon events** audit policy, IPSec records the success or failure of each main mode and quick mode negotiation and the establishment and termination of each negotiation as separate events. In many cases, it might be necessary to enable success auditing for the **Audit logon events** audit policy, to track user activity. Keep in mind, however, that enabling this type of auditing can cause the security log to fill with IKE events. You can disable auditing of IKE events by modifying the registry.

To disable auditing of IKE events in the security log, do the following:

1. Set the **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Control\Lsa\Audit\DisableIKEAudits** registry setting to a value of **1**.

   The **DisableIKEAudits key** does not exist by default and must be created.

2. Do one of the following:

   - Restart the computer
   - Stop, and then restart the IPSec service by running the **net stop policyagent** and **net start policyagent** commands at the command prompt.

   **Note**

Stopping and restarting the IPSec service can disconnect all of the computers that are using IPSec from the computer on which the IPSec service is stopped, and it can prevent further communication with that computer. If you restart the IPSec service immediately, TCP-based communication might resume, due to the retransmit behavior of TCP, after new IKE and IPSec SAs are established.

**CRL Checking**

By default, in Windows XP and Windows Server 2003, IPSec CRLs are automatically checked during IKE certificate authentication, but a fully successful CRL check is not required for the certificate to be accepted. However, if enhanced security is required, a fully successful CRL check is also required. CRL checking can cause delays in authentication or unnecessary failures, and some third-party PKI systems might not support it. You can disable IPSec CRL checking or specify a stronger level of IPSec CRL checking by using the Netsh IPSec context or by modifying the registry.

To disable IPSec CRL checking or specify a different level of IPSec CRL checking by using the Netsh IPSec context, use the following command:

```
netsh ipsec dynamic set config strongcrlcheck value={0 | 1 | 2}
```

**To disable IPSec CRL checking or specify a different level of IPSec CRL checking**

1. Under **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\PolicyAgent**, add a new **Oakley** key, with a DWORD entry named **StrongCRLCheck.**

2. Assign this entry any value from **0** through **2**, where:

   - A value of **0** disables CRL checking.
   - A value of **1** enables the default level of CRL checking for Windows Server 2003 IKE. When this level of CRL checking is performed, certificate validation fails only if the certificate is revoked.
   - A value of **2** enables strong CRL checking, which means that certification validation fails if any error is encountered during CRL processing.

3. Do one of the following:

   - Restart the computer.
   - Stop, and then restart the IPSec service by running the **net stop policyagent** and **net start policyagent** commands at the command prompt.

**Caution**

- Do not edit the registry unless you have no alternative. The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Windows Server 2003 Resource Kit Registry Reference on the *Windows Server 2003 Deployment Kit* companion CD or at http://www.microsoft.com/reskit.

Note that IPSec CRL checking does not guarantee that certificate validation fails immediately when a certificate is revoked. There is a delay between the time that the revoked certificate is placed on an updated and published CRL and the time when the computer that performs the IPSec CRL checking retrieves this CRL. The computer does not retrieve a new CRL until the current CRL has expired or until the next time the CRL is scheduled to be published. By default, IKE requests that Crypto API (CAPI) waits 15 seconds to complete the CRL retrieval. If the CRL cannot be retrieved at that time, IKE either ignores the error (if the value of the **StrongCRLCheck** registry key is set to **1**, or it causes authentication to fail (if the value of **StrongCRLCheck** is set to **2**). CRLs are cached in memory and in \Documents and Settings*UserName*\Local Settings\Temporary Internet Files by CAPI. Because CRLs persist across computer restarts, if a CRL cache problem occurs, restarting the computer does not resolve the problem. For more information about CRLs, see the Troubleshooting Certificate Status and Revocation link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Certificate-to-Account Mapping**

In Windows Server 2003, a specific group of computers can be authorized to use IPSec when either Kerberos V5 or certificates are used for IKE authentication. This capability enables much stronger peer authentication and IPSec to be used to restrict network access to a server. When you enable IPSec certificate-to-account mapping, the IKE protocol associates (that is, maps) a computer certificate to a computer account in an Active Directory domain or forest, and then retrieves an access token, which includes the list of computer security groups. This process ensures that the certificate offered by the IPSec peer corresponds to an active computer account in the domain, and that the certificate is one that should be used by that computer.

Certificate-to-account mapping can only be used for computer accounts that are in the same forest as the computer performing the mapping. This provides much stronger authentication than simply accepting any valid certificate chain. For example, you can use this capability to restrict access to computers that are only within the same forest. Certificate-to-account mapping, however, does not ensure that a specific trusted computer is being allowed IPSec access.

Certificate-to-account mapping is especially useful if the certificates come from a PKI that is not integrated with your Active Directory deployment, such as if business partners obtain their certificates from third-party providers. You can configure the IPSec policy authentication method to map certificates to a domain computer account for a specific root CA. You can also map all certificates from an issuing CA to one computer account. This allows IKE certificate authentication to be used to limit which forests are allowed IPsec access in an environment where many forests exist and each perform autoenrollment under a single internal root CA. If the certificate-to-account mapping process is not completed properly, authentication will fail and IPSec-protected connections will be blocked. For more information about establishing certificate-to-account mapping, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

**Excluding the CA Name from Certificate Requests**

If you use certificate authentication to establish trust between IPSec peers, you can also use Windows Server 2003 to exclude CA names from certificate requests. Excluding the CA name prevents a malicious user from learning sensitive information about the trust relationships of a computer, such as the name of the company that owns the computer and the domain membership of the computer (if an internal PKI is being used). Although excluding the CA name from certificate requests enhances security, computers with multiple certificates from different roots might require the CA root names to select the correct certificate. Also, some third-party IKE implementations might not respond to a certificate request that does not include a CA name. For these reasons, excluding the CA name from certificate requests might cause IKE certificate authentication to fail in certain cases.

# Preshared Key

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you are not using Kerberos V5 authentication and do not have access to a CA, a preshared key can be used. For example, a stand-alone computer on a network that does not connect to the Internet might need to use a preshared key, because neither Kerberos authentication through the computer's domain account nor access to a CA on the Internet are available.

A *preshared key* is a shared secret key that has been agreed upon by administrators who wish to secure the computer's communications by using IPSec. Administrators must manually configure their systems to use the same preshared key.

**Important**

- Microsoft does not recommend the use of preshared key authentication, because the authentication key is stored in plaintext format in the system registry and hex-encoded in Active Directory–based IPSec policy. Well-known methods can enable attackers with access to these data stores to discover weak preshared key values.

Use preshared key authentication only where no stronger method can be used. Using Kerberos or certificate-based authentication is recommended to avoid security risks associated with preshared key authentication.

If you must use preshared key authentication, use only local or persistent IPSec policy, a 25-character or longer random key value, and a different preshared key for each IP address pair. These practices result in different security rules for each destination, and ensure that a compromised preshared key compromises only those computers that share the key. For more information about local or persistent IPSec policies, see "Assigning IPSec Policies Locally" later in this chapter.

# IKE Authentication Security

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use Windows Server 2003 IPSec policies and IKE authentication to limit network access to trusted computers. In most scenarios, successful IKE authentication results in successful network access to a computer. IKE is not aware of the identity or the public key that is expected from the peer. Therefore, if the certificate private key or domain password for a computer were compromised, an attacker might be able to use that computer to successfully authenticate and gain access to another IPSec-protected computer or to conduct trusted man-in-the-middle attacks on IPSec communication. To ensure that IPSec provides the appropriate network access controls, carefully consider the following:

- How computers are joined to an Active Directory security domain.
- How trusts between domains and forests are controlled.
- How computers obtain a certificate from a trusted root CA (or an issuing CA).
- How PKI trust is controlled (for example, how cross certificates are handled).
- How to reduce the number of trusted computers.

# Assigning IPSec Policies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As a domain administrator, you can configure IPSec policies to meet the security requirements of a user, group, application, domain, site, or global enterprise from a domain controller. IPSec policy can also be implemented in a non-Windows 2000-based domain environment by using local IPSec policies.

Follow the steps shown in Figure 6.10 to assign IPSec policies during your deployment.

**Figure 6.10 Assigning IPSec Policies**

Make sure that you test these IPSec policies before you actually assign them in your production environment. For more information about testing IPSec policies, see "Testing Your Policies in a Test Lab" later in this chapter.

First determine whether to use Active Directory to apply IPSec policy to clients. If you decide to do so, make sure that you understand how Group Policy inheritance affects the way in which the IPSec policies are applied and how IPSec policy precedence differs from standard Group Policy inheritance.

# Understanding the New Default IP Security Policies Container Permissions

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Domain-based IPSec objects are stored in the IP Security Policies container in Active Directory, which is separate from the Group Policy objects (GPOs) to which the IPSec policies are applied. By default in Windows Server 2003, Active Directory restricts Read permissions on the IP Security Policies container more than in Windows 2000. In Windows Server 2003, only members of the Group Policy Creator Owners and the Domain Computers groups have Read permissions on the IP Security Policies container. The domain administrator must grant permissions to the IP Security Policies container for other delegated administrators to administer IPSec policies.

If you perform a new installation of Windows Server 2003 and create a domain controller, the domain controller will have the following new default permissions on the IP Security Policies container:

- Owner: Domain Admins
- Group: Domain Admins
- Allow domain computers: Read only
- Allow Group Policy Creator Owners: Read only
- Allow Domain Admins: Full Control

When you run the Adprep tool (available in the I386 directory in the Windows Server 2003 product CD) to prepare Windows 2000 domains and forests for an upgrade to Windows Server 2003, it will change the permissions on the IP Security Policies container to these new settings, unless you have already changed the default permissions in Windows. When you create new objects in the IP Security Policies container, those objects inherit the permissions of that container. Upgrading from Windows 2000 will not modify the permissions on existing IPSec policy objects.

Due to the more restrictive permissions in Windows Server 2003, a member of the Domain Admins group must explicitly allow the assignment of an IPSec policy to child domains within a forest by enabling child domain computers to read the IP Security Policies container in the directory. For these computers to retrieve domain-based IPSec policy from Active Directory, the Local System account for each computer must have Read permissions on the IP Security Policies container. If computer accounts in child domains must read a parent domain-based IPSec policy, you must modify the permissions on the IP Security Policies container to allow this.

Make sure to carefully control Modify access to the IP Security Policies container. Do not assign specific permissions for individual IPSec policies. The IPSec policies are a collection of related directory objects, some of which can be shared between policies. Accordingly, you should control permissions on the IP Security Policies container itself.

An IPSec policy administrator typically has Write access to all IPSec policies. You can restrict who can create and modify GPOs so that only authorized individuals can assign a domain-based IPSec policy. Make sure to investigate these permissions and set them as needed for your environment.

Standard delegation tools cannot be used to delegate permissions to administer IPSec policies. Instead, domain administrators must use the Active Directory Service Interfaces (ADSI) Edit tool for this purpose. ADSIEdit is a Microsoft Management Console (MMC) snap-in that domain administrators can use to edit objects in the Active Directory database. When domain administrators delegate permissions to others to administer IPSec policies, the delegated administrators must have Full Control permissions to all IPSec policy objects in the IP Security Policies container. After an IPSec administrator creates an IPSec policy, a member of the Group Policy Owner Creators group or other delegated owner of the GPO can assign the IPSec policy to the appropriate GPOs.

**Caution**

To modify access control lists (ACLs) on the IP Security Policies container, domain administrators should use the tools that are provided with the Windows 2000 or Windows Server 2003 operating system CD. When domain administrators modify ACLs on the IP Security Policies container, they must specify that all modifications are also propagated to all child objects. Incorrect modification of the ACLs on the IP Security Policies container, failure to propagate modifications to the child objects of this container, or both, can result in the failure of IPSec policy settings to be properly applied.

ADSIEdit is one of the Windows Support tools included on the Windows 2000 and Windows Server 2003 operating system CDs. You can install these tools by running the Support Tools Setup program, Suptools.msi, from the \Support\Tools folder.

For more information about permissions for the IPSec Policies container, see article 329194, "IPSec Policy Permissions in Windows 2000 and Windows Server 2003" in the Microsoft Knowledge Base at http://go.microsoft.com/fwlink/?LinkID=106552.

# Understanding IPSec Policy Precedence

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To know how to apply IPSec policy in a domain environment, you must understand IPSec policy precedence. Unlike most Group Policy settings, which are cumulative, only one IPSec policy can be assigned to a computer at a time. Therefore, if there are multiple IPSec policies assigned at different levels, the last one applied is the one that takes effect. IPSec policy uses the same precedence sequence as other Group Policy settings, which is from lowest to highest, as follows:

- **Local GPO.** Each computer has one local GPO. For a computer that is not a member of a domain, this is the only place where IPSec policy can be assigned. Although you can assign an IPSec policy by editing the local GPO, you can also assign a local policy directly in the IP Security Policy Management snap-in, outside of the Group Policy context, or by using the Netsh IPSec context. When IPSec policy assignments are made outside of the GPO context, the GPO cannot display the local IPSec policy that is assigned.

- **Site.** IPSec policies are not often assigned at the site level because all computers within a site must have the same security needs, which is unlikely. Furthermore, if the computer moves to another subnet — such as when a user travels to another location with a laptop that uses DHCP — different policies are applied, which results in different security behaviors.

- **Domain.** Simple IPSec policies are often assigned at the domain level and then superseded by more specific IPSec policies, as required on various OUs.

- **OU.** Specific IPSec policies are assigned to groups of computers. This is the last policy applied under normal conditions, and, therefore, the policy takes precedence. If an OU is nested within another OU, the IPSec policy assigned to the nested OU takes precedence.

Note that this is the default order in which policies of different types are applied. This order can be overridden by using a number of options, including **Enforced**, **Block Policy Inheritance**, and **Loopback** processing. For more information about the results of these options, see "Designing a Group Policy Infrastructure" in *Designing a Managed Environment* of this kit.

**Note**

- If you create a persistent policy, this policy adds to or overrides the local or Active Directory policy and remains in effect regardless of whether other policies are applied. For more information about persistent IPSec policy, see "Assigning IPSec Policies Locally" later in this chapter.

# Selecting a Method for Assigning IPSec Policies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The next step is to decide how to distribute and assign IPSec policies. This might include storing and assigning IPSec policies from Active Directory as part of Group Policy, storing and assigning them from the local computer, or assigning them from a remote computer.

The primary method of building the IPSec policy is using the graphical user interface provided by the IP Security Policy Management snap-in. You can use the IP Security Policy Management snap-in to create, modify, and activate IPSec policies, and then assign them to an OU in Active Directory that contains the server using the Group Policy Object Editor snap-in. Use this for situations where larger numbers of computers need to be managed in a consistent fashion. A Group Policy–based management solution addresses this situation well.

If a computer is not a member of a Windows 2000 domain or a Windows Server 2003 domain, it cannot retrieve IPSec policy from Active Directory. The IPSec policy configuration for a server can be distributed two ways that do not use Active Directory:

- As a Netsh IPSec script that is included as a startup script for the computer.
- As an IPSec file that can be imported from another computer by using the IP Security Policy Management snap-in or Netsh if the computer is running Windows Server 2003. Use this method when computers need to secure their communications, but there are few enough of them that applying policies to OUs is inconvenient. After the policy is imported, you can use the IP Security Policy Management snap-in to assign the policy to the computer.

If you use either of these two methods, make sure you use strict version and change control processes to ensure that the policy file cannot be altered after it was created. If the policy is accessed by using Lightweight Directory Access Protocol (LDAP), the IPSec policy configuration data can be authenticated and encrypted.

Using explicit credentials for remote management and monitoring of IPSec is not supported. Instead, the IP Security Policy Management and IP Security Monitor snap-ins use the credentials that are provided during the desktop logon process to authenticate to a remote computer.

# Assigning Domain-based, OU-Level, and Local IPSec Policies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

IPSec policies can be applied to local computers, domains, sites, organizational units, or any Group Policy object in Active Directory. The following sections describe deployment considerations for domain-based, OU-level, and local IPSec policies.

# Assigning Domain-based IPSec Policy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you determine where you want to protect data and create IPSec policies for each of those areas, you must determine which IPSec policy to assign to GPOs.

A GPO defines access, configuration, and usage settings for accounts and resources. When an IPSec policy is assigned to a GPO, the IPSec policy is propagated to any computer accounts that are affected by the GPO.

Keep these factors in mind when selecting GPOs for IPSec policy assignment:

- IPSec policies can be assigned to the GPO of a site, domain, or OU. However, only a single local or domain-based IPSec policy can be assigned to a specific computer.
- Like Group Policy settings, the assignment precedence for IPSec policies, from lowest to highest, is local, site, domain, and OU. In addition, persistent IPSec policy has the highest precedence of all, even though it is stored on the local computer.
- Unlike Group Policy settings, IPSec policies from different OUs are never merged.
- The highest level of the Active Directory hierarchy is typically used to broadly assign IPSec policies, to reduce the amount of configuration and administration required.
- For domain-based IPSec policy, limit the number of rules to 10 or less, even though Windows Server 2003 supports over 1500 rules per policy.
- Create and apply an IPSec policy at the domain level to provide a baseline of IPSec protection. For example, the default domain policy GPO can often be used to assign IPSec policy for all clients in a domain.
- A new IPSec policy can be tested as a local policy on a server or a client first before it is uploaded into the domain. Be sure to adequately test the impact of new IPSec policies before assigning them in the domain.
- When configuring the **Negotiate security** filter action, select the **Allow unsecured communication with non-IPSec aware computers** check box during the rollout phase, so that communication will not be blocked after a computer starts using IPSec policy. After verifying that all computers have IPSec policy and are working correctly, clear this check box to require only IPSec-secured communications.
- Use the **Export Policies** and **Import Policies** commands in the IP Security Policy Management console to back up and restore all of the IPSec policy objects in the IP Security Policies container in Active Directory. The **Export Policies** command exports all IPSec policy objects from the policy store into one .ipsec file. The **Import Policies** command imports all IPSec policy objects in the .ipsec file into the destination policy store. Note that importing IPSec policy into Active Directory will overwrite existing IPSec policy objects.

**Caution**

- When importing or editing IPsec policy in Active Directory, do not close the IP Security Policy Management snap-in (or exit the Netsh environment, if you are using the **netsh ipsec static importpolicy** command) before all IPSec policy data has been written to Active Directory. If the IP Security Policy Management snap-in or Netsh Ipsec cannot finish writing all of the policy data into Active Directory, IPSec policy corruption might result.
- If you detect IPSec policy corruption, you can try to reimport the IPSec policy file. In some cases, you must use either LDP.exe or ADSIedit.exe to delete the IPSec policy objects. (LDP.exe is a Support Tool that was included in the Support Tools folder of the Windows 2000 operating system CD, and is included in the Support Tools folder of the Windows XP and Windows Server 2003 operating system CDs). The IPSec policy objects must be deleted so that a new IPSec policy import operation can be successfully completed. If you are managing IPSec policy remotely over slow links, transfer the

IPSec policies in .ipsec export files by using a file copy technique first. Then use Remote Desktop Connection to connect to the remote server and perform the import operation quickly.

# Assigning OU-Level IPSec Policies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After assigning a domain-based IPSec policy as a baseline for IPSec protection, you can assign other IPSec policies to specific OUs to provide tighter IPSec filtering in sensitive areas of your network. By default, the IPSec policies assigned to a GPO at the OU level override the baseline policy for the domain.

For example, you can organize the computer accounts in the domain to keep domain clients in one OU and IPSec-protected servers in another OU, so that client policy will not affect servers.

**Note**

- Assigning an IPSec policy to a GPO (such as an OU) records a pointer to the IPSec policy inside the GPO. Thus Group Policy only detects changes in IPSec policy assignments, not changes made within an IPSec policy after it is assigned to a GPO. The IPSec service detects changes in the related IPSec policy. You can specify the frequency of this detection process, known as the *IPSec polling interval,* by setting a value on the **General** tab of the properties of a policy by using the IP Security Policy Management snap-in.

It is recommended that you test your new IPSec policies as a local policy on a server or a client first before assigning them into the domain.

# Assigning IPSec Policies Locally

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Each computer running Windows Server 2003 has one local GPO, which is also known as the *local computer policy*. When this local GPO is used, Group Policy settings can be stored on individual computers regardless of whether they are members of an Active Directory domain. The local GPO can be overridden by GPOs assigned to sites, domains, or OUs in an Active Directory environment that have higher precedence. On a network without an Active Directory domain (that is, a domain that does not have a domain controller running Windows 2000 or Windows Server 2003), the local GPO settings determine IPSec behavior because they are not overridden by other GPOs.

Local policy assignment is a way to enable IPSec for computers that are not members of a domain.

You can also create and assign *persistent IPSec policy*, which secures a computer even if a local IPSec policy or an Active Directory–based IPSec policy cannot be applied. This policy adds to or overrides the local or Active Directory policy, and remains in effect regardless of whether other policies are applied or not. Persistent IPSec policies enhance security by providing a secure transition from computer startup to IPsec policy enforcement. Persistent policy also provides backup security in the event of an IPSec policy corruption, or if errors occur during the application of local or domain-based IPSec policy. To configure persistent policies, you must use the **`netsh ipsec static set store location=persistent`** command.

When designing persistent IPSec policy, it is important to consider the potential impact of persistent policy on remote management. If local or domain-based IPSec policy is not applied and the persistent IPSec policy is the only policy that is applied, attempts to remotely diagnose an issue might be blocked by the persistent IPSec policy. To allow for remote management in case troubleshooting is required, it is recommended that you create appropriate permit filters when configuring persistent IPSec policy.

To enable remote management, add the following exemption by using the Netsh IPSec context command:

```
        netsh ipsec dynamic set config bootexemptions tcp:0:3389:inbound
UDP:0:68:inbound
```

This command specifies two things: that the destination port 3389 for inbound TCP connections is permitted, thereby enabling clients to use Remote Desktop Connection or Remote Assistance; and that destination port 68 for inbound UDP connections is permitted, thereby preserving DHCP functionality.

If an error occurs when persistent IPSec policy is applied, the IPSec driver will block all traffic except for that which matches any specific permit filters that you configure (by using the **netsh ipsec dynamic set config bootexemptions** command), and DHCP.

For more information about assigning local IPSec policies, see "Creating, modifying, and assigning IPSec policies" in Help and Support Center for Windows Server 2003.

# Understanding IPSec Protection During Computer Startup

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 IPSec provides several options for protection during computer startup. To provide maximum protection against attacks during computer startup, it is highly recommended that you configure and assign a persistent IPSec policy. If you do not configure a persistent policy, the IPSec driver cannot enforce IPSec policy until domain-based or local IPSec policy is retrieved and applied.

# Understanding IPSec Driver Startup Modes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To understand how IPSec policies are processed and applied, it is important to understand the modes in which the IPSec driver operates. The IPSec driver can perform in any of three following computer startup modes:

- **Permit.** In this mode, the IPSec driver permits all inbound and outbound traffic. After persistent, local, or domain-based IPSec policy is applied, the IPSec driver no longer operates in this mode.

- **Block.** In this mode, the IPSec driver blocks all inbound and outbound traffic until persistent policy is applied, except for traffic that matches any specific permit filters that you configure (by using the **netsh ipsec dynamic set config bootexemptions** command), and DHCP traffic.

- **Stateful.** In this mode, the IPSec driver permits all outbound traffic initiated by the computer during startup. Inbound traffic that is sent in response to the outbound traffic is permitted, specific to the peer IP address, protocol, and source and destination ports. The IPSec driver also permits inbound traffic that matches any specific filters that you configure (by using the **netsh ipsec dynamic set config bootexemptions** command), and DHCP traffic. All other inbound unicast, broadcast, and multicast packets are dropped. The stateful inbound permit filters are discarded after the IPSec service starts and sets persistent IPSec policy.

If a persistent, local, or domain-based IPSec policy has been assigned to a computer, the IPSec Policy Agent sets the stateful mode for the IPSec driver by default. You can change the default startup mode for the IPSec driver by using the Netsh IPSec context or by modifying the registry.

To change the default startup mode of the IPSec driver by using the Netsh IPSec context, use the following command:

```
netsh ipsec dynamic set config bootmode value={stateful | block | permit}
```

**To change the default startup mode of the IPSec driver by modifying the registry**

1. Under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\IPSEC**, add a new DWORD entry named **OperationMode**

2. Assign this new registry entry any value from **0, 1, or 3** where:

   - A value of **0** specifies that the IPSec driver operate in Permit mode, to allow all inbound and outbound traffic.

   - A value of **1** specifies that the IPSec driver operate in Block mode, except to allow traffic that matches any specific permit filters that you configure by using Netsh, and DHCP traffic.

   - A value of **2** is reserved.

   - A value of **3** specifies that the IPSec driver operate in Stateful mode and permits inbound traffic that matches any specific filters that you configure (by using the **netsh ipsec dynamic set config bootexemptions** command), and DHCP traffic.

3. Restart the computer.

**Caution**

- Do not edit the registry unless you have no alternative. The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Windows Server 2003 Resource Kit Registry Reference on the *Windows Server 2003 Deployment Kit*

companion CD or at http://www.microsoft.com/reskit.

# Using IPSec in Safe Mode with Networking

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When a computer is started in Safe Mode with Networking (for example, if you are performing Directory Service Restore Mode operations), the IPSec service does not start. As a result, no persistent, local, or domain-based IPSec policy can be applied, and IKE cannot negotiate security for network traffic. However, if an IPSec policy has been assigned to a computer, IPSec still can provide some level of filtering protection. If the IPSec service startup type is set to Automatic, the IPSec driver remains in computer startup mode (which is Stateful mode, by default). When the IPSec driver operates in this mode, you can configure specific permit filters to allow inbound traffic over specific protocols and ports.

If you must change the IPSec driver mode to Permit to allow all inbound connections, you must either set the **OperationMode** registry key to a value of **0** or change the IPSec service startup type to Manual or Disabled, and then restart the computer in Safe Mode with Networking again. Note that in this case, you cannot use the **netsh ipsec dynamic set config bootmode value=** command to change the IPSec driver startup type,because Netsh IPSec requires the IPSec service to be running.

**Caution**

- Do not edit the registry unless you have no alternative. The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Windows Server 2003 Resource Kit Registry Reference on the *Windows Server 2003 Deployment Kit* companion CD or at http://www.microsoft.com/reskit.

# Using Netsh Scripts to Assign IPSec Policies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In Windows Server 2003, the Netsh IPSec tool provides a scriptable command-line method of building an IPSec policy. This is useful in cases such as when a computer is not a domain member or is running an older version of Windows. Netsh IPSec can create a persistent policy or a local policy, both of which are stored in the local computer registry, or it can create a policy that is stored in Active Directory.

The IPSec context of the Netsh tool can also dynamically insert new IPSec rules into the run-time system. This "dynamic mode" IPSec policy is part of the run-time state and is not stored; therefore, it is lost when the IPSec service is stopped either administratively or during a restart.

The IPSec internal infrastructure components were significantly modified for Windows Server 2003 such that the Netdiag.exe, IPSecpol.exe, and IPSeccmd.exe tools from earlier Windows releases cannot run properly. You do not need to import policies created by these tools during an upgrade – policies in place before an upgrade to Windows Server 2003 continue to function after the upgrade has been completed. In all cases, the user or process that sets the IPSec policy must be running as a local or domain administrator.

For more information about importing IPSec policies, see "Creating, modifying, and assigning IPSec policies" in Help and Support Center for Windows Server 2003.

Windows 2000, Windows XP, and Windows Server 2003 do not have published programmatic APIs in the Microsoft Windows Platform Software Development Kit for IPSec policy. Command-line scripting using the Netsh IPSec tool is the only method of managing policy in an automated fashion.

# Coordinating IPSec Client and Server Policies in a Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Both clients and servers need IPSec policy before secure communications can be enabled. Because the initial application of IPSec policy and policy changes can briefly interrupt connectivity, make sure to schedule these tasks during low use periods as much as possible. When policies are changed, the IPSec system might be forced to delete existing IPSec SAs, so that new SAs can be negotiated according to the new IPSec policy. This can cause a temporary loss of communication.

Remember that domain IPSec policy will override local IPSec policy. If a local administrator has secured a server with local IPSec policy, applying a domain policy might make the server less secure or break its secure communication. If persistent policy was used, the domain policy cannot override it, but can enhance that baseline security.

# Deploying Your IPSec Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After scoping your needs, building IPSec policies, and determining your strategy for assigning the policies to specific OUs, test the IPSec policies in a lab environment and conduct a pilot project before rolling them out for production use.

To ensure that IPSec policy functions as expected and provides the appropriate level of security, test specific IPSec policy configurations on clients and servers in a lab environment, and then conduct pilot or beta tests in a limited operational environment before conducting a full-scale deployment. Test both functional behavior and the policy assignment steps required to ensure that one end of the communication does not receive a policy that blocks communication until the other end receives a compatible policy.

Follow the steps shown in Figure 6.11 to deploy IPSec.

**Figure 6.11 Deploying Your IPSec Solution**

# Testing Your Policies in a Test Lab

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you roll out IPSec into your production environment, test your IPSec policies by following these steps:

1. Configure a lab in a controlled environment separate from your production network. Make the lab simulate your production environment as closely as possible. For example, you might want to include a perimeter network, a data center server, firewalls or filtering routers, clients with various operating systems, application test configurations, multiple domains with various OUs, and a network with varying connection speeds. Also, make sure to activate those Active Directory services that are running in your production environment.

2. Use the RSoP component of Group Policy to verify that the IPSec policies are being applied the way in which you assigned them, and that the policy you expect takes precedence if multiple policies are applied.

3. Implement your policies on the server and clients to test communication of all software and services. Use the IP Security Monitor snap-in or the **netsh ipsec dynamic show mmfilter** and **netsh ipsec dynamic show qmfilter** commands to verify that specific filters are being applied as expected. In the IP Security Monitor snap-in, the **Specific Filters** nodes display quick mode and main mode filters configured for persistent, local, or domain-based IPSec policies. However, default exemptions to IPSec filtering are not displayed.

4. Look for communications that have failed. Check if any network traffic was blocked by any of the IPSec polices that you have implemented.

5. Simulate a load on the network that is similar to what your network would experience, to test for performance impact.

6. Complete penetration tests to verify that the filters are configured properly and behave as you expect. Verify that the exemptions to IPSec filtering are appropriate.

Use the IP Security Monitor snap-in to gather information you can use to identify problems and optimize performance where IPSec is deployed. For example, you can view details about IPSec policies and filters, statistics about performance, and SAs.

For more information about the IP Security Monitor snap-in, see "Viewing details about active IPSec policies in IP Security Monitor" in Help and Support Center for Windows Server 2003. For more information about setting up a test environment, see "Designing a Test Environment" in *Planning, Testing, and Piloting Deployment Projects* of this kit.

# Using RSoPd to Analyze IPsec Policy Assignments

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use RSoP to analyze IPSec policy assignments. RSoP is a Group Policy–related snap-in that you can use to view IPSec policy assignments for a computer or for members of a Group Policy container.

To view IPSec policy assignments in RSoP, you must first open the RSoP snap-in, and then run a query. RSoP allows you to troubleshoot policy precedence issues and determine the exact set of policies that are being used by IPSec clients.

For more information about RSoP, see "Using Resultant Set of Policy to view IPSec policy assignments" in Help and Support Center for Windows Server 2003. For more information about IPSec policy precedence, see "Understanding IPSec Policy Precedence" earlier in this chapter.

# Testing Your Policies in a Pilot Project

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Verifying successful IPSec operation is an important, and often neglected, step in deploying IPSec. Incorrectly configuring IPSec and related Windows networking components can cause network traffic to be unintentionally blocked or sent unprotected. The specifics of how to verify successful operation depend on the particulars of your deployment. You might need to engage the Help desk and conduct training in the technology, as well as create FAQs or self-help documents and procedures, so that you can quickly isolate problems.

Testing successful IPSec operations is uniquely different from testing other networking components. You can often test for successful operation of a system by performing tests to see if the applications behave as expected. However, applications in the overall system can perform properly while not protected by IPSec. Testing IPSec involves testing that the applications work, and that IPSec is in fact restricting access and performing protection.

It is also important to test IPSec policy management procedures and key IT operations processes, such as:

- Importing and exporting IPSec policy
- Remotely managing IPSec policy
- Initially assigning IPSec policy to different types of computers
- Changing IPSec policy on each computer
- Backup and restore operations
- Server and network monitoring
- Deploying new domain controllers
- Unassigning IPSec policy
- Adding subnets to the network
- Server scaling
- Cross-platform IPSec policy compatibility

Finally, coordinate with your network operations team to determine how procedures for responding to internal network attacks might impact the use of IPSec in your network.

For more information about planning and rolling out a pilot project, see "Designing a Pilot Project" in *Planning, Testing, and Piloting Deployment Projects* in this kit.

# Deploying IPSec Across Your Network

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The general steps for assigning IPSec policy by using Group Policy are:

1. Create the IPSec policy in the directory. If you have a computer dedicated to using local IPSec policy, you can use the **netsh ipsec static importpolicy** command or the IP Security Policy Management snap-in.

2. Create a new GPO or identify an existing GPO to use to deliver the IPSec policy assignment. Remember that only members of the Domain Admins group can modify the GPO and assign IPSec policy.

3. Assign the GPO to the domain level or an appropriate OU level, and then resolve any IPSec policy precedence issues. Group Policy objects, which include IPSec policies, can be configured to not be updated over slow links. IPSec policy should *always* be implemented, regardless of whether the updates must use slow links. If you prevent IPSec policy updates over slow links, communication failures might occur.

4. Plan the rollout of the IPSec policy on both the client and server side. Determine whether to use Group Policy, the IP Security Policy Management snap-in, executable files, or some combination to deploy this technology. If you are going to secure a server, make sure to enable client-side IPSec policy first, allow time for all clients to retrieve the policy, then enable the server-side policy. When configuring the **Negotiate security** filter action, select the **Allow unsecured communication with non-IPSec aware computers** check box, so that IKE can fall back to unsecured communication if a remote computer has not yet retrieved IPSec policy.

5. Ensure that IPSec authentication methods are ready before rolling out IPSec policy. All certificate autoenrollment problems must be investigated and resolved before assigning IPSec policy. Any cross-certificate trusts must be established and deployed to all systems first. Likewise, if Kerberos is being used, ensure that all domain trusts between clients and servers are mutually trusted and that Kerberos traffic is permitted. After IPSec policy is applied, if IKE authentication fails, communication will be blocked. For more information about certificate autoenrollment, see "Designing a Public Key Infrastructure" in *Designing and Deploying Directory and Security Services* of this kit.

# Additional Resources for Deploying IPSec

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information related to this chapter.

# Deploying Internet Authentication Service (IAS)

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Servers running the Internet Authentication Service (IAS) component of the Microsoft® Windows® Server 2003 operating system perform centralized authentication, authorization, auditing, and accounting for many types of network access, including dial-up, virtual private network (VPN), wireless, and 802.1X authenticating switch access. IAS is the Microsoft implementation of the Remote Authentication Dial-In User Service (RADIUS) protocol. A number of design, implementation, and deployment issues must be considered when rolling out a scalable and robust IAS solution.

Information about deploying remote access clients can be found in other chapters in this book.

# Overview of IAS Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use IAS to provide authentication and authorization for dial-up, VPN, wireless, and authenticating switch access to your network. For example, organizations that outsource network access and perform joint ventures with other organizations require the authentication of user accounts from outside of the private network. In addition, organizations that provide outsourcing services, such as Internet service providers (ISPs), require remote user connection accounting so that they can charge subscribers.

Windows Server 2003 IAS enables you to centralize authorization, authentication, and accounting for remote access clients, enhancing the security of your network. Windows Server 2003 IAS works with other standards-based implementations of the Remote Authentication Dial-In User Service (RADIUS) protocol, so that you can use it with any standards-compliant RADIUS client, server, or proxy server.

Windows Server 2003 IAS is included in Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; and Windows® Server 2003, Datacenter Edition. IAS is not provided with Microsoft® Windows® Server 2003, Web Edition. In addition, Windows Server 2003, Standard Edition, limits some IAS features. For more information, see "Concepts for IAS" later in this chapter.

Windows Server 2003 IAS provides the following solutions for organizations that require secure network access:

- Compatibility with RADIUS servers and clients from any vendor that meets the specifications outlined in RFCs 2865, 2866, and 2869.
- Integration with the Active Directory® directory service. IAS allows you to take advantage of Active Directory for user authentication, authorization, and client configuration, thus reducing management costs.
- Use of standards-based strong authentication methods for network access.
- Management of network access that is outsourced to an ISP. IAS allows you to create an agreement between your organization and the ISP in which the ISP can charge a roaming user's department for that employee's network usage. In this way, each employee does not need to submit an expense statement or create a roaming account to connect to the corporate network remotely.
- Dynamic key management for wireless access points as a means to increase network security.

# IAS Deployment Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The process of deploying IAS involves deciding what role IAS will play in your network infrastructure, configuring connection request and remote access policies to allow users to access the network, and securing and optimizing the design. Figure 7.1 shows the IAS deployment process.

**Figure 7.1 Deploying IAS**

# Concepts for IAS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

IAS implements the Internet Engineering Task Force (IETF) standard Remote Authentication Dial-In User Service (RADIUS) protocol, specified in RFCs 2865, 2866, and 2869, which enables the use of a homogeneous or heterogeneous network of dial-up, VPN, wireless, or authenticating switch equipment. When a remote client tries to connect to an access server configured to use the RADIUS protocol, the access server sends the connection request to the IAS server by using the RADIUS protocol. When an IAS server is a member of an Active Directory® domain, IAS uses the directory service as its user account database and is part of a single sign-on solution. The same set of credentials is used for network access control (authenticating and authorizing access to a network) and to log on to an Active Directory domain.

In addition, the IAS server can accept or reject the request based on conditions that you specify in the remote access policies. *Remote access policies* are an ordered set of rules that define how connections are either authorized or rejected. For each rule, there are one or more conditions, a set of profile settings, and a remote access permission setting. Access to the network resources can be controlled by applying policies to users or groups of users. For more information about using remote access policies to grant access, see "Remote Access Policies" in Help and Support Center for Windows Server 2003.

When using IAS in Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition, you can configure an unlimited number of RADIUS clients and remote RADIUS server groups. In addition, you can configure RADIUS clients by specifying an IP address range. However, when using Windows Server 2003, Standard Edition, you can configure IAS with a maximum of 50 RADIUS clients and a maximum of two remote RADIUS server groups. You can define a RADIUS client using a fully qualified domain name or an IP address, but you cannot define groups of RADIUS clients by specifying an IP address range. If the fully qualified domain name of a RADIUS client resolves to multiple IP addresses, the IAS server uses the first IP address returned in the DNS query.

RADIUS is a client/server protocol that requires a RADIUS client and a RADIUS server to provide network access. An access server or a RADIUS proxy is a *RADIUS client*, and the computer making the determination of authentication and authorization is a *RADIUS server*.

Figure 7.2 shows a typical IAS architecture. An access client contacts an IAS RADIUS proxy located at an ISP by using a local telephone connection. The IAS proxy examines the user name, which contains two elements – the identification of the user account name and the identification of the user account location (also known as a *realm*). Based on the realm portion of the user name in the connection request, the IAS RADIUS proxy forwards the connection request to a RADIUS server on a private network, which authenticates and authorizes the connection attempt with the Active Directory user accounts database and user account properties.

**Figure 7.2 IAS Architecture**

For more information about Internet Authentication Service (IAS), see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit) and "Internet Authentication Service" in Help and Support Center for Windows Server 2003.

For more information about realm names, see "Realm names" in Help and Support Center for Windows Server 2003.

A general understanding of the following topics is also essential to proper IAS deployment:

- Remote access.
- The Windows Server 2003 implementation of remote access.
- Any network access mechanism your users require, such as dial-up, VPN, wireless, or authenticating switch access.
- Network security.

- Active Directory.
- Authentication.
- Accounting.

For more information about any of these topics, see the Windows Server 2003 Technical Reference and Help and Support Center for Windows Server 2003.

**New in Windows Server 2003**
Windows Server 2003 IAS includes the following new features:

- **Support for RADIUS proxy**. With RADIUS proxy support, you can use IAS as a RADIUS message router or forwarder between access servers and other IAS servers. Based on attributes in the incoming RADIUS message, the RADIUS proxy forwards the message to a specific RADIUS server or client.
- **Support for mapping network authentication and authorization for IAS proxy**. The proxy component of IAS supports the ability to separate the authentication and authorization of connection requests from access servers. The IAS proxy can forward password-based user credentials to an external RADIUS server for authentication, and perform authorization against a user account in an Active Directory domain and a locally configured remote access policy. Alternate user authentication databases can be used but connection authorization and restrictions are still determined through local administration. You can configure the proxy component with the **Remote-RADIUS-to-Windows-User-Mapping** attribute in the advanced properties of a connection request policy. For more information, see "Mapping network authentication and authorization" and "Connection request policies" in Help and Support Center for Windows Server 2003.
- **Support for IEEE 802.1X wireless and authenticating switches**. IAS provides authentication, authorization, and accounting for connections that use the link-layer standard IEEE 802.1X for wireless and authenticating switch access. For more information about configuring IAS for wireless access authentication, see "Checklists: Configuring IAS for Wireless Access" and "Wireless access" in Help and Support Center for Windows Server 2003.
- **Support for Protected Extensible Authentication Protocol (PEAP) for 802.11 wireless clients**. Protected Extensible Authentication Protocol (PEAP) provides protection for clients and authenticators (IAS or RADIUS servers) that are using Extensible Authentication Protocol (EAP). The next generation of EAP, PEAP uses Transport Layer Security (TLS) to create end-to-end communication between client and authenticator after the identity of the authenticator is verified. For more information, see "PEAP" in Help and Support Center for Windows Server 2003.
- **Enhanced EAP configuration for remote access policies**. In Microsoft® Windows® 2000 Server, you can select only a single EAP type for a remote access policy. In Windows Server 2003 IAS, this limitation is removed. For example, you can select different computer certificates for VPN connections and EAP-TLS authentication for wireless connections, or you can select multiple EAP types for wireless connections in the circumstance where some of your wireless clients use EAP-TLS authentication and some of them use PEAP with Microsoft Challenge Handshake Authentication Protocol version 2 (EAP-MS-CHAPv2). For more information, see "EAP" and "Configure PEAP and EAP methods" in Help and Support Center for Windows Server 2003.
- **Support for IAS Network Access Quarantine Control**. IAS Network Access Quarantine Control provides phased network access, which restricts the access of remote clients to quarantine mode until each client is either verified as meeting or configured according to organization network access policy. After the client computer configuration is verified as meeting organization network policy, the quarantine restrictions, which consist of Quarantine IP-Filters and Session Timers, are removed and standard remote access policy is applied to the connection. For more information, see "IAS Network Access Quarantine Control" in Help and Support Center for Windows Server 2003.
- **Support for logging to MSDE 2000 and SQL Server 2000 databases**. You can use an XML-compliant database, such as Microsoft® SQL Server™ 2000 and SQL Server Desktop Engine (MSDE 2000), to log user authentication requests, periodic data, and accounting requests received from one or more access servers. For more information, see "SQL Server database logging" in Help and Support Center for Windows Server 2003.
- **Support for ignoring the dial-in properties of user accounts**. You can configure a RADIUS attribute on the profile

properties of a remote access policy to ignore the dial-in properties of user accounts. To support multiple types of connections for which IAS provides authentication and authorization, it might be necessary to disable the processing of user account dial-in properties. This can be done to support scenarios in which specific dial-in properties are not required. For more information, see "New features for IAS" in Help and Support Center for Windows Server 2003.

- **Support for configuring RADIUS clients by IP address range**. For IAS in Windows 2000, you must specify a RADIUS client by IP address or by Domain Name System (DNS) name. In addition, you must configure each RADIUS client separately, even if you have a number of RADIUS clients on the same subnet. While this is not an issue for typical dial-in or VPN access server configurations, numerous wireless access points can be placed on the same subnet, creating a circumstance where use of an IP address range simplifies configuration and administration. In Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition, IAS allows you to specify a RADIUS client by using an IP address range. All of the RADIUS clients in the range must use the same configuration and shared secret. For more information, see "Configure RADIUS Clients" in Help and Support Center for Windows Server 2003.

- **Support for computer authentication**. In Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition, Active Directory and IAS support the authentication of computer accounts by using standard user authentication methods such as Point-to-Point Protocol (PPP). This allows a computer and its computer certificate to be authenticated for wireless or authenticating switch access clients.

- **Support for checking user certificate purposes**. To enforce the use of specific types of user certificates for specific connection types, you can configure IAS to check the purposes (also known as *object identifiers* or*OIDs*) of certificates in their Enhanced Key Usage (EKU) extensions. You can configure a list of object identifiers that are required to be present in the user certificate. For more information, see "Network access authentication and certificates" and "Add RADIUS attributes to a remote access policy" in Help and Support Center for Windows Server 2003.

- **Improved attribute manipulation**. In Windows 2000, you can use IAS to manipulate the contents of the User-Name RADIUS attribute. Using connection request policies in IAS for Windows Server 2003, you can manipulate the User-Name, Called-Station-ID, and Calling-Station-ID RADIUS attributes. For more information, see "Connection request policies" in Help and Support Center for Windows Server 2003.

- **Support for the Authentication Type remote access policy condition**. You can create remote access policies by using the Authentication Type condition in IAS for Windows Server 2003. You can use the Authentication Type condition to specify connection constraints that are based on the authentication protocol or method that is used by the access client. For more information, see "Elements of a remote access policy" in Help and Support Center for Windows Server 2003.

- **Improved support for the Class attribute**. In Windows 2000, IAS automatically generates a value for the Class attribute and appends it to the existing value of the Class attribute received in the RADIUS request message. The result is the Class attribute in the RADIUS response message. In Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition, you can disable the automatic generation of a value for the Class attribute by using the **Generate-Class-Attribute** setting on the **Advanced** tab in the properties of a remote access policy profile. Automatic generation of a value for the Class attribute is disabled by default. Instead of appending the generated value of the Class attribute to the existing Class attribute, IAS creates a separate Class attribute. The RADIUS response message contains both the original Class attribute and the second Class attribute that is generated by IAS. For more information, see "Add RADIUS attributes to a remote access policy" in Help and Support Center for Windows Server 2003.

#### IAS Terms and Definitions

This section provides brief definitions of important IAS terms. For more information, see the sources mentioned in "Additional Resources for Remote Access" later in this chapter, or Help and Support Center for Windows Server 2003.

**Internet Authentication Service (IAS)** A component of Windows Server 2003 that performs centralized authentication, authorization, auditing, and accounting for a variety of different types of network access, including dial-up, VPN, wireless, and authenticating switch access.

**Remote Authentication Dial-In User Service (RADIUS) protocol** A protocol, specified in RFCs 2138 and 2139, that enables use of a homogeneous or heterogeneous network of dial-up or VPN equipment.

**RADIUS server** A server that implements the RADIUS protocol. A RADIUS server performs authentication, authorization, and

accounting on behalf of a RADIUS client.

**RADIUS client** A network access server that uses a RADIUS server to perform authentication, authorization, and accounting for its access clients.

**RADIUS proxy** A server that forwards incoming RADIUS messages to specific RADIUS servers for additional processing, based on RADIUS attributes in the incoming RADIUS message. An IAS server can act as a RADIUS server for some requests and a RADIUS proxy for others.

**Authentication** The process of performing identity verification of the entities that communicate over a network; for example, the process that verifies the identity of a user who logs on to a computer either locally, at a computer's keyboard, or remotely, by means of a network connection.

**Authorization** The process that determines what a user is permitted to do on a computer system or network. For remote access or demand-dial routing connections, the verification that the connection attempt is allowed. Authorization occurs after successful authentication. With IAS, you can manage authorization using remote access policies and Active Directory user account properties.

**Auditing** The process that tracks the activities of users by recording selected types of events in the security log of a computer.

**Accounting** A method of tracking account activity information such as logon and logoff records, to help maintain records for billing purposes. With IAS, you can also track authentication information, such as each accept, reject, and automatic account lockout.

# Designing IAS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After taking an inventory of your network environment, the first step in designing an IAS solution is to determine the role of the IAS server. For example, determine whether you need the IAS server to authenticate the connection request that it receives, forward the request to another IAS server for authentication, or perform a mixture of both functions depending on context. Finally, an important step in the design process is to configure IAS to work with different types of clients.

Figure 7.3 shows the process for designing IAS.

**Figure 7.3 Designing IAS**

# Inventory Your Current Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When beginning your design process, make sure to have specifications about your current network environment available for use. Specifically, your hardware and software inventory and a map of network topology can be very helpful in reducing time spent during the design phase. For more information about creating those documents, see "Planning for Deployment" in *Planning, Testing, and Piloting Deployment Projects* of this kit.

# Determine the Role of the IAS Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can configure your IAS server to act as a RADIUS server, a RADIUS proxy, or both, depending on where you want network access requests to be authenticated.

**RADIUS server**
If you want your IAS server to authenticate the connection requests that it receives, rather than forwarding connection requests to another IAS server, use the IAS server as a RADIUS server. For example, if your access servers connect directly to your network, then the IAS server is configured as a RADIUS server to authenticate the connection.

Figure 7.4 shows an IAS server configured as a RADIUS server. An access client connects to an access server. The access server sends a connection request to an IAS RADIUS server located on the corporate network, which authenticates and authorizes the connection attempt.

**Figure 7.4 IAS Configured as a RADIUS Server**

**RADIUS proxy**
If you want an IAS server to forward connection requests to another IAS server, use IAS as a RADIUS proxy. Use the RADIUS proxy capabilities in the following situations.

**Using IAS proxy at a third-party ISP**
You are an ISP providing outsourced network connection services to multiple customers. Your network access servers send connection requests to the IAS RADIUS proxy. Based on the realm portion of the user name in the connection request, the IAS RADIUS proxy forwards the connection request to a RADIUS server maintained by the customer that can authenticate and authorize the connection attempt.

Figure 7.5 shows an IAS server configured as a RADIUS proxy. An access client contacts an access server at an ISP. The ISP access server sends a connection request to an IAS RADIUS proxy. Based on the realm portion of the user name in the connection request, the IAS RADIUS proxy forwards the connection request to a RADIUS server located on the corporate network, which authenticates and authorizes the connection attempt.

**Figure 7.5 IAS Configured as a RADIUS Proxy at a Third-Party ISP**

**Using IAS proxy with multiple forests**
You have multiple forests and want to perform cross-forest authentication with Extensible Authentication Protocol-Transport Layer Security (EAP-TLS). Rather than configuring your access servers to send their connection requests to an IAS RADIUS server, configure them to send their connection requests to an IAS RADIUS proxy.

Figure 7.6 shows an IAS server configured as a RADIUS proxy forwarding RADIUS messages to RADIUS servers in multiple forests. The IAS RADIUS proxy uses the domain name portion of the user name and forwards the request to an IAS server in each forest.

**Figure 7.6 IAS as a RADIUS Proxy with Multiple Forests**

**Using IAS proxy for load balancing**

You want to increase the capacity for connection requests. In this case, rather than configure your access servers to attempt to load balance across multiple RADIUS servers, configure them to send their connection requests to an IAS RADIUS proxy. The IAS RADIUS proxy can load balance across multiple RADIUS servers and scale up to large numbers of RADIUS clients and authentications per second.

Figure 7.7 shows an access server forwarding a request to a RADIUS proxy to load balance to multiple RADIUS servers. The remote client connects to a RADIUS client, such as an access server. The access server sends the authentication request to the RADIUS proxy, which load balances the request across different IAS servers.

**Figure 7.7 Load Balancing**

**IAS server and proxy**

If you need your IAS server to authenticate some requests and forward other requests, use IAS as both a RADIUS server and a RADIUS proxy. For example, if you are performing cross-forest authentication, use your IAS server as a RADIUS server to authenticate users in the same forest, and use it as a RADIUS proxy to forward authentication requests to another IAS server for users in another forest.

Figure 7.8 shows an IAS server configured to be both a RADIUS server and a RADIUS proxy. The remote client connects to an IAS server configured as both a RADIUS server and a RADIUS proxy. Based on the realm portion of the access client user name, the IAS server determines whether to authenticate the request directly or forward the authentication request on to another IAS server in a different forest.

**Figure 7.8 IAS Configured as Both a RADIUS Server and a RADIUS Proxy**

# Design IAS as a RADIUS Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Designing IAS as a RADIUS server involves some or all of the following tasks:

- Determining the IAS server domain membership
- Planning for RADIUS clients
- Planning authentication
- Determining compatibility with third-party access servers
- Adding RADIUS or vendor-specific attributes (VSAs) to the remote access policy
- Installing a backup IAS server

For more information about configuring IAS as a RADIUS server, see "Deploy IAS as a RADIUS Server" later in this chapter and "IAS as a RADIUS server" in Help and Support Center for Windows Server 2003.

**Determine IAS Server Domain Membership**

You must determine which domain the IAS server computer will belong to. In multiple-domain environments, an IAS server can authenticate user credentials for user accounts in the domain in which it is a member and for user accounts in all domains that have a two-way trust relationship with the domain in which it is a member. For increased performance, install IAS on the domain controllers in the domain that will authenticate the users. If you install IAS on a domain controller, you do not have to add the domain controller computer account to the RAS and IAS Servers group of the domain.

For more information about configuring IAS servers, see "Implementing Your IAS Solution" later in this chapter.

**Plan for RADIUS Clients**

A RADIUS client can be an access server (for example, a dial-up or VPN server, a wireless access point, or an Ethernet authenticating switch) or a RADIUS proxy. IAS supports all access servers and RADIUS proxies that comply with RFC 2865, *Remote Authentication Dial-in User Service (RADIUS)*.

Configure each access server or RADIUS proxy that sends RADIUS request messages to the IAS server as a RADIUS client. For each RADIUS client, you can configure a friendly name, an IP address or DNS name, the client vendor, the shared secret, and whether the RADIUS **Message-Authenticator** attribute is used.

You can specify IP addresses or DNS names for RADIUS clients. In most cases, it is better to specify RADIUS clients with IP addresses. When you use IP addresses, IAS is not required to resolve host names at startup and starts more quickly as a result. This is especially beneficial if your network contains a large number of RADIUS clients. You can use DNS names to specify RADIUS clients when you require something other than administrative flexibility (for example, the ability to map multiple RADIUS client IP addresses to a single DNS name).

If you are using Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition, you can specify a RADIUS client by using an IP address range. All of the RADIUS clients in the range must use the same configuration and shared secret. This configuration is useful, for example, if you place many wireless access points on the same subnet.

The address range for RADIUS clients is expressed in the network prefix length notation *w.x.y.z/p*, where *w.x.y.z* is the dotted decimal notation of the address prefix and *p* is the prefix length (the number of high order bits that define the network prefix). This is also known as *Classless Inter-Domain Routing (CIDR) notation*. An example is 192.168.21.0/24. For more information, see "Configure RADIUS Clients" in Help and Support Center for Windows Server 2003.

**Plan Authentication**

When designing network authentication solutions, protecting the authentication channel can prevent potential security attacks.

Most password-based authentication methods, such as CHAP and MS-CHAP, do not provide privacy-protected channels to guard against offline dictionary attacks by hackers that intercept authentication traffic on the network. Because of this, ensure that password-based authentication methods are always deployed with protection from IPSec or PEAP.

**EAP-TLS**
Certificate-based authentication methods are much more secure than password-based authentication methods. Use certificate-based authentication methods, such as PEAP and EAP, in all possible circumstances because they protect the authentication channel and provide strong security. EAP-TLS is designed, in part, to protect against spoofing or other attacks and can be deployed without protection from IPSec or PEAP. EAP-TLS requires a public key infrastructure (PKI) and is an authentication method that can be used with all connection types supported by IAS (wireless, authenticating switch, VPN, and dial-up).

By using Group Policy in Windows Server 2003, you can easily distribute certificates to clients and servers with auto-enrollment. For the maximum strength user credentials, deploy EAP-TLS with a smart cards. Smart cards provide maximum strength with two-factor authentication. Certificates installed in the computer certificate store (without smart cards) offer single-factor authentication.

**PEAP**
PEAP uses Secure Sockets Layer (SSL) technology to privacy-protect authentication communications, and to key the encryption of link layer network connections. You can deploy PEAP with either EAP-MS-CHAPv2 or EAP-TLS as the authentication type. PEAP-EAP-MS-CHAPv2 is a secure password authentication method recommended for wireless deployments. However, PEAP is not available for VPN or dial-up connections.

PEAP provides protection for the EAP method negotiation that occurs between client and server through a TLS channel. This helps prevent an attacker from injecting packets between the client and the access server to cause the negotiation of a less secure EAP method.

Clients using PEAP as the authentication method have the ability to authenticate the IAS or RADIUS server. Because the server also authenticates the client, mutual authentication occurs.

PEAP fast reconnect, which reduces the delay in time between an authentication request by a client and the response by the IAS or RADIUS server, allows wireless clients to move between wireless access points without repeated requests for authentication. This reduces resource requirements for both client and server, and allows users to move between access points without reentering credentials.

If you deploy PEAP, do not deploy the same authentication type both inside of the PEAP Transport Layer Security (TLS) channel and outside of the PEAP TLS channel. For example, do not deploy both PEAP-EAP-TLS and EAP-TLS on the same network. You can deploy different authentication types inside and outside the TLS channel. For example, you can deploy PEAP-EAP-MS-CHAPv2 and EAP-TLS on the same network.

**Authentication and PPP and PPTP Connections**
For dial-up Point-to-Point Protocol (PPP) or Point-to-Point Tunneling Protocol (PPTP) VPN connections, it is recommended that you use EAP-TLS with smart cards or certificates as the authentication method.

For L2TP/IPSec VPN connections, you can use MS-CHAPv2 as the authentication method. Internet Protocol security (IPSec) uses computer certificates to establish a secure channel before authentication proceeds, providing the necessary protection for authentication and other communication.

When planning authentication:

- For wireless connections, you can configure all the connection properties on the client (including authentication methods) using Windows Server 2003 Group Policy. For example, you can configure wireless connections to specific networks to require use of EAP-TLS.

- You can use Connection Manager Administration Kit (CMAK) to create a Connection Manager profile for installation on client computers. With Connection Manager, you can manage the client connection properties (including authentication methods) used for access to your network.

- Configure remote access policies at the IAS server to only allow the authentication methods you want to allow per connection type, such as dial-up or VPN. .

For more information, see "Authentication methods" and "Public Key Infrastructure" in Help and Support Center for Windows Server 2003.

**Add RADIUS or VSA Attributes to Remote Access Policy**
If you plan to return additional RADIUS attributes or VSAs with the responses to RADIUS requests, you must add the RADIUS attributes or VSAs to the appropriate remote access policy.

**Install Backup IAS Servers**

To provide fault tolerance for RADIUS-based authentication and accounting, you must always use at least two IAS servers working together in the same location. One IAS server is used as the primary RADIUS server, and the other is used as a backup. RADIUS proxies are configured to use both IAS servers. When the primary IAS server becomes unavailable, the RADIUS proxies automatically use the backup IAS server instead.

# Design IAS as a RADIUS Proxy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Designing IAS as a RADIUS proxy involves some or all of the following tasks:

- Planning the connection request policy
- Adding RADIUS and VSA attributes
- Planning for load balancing and failure detection
- Installing backup IAS proxies

For more information about configuring IAS as a RADIUS proxy, see "Deploy IAS as a RADIUS Proxy" later in this chapter and "Deploy IAS as a RADIUS Proxy" in Help and Support Center for Windows Server 2003.

**Plan the connection request policy**
The default connection request policy **Use Windows authentication for all users** is configured for IAS when it is used as a RADIUS server. To create a connection request policy to use IAS as a RADIUS proxy, complete the following steps:

1. Create a remote RADIUS server group on the domain that will authenticate the users.
2. Create a connection request policy that forwards authentication requests to the remote RADIUS server group.
3. Either delete the default connection request policy, or set the new connection request policy first in the order before the default connection request policy so that it is evaluated first.

**Add RADIUS attributes and VSAs**
If you plan to return additional RADIUS attributes and VSAs with RADIUS requests, you must add the RADIUS attributes and VSAs to the appropriate connection request policy.

**Plan for load balancing and failure detection**
When you configure multiple servers in a remote RADIUS server group, you can configure settings that determine how the IAS proxy server balances the load of authentication and accounting requests over the RADIUS servers in the group. You can use additional settings to configure IAS to detect and recover from the failure of a remote RADIUS server group member.

For more information about load balancing for remote RADIUS server group members, see "Configure the load balancing properties of a group member" in Help and Support Center for Windows Server 2003.

**Install backup RADIUS proxies**
To provide fault tolerance for RADIUS-based authentication and accounting, you must always use at least two IAS proxy servers. One IAS server is used as the primary RADIUS proxy, and the other is used as a backup. RADIUS clients (access servers or other RADIUS proxies) are configured on both IAS proxy servers. In addition, configure both the primary and backup IAS proxy servers on each RADIUS client. When the primary IAS proxy becomes unavailable, the access servers automatically use the backup RADIUS server instead.

For more information about synchronizing the configuration of multiple IAS servers, see "Managing multiple IAS servers" in Help and Support Center for Windows Server 2003.

# Designing Support for Client Access

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you have designed your IAS infrastructure and determined what role IAS will play in your network, you must consider what types of network and remote access clients you will need to support. For each type, your IAS server configuration will differ, and you will need to make different planning decisions.

Windows Server 2003 IAS supports the following forms of network access:

- Dial-up remote
- VPN
- Wireless
- Authenticating switch

**Note**

- You can use the Routing and Remote Access service included with Windows Server 2003 or the Microsoft® Windows® 2000 operating system to provide network access. However, you can also use third-party network access servers with Windows Server 2003 IAS. To ensure that the third-party access server works with Windows Server 2003 IAS, check with the manufacturer to confirm that the product supports RFCs 2865, 2866, and 2869.

# Designing Support for Dial-up Access

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 has extensive support for remote access technology to connect dial-up and other types of remote clients to corporate networks or to the Internet. For information about how to plan, design, and implement Windows Server 2003 components (such as Routing and Remote Access Service and Connection Manager) in an enterprise environment, see "Deploying Remote Access Clients Using Connection Manager" in this book.

IAS supports both voluntary and compulsory tunneling. Table 7.1 describes the differences between both types of tunneling and when you might use each type.

**Table 7.1 Comparison of Voluntary and Compulsory Tunneling**

| Tunnel Type | When to Use It | Which IAS Components to Use |
|---|---|---|
| Voluntary tunneling | Use this option if your clients need to choose their tunneling location themselves.<br><br>For example, the user dials in to an ISP. At the client's request, the ISP creates a tunnel to the corporation. The user can alternatively request a tunnel to somewhere else, such as the Internet. | The ISP uses IAS as a RADIUS proxy to forward the request to the corporate IAS server.<br><br>The corporation uses IAS as a RADIUS server to authorize and authenticate the request.<br><br>Either the ISP or the corporation can use a third-party RADIUS server. |
| Compulsory tunneling | Use this option if you want to use one tunnel for many clients.<br><br>For example, if a corporation has clients in geographically dispersed locations, it can contract with an ISP to deploy regional tunnel servers. Any client can dial in to any of the tunnel servers, which then creates a compulsory tunnel to the corporation. Compulsory tunneling is typically used for dial-up clients, but can also be used for VPN clients. | The ISP uses IAS as a RADIUS server to authorize the request.<br><br>The corporation uses IAS as a RADIUS server to authorize and authenticate the request.<br><br>Either the ISP or the corporation can use a third-party RADIUS server. |

**Voluntary Tunneling**

In voluntary tunneling, during the authorization phase, the corporate IAS server restricts the client connection to use a specificVPN protocol (PPTP or L2TP/IPSec) if an administrator has configured remote access policies to restrict connections to those using the specified protocol. The designated protocol must be installed on the client or the connection attempt is rejected. After the access request is authenticated and authorized, the client establishes a VPN tunnel to the corporate access server.

A user or client computer can issue a VPN request to configure and create a voluntary tunnel. In this case, the user's computer is a tunnel endpoint that acts as the tunnel client. Voluntary tunneling occurs when a workstation or router uses tunneling client software to create a VPN connection to the target tunnel server. In order to accomplish this, the appropriate tunneling protocol must be installed on the client computer. In a dial-up situation, which is the most common use, the client must establish a dial-up connection to the internetwork before the client can set up a tunnel. A good example of this is the dial-up

Internet user, who must dial an ISP and obtain an Internet connection before a tunnel over the Internet is created.

Voluntary tunneling is not different from other types of network access, and IAS can be used for authentication, authorization, and accounting.

**Compulsory Tunneling**

Compulsory tunneling is the creation of a secure tunnel by another computer or network device on the client computer's behalf. Compulsory tunnels are configured and created automatically for users without their knowledge or intervention. With a compulsory tunnel, the user's computer is not a tunnel endpoint. Another device between the user's computer and the tunnel server is the tunnel endpoint, which acts as the tunnel client.

The computer or network device that provides the tunnel for the client computer is known as a front-end processor (FEP) in PPTP, an L2TP access concentrator (LAC) in L2TP, or an IP security gateway in IPSec. The term *FEP* is used to describe tunnel creation functionality, regardless of the protocol used. To perform its function, the FEP must have the appropriate tunneling protocol installed and must be capable of establishing the tunnel when the client computer attempts a connection. In Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; and Windows 2000, the Routing and Remote Access service cannot be used as a FEP.

An organization can contract with an ISP to deploy a nationwide set of FEPs. These FEPs can establish tunnels across the Internet to a VPN server that is connected to the organization private network, thereby consolidating calls from geographically diverse locations into a single Internet connection at the organization network.

There are two types of compulsory tunneling. In the first type, the tunnel is created before the access client is authenticated. Based on the realm name or the caller ID of the access client, the FEP sends an Access-Request message to an IAS server. The IAS server sends back an immediate Access-Accept message with RADIUS attributes for the tunnel creation without performing authentication and authorization. After the tunnel is created, the access client authenticates against the tunnel server.

In the second type of compulsory tunneling, the tunnel is created after the access client is authenticated by the FEP. In this case, the FEP sends the Access-Request message with the client credentials to an IAS server. The IAS server authenticates and authorizes the connection attempt and returns RADIUS attributes in the Access-Accept message, which specify to the NAS how to initiate a tunnel to a VPN server. The tunnel endpoint (the VPN server at which the tunnel is terminated), can be changed on the basis of conditions in a remote access policy. For example, the tunnel endpoint can be changed on the basis of the user name or the user account group membership. Controlling compulsory tunnels with remote access policies provides more flexibility than static tunneling (which requires a dedicated access server) or realm-based tunneling (which requires all users in a specific realm to use the same tunnel settings).

For more information, see "IAS and tunnels" in Help and Support Center for Windows Server 2003.

# Designing Support for VPN Access

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Depending on the credentials of the authenticating user, you can configure IAS to direct the traffic from a VPN client through a tunnel to specific parts of the enterprise network. Both voluntary and compulsory tunneling can be used for outsourced VPN access.

**Special Considerations for VPN Access**
Consider the following access server compatibility issues:

- IAS can provide compulsory tunneling connection attributes for network access servers (NASs) that support compulsory tunneling. However, the Windows Server 2003 Routing and Remote Access service does not support compulsory tunneling.

- VPN servers running the Microsoft® Windows NT® version 4.0 operating system must also be running Routing and Remote Access Service (RRAS) if you want to configure them as RADIUS clients.

For more information about Internet Authentication Service, including the authorization and authentication process used in voluntary and compulsory tunneling, see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

For information about the RADIUS attributes used with compulsory tunneling, see "Compulsory tunnels" in Help and Support Center for Windows Server 2003.

# Designing Support for Wireless Access

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Wireless networking technology is becoming more widespread with the adoption of industry standards such as IEEE 802.11 and 802.11b. Wireless networking allows a user to roam around a building or campus and automatically connect to the network after the user is in proximity to a wireless access point (wireless AP).

You can use IAS to support wireless access in the following scenarios:

- Wireless LAN access
- Outsourced wireless access

**Countering Wireless Security Risks**

While providing convenience, wireless networking technologies and wireless APs represent the following security risks:

- Anyone who has a compatible wireless network adapter can gain access to the network.
- Wireless networking signals use radio waves to send and receive information. Anyone within an appropriate distance to a wireless access point can detect and receive all data sent to and from the wireless access point.

IAS provides enhanced security for wireless access. To counter the first security risk, you can set up the wireless access point as a RADIUS client, and then configure it to send access requests and accounting messages to a central RADIUS server running IAS.

To counter the second security risk, you can encrypt the data sent between the wireless devices and the wireless access points. The authentication method used by the wireless client must be able to use encryption keys.

**Special Considerations for Wireless Access**

If you will be supporting wireless access, include the following elements in your design:

- An authentication mechanism. With wireless access, you can use Protected Extensible Authentication Protocol (PEAP), EAP-TLS, or unauthenticated wireless access. For more information about PEAP, see "PEAP" in Help and Support Center for Windows Server 2003.
- Certificates and a certification authority, if you are deploying authentication methods that use certificates on both the client and server, such as EAP-TLS. For more information, see "Integrate IAS with the Certificate Infrastructure" later in this chapter.
- The **Wireless-IEEE 802.11** and **Wireless-Other** port types for the **NAS-Port-Type** condition of remote access policies. By using these port types, you can create a separate remote access policy that contains connection parameters and encryption settings specifically designed for wireless devices.
- The **Ignore-User-Dialin-Properties** attribute in the profile settings of a remote access policy. The dial-in properties of the user account are designed for clients dialing into an access server, not for clients connecting to a wireless port or authenticating switch. You can disable them on the remote access policy. For more information about profile settings, see Dial-in properties of a user account in Help and Support Center for Windows Server 2003.

# Designing Support for Authenticating Switch Access

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A network switch filters the traffic received on each port of the switch and allows better traffic management by segmenting a network. A typical switch, however, sends and receives packets to any node that is connected to it. This can create a security risk, especially for switch ports in a conference room of an organization, which might be accessed by visitors or employees of partner organizations.

**Securing Authenticating Switch Access with IAS**

To prevent physical layer access to the network, use authenticating switches as RADIUS clients and use the industry-standard RADIUS protocol to send access requests and accounting messages to a central RADIUS server. The RADIUS server has access to a user account database and a set of rules for determining whether to grant authorization.

If you need to grant access to different types of users for different parts of your network, you can use authenticating switch access. For example, a corporate conference room has a virtual local area network (VLAN) for visitors. A visitor logging on without presenting credentials is granted access to the conference room VLAN. At the same time, an employee logging on with appropriate credentials is granted access to the entire corporate network. Thus, administrators can use IAS with authenticating switch access to secure parts of the network from malicious users and from inexperienced users who might inadvertently cause errors in network configuration. You can also use VLANS with IAS for wireless access configurations.

Because the data sent between the node and the authenticating switch physically travels on a dedicated wire, encryption of the data is not required or typically implemented.

**Special Considerations for Authenticating Switch Access**

If you will be supporting authenticating switch access, include the following elements in your design:

- An authentication mechanism. You can use EAP-TLS or secure password-based authentication by using PEAP-EAP-MS-CHAPv2. For more information, see "Select Authentication Protocols" later in this chapter.

- Certificates and a certification authority, if you are deploying authentication methods that use certificates on both the client and server, such as EAP-TLS. For more information, see "Integrate IAS with the Certificate Infrastructure" later in this chapter.

- The use of the **Ethernet** port type for the **NAS-Port-Type** condition of remote access policies. By using this port type, you can create a separate remote access policy that contains connection parameters specifically designed for nodes connecting to the network through an authenticating switch. For more information, see "Elements of a remote access policy" in Help and Support Center for Windows Server 2003.

- The **Ignore-User-Dialin-Properties** attribute in the profile settings of a remote access policy. The dial-in properties of the user account are designed for clients dialing into an access server, not for clients dialing into a wireless port or authenticating switch. You can disable them on the remote access policy. For more information, see "Dial-in properties of a user account" in Help and Support Center for Windows Server 2003.

# Designing an Optimized IAS Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Optimize your IAS design by planning how to scale your IAS servers, whether or not to add IAS servers, where to place your IAS servers, and other steps as illustrated in Figure 7.9.

**Figure 7.9 Designing an Optimized IAS Solution**

IAS RADIUS clients and servers require minimal management and administration. However, over time, changes in the number of access clients, changes in WAN technology, and other factors can reduce the performance of IAS.

You can optimize IAS performance by positioning your IAS servers strategically. Use the following guidelines when deciding where to position your IAS servers:

- Locate IAS servers in the same domain with the server that provides remote user account authentication.
- Locate IAS on a domain controller and store the user account database in Active Directory.

In addition, the following factors can negatively impact IAS performance:

- The current load of the domain controller.
- The resolution of user principal names, resulting in an additional remote procedure call (RPC) query against the computer that contains the global catalog.
- EAP-based authentication methods, involving multiple challenge-response exchanges.
- The type of hardware in use.
- Network latency between:
    - The IAS server and the domain controller.
    - The IAS server and the computer that contains the global catalog.

- The IAS server and the access server.

You can optimize the performance of an IAS solution by scaling IAS to meet increasing demands in your organization and by including more than one RADIUS client and server in your network design.

# Scale an IAS Server to Optimize Performance

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

IAS servers can accommodate a large volume of accounts and authentications per second. For this reason, they perform well in large organizations. A single IAS server can often meet the dial-up and VPN connection needs for an entire network. However, if you have more complex network access needs, you might need to scale even a single IAS server. For example, certificate-based authentication can generate a large volume of authentication traffic that is transmitted every time a client logs onto the network. If you use certificate-based authentication, you must scale IAS to meet all of your Internet authentication needs.

For more information about scaling IAS, see "Deploying IAS as a RADIUS Proxy" in Help and Support Center for Windows Server 2003.

# Add IAS Servers to Optimize Availability

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is important to prevent an IAS server from becoming a single point of failure.

To prevent an IAS server from becoming a single point of failure, deploy IAS servers either in pairs (a primary and a backup IAS server) to provide fault tolerance, or in multiples, to balance the load of a large volume of authentication and accounting requests. Add at least two additional IAS servers per forest.

The level of availability that you need to provide depends on the following:

- How likely it is that a network link will fail
- How important it is to provide uninterrupted authentication to your clients at all times

Balance your need for availability against your need to minimize the costs of the hardware investment. Keep in mind that you can add IAS to existing domain controllers.

When you deploy more than one IAS server, make sure to design your IAS servers to use RADIUS proxies for load balancing and synchronization of the server configurations.

# Use Load Balancing with Multiple IAS Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you add multiple IAS servers for performance reasons, you must load balance the servers. You can load balance and provide failover at each access server by configuring the access server to send queries to multiple RADIUS servers in a specified order of importance. You can also load balance by using IAS as a RADIUS proxy server that forwards connection requests to IAS servers in groups called remote RADIUS server groups. These configurations are useful for the following:

- Organizations that use EAP-TLS for authentication, which increases the load on RADIUS proxies and servers. For example, ISPs and corporations that want to provide wireless or authenticating switch access often use EAP-TLS.
- Organizations that need to sustain continuous service availability.
- ISPs that outsource VPN access for other organizations. The outsourced VPN services can generate a large volume of authentication traffic.

You can use RADIUS proxies to balance the load of a large volume of authentication traffic. Without RADIUS proxies, each network access server balances its RADIUS requests across multiple RADIUS servers and detects unavailable RADIUS servers.

When RADIUS proxies are in place, the load of authentication, authorization, and accounting traffic is distributed across all of the IAS servers in the organization. Additionally, there is a consistent scheme for failure detection and RADIUS server failover.

# Duplicate IAS Server Configurations

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you deploy more than one IAS server to provide the same authentication, authorization, and accounting service to RADIUS clients and proxies, you must copy the configuration of one IAS server computer to the other IAS servers. To duplicate the configuration of one IAS server to multiple IAS servers, use the IAS snap-in. This duplication method is useful when the number of configuration changes is small or if you are duplicating the configuration to only a few IAS servers. You can use the snap-in to manage both local and remote IAS servers. If you make a configuration change to one IAS server, you must make the same configuration change to all of the IAS servers that provide the same service.

To duplicate one IAS server configuration when there are a large number of configuration changes or a larger number of IAS servers, you can copy the configuration of one IAS server to another IAS server in the following way:

- Make configuration changes on the primary IAS server.

- On the primary IAS server, use the **netsh aaaa dump** command to export the configuration of one IAS server to a Netsh script file. The **dump** command displays the configuration of the IAS database file (Ias.mdb) as a Netsh command script that you can use to duplicate the configuration of the server on which the command is executed. The Netsh command script contains the configuration of the IAS server, including the registry keys and database file (Ias.mdb), in a compressed text format as a large data block. This large data block is used by the **set config** command within the script to import the configuration of a saved data block into an existing IAS database on the same or another computer, which you can perform by using the **netsh exec** command. To save the Netsh command script to a file, type: **netsh aaaa show config >***Path\File.txt*

- On the target computers, use the **netsh exec** command to import the primary IAS server configuration to the other IAS servers.

By using these two Netsh commands, you can automate the process in a simple batch file or script for multiple IAS servers.

Use this method to manage RADIUS and remote access policy configurations in a large enterprise network.

The **netsh aaaa** commands also provide a way to export and import individual aspects of the IAS server configuration rather than the entire configuration. For example, you can export and import only the remote access policies, or you can export and import only the RADIUS clients configured on a server.

For more information, see "Netsh" and "Netsh commands for AAAA" in Help and Support Center for Windows Server 2003.

# Optimize RADIUS Client Performance

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Because RADIUS clients, such as VPN servers and dial-up access servers, manage access client connections, their performance directly affects access client performance. Providing highly available RADIUS clients ensures that access clients can reliably connect to the network and can always be authenticated by IAS.

You can optimize performance for access clients that are using all types of connections by doing any of the following:

- Upgrading the hardware of existing RADIUS clients. Choose this option if your hardware is outdated, and it is cost effective to upgrade it.
- Replacing existing RADIUS clients with higher-performance servers. Choose this option if you cannot upgrade the hardware of your existing resources.
- Adding RADIUS clients. Choose this option if your hardware is up-to-date, but you require more fault tolerance. Be sure to register redundant RADIUS clients with the IAS servers to ensure proper authentication and accounting.

You can optimize the performance of RADIUS clients that support dial-up connections by assigning remote access clients different primary and backup telephone numbers. This ensures that the remote access clients connect to different RADIUS clients. Choose this option if you require additional load balancing.

# Optimize Authentication and Accounting

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

RADIUS servers provide authentication and accounting for RADIUS clients, and interact with the authentication servers. As a result, RADIUS server performance and availability impacts authentication and accounting performance.

To optimize authentication in your network, ensure that all redundant IAS servers use the same user account database, thereby ensuring that the user accounts are available for authentication. Also, specify that RADIUS clients use the redundant IAS servers to ensure proper authentication and accounting.

In larger organizations with complex forest or domain topologies, use IAS as a RADIUS proxy to forward authentication requests to remote RADIUS server groups. You can also designate remote RADIUS server groups to process only accounting requests, freeing the servers performing authentication from handling accounting traffic.

- To optimize authentication and accounting performance in your IAS design, take the following actions:

    - Run IAS on the same computer as the domain controller. This speeds IAS access to the Active Directory user accounts database when IAS is performing user authentication and authorization.

    - Run IAS on the same computer that contains the global catalog. If it is not possible to run IAS on the same computer as the domain controller or the computer that contains the global catalog, verify that you have an efficient domain and site topology, and place the IAS server on the same subnet as a domain controller or global catalog server.

    - Reduce the number of user accounts in each domain by redesigning your domain topology.

    - Add IAS proxy servers to load balance authentication and accounting between servers in remote RADIUS server groups.

    - Upgrade the hardware resources of the existing IAS servers.

    - Replace existing IAS servers with higher performance servers.

    - Reduce the level of detail recorded in IAS accounting. IAS accounting can record user authentication requests, accounting requests, and periodic data. Make sure you are logging only the amount of information you need to troubleshoot network access.

    - If you configure IAS accounting for SQL Server logging, install SQL Server Desktop Engine (MSDE 2000) on the IAS server, and log to MSDE 2000 instead of directly to SQL Server 2000 running on another computer. This configuration assists in preventing logging failure due to network hardware failure or heavy network traffic. Use a custom application, service, or component to periodically publish the accounting logs from the MSDE 2000 database on each IAS server to the master SQL Server 2000 database.

    - For wireless deployments, use PEAP-EAP-MS-CHAPv2 with fast reconnect. PEAP uses cached TLS keys during re-authentication with access points configured as RADIUS clients of a single IAS server. Cached authentication is critical for wireless deployments because wireless clients authenticate each time they move to and associate with a new access point. In addition to improving performance, PEAP fast reconnect significantly reduces the latency of authentication and the public key operation overhead on both the client and the RADIUS server.

    - Use the **MaxConcurrentApi** registry entry (**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\ Parameters**) to increase the number of multiplexed connections to the domain controller.

**Caution**

- Do not edit the registry unless you have no alternative. The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Windows Server 2003 Resource Kit Registry Reference on the *Windows Server 2003 Deployment Kit* companion CD or at http://www.microsoft.com/reskit.

For more information, see "Remote Access Logging" in Help and Support Center for Windows Server 2003.

# Optimize IAS Deployment in Large Organizations

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can optimize IAS performance in large organizations by doing the following:

- If you are using remote access policies to restrict access for all but certain groups, create a universal group for all of the users to whom you want to allow access, and create a remote access policy that grants access for that universal group. If you have a large number of users on your network, create global groups within the universal group, and add the users to the global groups.

- Use IAS as a proxy server and configure connection request policies to distribute authentication requests to remote RADIUS server groups based on the realm name portion of the user name. In this manner you can load balance traffic based on domain membership, and authentication requests are sent to a remote RADIUS server group that resides in the same domain where the user account is located.

- Install IAS as a dedicated RADIUS server. If you choose not to run the IAS server on a domain controller with a global catalog, you can run it on a computer that has other services running on it, as long as the services are not resource-intensive.

In very large environments (such as an ISP with millions of remote access users and extremely heavy load conditions) that must process a large number of both authentication requests and accounting packets per second, you can optimize IAS performance by doing the following:

- Using a faster domain controller to yield better throughput. The number of authentications per second depends on the hardware used for the domain controller.

- Using separate IAS servers for authentication and accounting. IAS proxy servers can send all accounting requests to a specific remote RADIUS server group, while sending authentication requests to other groups. For more information, see "Configure accounting" in Help and Support Center for Windows Server 2003.

- Running the IAS server on a domain controller with a global catalog. Choose this option if you have a high-latency connection between your IAS server and your domain controller, or between your IAS server and your global catalog, but you do not have problems with your IAS performance.

- Increasing the number of concurrent authentication calls in progress at one time by using the **MaxConcurrentApi** registry entry. Keep in mind that if you assign too high a value to this registry entry, your IAS server can place an excessive load on your domain controller. Values from 2 to 5 provide the best performance.

  For more information about the **MaxConcurrentApi** registry entry, see the Windows Server 2003 Resource Kit Registry Reference on the *Windows Server 2003 Deployment Kit* companion CD or at http://www.microsoft.com/reskit.

**Caution**

- Do not edit the registry unless you have no alternative. The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Windows Server 2003 Resource Kit Registry Reference on the *Windows Server 2003 Deployment Kit* companion CD or at http://www.microsoft.com/reskit.

# Creating a Remote Access Policy Strategy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Remote clients connect to the network by using remote access policies. Plan an authorization method for security, and then plan your user groups and user accounts. Next, create your remote access policies to centralize management. Figure 7.10 illustrates this process.

**Figure 7.10 Creating a Remote Access Policy Strategy**

# Establish a Remote Client Access Authorization Method

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use remote access policies to authorize remote client access either by group or by user.

If you authorize access by group, you can restrict network access based on an account's group membership. For example, you can create one group for wireless users and another group for dial-in users, and create separate remote access policies for each group by using the **Windows-Groups** attribute (condition) of the remote access policy.

To authorize access by group in a Windows Server 2003 or a Windows 2000 native domain, set the remote access permission on every user account to **Control access through Remote Access Policy**. Remote access permissions are then determined by the remote access permission setting on the remote access policy.

For more information, see "Remote Access Policies" in Help and Support Center for Windows Server 2003.

# Plan Remote Access Policy Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can manage remote access authorization by user or by group. By using the Active Directory Users and Computers snap-in, you can create groups to which specific IAS remote access policies are applied, allowing you to grant different types of remote access to different groups. The functional level of the domain impacts the type of group that you can use.

In Windows Server 2003 domains or Windows 2000 native-mode domains, you can use universal and global groups as follows:

- Universal groups can include groups and accounts from any Windows Server 2003 or Windows 2000 domain in the domain tree or forest and can be granted permissions in any domain in the domain tree or forest.

- Global groups can include groups and accounts only from the domain in which the group is defined and can be granted permissions in any domain in the forest.

In Windows Server 2003 interim domains or Windows 2000 mixed-mode domains, you can use only global groups. Domain local groups cannot be used because they are created in a single domain, are visible only in that domain, and can be assigned permissions only to resources within that domain.

For more information about remote access policies, see "Remote Access Policies" in Help and Support Center for Windows Server 2003.

For more information about functional levels, see "Domain and forest functionality" in Help and Support Center for Windows Server 2003.

# Plan the User Accounts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition, the user account for a stand-alone server or server running Active Directory contains a set of dial-in properties that are used when performing authorization (allowing or denying a connection attempt made by a user). On a stand-alone server, you can set the dial-in properties on the **Dial-in** tab in the user account in the **Local Users and Groups** dialog box. On a server running Active Directory, you can set the dial-in properties on the **Dial-in** tab in the user account in the **Active Directory Users and Computers** snap-in. On these servers, you cannot use the Windows NT 4.0 User Manager for Domains administrative tool.

In Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition, you can configure a RADIUS attribute to ignore the dial-in properties of user and computer accounts in the profile properties of a remote access policy. To support multiple types of connections for which IAS provides authentication and authorization, it might be necessary to disable the processing of user account dial-in properties. This can be done to support scenarios in which specific dial-in properties are not required and is accomplished by configuring the **Ignore-User-Dialin-Properties** attribute on the **Advanced** tab of the profile settings for a remote access policy.

Computer accounts also have dial-in properties that are similar to user accounts. Therefore computers can be authenticated as if they were users when an IEEE 802.1X Ethernet client uses EAP-TLS and an installed computer certificate to authenticate itself to an Ethernet switch. Note that the **Ignore-User-Dialin-Properties** attribute disables the use of all dial-in properties for the user account. Specific dial-in properties cannot be individually disabled.

For more information about planning user accounts, see "Dial-in properties of a user account" in Help and Support Center for Windows Server 2003.

# Configure Remote Access Policies for Secure Remote Connections

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure Remote Access Policies**

You can create multiple remote access policies to accommodate the individual security requirements of your remote connections. For example, you can use remote access policies to grant or deny authorization according to the time of day and the day of the week, the Windows Server 2003 or Windows 2000 Server group to which the remote access user belongs, the type of connection being requested (dial-up networking or VPN connection), and so on. You can also configure settings within the remote access policies that limit the maximum session time, specify the authentication and encryption strengths, set Bandwidth Allocation Protocol (BAP) policies, and so forth.

Remote access policies are applied in the order in which they are listed. When a policy is found that contains conditions that match the connection attempt, access is granted or denied, regardless of the conditions specified by the other policies later in the list. Therefore, it is a good idea to list more specific remote access policies before general remote access policies.

If you do not implement any remote access policies, all connection attempts fail.

Before you configure remote access policies, you must make decisions about the following:

- Whether to use Network Access Quarantine Control for VPN and dial-up connections.
- Whether to use custom or common policies. When you use the New Remote Access Policy Wizard in the IAS snap-in, you can choose to create a common or a custom policy. For a common policy, you must configure an access method, whether to grant access permissions by user or by group, authentication methods, and levels of allowed encryption (depending on the access method selected). For a custom policy, you must configure a set of policy conditions, whether remote access permission for the policy is granted or denied, and remote access policy profile settings. For more information, see "Add a remote access policy" in Help and Support Center for Windows Server 2003.
- The groups and users to which the remote access policies apply.
- Whether the remote access policy grants or denies access to the users or the group.
- The restrictions that are placed on the users or the group.

For more information about Internet Authentication Service, including remote access policies, see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

# Using Network Access Quarantine Control

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Network Access Quarantine Control provides phased network access for client computers that connect to the network by using VPN or dial-up remote access. By using connection request policies and remote access policies, you can apply the MS-Quarantine-IPFilter attribute, the MS-Quarantine-Session-Timeout attribute, or both attributes to restrict clients to quarantine mode. During quarantine mode, an administrator-provided network policy requirements script is run on the client computer. After the client computer configuration is either brought into or determined to be in accordance with your organization's network policy, quarantine mode is removed by the network access server, and standard remote access policy is applied to the connection.

You can implement Network Access Quarantine Control with one or more servers running Windows Server 2003 and the Routing and Remote Access service, one or more servers running Windows Server 2003 and IAS, a Connection Manager (CM) profile created with Connection Manager Administration Kit (CMAK), an administrator-provided script, and two additional components: the notifier component and the listener component. You can create your own notifier and listener components, or you can use Rqs.exe (a listener component) and Rqc.exe (a notifier component), which are available in the Windows Deployment and Resource Kits.

For more information, see "Deploying Dial-up and VPN Remote Access Servers" and "Deploying Remote Access Clients Using Connection Manager" in this book.

# Using Common vs. Custom Policies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You must decide whether to use common or custom policies:

- A common policy includes typical settings for a particular access method.
- A custom policy includes a detailed configuration of a particular access method.

**Create Specifications for a Common Policy**
To create a common or custom policy, you must specify the following:

- An access method. The access method is used to configure the access server Port Type condition automatically. You can choose one of the following four access methods:
    - VPN access
    - Dial-up access
    - Wireless access
    - Ethernet switch access
- Whether to grant access permissions by user or by group. If you choose to grant access by group, the **Windows-Groups** condition is automatically set to the chosen groups.
- Authentication methods. For more information about how to configure authentication methods, see "Configure authentication" in Help and Support Center for Windows Server 2003.
- Levels of allowed encryption (depending on the access method chosen). For more information about how to configure encryption, see "Configure encryption" in Help and Support Center for Windows Server 2003.

When you create a common policy, the remote access permission is always set to **Grant remote access permission**.

**Create Specifications for a Custom Policy**
For each custom policy, create detailed specifications for the following elements:

- Conditions. Remote access policy conditions are one or more attributes that are compared to the settings of the connection attempt.
- Remote access permission. Specify whether the permission is granted or denied if the conditions of a remote access policy are met.
- Profile. Specify the remote access policy profile properties to set dial-in constraints and other restrictions.

For specific information about settings for each element, see Help and Support for Windows Server 2003 or the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

**Note**

- Not all network access servers send all of the RADIUS attributes. Consult the documentation for your network access server to see which attributes it sends.

**Conditions**
Specify the remote access conditions for each policy. Remote access policy conditions are one or more attributes that are compared to the settings of the connection attempt. In order for the connection attempt to match the policy, all conditions must match the settings of the connection attempt. Remote access policy profile settings are applied only if the connection attempt matches the policy. Thus, remote access policies are applied only if the connection attempt matches all of the conditions of the policy.

**Permission**
Specify whether the permission is granted or denied if the conditions of a remote access policy are met. You use the **Grant remote access permission** option or the **Deny remote access permission** option to set remote access permission for a policy.

During the authorization process, the dial-in properties of user accounts are evaluated before remote access policy is applied. If the dial-in properties for the user account are set to **Deny access**, the connection attempt is rejected and remote access policies are not evaluated. When dial-in properties for the user account are set to **Control access through Remote Access Policy**, the remote access policy alone determines whether the user is granted access.

When the dial-in properties for the user account are set to **Grant access**, remote access policies are evaluated next. In this circumstance it is possible for the user to be denied access by settings in the remote access policy. For example, if the remote access policy is configured to allow the user to connect only between the hours of 8 AM and 5 PM and the user is attempting to connect at 6 PM, the connection attempt fails due to the settings in the remote access policy.

**Profile**
Specify the remote access policy profile properties to set dial-in constraints and other restrictions. These properties are applied to a connection after the connection is authorized, whether the connection has been authorized through the user account permission setting or the remote access policy.

You can use these properties to specify the series of RADIUS attributes that are sent back to the RADIUS client by the IAS server, including any vendor-specific attributes you are using. For more information about VSAs, see "Configuring IAS for Compatibility with Third-Party Access Servers" later in this chapter.

### Note

- Elements of a remote access policy correspond to RADIUS attributes that are used during RADIUS-based authentication. For an IAS server, verify that the network access servers that you use are sending the RADIUS attributes that correspond to the configured remote access policy conditions and profile settings. If an access server does not send a RADIUS attribute that corresponds to a remote access policy condition or profile setting, then all RADIUS authentications from that access server are denied.

# Apply Policies to Users and Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you are controlling remote client access by means of groups, you must determine which groups the policies that you create will apply to. If you are using nested groups, make sure that policies configured for the parent group do not conflict with policies configured for the nested group.

If you are controlling remote client access by means of the access-by-user administrative model, you must establish the criteria that you use to determine whether the policy is applied; for example, you can use the client name, client IP address, access server IP address, or any other condition attribute.

Two of the attributes, **NAS-Port-Type** and **Tunnel-Type**, deserve special mention because they are used to support VPN, wireless, and authenticating switch access clients:

- The **NAS-Port-Type** attribute. This attribute allows you to specify the type of physical port that is used by the access server originating the request.

- The **Tunnel-Type** attribute. This attribute allows you to specify the type of tunnel that the access server can create. You can specify either Point-to-Point Tunneling Protocol (PPTP) or Layer Two Tunneling Protocol (L2TP).

For a detailed list of condition attributes, see "Connection request policies" in Help and Support Center for Windows Server 2003 and the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

# Determine Which Restrictions to Apply

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can specify dial-in conditions or any other profile property to restrict access. For a detailed list of profile properties that can be used to restrict access, see "Introduction to remote access policies" in Help and Support Center for Windows Server 2003 or the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

To achieve the highest level of security possible, begin by granting the least amount of access possible and increase access only when necessary.

# Configure Client-Specific Remote Access Policies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Different types of remote access clients need different settings in their remote access policies. The following sections describe design considerations for creating the different types of policies.

**Configure Remote Access Policies for VPN Clients**
For VPN clients, use the **Tunnel-Type** attribute to specify the type of tunnel that is created by the requesting client. Tunnel types include the Point-to-Point Tunneling Protocol (PPTP) and the Layer Two Tunneling Protocol (L2TP), which are used by remote access clients and demand-dial routers running Windows XP; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; and Windows 2000. You can use this condition to specify profile settings, such as authentication methods or encryption strengths for a specific type of tunneling technology.

**Configure Remote Access Policies for Wireless Access Clients**
For wireless access clients, create a wireless remote access policy, and then add the condition **NAS-Port-Type** with the values **Wireless-IEEE 802.11** and **Wireless-Other**.

For more information, see "Wireless access example" in Help and Support Center for Windows Server 2003.

**Configure Remote Access Policies for Authenticating Switch Access Clients**
For authenticating switch access clients, specify the use of the **Ethernet** port type for the **NAS-Port-Type** attribute. By using this port type, you create a separate remote access policy that contains connection parameters specifically designed for authenticating switch nodes.

# Configure a Quarantine Remote Access Policy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When deploying Network Access Quarantine Control, create a new policy called Quarantine Remote Access Policy, and then choose whether to quarantine clients with IP filters, whether to apply a session timer when clients connect to VPN or dial-up servers, or whether to apply both attributes to the connections. Specify the use of the **MS-Quarantine-IPFilter** attribute if you want to apply IP filters that restrict client access to the network. Specify the use of the **MS-Quarantine-Session-Timeout** attribute if you want to set a restriction on the amount of time the client network policy requirements script has to notify the access server that it has run successfully. When you create a Quarantine Remote Access Policy, position it as the first remote access policy so that it is evaluated before other policies.

Quarantine IP filters and session timers are for use only with the Windows Server 2003 Routing and Remote Access service.

For more information, see "Deploying Dial-up and VPN Remote Access Servers" and "Deploying Remote Access Clients Using Connection Manager" in this book.

# Securing Your Remote Access Strategy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use IAS authentication, authorization, and accounting to secure your remote access solutions. You can also implement security precautions to protect your IAS server and IAS-related traffic. Figure 7.11 illustrates this process.

**Figure 7.11 Securing Your Remote Access Strategy**

# Select Authentication Protocols

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

- Windows Server 2003 IAS can perform authentication on behalf of any access server that is configured as a RADIUS client. You can use one of a number of protocols to authenticate dial-up, VPN, wireless, and authenticating switch users before allowing them access to the network.

Before you deploy IAS, determine which authentication protocols you will use to authenticate remote access clients. Use the most secure protocols that your network access servers and clients can support. If you need a high degree of security, you can configure IAS to accept only a few very secure authentication protocols. Alternatively, if your organization requires more flexibility, you can configure IAS to accept less secure authentication protocols when attempts to use more secure authentication protocols are unsuccessful.

Table 7.2 lists the authentication protocols that IAS supports and summarizes the conditions for which each protocol is used and the requirements for each protocol.

**Table 7.2 Authentication Protocols That IAS Supports**

| Protocol | Type of Authentication | Protocol Characteristics | Protocol Requirements |
|---|---|---|---|
| Extensible Authentication Protocol-Transport Layer Security (EAP-TLS) | Certificate-based | Works for dial-up, VPN, wireless access, and authenticating switch access.<br><br>Provides authentication by means of a registry-based user certificate or a smart card.<br><br>Provides mutual authentication.<br><br>Generates cryptographic keys, which are needed for wireless LAN connections and for dial-up and VPN connections that use Microsoft Point-to-Point Encryption (MPPE).<br><br>Enables uninterrupted transfer between wireless access points (user does not need to re-enter credentials when moving between access points).<br><br>Enables unauthenticated access for visitors. | IAS must be a member of a Windows 2000 or Windows Server 2003 domain.<br><br>Both client and server must support this protocol.<br><br>The IAS server must have a certificate installed in the certificate store. The certificate must contain the Server Authentication purpose in EKU extensions. The certificate must meet all other certificate requirements.<br><br>The client computer or user certificate must contain the Client Authentication purpose in EKU extensions. The certificate must meet all other certificate requirements. The certificate can be installed in the client computer certificate store or on a smart card. |

| | | | |
|---|---|---|---|
| Protected Extensible Authentication Protocol (PEAP) | Certificate and password-based (depending upon the selected authentication method) | Currently for 802.1X wireless and authenticating switch clients only.<br><br>PEAP does not specify an authentication method, but provides a secure "wrapper" for other EAP authentication protocols, such as EAP-MS-CHAPv2, that operate within the outer TLS-encrypted channel provided by PEAP.<br><br>Enables uninterrupted transfer between wireless access points (user does not need to re-enter credentials when moving between access points).<br><br>Does not allow unauthenticated access for visitors. | Both client and server must support this protocol.<br><br>The IAS server must have a certificate installed in the certificate store. The certificate must contain the Server Authentication purpose in EKU extensions. The certificate must meet all other certificate requirements. |
| Microsoft Challenge Handshake Authentication Protocol version 2 (MS-CHAPv2) | Password-based | Provides mutual authentication.<br><br>Generates cryptographic keys, which are needed for dial-up and VPN connections that use MPPE.<br><br>Enables you to change passwords.<br><br>Works for dial-up and VPN access. | Both client and server must support this protocol. |
| EAP-MSCHAPv2 | Password-based | Provides mutual authentication.<br><br>Generates cryptographic keys, which are needed for dial-up and VPN connections that use MPPE.<br><br>Enables you to change passwords. | IAS must be a member of a Windows 2000 or Windows Server 2003 domain.<br><br>Both client and server must support this protocol. |
| Microsoft Challenge Handshake Authentication Protocol (MS-CHAP) | Password-based | Provides encrypted authentication for Microsoft® Windows® 98, Microsoft® Windows® Millennium Edition operating system, or Microsoft Windows NT 4.0 (with the latest dial-up networking upgrade).<br><br>Generates cryptographic keys, which are needed for dial-up and VPN connections that use Microsoft Point-to-Point Encryption (MPPE).<br><br>Enables you to change passwords. | Both client and server must support this protocol. |
| Extensible Authentication Protocol-Message Digest 5 (EAP-MD5) | Password-based | Provides less security than EAP-TLS.<br><br>Does not generate cryptographic keys.<br><br>Works for dial-up and authenticating switch–based access, but not wireless or PPTP-based VPN access. | Requires a reversibly encrypted password to be stored in the account database (local Security Accounts Manager (SAM) or domain).<br><br>IAS can be a member of a Windows NT 4.0 domain, a Windows 2000 domain, or a Windows Server 2003 domain.<br><br>Both client and server must support this protocol. |

| | | | |
|---|---|---|---|
| Challenge Handshake Authentication Protocol (CHAP) | Password-based | Provides encrypted authentication for a combination of different operating systems, such as Macintosh or UNIX operating systems.<br><br>Does not generate cryptographic keying material. | Requires a reversibly encrypted password to be stored in the account database (local SAM or domain).<br><br>Both client and server must support this protocol and reversibly encrypted passwords. |
| Password Authentication Protocol (PAP) | Password-based | Provides unencrypted authentication. Use only if clients do not support other protocols.<br><br>Does not generate cryptographic keying material. | Both client and server must support this protocol. |
| Unauthenticated Access | | Grants access when the remote access client does not supply authentication credentials.<br><br>Does not generate cryptographic keying material. | Both client and server must support this protocol. |

Before the IAS server can access Active Directory–based domains to authenticate user credentials and user access account properties, the IAS server must be registered in those domains.

# Integrate IAS with the Certificate Infrastructure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Whether you need a certificate infrastructure for IAS depends on whether you are using EAP-TLS as your authentication protocol. If you are using EAP-TLS, you need a certificate infrastructure for your clients. Otherwise, you do not.

A certificate infrastructure consists of the following components:

- One or more certificate servers
- An IAS server with a certificate
- Clients with certificates

For more information about how to design a certificate infrastructure, see "Designing a Public Key Infrastructure" in *Designing and Deploying Directory and Security Services* of this kit.

When planning how to distribute certificates to clients, decide the following:

- **Whether to use a computer certificate or a user certificate.** Computer certificates are available in Windows Server 2003 and Windows 2000. Use them for servers and for computers on a LAN that do not often move. User certificates are new for Windows Server 2003. Use them for roaming users, such as wireless users.
- **How to install the certificate.** After the certification authority (CA) is configured, you can install a certificate in three ways. Table 7.3 shows each method and when to use it.

**Table 7.3 Selecting a Certificate Installation Method**

| Installation Method | When to Use |
|---|---|
| By using Group Policy to configure auto-enrollment of computer certificates to computers in a Windows Server 2003 domain. | Use this method if you have large numbers of domain member clients that you need to enroll. In this case, setting up a Group Policy takes less time than manually obtaining certificates.<br>This method has the advantage that after auto-enrollment is configured and enabled, all domain member computers receive computer certificates when Group Policy is refreshed next, whether the refresh is triggered manually with the **gpupdate** command, or by logging on to the domain.<br>If you use auto-enrollment for user certificates, any user with a valid password can obtain a certificate. This makes your certificate authentication the same as password-based authentication. |
| By using Certificate Manager to obtain a computer certificate. | Use this method if you have only a few computers, such as IAS servers. |
| By using Microsoft Internet Explorer and Web-based enrollment. | Use this method if the client is not a member of the domain.<br>Use this method or smart cards for user certificates. |

For specific information about how to perform these steps, see "Computer certificates for certificate-based authentication" in Help and Support Center for Windows Server 2003.

For more information about certificate enrollment methods and domain membership, see "Network access authentication and certificates" in Help and Support Center for Windows Server 2003.

# Install Computer Certificates for IAS Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you are using PEAP-EAP-MS-CHAPv2 or EAP-TLS, you must install a computer certificate on your IAS servers. That certificate must be issued from a CA that can follow a certificate chain to a root CA that is trusted by the access clients. Likewise, the IAS server must trust the root CA of the CA that issued the user or computer certificate to the access client.

You can install multiple computer certificates on the IAS servers and configure separate remote access policies to use different computer certificates. However, you can select only a single certificate for all remote access policies that specify authentication by using EAP-TLS.

The server certificate must also contain the Server Authentication purpose in Enhanced Key Usage extensions, and meet other certificate requirements for PEAP and EAP authentication.

To install a certificate on the IAS server, you can use Group Policy and auto-enrollment, the CA Web enrollment tool provided with Certificate Services for Windows Server 2003, or you can request a certificate by using the Certificates snap-in.

For more information about certificate requirements for PEAP and EAP, see "Network access authentication and certificates" in Help and Support Center for Windows Server 2003.

# Install Computer Certificates for Access Clients

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In addition to adding a certificate to your IAS servers, you must add a certificate to any computer that uses EAP-TLS or PEAP-EAP-TLS authentication. The certificate must be issued from a certification authority (CA) that can follow a certificate chain to a root CA that is trusted by the IAS server.

The computer certificate must also contain the Client Authentication purpose in Enhanced Key Usage extensions and meet other certificate requirements for PEAP and EAP authentication.

For more information about creating a certificate infrastructure, see "Designing a Public Key Infrastructure" in *Designing and Deploying Directory and Security Services* of this kit.

# Secure the IAS RADIUS Server and RADIUS Proxy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is important to secure your IAS server. Regardless of whether you configure your IAS server as a RADIUS server or a RADIUS proxy, you must apply a number of basic security precautions.

**Use strong shared secrets**
RADIUS supports a simple password called a secret. Configure strong shared secrets to prevent dictionary attacks, and change them frequently. RADIUS secrets are combined with a 16-byte random number and then passed through a one-way Message Digest 5 (MD5) hash to create a 16-byte encryption value. The 16-byte encryption value is stored with the password entered by the remote access user.

Include RADIUS secrets in your remote access design when you are mutually authenticating RADIUS computers and you encrypt the remote user password. It is best to specify RADIUS secrets that are at least 16 characters in length and that include uppercase letters, lowercase letters, numbers, and punctuation.

**Use the Message-Authenticator attribute**
Use the **Message-Authenticator** attribute (also known as a digital signature or the signature attribute) for connection requests that use the PAP, CHAP, MS-CHAP, and MS-CHAPv2 authentication protocols. This attribute ensures that an incoming RADIUS Access-Request message was sent from a RADIUS client configured with the correct shared secret. You must enable the use of the **Message-Authenticator** attribute on both the IAS server (as part of the configuration of the RADIUS client) and the RADIUS client (the network access server or RADIUS proxy). Ensure that the RADIUS client supports the **Message-Authenticator** attribute before you enable the attribute. The **Message-Authenticator** attribute is always used with EAP, regardless of whether it is enabled on the IAS server and access server.

**Configure your Internet firewall**
In the most common configuration, the Internet firewall is situated on your perimeter network between your secure network and the Internet. The perimeter network (also known as a *screened subnet*) is an IP network segment that contains resources (such as Web and VPN servers) that are available to Internet users. In this configuration, the IAS server is an intranet resource that is connected to the perimeter network.

If your IAS server is on a perimeter network, configure your Internet firewall to allow RADIUS messages to pass between your IAS server and RADIUS clients on the Internet. You might need to configure an additional firewall that is placed between your perimeter network and your intranet, which allows traffic to flow between the IAS server on the perimeter network and domain controllers on the intranet.

If your IAS server is on the perimeter network, it might use either of the following to contact a domain controller on the intranet:

- An interface on the perimeter network and an interface on the intranet (IP routing is not enabled).
- A single interface on the perimeter network. In this configuration, IAS communicates with intranet domain controllers through another firewall that connects the perimeter network to the intranet.

For more information about Internet firewalls, see "Deploying ISA Server" in this book.

**Enable remote access account lockout**
Enable remote access account lockout to protect against online dictionary attacks. Remote access account lockout disables network access for user accounts after a configured number of failed connection attempts has been reached.

Remote access account lockout can also be used to prevent a malicious user from intentionally locking out a domain account by attempting to make multiple dial-up or VPN connections with the wrong password. You can set the number of failed attempts for remote access account lockout to a number that is lower than the number of logon retries for domain account lockout. By doing this, remote access account lockout occurs before domain account lockout, which prevents the domain account from being intentionally locked out.

For more information about account lockout, see "Remote access account lockout" in Help and Support Center for Windows Server 2003.

# Protect Against Access Server Vulnerabilities

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Some access servers expose the network to unwanted visitors who can gain access to your network. For example, intruders might connect to an authenticating switch accessible from a conference room network port, set up their own access server to connect to your network, and access your resources. To protect against this form of attack, configure mutual authentication by using PEAP-EAP-MS-CHAPv2 or EAP-TLS as the authentication method for network access connections. For more information about configuring mutual authentication, see "PEAP" in Help and Support Center for Windows Server 2003.

Authenticating RADIUS clients and RADIUS servers also protects against this type of network attack. You can use three methods to authenticate RADIUS clients and RADIUS servers.

**RADIUS shared secrets**
Include RADIUS shared secrets in your network access design. Specify RADIUS secrets that are at least 22 characters in length and consist of a random sequence of uppercase letters, lowercase letters, numbers, and punctuation.

**Secure RADIUS traffic with IPSec**
Securing RADIUS traffic with Internet Protocol security (IPSec) provides you with the ability to secure RADIUS servers against unwanted traffic by filtering on specific network adapters (allowing or blocking specific protocols) and enabling you to choose source IP addresses from which traffic is allowed. For organizational units, you can create IPSec policies, which are stored in Active Directory, or you can create local policies on RADIUS servers, and then apply the local policies to specific computers. If you create IPSec policies for an organizational unit, the policy is applied by using Group Policy.

You can enable IPSec between IAS proxies and IAS servers, or between RADIUS clients and IAS servers.

For more information about securing RADIUS traffic with IPSec, see "Securing RADIUS traffic with IPSec" in Help and Support Center for Windows Server 2003.

**VPN tunnels**
All RADIUS computers that require authorization support VPNs.

# Implementing Your IAS Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Deploying IAS involves configuring IAS as a RADIUS server or proxy, optimizing your IAS configuration to best meet your needs, and configuring compatibility with third-party access servers. Figure 7.12 illustrates this process.

**Figure 7.12 Implementing Your IAS Solution**

# Deploy IAS as a RADIUS Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Deploying IAS as a RADIUS server on your network involves configuring Active Directory, configuring the primary and backup IAS servers, and configuring the access servers. Figure 7.13 illustrates this process.

**Figure 7.13 Deploying IAS as a RADIUS Server**

# Configure User Accounts and Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure user accounts and groups, do the following:**

1. Ensure that all users that are making remote access connections have a corresponding user account.

2. Set the remote access permission on user accounts to **Grant access** or **Deny access** to manage network access by user. Or, to manage network access by group, set the remote access permission on user accounts to **Control access through Remote Access Policy**.

3. Organize remote access users into the appropriate universal and nested groups in order to take advantage of group-based remote access policies.

4. If you are using CHAP, enable support for reversibly encrypted passwords in the appropriate domains. You can configure reversibly encrypted passwords by using Group Policy. For more information, see "Enable reversibly encrypted passwords in a domain" in Help and Support Center for Windows Server 2003.

5. If you are using certificate-based authentication, configure the domain in which IAS server computers will be members for the auto-enrollment of certificates. With Windows Server 2003, you can auto-enroll both user and computer certificates.

For more information about configuring user accounts for IAS, see "Dial-up and VPN remote access" in Help and Support Center for Windows Server 2003.

For more information about reversibly encrypted passwords, see "Enable reversibly encrypted passwords in a domain" in Help and Support Center for Windows Server 2003.

# Configure the Primary IAS Server on a Domain Controller

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure the primary IAS server on a domain controller, do the following:**

1. On the domain controller, install IAS by using **Add/Remove Windows Components**. For more information, see "Install IAS" in Help and Support Center for Windows Server 2003.

2. Configure the IAS server to read the properties of user accounts in the domain. For more information, see "Enable the IAS server to read user accounts in Active Directory" in Help and Support Center for Windows Server 2003.

3. If the IAS server authenticates connection attempts for user accounts in other domains, use the Active Directory Domains and Trusts snap-in to verify that these domains have a two-way trust with the domain in which the IAS server is a member. Next, configure the IAS server to read the properties of user accounts in other domains by adding the IAS server to the **RAS and IAS Servers** security group on all domain controllers with user account databases to be accessed by the IAS server. For more information, see "Enable the IAS server to read user accounts in Active Directory" in Help and Support Center for Windows Server 2003.

4. Enable file logging for accounting and authentication events. You can log session information to text files in either IAS format or database-compatible format, or you can log to a server running SQL Server 2000 or later. In addition, you can configure which information you want to log. For more information, see "Remote Access Logging" in Help and Support Center for Windows Server 2003.

5. If needed, configure additional User Datagram Protocol (UDP) ports for authentication and accounting messages that are sent by RADIUS clients. By default, IAS uses UDP ports 1812 and 1645 for authentication and ports 1813 and 1646 for accounting.

6. Add the access servers as RADIUS clients of the IAS server. Verify that you are configuring the correct name or IP address and shared secrets. Enable the use of the **Message-Authenticator** attribute, but only when it is also supported by the RADIUS client.

7. Create remote access policies that reflect your network access usage scenarios.

8. If you have created new remote access policies, either delete the default remote access policies or move them so that they are the last policies to be evaluated.

For more information about configuring IAS, see "Dial-up and VPN remote access" in Help and Support Center for Windows Server 2003.

# Configure the Secondary IAS Server on a Different Domain Controller

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure the secondary IAS server on a different domain controller, do the following:**

1. On the other domain controller in the same domain, install IAS by using **Add/Remove Windows Components**. For more information, see "Install IAS" in Help and Support Center for Windows Server 2003.

2. Configure the secondary IAS server to read the properties of user accounts in the domain by adding the IAS server to the **RAS and IAS Servers** security group. For more information, see "Enable the IAS server to read user accounts in Active Directory" in Help and Support Center for Windows Server 2003.

3. If the secondary IAS server authenticates connection attempts for user accounts in other domains, verify that the other domains have a two-way trust with the domain in which the secondary IAS server is a member. Next, configure the secondary IAS server to read the properties of user accounts in other domains by adding the IAS server to the **RAS and IAS Servers** security group in those domains. For more information, see " Enable the IAS server to read user accounts in Active Directory" in Help and Support Center for Windows Server 2003.

4. Copy the configuration of the primary IAS server to the secondary IAS server.

For more information about copying IAS configuration, see "Copy the IAS configuration to another server" in Help and Support Center for Windows Server 2003.

# Configure RADIUS Clients for Use with IAS Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To configure each RADIUS client to use the primary and secondary IAS servers for authentication, authorization, and accounting of remote access connections, do the following:

- If the RADIUS client is a computer running Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition, Windows Server 2003, Datacenter Edition; or Windows 2000 and the Routing and Remote Access service, use the Routing and Remote Access snap-in to configure the RADIUS client to use the primary and secondary IAS servers as RADIUS servers. For more information about configuring the RADIUS client, see "Use RADIUS authentication" and "Use RADIUS accounting" in Help and Support Center for Windows Server 2003.

- If the RADIUS client is a computer running Windows NT 4.0 and the Routing and Remote Access Service (RRAS), see Windows NT 4.0 Help for information about how to configure RRAS to use the primary and secondary IAS servers as RADIUS servers for RADIUS authentication.

- If the RADIUS client is a third-party network access server, see the documentation for the NAS to determine how to configure it as a RADIUS client with two RADIUS servers (the primary and secondary IAS servers).

# Deploy IAS as a RADIUS Proxy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Deploying IAS as a RADIUS proxy on your network involves configuring the primary and secondary IAS proxies, configuring the Internet firewalls, and configuring for compatibility with third-party access servers. Figure 7.14 illustrates this process.

**Figure 7.14 Deploying IAS as a RADIUS Proxy**

# Configure the Primary IAS Proxy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure the primary IAS proxy in the perimeter network, do the following:**

1. On a computer running Windows Server 2003, Standard Edition or Windows Server 2003, Enterprise Edition in the perimeter network, install IAS by using **Add/Remove Windows Components**. For more information, see "Install IAS" in Help and Support Center for Windows Server 2003. The computer on which IAS is installed does not need to be dedicated to forwarding RADIUS messages. You can install IAS on a computer running other services, such as a DHCP server, a file server, or a DNS server.

2. If needed, configure additional UDP ports for RADIUS messages that are sent by the RADIUS proxies. By default, IAS uses UDP ports 1812 and 1645 for authentication and ports 1813 and 1646 for accounting.

3. Add the RADIUS proxies as RADIUS clients of the IAS server. Verify that you are configuring the correct name or IP address and shared secrets.

4. Create a remote RADIUS server group that contains the IAS servers in your organization.

5. Create a connection request policy that forwards RADIUS request messages based on the realm name of your organization. For more information about realm names, see "Realm names" in Help and Support Center for Windows Server 2003.

6. Use the New Connection Request Policy Wizard to create a connection request policy that forwards connection requests to a remote RADIUS server group and where the realm name matches the realm name of the user accounts in your organization. Clear the check box that removes the realm name for authentication. In the New Connection Request Policy Wizard, use the New Remote RADIUS Server Group Wizard to create a remote RADIUS server group with members that include the two IAS servers within your intranet.

7. Delete the default connection request policy named **Use Windows authentication for all users**.

For more information about configuring IAS proxies in the perimeter network, see "Outsourced dial and a proxy in the perimeter network" in Help and Support Center for Windows Server 2003.

# Configure the Secondary IAS Proxy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To configure the secondary IAS proxy in the perimeter network, do the following:**

1. On another computer running Windows Server 2003, Standard Edition or Windows Server 2003, Enterprise Edition in the perimeter network, install IAS by using **Add/Remove Windows Components**. For more information, see "Install IAS" in Help and Support Center for Windows Server 2003.

2. Using Netsh, copy the configuration of the primary IAS proxy to the secondary IAS proxy in the perimeter network.

For more information about copying IAS configuration, see "Copy the IAS configuration to another server" in Help and Support Center for Windows Server 2003.

# Configure the Intranet and Internet Firewalls

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To support RADIUS traffic, you must take two steps. First, configure the Internet firewall to allow RADIUS traffic between the IAS proxies on the perimeter network and the RADIUS clients on the Internet. Then configure the intranet firewall to allow RADIUS traffic between the IAS proxies on the perimeter network and the IAS servers on the intranet.

**Filters on the Internet Interface**

Configure the following input packet filters on the Internet interface of the firewall to allow the following types of traffic:

- Destination IP address of the IAS server's perimeter network interface and UDP destination port of 1812 (0x714).

  This filter allows RADIUS authentication traffic from Internet-based RADIUS clients to the IAS server. This is the default UDP port used by IAS as defined in RFC 2856. If you are using a different port, substitute that port number for 1812, as used in this example.

- Destination IP address of the IAS server's perimeter network interface and UDP destination port of 1813 (0x715).

  This filter allows RADIUS accounting traffic from Internet-based RADIUS clients to the IAS server. This is the default UDP port used by IAS as defined in RFC 2857. If you are using a different port, substitute that port number for 1813, as used in this example.

Configure the following output filters on the Internet interface of the firewall to allow the following types of traffic:

- Source IP address of the IAS server's perimeter network interface and UDP source port of 1812 (0x714).

  This filter allows RADIUS authentication traffic from the IAS server to Internet-based RADIUS clients. This is the default UDP port used by IAS as defined in RFC 2856. If you are using a different port, substitute that port number for 1812, as used in this example.

- Source IP address of the IAS server's perimeter network interface and UDP source port of 1813 (0x715).

  This filter allows RADIUS accounting traffic from the IAS server to Internet-based RADIUS clients. This is the default UDP port used by IAS as defined in RFC 2857. If you are using a different port, substitute that port number for 1813, as used in this example.

**Filters on the Perimeter Network Interface**

Configure the following input filters on the perimeter network interface of the firewall to allow the following types of traffic:

- Source IP address of the IAS server's perimeter network interface and UDP source port of 1812 (0x714).

  This filter allows RADIUS authentication traffic from the IAS server to Internet-based RADIUS clients. This is the default UDP port used by IAS as defined in RFC 2856. If you are using a different port, substitute that port number for 1812, as used in this example.

- Source IP address of the IAS server's perimeter network interface and UDP source port of 1813 (0x715).

  This filter allows RADIUS accounting traffic from the IAS server to Internet-based RADIUS clients. This is the default UDP port used by IAS as defined in RFC 2857. If you are using a different port, substitute that port number for 1813, as used in this example.

Configure the following output packet filters on the perimeter network interface of the firewall to allow the following types of traffic:

- Destination IP address of the IAS server's perimeter network interface and UDP destination port of 1812 (0x714).

This filter allows RADIUS authentication traffic from Internet-based RADIUS clients to the IAS server. This is the default UDP port used by IAS as defined in RFC 2856. If you are using a different port, substitute that port number for 1812, as used in this example.

- Destination IP address of the IAS server's perimeter network interface and UDP destination port of 1813 (0x715).

  This filter allows RADIUS accounting traffic from Internet-based RADIUS clients to the IAS server. This is the default UDP port used by IAS as defined in RFC 2857. If you are using a different port, substitute that port number for 1813, as used in this example.

For added security, if you know the IP address of each RADIUS client sending the packets through the firewall, you can configure more specific filters for traffic between the IP address of the RADIUS client and the IP address of the IAS server on the perimeter network.

For more information about configuring packet filters, see "Manage Packet Filters" and "Apply packet filters for business partner extranet" in Help and Support Center for Windows Server 2003.

# Configure RADIUS Clients for Use with IAS Proxies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To configure each RADIUS client to use the primary and secondary IAS proxies, do the following:

- If the RADIUS client is a computer running Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; or Windows 2000 and the Routing and Remote Access service, use the Routing and Remote Access snap-in to configure the RADIUS client to use the primary and secondary IAS servers.

- If the RADIUS client is a computer running Windows NT 4.0 and the Routing and Remote Access Service (RRAS), see Windows NT 4.0 Help for information about how to configure RRAS to use the primary and secondary IAS proxies as RADIUS servers.

- If the RADIUS client is a third-party network access server, see the documentation for the NAS to determine how to configure it as a RADIUS client with two RADIUS servers.

For more information about configuring RADIUS accounting and authentication, see "Use RADIUS accounting" and "Use RADIUS authentication" in Help and Support Center for Windows Server 2003.

# Configuring IAS for Compatibility with Third-Party Access Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you are using Windows Server 2003 IAS with a third-party access server, you might need to configure the IAS server to prevent it from sending the class attribute. Specifically, if the IAS server sends the class attribute, some network access servers require the use of certain vendor-specific attributes to be included in the class attribute.

Alternatively, you can configure vendor-specific attributes and custom attributes to enable compatibility with a third-party access server.

For more information about how to configure the class attribute, see "Add RADIUS attributes to a remote access policy" in Help and Support Center for Windows Server 2003. For more information about configuring IAS for compatibility with a third-party access server, see "IAS as a RADIUS server design considerations" in Help and Support Center for Windows Server 2003.

# Configure Vendor-Specific Attributes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

IAS allows administrators to associate specific RADIUS attributes with each remote access policy. These attributes are described in RFC 2865. In addition to the standard RADIUS attributes, some access server manufacturers use vendor-specific attributes (VSAs) to provide functionality that is not supported in standard attributes.

If your access server manufacturer uses VSAs, you might need to associate those VSAs with remote access protocols so that your access server processes authentication requests properly. IAS enables you to create or edit VSAs to take advantage of proprietary functionality supported by some access server vendors.

To provide access server–specific support, you can add vendor-specific attributes to remote access policies. IAS includes VSAs from some vendors in its dictionary. You cannot add other VSAs to the dictionary.

**To configure IAS to support vendor-specific attributes, complete the following steps:**

1. Determine which vendor-specific attributes the access server requires. The third-party access server manufacturer documentation provides information about the individual attributes that must be specified.

2. Determine which attributes are standard RADIUS attributes and which require the addition of vendor-specific RADIUS attributes (attribute type 26). For more information, see "Interpreting IAS-formatted log files" in Help and Support Center for Windows Server 2003.

3. Specify the attribute values for the VSAs in the IAS remote access policy. When you add VSAs to the remote access policy profile to support proprietary functionality for your access point, you must determine whether the VSA conforms to the format recommended in RFC 2865. If it does, you must specify a network access vendor by either name or vendor code, a vendor-assigned attribute number, the attribute format (that is, the type of data, such as string or hexadecimal), and the attribute value. If it does not, you must specify a network access vendor by either name or vendor code and a hexadecimal attribute value that represents the attribute data. For more information, see "Vendor-specific attribute overview" in Help and Support Center for Windows Server 2003.

# Configure Custom Attributes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The IAS Software Development Kit (SDK), part of the Windows Server 2003 SDK, allows you to configure your IAS server to send custom attributes to the access server in addition to standard attributes. This enables you to build your own extension to the IAS snap-in.

For more information about configuring custom attributes, see the Software Development Kit (SDK) information in the MSDN Library link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Additional Resources for Remote Access

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information and tools related to this chapter.

# Deploying Dial-up and VPN Remote Access Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use the remote access and security technologies in the Microsoft® Windows® Server 2003 operating systems to provide remote users with secure and reliable access to your network resources. By using the Routing and Remote Access service in Windows Server 2003, you can design and deploy a dial-up solution or you can take advantage of the Internet by deploying a virtual private network (VPN) solution.

**In This Chapter**

Overview of Deploying Dial-up and VPN Remote Access Servers

Process for Deploying Dial-up and VPN Remote Access Servers

Choosing Dial-up or VPN

Designing a Remote Access Server Solution

Deploying a VPN Remote Access Server Solution

Deploying a Dial-up Remote Access Server Solution

Additional Resources for Deploying Dial-up and VPN Remote Access Servers

# Overview of Deploying Dial-up and VPN Remote Access Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To support users who require access to your network from remote locations, you can deploy a dial-up network, a VPN, or a combination of both. *Dial-up networking* enables remote users to dial in directly to a remote access server on your network using a phone line. A *virtual private network (VPN)* enables remote users who are connected to the Internet to establish a connection to a VPN server on your network.

In deciding which solution will best serve your organization, consider the relative cost-effectiveness of each solution and how well it meets your organization's requirements for security and availability. Also consider the network infrastructure of the intranet needed to support your remote access server design. Without proper design of the supporting infrastructure, remote access clients cannot obtain IP addresses and resolve intranet names, and packets cannot be forwarded between remote access clients and intranet resources.

Use the process described in this chapter to design and deploy a new remote access solution or to reexamine and improve your existing infrastructure. If you already have a dial-up or VPN infrastructure, you might benefit from replacing existing components because of anticipated obsolescence or failure of components, scalability limitations, or increased security requirements.

Before you begin work on your remote access server design, your organization should have deployed the following supporting technologies.

- Active Directory® directory service to store and manage information about network resources.
- A Public key infrastructure (PKI) to enable the use of certificate-based authentication.
- Internet Authentication Service (IAS) to provide authentication and authorization for dial-up and VPN network access. As a RADIUS server, Windows Server 2003 IAS performs authentication and authorization on behalf of any remote access server configured as a RADIUS client.

All editions of Windows Server 2003 support VPN connections. However, some limitations apply to the Microsoft® Windows® Server 2003, Web Edition, and Windows® Server 2003, Standard Edition, operating systems. On computers running either of these operating systems, you can create as many as 1,000 connections, using Point-to-Point Tunneling Protocol (PPTP) ports or Layer Two Tunneling Protocol (L2TP) ports. Windows Server 2003, Standard Edition, can accept 1,000 concurrent VPN connections; however, Windows Server 2003, Web Edition, accepts only one VPN connection at a time. For more information about features included in Windows Server 2003, Web Edition, see "Overview of Windows Server 2003, Web Edition" in Help and Support for Windows Server 2003.

# Process for Deploying Dial-up and VPN Remote Access Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The key to providing a secure and reliable remote access solution that meets your organization's needs is to carefully plan and test your remote access design after deciding whether to deploy a dial-up network, a VPN, or a combination of both. Deploying a VPN remote access server involves different tasks than are required to deploy a dial-up remote access server; however, often your remote access solution will involve elements of both. Figure 8.1 shows the process for designing and deploying dial-up and VPN remote access servers.

**Figure 8.1 Deploying Dial-up and VPN Remote Access Servers**

# Choosing Dial-up or VPN

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

With a secure network architecture based on Windows Server 2003 in place, the first step in designing a remote access server solution is deciding whether to provide network access to remote clients by using dial-up networking, a VPN solution, or a combination of both. Figure 8.2 shows the placement of this design decision in the process for designing and deploying dial-up and VPN remote access servers.

**Figure 8.2 Choosing Dial-up or VPN**

Each method for providing remote access has advantages and disadvantages that you must weigh based on the needs of your organization. A dial-up networking solution provides a secure data path over a circuit-switched connection, and it provides the convenience of direct dial-up connectivity to your network for mobile users. In contrast, a VPN solution, by using the Internet as a connection medium, saves the cost of long-distance phone service and hardware costs. To mitigate the public nature of the Internet, VPNs use a variety of security technologies, including tunneling, encryption, and authentication.

**Using Dial-up Networking for Remote Access**

In a dial-up networking solution, remote users call in to a remote access server on your network. Dial-up lines are inherently more private than a solution that uses a public network such as the Internet. However, with dial-up networking, your organization faces a large initial investment and continuing expenses throughout the life cycle of the solution. These expenses include:

- **Hardware purchase and installation.** Dial-up networking requires an initial investment in modems or other communication hardware, server hardware, and phone line installation.

- **Monthly phone costs.** Each phone line that is used for remote access increases the cost of dial-up networking. If you use toll-free numbers or the callback feature to defray long distance charges for your users, these costs can be substantial. Most businesses can arrange a bulk rate for long distance, which is preferable to reimbursing users individually at their more expensive residential rates.

- **Ongoing support.** The number of remote access users and the complexity of your remote access design significantly affect the ongoing support costs for dial-up networking. Support costs include network support engineers, testing equipment, training, and help desk personnel to support and manage the deployment. These costs represent the largest portion of your organization's investment.

Figure 8.3 shows an example of a simple dial-up remote access networking design.

**Figure 8.3 Dial-up Remote Access Design**

**Providing Remote Access over a VPN**

In a VPN solution for remote access, users connect to your corporate network over the Internet. VPNs use a combination of tunneling, authentication, and encryption technologies to create secure connections. To ensure the highest level of security for a VPN deployment, use Layer Two Tunneling Protocol with Internet Protocol security (L2TP/IPSec).

Many organizations with extensive remote access requirements implement a VPN solution. VPNs reduce remote access expenses by using the existing Internet infrastructure. You can use a VPN to partially or entirely replace your centralized, in-house, dial-up remote access infrastructure and legacy services.

VPNs offer two primary benefits:

- **Reduced costs.** Using the Internet as a connection medium saves long-distance phone expenses and requires less hardware than a dial-up networking solution does.

- **Sufficient security.** Authentication prevents unauthorized users from connecting. Strong encryption methods make it extremely difficult for an attacker to interpret the data sent across a VPN connection.

Figure 8.4 shows an example of a simple VPN remote access networking design.

**Figure 8.4 VPN Remote Access Design**

**Note**

- Regardless of the approach that you choose, you can increase manageability of your remote access server solution by using IAS to centralize VPN or dial-up networking authentication, authorization, and accounting. For the Microsoft® Windows® 2000 Server family, IAS is a RADIUS server; for the Windows Server 2003 family, IAS is a RADIUS server and proxy. For information about designing and deploying IAS, see "Deploying Internet Authentication Service (IAS)" in this book.

# Designing a Remote Access Server Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After choosing the remote access to deploy, begin the design process. The design for a remote access server solution encompasses hardware requirements, outsourcing options, placement of remote access servers on the network, routing for remote access clients, and a security plan. Before deploying your remote access server solution, optimize and test your design. Figure 8.5 shows the process for designing a remote access server solution.

**Figure 8.5 Designing a Remote Access Server Solution**

# Determining Hardware Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The first step in designing a remote access solution is to determine hardware requirements. Determine the capacity required for your dial-up or VPN servers, as well as additional hardware required, such as modem banks for a dial-up solution. When selecting server hardware, consider central processing unit (CPU), RAM, and network hardware requirements. For optimal performance, run lab tests on each model of equipment to be used in your production environment.

# Determining Hardware Requirements for Dial-up Networking

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Use the following guidelines when determining hardware requirements for your dial-up networking design:

- A dial-up remote access server must have a modem or a multiport adapter, and it must have access to an analog telephone line. Based on the maximum number of dial-up remote access clients that will dial in at one time, install modem bank equipment and phone lines that meet your organization's needs.

- Each server-side modem requires a serial port on the remote access server. For multiple modems (modem banks), use a multiport serial adapter or a high-density combination card. A multiport serial adapter can connect a large number of analog modems or Integrated Services Digital Network (ISDN) modems to one remote access server. A high-density combination card combines multiple modems and serial adapters in one device.

- For best performance, consider using intelligent communications adapters (multiport serial boards) to offload processing from the remote access server.

# Determining Hardware Requirements for VPN

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Use the following guidelines when determining network hardware requirements for your VPN design:

- For interfaces on the public network, use network adapters capable of IPSec hardware offload.
- Assuming that you have a 10/100 Ethernet infrastructure, set all devices to 100 Mbps Full Duplex.
- Connect interfaces on the private network directly to a high-capacity switch that also connects the data servers and routers that remote access clients will access frequently.

**CPU Requirements**

Use the following guidelines when determining CPU requirements for your VPN design:

- Processing inbound and outbound packets requires CPU cycles. By increasing the available processing power, you can increase throughput.
- Doubling the speed of a single processor is more effective than doubling the number of processors.
- In the case of multiprocessor platforms, binding one CPU to each network adapter can increase the efficiency of interrupt handling, freeing cycles and shrinking the performance gap between the use of a large number of less powerful CPUs and a few faster, more expensive CPUs.

**RAM Requirements**

Use the following guidelines when determining the RAM needed for VPN servers:

- Each active connection consumes a small block of nonpageable memory (approximately 40 KB). If you do not need to handle more than 1,000 concurrent calls from remote access users, 512 MB of RAM is adequate.
- If you require the capacity to handle more than 1,000 concurrent calls, for every 1,000 concurrent calls provide an extra 128 MB of RAM over recommended RAM capacity for the server, plus a base of 128 MB more for remote access and related services.

  For example, for a dedicated remote access server that will support as many as 2,000 simultaneous VPN calls, if the recommended RAM capacity for Windows Server 2003 is 256 MB, provide 768 MB of RAM:

  256 MB + (128 MB * 2) + (128 MB * 2)

**Performing Capacity Planning**

The two greatest potential performance constraints in your remote access server solution are the number of simultaneous connections and the overall data throughput.

The number of simultaneous connections that a VPN server can support is determined by the available nonpaged pool memory as well as other factors, such as the use of data compression. With compression, each connection uses more nonpaged pool memory and requires more processing. Turning off compression can improve performance.

The processing power that is available to a VPN server determines the server's data throughput capacity. Tunneling protocols also have an impact on data throughput. PPTP connections require less processing power than L2TP/IPSec connections do; however, L2TP/IPSec connections are the most secure. You can mitigate the impact of L2TP/IPSec on processing power by using IPSec hardware offload.

# Considering Outsourcing Options

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Outsourcing part or all of a remote access solution through a wholesale contract with an Internet service provider (ISP) can provide some organizations significant cost savings, minimizing both setup and operations costs. You can purchase a wholesale contract with an ISP that provides a guaranteed level of service for some or all components of your remote access solution. An ISP can provide access to an extensive network of connections across a wide geographical area for a fixed cost. Many ISPs provide a guaranteed level of service that rivals those of dial-up wide area network (WAN) connections.

If you are deploying a dial-up networking solution, consider outsourcing your deployment to avoid the long-distance charges that you are likely to accrue.

If you are deploying a VPN solution, an ISP can provide many of the components required to support VPN access, including:

- Network access servers (NASs) for access from various geographical access points.

  If you outsource support, ensure that the NASs that the ISP provides meet your access requirements. VPN users dial first into a NAS. Unless your outsourcing agreement specifies the support required from the ISP's NASs, including connection speeds, device support, and levels of service, the NASs can be the weak link in your VPN solution.

- RADIUS proxy servers for routing of access requests to the enterprise.

  You can either contract with the ISP to provide authentication services or have the ISP use a RADIUS proxy and send authentication requests to a RADIUS server that you manage.

- Phone book support for delivering the latest access numbers either to the enterprise or directly to the client.

# Placing Remote Access Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In deciding where to place remote access servers on your network, consider firewall placement and the placement of other network resources. Place remote access servers close to the network resources that remote access clients need. These resources might include a CA, a RADIUS server, a domain controller, or file and application servers.

In a dial-up remote access design, servers usually are placed behind the firewall. Because a VPN design involves Internet connectivity, server placement relative to the firewall is a greater issue.

If you are designing a VPN remote access solution, choose between two options for server placement, each with different design requirements:

- **VPN server behind the firewall.** The firewall is attached to the Internet, with the VPN server between the firewall and the intranet. This is the placement used in a perimeter network configuration, in which one firewall is positioned between the VPN server and the intranet, with another between the VPN server and the Internet.

- **VPN server in front of the firewall.** The VPN server is connected to the Internet, with the firewall between the VPN server and the intranet.

**VPN Server Behind the Firewall**

The most common configuration for a VPN remote access design is to locate the VPN server behind a firewall. In this configuration, the firewall is connected to the Internet, and the VPN server is an intranet resource that is connected to the perimeter network. The VPN server has an interface on both the perimeter network and the intranet. The Internet firewall (the firewall between the Internet and the VPN server) filters all traffic from Internet clients. The intranet firewall (the firewall between the VPN server and the intranet) filters intranet traffic from VPN clients.

Placing a VPN server behind the firewall requires the following configuration:

- Configure the Internet interface on the firewall with inbound and outbound filters that allow traffic to the VPN server. You can specify additional filters to allow traffic to the Web servers, File Transfer Protocol (FTP) servers, and other types of servers on the perimeter network.

- For an added layer of security, configure the perimeter network interface on the VPN server with PPTP or L2TP/IPSec packet filters.

**VPN Server in Front of the Firewall**

Another option is to place the VPN server in front of the firewall, directly connected to the Internet. For inbound traffic, the VPN server decrypts the tunneled data and forwards it to the firewall. The firewall acts as a filter for intranet traffic, and it can prevent access to specific resources, scan data for viruses, perform intrusion detection, and carry out other functions.

To place a VPN server in front of the firewall, you must configure inbound and outbound filters on the VPN server to allow only VPN traffic to and from the IP address of the VPN server's Internet interface.

### Note

- To enable access to services running on the VPN server, make sure that the network BIOS (NetBIOS) and DNS names of the VPN server's Internet interface are not registered in the intranet namespaces. This is the default behavior for Windows Server 2003 VPN servers.

# Determining Routing for VPN Remote Access Clients

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Because VPN remote access clients typically do not support routing protocols such as Routing Information Protocol (RIP) or Open Shortest Path First (OSPF), the clients often have very simple routing tables. Your remote access design must provide a method for routing packets from the remote access clients to the intranet and the Internet — in some cases simultaneously, depending on the needs of the remote user.

For example, a computer on a small local area network (LAN) has a route to its own subnet on the LAN, and it might have a default route to a gateway router on the LAN for all other traffic. Without routing protocol support, remote access clients cannot automatically determine the best route to a destination.

**Choosing Between Routing Approaches**

The preferred method for directing packets to a remote network is to create a default route on the remote access client that directs packets to the remote network (the default configuration for VPN remote access clients). Any packet that is not intended for the neighboring LAN segment is sent to the remote network. When a connection is made, the remote access client by default adds a default route to its routing table and increases the metric of the existing default route to ensure that the newest default route is used. The newest default route points to the new connection, which ensures that any packets that are not addressed to the local LAN segment are sent to the remote network.

Under this configuration, when a VPN client connects and creates a new default route, Internet sites that have been accessible are no longer accessible. This poses no problem for VPN remote access users who only require access to the organization's network. However, it is not acceptable for remote users who need access to the Internet while they are connected to the organization's network.

Based on whether or not the default route is added, the client has broad access either to Internet locations or to locations on the intranet, but not to both:

- If the default gateway on the remote network is not being used, Internet locations are reachable, but only intranet locations matching the address class of the assigned IP address can be reached.

- If the default gateway on the remote network is being used, all intranet locations are reachable, but only the IP address of the VPN server and locations available through other routes can be reached on the Internet.

For most VPN clients with an Internet connection, this does not present a problem, because the client is typically engaged in either intranet communication or Internet communication, but not both.

To work around this problem, instead of having the client create a new default route when a connection is made, you can configure the client's routing table with specific routes that direct packets to the organization's network over the VPN connection. While connected to the intranet, the client can obtain Internet access using the existing default route over the connection to the ISP. This configuration is known as *split tunneling*.

**Choosing Among Split Tunneling Options**

The VPN client can obtain the routes needed for split tunneling in several ways:

- If the VPN client has a configured connection without a default route, the client adds a route that it infers from the class of the IP address assigned to it for the current connection. For a simple target network, such as a small office, this one route is sufficient to allow packets to be routed to the target network. However, for a complex network, you need to configure multiple routes to successfully direct packets to the remote network.

- A client running the Microsoft® Windows® XP or Windows Server 2003 operating systems uses a DHCPINFORM message after the connection to obtain additional information about the connection, such as a DNS name or a set of routes for the target network. This additional information is only available if the DHCP server has been configured to provide the DHCP Classless Static Routes option, and if the remote access server has been configured to relay the DHCPINFORM message to the DHCP server.

- If the remote access client is managed using the Connection Manager component of Windows Server 2003, the network administrator can prepare a routing table for the remote access client and associate a post-connect action with the

managed connection to update the client's routing table when a connection is made. For more information about using Connection Manager, see "Deploying Remote Access Clients Using Connection Manager" in this book.

- If none of the above approaches meets your needs, the end user or network administrator can write a program or batch file that updates the routing table on the client with the necessary routes to the remote network.

**Security considerations for split tunneling**

Some network administrators consider split tunneling to be a needless security risk. Their concern is that an attacker might be able to compromise the network by enabling traffic to be routed between the Internet and the network using the remote access client. To prevent this, you can add packet filters to the remote access policy profile settings for the VPN connection to allow only inbound traffic that originates from remote access clients. The default remote access policy named **Connections to Microsoft Routing and Remote Access server** has these packet filters already configured.

**Obtaining IP Addresses for Remote Access Clients**

Use either of the following methods to obtain IP addresses to assign to remote access clients:

- Let Routing and Remote Access assign IP addresses obtained from a DHCP server to remote access clients.

- Configure a static pool of IP addresses to assign to remote access clients. You can specify either an on-subnet or off-subnet range of IP addresses for the static pool.

# Planning Security for a VPN

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Because a dial-up networking solution provides a secure data path over a circuit-switched connection, security is not a critical issue in your design for a dial-up remote access solution. In contrast, a VPN remote access solution routes data over a packet-switched connection that does not intrinsically provide the same level of security. Therefore, security is an important part of your VPN remote access server design.

The security of a VPN is based on the tunneling and authentication protocols that you use and the level of encryption that you apply to VPN connections. For the highest level of security, use a remote access VPN based on L2TP/IPSec with certificate-based IPSec authentication and Triple-DES for encryption. If you decide to use a PPTP-based VPN solution to reduce costs and improve manageability and interoperability, use Microsoft Challenge Handshake Authentication Protocol version 2 (MS-CHAPv2) as the authentication protocol.

In designing security for your VPN remote access server solution, perform the following tasks:

- Select a VPN protocol.
- Select authentication protocols.
- Select the scope and level of encryption.
- If needed, plan a certificate infrastructure to support client authentication for remote access.
- Optionally, plan for Network Access Quarantine Control.
- Optionally, enhance security by using remote access account lockout.

**Note**

- You can increase the security and manageability of your remote access server solution by using IAS to centralize VPN or dial-up networking authentication, authorization, and accounting. In operating systems in the Windows 2000 Server family, IAS is an implementation of a RADIUS server; in Windows Server 2003, IAS is an implementation of a RADIUS server and proxy. For information about designing and deploying Internet Authentication Service (IAS), see "Deploying Internet Authentication Service (IAS)" in this book.

# Selecting a VPN Protocol

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Tunneling and authentication protocols, and the encryption levels applied to VPN connections, determine VPN security. L2TP/IPSec provides the highest level of security. For a VPN design, determine which VPN protocol best meets your requirements. Windows Server 2003 supports two VPN protocols: Point-to-Point Tunneling Protocol (PPTP) and Layer Two Tunneling Protocol with Internet Protocol security (L2TP/IPSec).

**PPTP**

PPTP uses Point-to-Point Protocol (PPP) user authentication methods and Microsoft Point-to-Point Encryption (MPPE) to encrypt IP traffic. When used with MS-CHAP v2 for password-based authentication and strong passwords, PPTP is a secure VPN technology. For stronger authentication for PPTP connections, you can implement a PKI using smart cards or certificates and Extensible Authentication Protocol — Transport Level Security (EAP-TLS).

PPTP is widely supported and easily deployed, and it works with most network address translators (NATs).

**L2TP/IPSec**

The more secure of the two VPN protocols, L2TP/IPSec uses PPP user authentication methods and IPSec encryption to encrypt IP traffic. This combination uses certificate-based computer identity authentication to create IPSec security associations in addition to PPP-based user authentication. L2TP/IPSec provides data integrity, data origin authentication, data confidentiality, and replay protection for each packet.

Support for L2TP/IPSec is provided with Windows Server 2003, as well as with Windows 2000 and Windows XP. To use L2TP/IPSec with the Microsoft® Windows® 98, Windows® Millennium Edition (Windows Me), or Windows NT® Workstation 4.0 operating system, download and install Microsoft L2TP/IPSec VPN Client (Mls2tp.exe). For information about Mls2tp.exe, see the Microsoft L2TP/IPSec VPN Client link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

Table 8.1 summarizes the advantages and constraints associated with the use of the PPTP and L2TP/IPSec protocols.

**Table 8.1 Advantages and Constraints of the PPTP and L2TP/IPSec VPN Protocols**

| Factor | PPTP Advantages and Constraints | L2TP/IPSec Advantages and Constraints |
|---|---|---|
| Client operating systems supported | Supported on clients running Windows 2000, Windows XP, Windows Server 2003, Windows NT Workstation 4.0, Windows Me, or Windows 98. | Natively supported on clients running Windows 2000, Windows XP, or Windows Server 2003.<br><br>With Mls2tp.exe installed, supported on clients running Windows 98, Windows Me, or Windows NT Workstation 4.0. |
| Certificate support | For EAP-TLS authentication to issue computer certificates to the authenticating server and user certificates to all VPN clients or to issue smart cards to all users, PPTP requires a certificate infrastructure. | To issue computer certificates to the VPN server and all VPN clients, L2TP/IPSec requires a certificate infrastructure or a preshared key (PSK). |
| Security | Provides data confidentiality. (Captured packets cannot be interpreted without the encryption key.)<br><br>Does not provide data integrity (proof that the data was not modified in transit) or data origin authentication (proof that the data was sent by the authorized user).<br><br>To increase security, use MS-CHAP v2 as the authentication protocol with strong passwords. | Offers the highest level of security, providing data confidentiality, data integrity, data origin authentication, and replay protection. |

| | | |
|---|---|---|
| Performance | A VPN server supports more PPTP connections than L2TP/IPSec connections. | Because IPSec encryption is processing intensive, a VPN server supports fewer L2TP connections than PPTP connections. To support additional L2TP connections, increase CPU processing power or use offload network adapters. |
| NAT support | PPTP-based VPN clients can be located behind a NAT if the NAT includes an editor that can translate PPTP. | If you locate L2TP/IPSec–based clients or servers behind a NAT, both client and server must support IPSec NAT traversal (NAT-T). |

**NAT Requirements for VPN Protocols**

If you are using a NAT with your VPN remote access server solution, your security plan for remote access must include the required setup for placing VPN clients behind a NAT. The VPN protocol that you deploy affects the NAT requirements.

A *network address translator (NAT)* translates the IP addresses and Transmission Control Protocol / User Datagram Protocol (TCP/UDP) port numbers of packets that are forwarded between a private network and the Internet. The NAT on the private network can provide IP address configuration information to the other computers on the private network.

The NAT can act as a simplified DHCP server that allocates an IP address, a subnet mask, a default gateway, and the IP address of a DNS server. The NAT can become the DNS proxy for the computers on the private network. When the NAT receives name resolution requests from a computer on the private network, it forwards the request to a specified Internet-based DNS server and returns a response to the requesting computer on the private network.

**Using a NAT with PPTP connections** If a VPN client that uses a PPTP connection is behind a NAT, the NAT must include a NAT editor that can translate PPTP traffic. The NAT editor is required, because PPTP tunneled data has a Generic Routing Encapsulation (GRE) header rather than a TCP header or a UDP header. The NAT editor uses the Call ID field in the GRE header to identify the PPTP data stream and translate IP addresses and call IDs for PPTP data packets that are forwarded between a private network and the Internet.

The NAT/Basic Firewall routing protocol component of the Routing and Remote Access service includes a NAT editor for PPTP traffic.

**Using a NAT with L2TP connections** *IPSec NAT Traversal (NAT-T)* enables IPSec peers to communicate when behind a NAT. IPSec NAT-T provides UDP encapsulation of IPSec packets to enable Internet Key Exchange (IKE) and Encapsulating Security Payload (ESP)–protected traffic to pass through a NAT. IKE automatically detects that a NAT is present and uses User Datagram Protocol — Encapsulating Security Payload (UDP-ESP) encapsulation to enable ESP-protected IPSec traffic to pass through the NAT.

To use NAT-T, both the remote access VPN client and the remote access server must support IPSec NAT–T. IPSec NAT-T is supported by Windows Server 2003 and Microsoft L2TP/IPSec VPN Client.

# Selecting an Authentication Protocol

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Because L2TP/IPSec user authentication occurs after the VPN client and the VPN server have established a secure channel of communication, your choice of authentication protocol has no effect on VPN security if you use L2TP/IPSec. However the use of MS-CHAP v2 and EAP-TLS is recommended.

To use encryption on a PPTP connection, you must use one of the following authentication protocols:

- MS-CHAP
- MS-CHAP v2
- EAP-TLS

**Authentication Protocols for PPTP VPN Connections**
PPTP VPN connections require the use of the MS-CHAP, MS-CHAP v2, or EAP-TLS authentication protocols. Only these three authentication protocols provide a mechanism to generate the same encryption key on both the VPN client and the VPN server. MPPE uses this encryption key as a basis for encrypting all PPTP data sent over the VPN connection.

**MS-CHAP and MS-CHAP v2** MS-CHAP and MS-CHAP v2 are password-based authentication protocols. In the absence of certificates or smart cards, use MS CHAP v2, a stronger authentication protocol than MS CHAP, which provides mutual authentication. With *mutual authentication*, the VPN server authenticates the VPN client, and the VPN client authenticates the VPN server.

**Note**

- If you must use a password-based authentication protocol, enforce the use of strong passwords on your network. A strong password has more than eight characters and a random mixture of uppercase and lowercase letters, numbers, and punctuation marks. For example, "f3L*q02~>xR3w#4o" is a strong password. In an Active Directory domain, use Group Policy settings to enforce strong user passwords.

**EAP-TLS** The EAP-TLS authentication protocol is designed for use with a certificate infrastructure and either certificates or smart cards. With EAP-TLS, the VPN client sends its user certificate for authentication, and the authenticating server for the VPN server sends a computer certificate for authentication. This is the strongest authentication method, because it does not rely on passwords. For more information about EAP-TLS authentication, see "Connecting Remote Sites" in this book.

You can use Certificate Services in Windows Server 2003 as the CA for your organization, or you can use a third-party CA when you deploy EAP-TLS as your authentication method. For information about certificate requirements with Certificate Services, see "Network access authentication and certificates" in Help and Support Center for Windows Server 2003.

Using a third-party CA requires the following setup:

- The certificate in the computer store of the authenticating server must contain the Server Authentication certificate purpose in Enhanced Key Usage (EKU) extensions. A certificate purpose is identified with an object identifier (OID). The object identifier for Server Authentication is 1.3.6.1.5.5.7.3.1.
- The Subject Alternative Name property of the computer certificate must contain the fully qualified domain name (FQDN) of the computer account of the authenticating server.
- The cryptographic service provider for the computer certificates on the authenticating server must support the secure channel (Schannel) security package. Without support for Schannel, the authenticating server cannot use the certificate, and the certificate will not be available for use in the remote access policy.
- The certificate installed on a remote access client that is running Windows Server 2003 must contain the Client Authentication certificate purpose (OID 1.3.6.1.5.5.7.3.2).

- The Subject Alternative Name property of the user certificate must contain the FQDN of the user account of the VPN client.

- Both the certificate in the computer store of the authenticating server and the user certificate of the remote access client must contain a private key.

**Authentication Protocols for L2TP/IPSec Connections**

For L2TP/IPSec connections, you can use any user authentication protocol, because the authentication occurs after the VPN client and VPN server have established a secure channel of communication. This is referred to as an *IPSec security association (SA)*. It is strongly recommended that you use either MS-CHAP v2 or EAP-TLS to provide the most secure user authentication that is available.

**Guidelines for Selecting Authentication Protocols**

Consider the following factors when choosing an authentication protocol for VPN connections:

- If you use smart cards or have a certificate infrastructure that issues user and computer certificates, use the EAP-TLS authentication protocol for both PPTP and L2TP connections. EAP-TLS is supported by VPN clients running Windows 2000, Windows XP, or Windows Server 2003.

- If you must use a password-based authentication protocol, use MS-CHAP v2, and enforce strong passwords using Group Policy. MS-CHAP v2 is supported by VPN clients running Windows XP, Windows Server 2003, Windows 2000, Windows NT Workstation 4.0 with Service Pack 4 (SP4) and later, Windows Millennium Edition, or Windows 98.

- Use the most secure protocols that your network access servers and clients can support. If you need a high level of security, configure the remote access server and the authenticating server to accept only a few very secure authentication protocols. Alternatively, if flexibility is more important than maintaining a high level of security, configure the authenticating server to accept less secure authentication protocols. For more information about designing and deploying IAS, see "Deploying Internet Authentication Service (IAS)" in this book.

# Selecting the Scope and Level of Encryption

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

On a VPN, you protect your data by encrypting it between the VPN client and the VPN server. Always use data encryption for VPN connections when private data is sent across a public network, which always presents a risk of interception. For VPN connections, Windows Server 2003 uses MPPE for PPTP connections and IPSec encryption for L2TP connections.

**Note**

- Nonencrypted PPTP connections (over which the PPP frame is sent in plaintext) and nonencrypted non-IPSec-based L2TP connections (over which the PPP frame is sent in plaintext) are not secure, and they are not recommended for VPN connections over the Internet.

To ensure successful encryption and decryption, the sender and the receiver must use a common encryption key. The length of the encryption key is an important security parameter, especially over public networks. To ensure the highest level of encryption, use the largest key size.

**Protection Provided by Link Encryption**

In *link encryption,* data is encrypted only on the link between the VPN client and the VPN server. A VPN connection has link encryption, regardless of the VPN protocol in use. PPTP connections use MPPE with MS-CHAP, MS-CHAP v2, or EAP-TLS authentication. For L2TP/IPSec connections, IPSec provides encryption on the link between the VPN client and the VPN server.

When data encryption is performed between the VPN client and the VPN server, you do not need to encrypt the data on the communication link between a dial-up client and its ISP. For example, a mobile user might use a dial-up networking connection to dial in to a local ISP. After the Internet connection is made, the user creates a VPN connection with the enterprise VPN server. Because the VPN connection is encrypted, no encryption is needed on the dial-up networking connection between the user and the ISP.

**Providing End-to-End Encryption**

For an additional layer of security, configure end-to-end encryption. *End-to-end encryption* encrypts the data between the source host and the destination host. After a VPN connection is made, IPSec can be used to provide end-to-end encryption. For an L2TP/IPSec connection, IPSec end-to-end encryption is used in addition to IPSec link encryption.

Table 8.2 shows which authentication methods support specific encryption requirements.

**Table 8.2 Encryption Support Provided Under CHAP, MS-CHAP, and EAP-TLS**

| Requirement | Authentication Protocols | Encryption Enforcement |
|---|---|---|
| Secured password with no data encryption | CHAP, MS-CHAP, MS-CHAP v2 | Optional encryption. (Connect even if no encryption.) |
| Secured password with MPPE data encryption | MS-CHAP, MS-CHAP v2 | Required encryption. (Disconnect if server declines.) |
| Smart card with no data encryption | EAP-TLS | Optional encryption. (Connect even if no encryption.) |
| Smart card with data encryption | EAP-TLS | Require encryption. (Disconnect if server declines.) |

Data encryption for L2TP connections relies on IPSec, which does not require any specific authentication protocol. IPSec enforces the encryption; if the server declines data encryption, the connection is denied.

The strength of link encryption is set through the remote access policies that govern PPTP and L2TP connections on the server. A *remote access policy* is a collection of conditions and settings that define authorization and access privileges for connection attempts. For IAS servers and servers running Routing and Remote Access, remote access policies are used to determine whether a connection attempt is accepted or rejected.

Table 8.3 shows the encryption support provided for PPTP and L2TP/IPSec connections by each level of encryption that is set in a remote access policy.

**Table 8.3 Encryption Required at Each Encryption Level for PPTP and L2TP/IPSec Connections**

| Encryption Level | PPTP Encryption Required | L2TP Encryption Required |
|---|---|---|
| **No Encryption** | No encryption required. | No encryption required. |
| **Basic** | MPPE 40-bit data encryption | IPSec 56-bit Data Encryption Standard (DES) |
| **Strong** | MPPE 56-bit data encryption | IPSec 56-bit DES |
| **Strongest** | MPPE 128-bit encryption | IPSec 168-bit Triple DES (3DES) |

For a procedure for setting the encryption level in a remote access policy, see "Configuring authentication and data encryption" in Help and Support Center for Windows Server 2003. For more information about using Windows Server 2003 remote access policies, see "Introduction to remote access policies" in Help and Support Center for Windows Server 2003.

# Planning a Certificate Infrastructure to Support Client Authentication

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The authentication methods that are deployed for remote access clients determine whether or not your remote access design requires a certificate infrastructure.

A certificate infrastructure is required for L2TP/IPSec-based VPN connections, because certificates are used to negotiate IPSec peer authentication. For PPTP-based VPN connections, a certificate infrastructure is required if either smart cards or certificates and EAP-TLS authentication are in use. Password-based authentication protocols, such as MS-CHAP v2, do not use certificates in authentication; therefore, a certificate infrastructure is not required.

Table 8.4 shows where you must install certificates to support remote access clients over L2TP/IPSec-based VPN connections and over PPTP-based connections using EAP-TLS. For EAP-TLS authentication, L2TP/IPSec-based VPN connections require one more certificate on the VPN client than PPTP-based VPN connections require.

**Table 8.4 Certificate Infrastructures Required for Remote Access Client Authentication**

| VPN/Authentication Protocol | Required Certificate Infrastructure |
|---|---|
| L2TP/IPSec-based VPN connection | • Install a computer certificate on the VPN server.<br>• Install a computer certificate on each VPN client. |
| PPTP-based VPN connection using smart cards and EAP-TLS | • Install a computer certificate on the authenticating server for the VPN server.<br>• Install a user certificate on each smart card. |
| PPTP-based VPN connection using registry-based user certificates and EAP-TLS | • Install a computer certificate on the authenticating server for the VPN server.<br>• Install a user certificate on each VPN client. |

If your PPTP-based VPN connections require a certificate infrastructure, install a computer certificate on the authenticating server for the VPN server. If you are using smart cards, install a user certificate on each smart card distributed to a VPN client user. If you are using registry-based user certificates with EAP-TLS authentication, install a user certificate on each VPN client.

For an L2TP/IPSec-based VPN connection, install a computer certificate on all VPN clients and on the VPN server. A certificate infrastructure is also required when you are using either smart cards or certificates and EAP-TLS for user authentication.

For more information about certificate requirements, see "Network access authentication and certificates" in Help and Support Center for Windows Server 2003.

For more information about deploying certificate services to support L2TP/IPSec, see "Designing a Public Key Infrastructure" in *Designing and Deploying Directory and Security Services* of this kit.

# Planning for Network Access Quarantine Control

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Because typical remote access connections only validate the credentials of a remote access user, a remote access client that connects to a private network can access network resources even if the configuration of the remote access client does not comply with corporate network policies. You can implement Network Access Quarantine Control to delay normal remote access to a private network until the configuration of the remote access client has been examined and validated by a client-side script.

When a remote access client initiates a connection to a remote access server, the user is authenticated, and the remote access client is assigned an IP address. If Network Access Quarantine Control is in use, the connection is placed in quarantine mode until a client-side script is run on the remote access client and the configuration of the remote access client is validated against current network policies. While the remote access connection is in quarantine mode, network access is limited. When the remote access server is notified that the configuration of the remote access client is validated against current network policies, quarantine mode is removed, and the remote access client is granted normal remote access.

The components for Network Access Quarantine Control are included in the *Microsoft® Windows® Server 2003 Resource Kit Tools*. For instructions on setting up Network Access Quarantine Control, see "Configuring Network Access Quarantine Control" later in this chapter.

**Note**

- Network Access Quarantine Control is designed to prevent clients with unsafe configurations from attaching to a private network. It does not protect a private network from malicious users who have obtained a valid set of credentials.

**Processing a Connection Attempt Under Network Access Quarantine Control**

Under Network Access Quarantine Control, the user on a quarantine-compatible remote access client uses an installed Connection Manager profile to connect with a quarantine-compatible remote access server. The remote access client passes its authentication credentials to the remote access server. The Routing and Remote Access service sends a RADIUS Access-Request message to the IAS server. The IAS server validates the authentication credentials of the remote access client and, assuming valid credentials, checks its remote access policies. If the connection attempt matches the quarantine policy, the connection is accepted with quarantine attributes and the connection is placed in quarantine mode.

While the connection attempt is in quarantine mode, the remote access server implements a set of network restrictions for the connection. These network restrictions are configured in IAS. The IAS server sends a RADIUS Access-Accept message that contains the MS-Quarantine-IPFilter and MS-Quarantine-Session-Timeout attributes. The remote access client completes the remote access connection, obtaining an IP address and other configuration settings, and the Windows Server 2003 Routing and Remote Access service configures the MS-Quarantine-IPFilter and MS-Quarantine-Session-Timeout settings for the connection. At this point, the remote access client can only successfully send traffic that matches the quarantine filters. The client must notify the remote access server that the client has passed network compliance testing within the time limit (in seconds) specified by the MS-Quarantine-Session-Timeout attribute in the quarantine remote access policy.

**Note**

- The process described in this section incorporates the use of both the MS-Quarantine-IPFilter attribute and the MS-Quarantine-Session-Timeout attribute. Both attributes are optional.

The Connection Manager profile initiates a post-connect action, which runs the embedded client-side script. The script verifies that the remote access computer's configuration complies with network policy requirements. If the script runs successfully, the script runs the notification component, Rqc.exe, which notifies the remote access server that the remote access client complies with network policy.

The listener component on the remote access server, known as the Remote Access Quarantine Agent service (Rqs.exe), receives the notification. Routing and Remote Access removes the MS-Quarantine-IP Filter and MS-Quarantine-Session-Timeout settings from the connection, giving the remote access client normal access to the intranet.

**Components of Network Access Quarantine Control**

Figure 8.6 shows the components of Windows remote access for Network Access Quarantine Control.

**Figure 8.6 Components of Network Access Quarantine Control for Remote Access**

This configuration consists of the following components:

- Quarantine-compatible access clients
- Quarantine-compatible access server
- Quarantine-compatible RADIUS server
- Quarantine resources
- Accounts database
- Quarantine remote access policy

**Quarantine-compatible access clients**

The remote access client must be a computer running one of the following operating systems: Microsoft® Windows® XP Professional, Windows® XP Home Edition, Windows 2000, Windows Millennium Edition, Windows 98 Second Edition, or Windows Server 2003.

These versions of Windows support Connection Manager profiles that are created by the Connection Manager Administration Kit (CMAK) provided with Windows Server 2003 and contain:

- A post-connect action setting that runs a network policy requirements script.

  The post-connect action setting is configured when the CM profile is created with CMAK.

- A network policy requirements script

  The network policy requirements script performs validation checks on the remote access client computer to verify that it conforms to network policies. The script can be a custom executable file or as simple as a command file (also known as a batch file).

- A notifier component.

  When the script has run successfully and the connecting computer has satisfied all of the network policy requirements verified by the script, the script executes a notifier component (an executable file) with the appropriate parameters. The notifier component sends a message to the quarantine-compatible remote access server that indicates a successful execution of the script. You can use your own notifier component or you can use Rqc.exe, which is provided with the *Windows Server 2003 Resource Kit Tools*.

With these components installed, the remote access client computer uses the CM profile to perform its own network policy requirements check and indicate its success to the remote access server as part of the connection setup.

**Quarantine-compatible access server**
A quarantine-compatible remote access server requires the following components:

- A computer running Windows Server 2003 and the Routing and Remote Access service.

  Routing and Remote Access with Windows Server 2003 supports the use of a listener component and the MS-Quarantine-IPFilter and MS-Quarantine-Session-Timeout RADIUS vendor-specific attributes (VSAs), which are used to specify quarantine settings.

- A listener component.

  The listener component listens for messages from quarantine-compatible remote access clients that indicate that their scripts have run successfully. You can create your own custom listener component (matched with your own custom notifier component) or you can install the Remote Access Quarantine Agent service (Rqs.exe) from the *Windows Server 2003 Resource Kit Tools*.

With these components installed, the remote access server implements quarantine mode for connecting remote access clients and listens for notifier messages that the clients have satisfied network policy requirements and can be taken out of quarantine mode.

**Quarantine-compatible RADIUS server**
A quarantine-compatible RADIUS server requires a computer running Windows Server 2003 and IAS, which supports the configuration of the MS-Quarantine-IPFilter and MS-Quarantine-Session-Timeout RADIUS vendor-specific attributes (VSAs) to specify quarantine settings for the quarantine-compatible remote access server.

**Quarantine resources**
In quarantine mode, a remote access client must have access to the following resources:

- To perform name resolution, the client must have access to DNS servers.

- To obtain the latest version of the script, the client must have access to file servers with anonymous access allowed.

- To obtain instructions and components needed to bring the remote access client into compliance with network policies, the client must have access to Web servers with anonymous access allowed.

**Accounts database**
For Windows Server 2003-based networks, the Active Directory service is used as the accounts database to store user accounts and their dial-in properties.

**Quarantine remote access policy**
For Network Access Quarantine Control, you must configure a quarantine remote access policy with the appropriate conditions for remote access connections, and with profile settings that specify the MS-Quarantine-IPFilter and MS-Quarantine-Session-Timeout attributes (configured on the **Advanced** tab of the profile).

- The MS-Quarantine-IPFilter attribute is used to configure inbound and outbound packet filters to allow only the traffic generated by the notifier component. If you are using Rqc.exe, configure a single inbound packet filter to only allow traffic from TCP port 7250 and to TCP port 7250 (the default TCP port for Rqc.exe), and specify that all other traffic be discarded. Additional packet filters are needed in order for the quarantined remote access client to access the quarantine resources. These include filters that allow the remote access client to access DNS servers, file shares, and Web servers.

  The packet filters configured for the MS-Quarantine-IPFilter attribute provide the quarantine, or isolation, of the traffic of the remote access client until the notifier component on the remote access client indicates that the computer is in compliance with network policies.

- The MS-Quarantine-Session-Timeout attribute specifies how long the remote access server waits to receive the notification that the script has executed successfully before terminating the connection.

# Enhancing Security by Using Remote Access Account Lockout

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To prevent dictionary attacks on remote server accounts, you can use remote access account lockout. When deciding whether or not to use remote access account lockout, remember that if you enable remote access account lockout, a malicious user can intentionally attempt multiple authentications for a user account to force the account to be locked out, thereby preventing the authorized user from being able to create a remote access connection.

Remote access account lockout is configured in the registry in Windows Server 2003. It is not related to the account lockout policy for domain or local user accounts.

To enable remote access account lockout, modify the following subkey in the registry on the server that authenticates remote access requests:

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\RemoteAccess \Parameters\AccountLockout

If the remote access server is configured for Windows authentication, modify the registry on that server. If the remote access server is configured for RADIUS authentication, and you are using IAS, modify the registry on the IAS server.

For more information about modifying the AccountLockout subkey, see "Configuring Remote Access Account Lockout for a VPN Solution" later in this chapter.

**Caution**

- Do not edit the registry unless you have no alternative. The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Registry reference on the *Microsoft® Windows® Server 2003 Deployment Kit* companion CD or at http://www.microsoft.com/reskit.

If your organization is using smart cards, the smart card manufacturer controls account lockout for personal identification numbers (PINs) that are not valid. Recovery from account lockout as a result of an invalid PIN might require smart card replacement.

For more information about remote access account lockout, see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

# Optimizing Your Remote Access Server Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In addition to increasing performance by upgrading server hardware, consider increasing availability, security, and performance by incorporating the following elements in your remote access design:

- Redundant servers for increased availability
- Network Load Balancing for increased availability and performance

**Increasing Availability by Using Redundant Servers**
Remote access solutions with redundant servers can provide higher availability for remote access clients. If degradation of service is not a critical issue, you can use your primary remote access servers as backups for each other. If service degradation is not acceptable, provide redundancy by enlisting an extra server to provide failure protection.

If one or more user groups require high-priority access, consider using separate remote access servers for these user groups.

**Increasing Performance by Using Network Load Balancing**
By using Network Load Balancing, which is available in Windows Server 2003, you can increase VPN server performance and availability. Network Load Balancing distributes traffic from remote access VPN clients among multiple VPN servers.

Network Load Balancing also provides immediate failover if a VPN server fails. If a VPN server fails, client sessions handled by that server also fail. Clients are prompted to log on again, and their new session is handled by one of the remaining hosts.

To provide load balancing for VPN clients, use the default port rule in configuring all hosts, as follows:

- Set the port range to 0–65535 (the default). The default range covers all of the ports, so the port rule remains valid even if there is a change in the port numbers that you want to cover.
- Accept the default filtering mode, load weight/equal load distribution, and affinity settings.

For more information about using Network Load Balancing in a VPN scenario, see "Deploying Network Load Balancing" in *Planning Server Deployments* of this kit.

# Testing Your Remote Access Server Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you complete the design of your remote access server solution, test the design. Testing the design includes testing individual VPN client access to VPN servers, as well as comprehensive testing of the entire external connectivity design. If you are integrating multiple remote access solutions, test them together after testing them individually.

Because of vulnerabilities that exposure to the Internet might introduce, isolate your network perimeter from your intranet during testing. Do not integrate your network perimeter with your intranet until you are confident that you have addressed all security issues.

Be sure to test the ISP infrastructure, including the RADIUS proxy (if applicable), and a representative sampling of access points.

Testing is critical to the security of any external connectivity solution, and it is important for ensuring that the connections function as planned. Before testing, simulate both internal and external connections to prevent exposure and corruption of any part of your network.

**Tools for Testing a Remote Access Server Design**

The following tools are useful in testing a remote access server design:

- TCP/IP troubleshooting tools, including Netsh, Ping, Pathping, Route, and Tracert.
- Remote access logging in the Routing and Remote Access snap-in. The log includes authentication and accounting information.
- Event Viewer. This is an administrative tool for Windows Server 2003 that displays monitoring and troubleshooting information from Windows and other programs.
- Network Monitor. This is an optional networking component for Windows Server 2003 that allows a system administrator to capture and examine packets on a LAN and save the packets to a capture file.
- Remote Access Event Tracing. This is enabled through Netsh.

# Deploying a VPN Remote Access Server Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Deploying a remote access server solution involves configuring the server as a VPN remote access server; configuring routing on the VPN server and the VPN clients; and implementing security — installing any certificates required for the authentication of remote clients, configuring encryption in requirements the remote access policy for VPN connections, and optionally configuring remote access account lockout. Figure 8.7 shows the process for deploying a VPN remote access server solution.

**Figure 8.7 Deploying a VPN Remote Access Server Solution**

**Important**

- The procedures for deploying a VPN remote access server solution assume that you have deployed Active Directory on the server, have a PKI in place, and have deployed an IAS server.

- For information about designing and deploying a PKI, see "Designing a Public Key Infrastructure" in *Designing and Deploying Directory and Security Services* of this kit. For information about designing and deploying IAS, see "Deploying Internet Authentication Service (IAS)" in this book. For more information about Active Directory, see "Designing the Active Directory Logical Structure" in *Designing and Deploying Directory and Security Services* of this kit.

# Configuring a VPN Remote Access Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The configuration of a VPN remote access server involves the following tasks:

- Configure the server as a VPN remote access server.
- Configure TCP/IP on the server.
- Configure name resolution on the server.
- Configure packet filters for the server.
- Optionally, configure Network Access Quarantine Control.

# Configuring the Server as a VPN Remote Access Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To configure the server as a VPN remote access server, use the Configure Your Server Wizard and select **Remote access/VPN server** as the server role, or use the Rounting and Remote Access snap-in. For instructions on using the wizard, see "Remote access/VPN server role: Configuring a remote access/VPN server" in Help and Support Center for Windows Server 2003.

# Configuring TCP/IP on the VPN Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After configuring the server as a remote access server, configure the TCP/IP settings for the Internet or perimeter network interface and for the intranet interface.

**Note**

- Because of routing issues related to configuring TCP/IP automatically, it is recommended that you not configure a VPN server as a DHCP client. Instead, manually configure TCP/IP on the intranet interfaces of a VPN server. For a full discussion of the routing options for a VPN server, see "Configuring Routing on a VPN Server" later in this chapter.

Manually configure the Internet or perimeter network interface of the VPN server with a default gateway. Configure the TCP/IP settings with a public IP address, a subnet mask, and the default gateway of either the firewall (if the VPN server is connected to a perimeter network) or an ISP router (if the VPN server is connected directly to the Internet).

**To configure TCP/IP for the Internet or perimeter network interface**

1. In **Control Panel**, double-click **Network Connections**, and then double-click the network adapter for the Internet or perimeter network interface.

2. In the network adapter status dialog box (for example, **Local Area Connection Status**), click **Properties**.

3. SelectInternet Protocol (TCP/IP), and then click **Properties**.

4. On the **General** tab, configure the IP address, subnet mask, and default gateway.

   The IP address must be a public IP address assigned by an ISP. As an option, you can configure the VPN server with a private IP address but assign it a published static IP address by which it is known on the Internet. When packets are sent to and from the VPN server, a NAT that is positioned between the Internet and the VPN server translates the published IP address to the private IP address.

   When you configure a VPN connection, give your VPN servers names that can be resolved to IP addresses using DNS.

5. Click **Advanced** to display the **Advanced TCP/IP Settings** dialog box.

6. To prevent the VPN server from dynamically registering the public IP address of its Internet interface with an intranet DNS server, on the **DNS** tab, clear the **Register this connection's addresses in DNS** check box. This check box is cleared by default.

7. To prevent the VPN server from registering the public IP address of its Internet interface with intranet WINS servers, on the **WINS** tab, select the **Disable NetBIOS over TCP/IP** check box. This check box is selected by default.

When you configure TCP/IP for the VPN server's intranet interface, do not configure the default gateway on the intranet connection. This will prevent default route conflicts with the default route pointing to the Internet.

**To configure TCP/IP for the intranet interface**

1. In **Control Panel**, double-click **Network Connections,** and then double-click the network adapter for intranet interface.

2. In the network adapter status dialog box (for example, **Local Area Connection 2 Status**), click **Properties**.

3. Select **Internet Protocol (TCP/IP),** and then click **Properties**.

4. On the **General** tab, configure the IP address, subnet mask, and DNS server address.

To prevent default route conflicts with the default route pointing to the Internet, do not configure the default gateway on the intranet connection.

5. Click **Advanced** to display the **Advanced TCP/IP Settings** dialog box.

6. On the **WINS** tab, configure the IP addresses of your WINS servers.

# Configuring Name Resolution on a VPN Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you use Domain Name System (DNS) to resolve intranet host names or Windows Internet Name Service (WINS) to resolve intranet NetBIOS names, manually configure the VPN server with the IP addresses of the appropriate DNS and WINS servers.

During the PPP connection setup process, VPN clients receive the IP addresses of DNS and WINS servers. By default, the VPN clients inherit the DNS and WINS server IP addresses configured on the VPN server. However, VPN clients that are capable of sending a DHCPINFORM message (computers running Windows 2000, Windows XP, or Windows Server 2003) get their DNS and WINS server IP addresses from the DHCP server.

# Configuring Packet Filters for a VPN Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The firewall is configured with rules to filter the packets that a VPN server sends and receives and control intranet traffic to and from VPN clients, based on your network security policies. Packet filtering is based on the fields of inbound and outbound packets.

The Routing and Remote Access Server Setup Wizard for Windows Server 2003 and Windows Server 2000 Service Pack 2 (SP2) or later automatically configures the appropriate packet filters for VPN traffic. Alternatively, you can use the Routing and Remote Access snap-in to configure the packet filters.

The following sections summarize the packet filters that are required when the VPN server is placed behind a firewall or in front of a firewall. For procedures explaining how to enter the packet filter configurations, see "VPN servers and firewall configuration" in Help and Support Center for Windows Server 2003.

**Configuring Filters for a VPN Server Behind a Firewall**

If the VPN server is behind a firewall, you must configure packet filters for both an Internet interface and a perimeter network interface. In this configuration, the firewall is connected to the Internet, and the VPN server is an intranet resource that is connected to the perimeter network. The VPN server has an interface on both the perimeter network and the Internet.

**PPTP connections**

For a PPTP connection, configure the following packet filters on the Internet and perimeter network interfaces of the firewall.

**Internet interface of the firewall** On the firewall's Internet interface, configure the inbound and outbound filters in Table 8.5, specifying that all packets are dropped except those that are selected by the filters.

**Table 8.5 VPN Server Behind a Firewall: PPTP Filters on the Firewall's Internet Interface**

| | Filter | Action |
|---|---|---|
| Inbound | **Destination IP address** = Perimeter network interface of VPN server<br><br>**TCP destination port** = 1723 (0x6BB) | Allows PPTP tunnel maintenance traffic from the PPTP client to the PPTP server. |
| | **Destination IP address** = Perimeter network interface of VPN server<br><br>**IP Protocol ID** = 47 (0x2F) | Allows PPTP tunneled data from the PPTP client to the PPTP server. |
| | **Destination IP address** = Perimeter network interface of VPN server<br><br>**TCP source port** = 1723 (0x6BB) | Required only when the VPN server is acting as a VPN client (a calling router) in a site-to-site (also known as router-to-router) VPN connection. If you allow all traffic to the VPN server from TCP port 1723, network attacks can emanate from sources on the Internet that use this port. You should only use this filter in conjunction with the PPTP filters that are also configured on the VPN server. |

| | | |
|---|---|---|
| Outbound | **Source IP address** = Perimeter network interface of VPN server<br><br>**TCP source port** = 1723 (0x6BB) | Allows PPTP tunnel maintenance traffic from the PPTP server to the PPTP client. |
| | **Source IP address** = Perimeter network interface of VPN server<br><br>**IP Protocol ID** = 47 (0x2F) | Allows PPTP tunneled data from the PPTP server to the PPTP client. |
| | **Source IP address** = Perimeter network interface of VPN server<br><br>**TCP destination port** = 1723 (0x6BB) | Required only when the VPN server is acting as a VPN client (a calling router) in a site-to-site VPN connection. If you allow all traffic from the VPN server to TCP port 1723, network attacks can emanate from sources on the Internet using this port. You should only use this filter in conjunction with the PPTP filters that are also configured on the VPN server. |

**Perimeter network interface of the firewall** On the firewall's perimeter network interface, configure the inbound and outbound filters in Table 8.6, specifying that all packets are dropped except those that are specified by the filters.

**Table 8.6 VPN Server Behind a Firewall: PPTP Filters on the Perimeter Network Interface**

| | Filter | Action |
|---|---|---|
| Inbound | **Source IP address** = Perimeter network interface of VPN server<br><br>**TCP source port** = 1723 (0x6BB) | Allows PPTP tunnel maintenance traffic from the VPN server to the VPN client. |
| | **Source IP address** = Perimeter network interface of VPN server<br><br>**IP Protocol ID** = 47 (0x2F) | Allows PPTP tunneled data from the VPN server to the VPN client. |
| | **Source IP address** = Perimeter network interface of VPN server<br><br>**TCP destination port** = 1723 (0x6BB) | Required only when the VPN server is acting as a VPN client (a calling router) in a site-to-site VPN connection. If you allow all traffic from the VPN server to TCP port 1723, network attacks can emanate from sources on the Internet using this port. |

| | | |
|---|---|---|
| Outbound | **Destination IP address** = Perimeter network interface of VPN server<br><br>**TCP source port** = 1723 (0x6BB) | Allows PPTP tunnel maintenance traffic from the PPTP client to the PPTP server. |
| | **Destination IP address** = Perimeter network interface of VPN server<br><br>**IP Protocol ID** = 47 (0x2F) | Allows PPTP tunneled data from the PPTP client to the PPTP server. |
| | **Destination IP address** = Perimeter network interface of VPN server<br><br>**TCP source port** = 1723 (0x6BB) | Required only when the VPN server is acting as a VPN client (a calling router) in a site-to-site VPN connection. If you allow all traffic to the VPN server from TCP port 1723, network attacks can emanate from sources on the Internet using this port. |

**L2TP/IPSec connections**

For an L2TP/IPSec connection, configure the following packet filters on the Internet and perimeter network interfaces of the firewall.

**Internet interface of the firewall** On the firewall's Internet interface, configure the inbound and outbound filters in Table 8.7, specifying that all packets are dropped except those that are specified by the filters.

**Table 8.7 VPN Server Behind a Firewall: L2TP/IPSec Filters on the Firewall's Internet Interface**

| | Filter | Action |
|---|---|---|
| Inbound | **Destination IP address** = Perimeter network interface of VPN server<br><br>**UDP destination port** = 500 (0x1F4) | Allows IKE traffic to the VPN server. |
| | **Destination IP address** = Perimeter network interface of VPN server<br><br>**UDP destination port** = 4500 (0x1194) | Allows IPSec NAT-T traffic to the VPN server. |
| | **Destination IP address** = Perimeter network interface of VPN server<br><br>**IP Protocol ID** = 50 (0x32) | Allows IPSec ESP traffic to the VPN server. |
| Outbound | **Source IP address** = Perimeter network interface of VPN server<br><br>**UDP source port** = 500 (0x1F4) | Allows IKE traffic from the VPN server. |
| | **Source IP address** = Perimeter network interface of VPN server<br><br>**UDP source port** = 4500 (0x1194) | Allows IPSec NAT-T traffic from the VPN server. |
| | **Source IP address** = Perimeter network interface of VPN server<br><br>**IP Protocol ID** = 50 (0x32) | Allows IPSec ESP traffic from the VPN server. |

No filters are required for L2TP traffic at UDP port 1701. All L2TP traffic at the firewall, including tunnel maintenance and tunneled data, is encrypted as an IPSec ESP payload.

**Perimeter network interface of the firewall** On the firewall's perimeter network interface, configure the inbound and outbound filters in Table 8.8, specifying that all packets are dropped except those that are selected by the filters.

**Table 8.8 VPN Server Behind a Firewall: L2TP/IPSec Filters on the Firewall's Perimeter Network Interface**

| | Filter | Action |
|---|---|---|
| Inbound | **Source IP address** = Perimeter network interface of VPN server<br><br>**UDP source port** = 500 (0x1F4) | Allows IKE traffic from the VPN server. |
| | **Source IP address** = Perimeter network interface of VPN server<br><br>**UDP source port** = 4500 (0x1194) | Allows IPSec NAT-T traffic from the VPN server. |
| | **Source IP address** = Perimeter network interface of VPN server<br><br>**IP Protocol ID** = 50 (0x32) | Allows IPSec ESP traffic from the VPN server. |
| Outbound | **Destination IP address** = Perimeter network interface of VPN server<br><br>**UDP destination port** = 500 (0x1F4) | Allows IKE traffic to the VPN server. |
| | **Destination IP address** = Perimeter network interface of VPN server<br><br>**UDP destination port** = 4500 (0x1194) | Allows IPSec NAT-T traffic to the VPN server. |
| | **Destination IP address** = Perimeter network interface of VPN server<br><br>**IP Protocol ID** = 50 (0x32) | Allows IPSec ESP traffic to the VPN server. |

**Configuring Filters for a VPN Server in Front of a Firewall**

When a VPN server is in front of a firewall and connected to the Internet, configure inbound and outbound packet filters on the VPN server to allow only VPN traffic to and from the IP address of the VPN server's Internet interface. Use this configuration if your VPN server is in a perimeter network, with one firewall positioned between the VPN server and the intranet and another between the VPN server and the Internet.

**PPTP connections**

For a PPTP connection, configure the VPN server with the inbound and outbound filters in Table 8.9, specifying that all packets be dropped except those that are specified by the filters. These filters are automatically configured when you:

- Rrun the Routing and Remote Access Server Setup Wizard and choose the **Remote access (dial-up or VPN)** option.
- Select the correct interface.
- Select the **Enable security on the selected interface by setting up packet filters** option on the VPN Connection page. This setting is enabled by default.

**Table 8.9 VPN Server in Front of a Firewall: Packet Filters for PPTP**

| | Filter | Action |
|---|---|---|
| Inbound | **Destination IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**TCP destination port** = 1723 | Allows PPTP tunnel maintenance to the VPN server. |

| | | |
|---|---|---|
| | **Destination IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**IP Protocol ID** = 47 | Allows PPTP tunneled data to the VPN server. |
| | **Destination IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**TCP (established) source port** = 1723 | Required only when the VPN server is acting as a VPN client (a calling router) in a site-to-site VPN connection. Accepts TCP traffic only when a VPN server initiates the TCP connection. |
| Outbound | **Source IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**TCP source port** = 1723 | Allows PPTP tunnel maintenance traffic from the VPN server. |
| | **Source IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**IP Protocol ID** = 47 | Allows PPTP tunneled data from the VPN server. |
| | **Source IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**TCP (established) destination port** = 1723 | Required only when the VPN server is acting as a VPN client (a calling router) in a site-to-site VPN connection. Sends TCP traffic only when a VPN server initiates the TCP connection. |

**L2TP/IPSec connections**

For an L2TP/IPSec connection, configure the VPN server with the inbound and outbound filters in Table 8.10, specifying that all packets be dropped except those that are specified by the filters.

**Table 8.10 VPN Server in Front of a Firewall: Packet Filters for L2TP/IPSec**

| | Filter | Action |
|---|---|---|
| Inbound | **Destination IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**UDP destination port** = 500 | Allows IKE traffic to the VPN server. |

| | | |
|---|---|---|
| | **Destination IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**UDP destination port** = 1701 | Allows L2TP traffic from the VPN client to the VPN server. |
| | **Destination IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**UDP destination port** = 4500 | Allows IPSec NAT-T traffic from the VPN client to the VPN server. |
| Outbound | **Source IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**UDP source port** = 500 | Allows IKE traffic from the VPN server. |
| | **Source IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**UDP source port** = 1701 | Allows L2TP traffic from the VPN server to the VPN client. |
| | **Source IP address** = Internet interface of VPN server<br><br>**Subnet mask** = 255.255.255.255<br><br>**UDP source port** = 4500 | Allows IPSec NAT-T traffic from the VPN server to the VPN client |

# Configuring Network Access Quarantine Control

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Perform the following steps to configure Network Access Quarantine Control:

1. Create quarantine resources.

   a. Configure a DNS server, a file server and share point for updated scripts, and a Web server as quarantine resources.

   b. Create Web pages containing network policy compliance instructions.

2. Create a *notification component* that notifies the remote access server that the remote access client complies with network policy requirements. The notification component sends a notifier message that indicates that a client-side script has run successfully on the remote access client, network policy requirements have been met, and the remote access connection quarantine restrictions can be removed. If you do not want to create your own notification component, you can use Rqc.exe in the *Windows Server 2003 Resource Kit Tools*.

3. Create a *client-side script* that validates the client configuration based on your network policy requirements. If all of the verification checks in the script are successful, the script executes the notification component with the appropriate parameters.

4. Create a *listener component* that receives the network policy compliance notification from the notification component. If you do not want to create a listener component, use Rqs.exe in the *Windows Server 2003 Resource Kit Tools*.

   **Note**

   - Rqs.exe and Rqc.exe use TCP port 7250 by default. When you create the quarantine policy, you must configure quarantine inbound filters to allow network traffic on TCP port 7250. Otherwise, Rqc.exe, which runs on client computers, cannot notify Rqs.exe that the client-side script has run successfully. If you specify another TCP port for Rqc.exe and Rqs.exe, you must configure the filter to allow traffic on that TCP port.

5. Create a quarantine Connection Manager profile, to be installed on all remote access clients that access servers participating in Network Access Quarantine Control. Only those remote access clients that have the quarantine Connection Manager profile installed can obtain a full-access connection.

   Use the Windows Server 2003 Connection Manager Administration Kit (CMAK) to create a profile with the following elements:

   - Specify a post-connect action to run the client-side script with the appropriate parameters.

   - Embed the client-side script and the notification component within the profile.

   For information about creating a Connection Manager profile using CMAK, see "Deploying Remote Access Clients Using Connection Manager" in this book.

6. Install the Quarantine Connection Manager profile on all remote access clients that access servers participating in Network Access Quarantine Control.

7. Use the New Remote Access Policy Wizard to create a *quarantine remote access policy* that restricts a remote access client's access while the client computer's configuration is verified against network policy requirements. The quarantine remote access policy can contain the following attributes:

- MS-Quarantine-IPFilter, to restrict a quarantined remote access client's access to only quarantine resources and the port designated for notification traffic.

- MS-Quarantine-Session-Timeout, to restrict the length of time during which a client can remain connected in quarantine mode before being disconnected.

To be quarantine-compatible, a remote access server must be running Windows Server 2003 and the Routing and Remote Access service. Routing and Remote Access with Windows Server 2003 supports the use of a listener component and the RADIUS vendor-specific attributes (VSAs) MS-Quarantine-IP Filter and MS-Quarantine-Session-Timeout, which are used to specify quarantine settings.

**Note**

- For an overview of Network Access Quarantine Control, see "Planning for Network Access Quarantine Control" earlier in this chapter.

# Configuring Routing for a VPN Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Configure routing on your intranet to allow computers to reach VPN clients. After either configuring static routing on the VPN server or configuring the server as a dynamic router, configure routing on the VPN clients.

# Configuring Routing on a VPN Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To enable a VPN server to correctly forward traffic to locations on your intranet, perform one of two routing configurations:

- Configure the server with static routes that summarize all possible IP addresses on the intranet.
- Configure the server with routing protocols that enable it to act as a dynamic router, automatically adding routes for intranet subnets to its routing table.

In a small, stable networking environment, static routing might be an appropriate choice for a VPN solution. However, in most corporate networking environments, the increased administrative overhead required to maintain static routes is prohibitive. The preferred method for a VPN solution is to configure the VPN server as a dynamic router.

**Configuring Static Routes on the Server**
If you manually configure IP address ranges for a static address pool on any of your VPN servers, and if any of the ranges is an off-subnet range, your intranet routing infrastructure must include routes representing the off-subnet address ranges. To provide the best summarization of address ranges for routes, choose your address ranges so that they can be expressed using a single prefix and subnet mask.

To ensure this, add static routes representing the off-subnet address ranges to the routers neighboring the VPN servers, and then use the routing protocol of your intranet to propagate the off-subnet routes to other routers. When you add the static routes to the neighboring routers, specify that the gateway or the next hop address is the intranet interface of the VPN server.

For information about adding static routes, see "Configuring the branch office network" in Help and Support Center for Windows Server 2003.

**Configuring the Server as a Dynamic Router**
If you are using RIP or OSPF, you can configure any VPN server that is using off-subnet address ranges as a RIP or OSPF router.

For OSPF, you must also configure the VPN server as an autonomous system boundary router (ASBR). For more information, see "OSPF design considerations" in Help and Support Center for Windows Server 2003.

If you use a routing protocol other than a RIP or OSPF, such as Interior Gateway Routing Protocol (IGRP), on the VPN server's neighboring intranet router, configure the interface connected to the subnet to which the VPN server is assigned for RIP or OSPF and configure all other interfaces for IGRP.

To configure the VPN server with an on-subnet address range, configure the VPN server to obtain IP addresses through DHCP or manually configure on-subnet address ranges.

For information about:

- Configuring the VPN server as a RIP router, see "Configure RIP for IP" in Help and Support Center for Windows Server 2003.
- Configuring the VPN server as an OSPF router, see "OSPF design considerations" and "Configure OSPF" in Help and Support Center for Windows Server 2003.

# Configuring Routing on a VPN Client

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

By default, when a Windows-based VPN client makes a VPN connection, the VPN client automatically adds a new default route for the VPN connection and sets a higher metric for the existing default route. Because a new default route has been added, all Internet locations, except for the IP address of the tunnel server and locations based on other routes, are not reachable for the duration of the VPN connection.

Whether the default route is acceptable for the VPN connection depends on your remote access clients' needs (whether they need simultaneous access to both the intranet and the Internet) and security issues. For a full discussion of the routing options for VPN remote access clients, see "Determining Routing for VPN Remote Access Clients" earlier in this chapter.

Based on your design, implement one of the following routing options on the VPN client:

- If the remote access user does not require concurrent access to intranet and Internet resources, use the default gateway for the VPN connection.

- If the remote access user requires concurrent access to intranet and Internet resources over a VPN connection, choose one of the following options:

    - If you want to allow Internet access through the organization's intranet, use the default gateway for your VPN connection.

      Internet traffic between the VPN client and Internet hosts passes though firewalls or proxy servers as though the VPN client were physically connected to the organization's intranet. This method can affect performance, but it enables an organization to filter and monitor Internet access according to its network policies while the VPN client is connected to the organization network.

    - If the addressing within your intranet is based on a single class-based network ID, and the addresses assigned to VPN clients are from that single class-based network ID, prevent the use of the default gateway for your VPN connection.

    - If the addressing within your intranet is not based on a single class-based network ID, prevent the use of the default gateway for your VPN connection. Then, use one of the split tunneling methods described in "Determining Routing for VPN Remote Access Clients" earlier in this chapter.

**To prevent the VPN client from creating a new default route during a VPN connection**

1. In **Control Panel**, double-click **Network Connections,** and then double-click the name of the VPN connection.

2. In the **Connect** dialog box, click **Properties**.

3. In the properties dialog box for the VPN connection, click the **Networking** tab.

4. SelectInternet Protocol (TCP/IP), and then click **Properties**.

5. On the **General** tab, click **Advanced** to display the **Advanced TCP/IP Settings** dialog box.

6. To prevent a default route from being created during a VPN connection, on the **General** tab, clear the **Use default gateway on remote network** check box.

   No default route will be created for the connection. However, a route corresponding to the Internet address class of the assigned IP address will be created. For example, if the IP address assigned during the connection process is 10.0.12.119, the Windows Server 2003–based or Windows XP–based VPN client creates a route for the class-based network ID 10.0.0.0 with the subnet mask 255.0.0.0.

# Implementing Security for a VPN Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After configuring the VPN server as a remote access server and configuring routing on both the server and the remote access clients, implement security of a VPN solution by performing the following tasks:

- Install certificates for L2TP/IPSec VPN connections.
- Configure the appropriate level of data encryption.
- Optionally, configure remote access account lockout.

# Installing Certificates for VPN Connections

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A certificate infrastructure is a requirement for L2TP/IPSec-based VPN connections. Certificates provide stronger authentication security than password-based authentication does.

To provide a certificate infrastructure for a VPN client that makes L2TP/IPSec connections:

1. Install a certificate in the Local Computer certificate store on the VPN server.

2. Install a user certificate in the Current User certificate store of each client.

   The certificate provides authentication for establishing IPSec security associations (SAs).

To provide a certificate infrastructure for user-level authentication with EAP-TLS:

1. Install a certificate on the authenticating server for the VPN server.

2. If you are not using smart cards, install a registry-based user certificate on each client.

   -Or-

   If you are using smart cards, install a certificate on each smart card distributed to a VPN client user.

Before you can install a certificate, a certification authority must be present and reachable. For a computer in a Windows Server 2003 domain, you can use auto-enrollment or the Certificates snap-in to install a certificate. Alternatively, you can install a certificate by using a Web browser to connect the VPN client to the CA Web enrollment agent. To install a certificate by using a CA Web enrollment agent, perform the following procedure:

**To use the CA Web enrollment tool to install a certificate on a VPN client**

1. Use a Web browser to connect the VPN client to the CA Web enrollment tool at http:**//***ServerName***/**certsrv, where *ServerName* is the name of the server hosting the CA.

2. Click Request a certificate, and then click Advanced Certificate Request.

3. Click **Create and submit a request to this CA** to display a Web form for entering certificate information.

4. Enter the required information on the Web form, and then click **Submit**.

5. Click **Install this certificate**.

For information about:

- Using the Certificates snap-in to install a certificate, see "Using Certificates" in Help and Support Center for Windows Server 2003.

- Using certificate autoenrollment to install a certificate, see "Certificate autoenrollment" in Help and Support Center for Windows Server 2003.

- Deploying smart cards, see "Planning a Smart Card Deployment" in *Designing and Deploying Directory and Security Services* of this kit.

# Configuring Encryption for a VPN Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In the remote access policy that governs VPN connections on the server, set the appropriate encryption strengths for PPTP and L2TP/IPSec connections. For a procedure for entering encryption settings in a remote access policy, see "Remote access/VPN server role: Configuring a remote access/VPN server" in Help and Support Center for Windows Server 2003.

For PPTP-based VPN connections, specify one of the following encryption strengths:

- To support MPPE with a 40-bit key, select **Basic**.
- To support MPPE with a 56-bit key, select **Strong**.
- To support MPPE with a 128-bit key, select **Strongest**.

For L2TP/IPSec-based VPN connections, specify one of the following encryption strengths:

- To support 56-bit DES, select either **Basic** or **Strong**.
- To support 3DES encryption, select **Strongest**.

**Note**

- The **No Encryption** level, which allows connections that do not use data encryption, is not recommended.

For more information about using Windows Server 2003 remote access policies, see "Introduction to remote access policies" in Help and Support Center for Windows Server 2003.

# Configuring Remote Access Account Lockout for a VPN Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you will use remote access account lockout to prevent online dictionary attacks, enable remote access account lockout by modifying the AccountLockout subkey in registry on the server that authenticates remote access requests.

If the remote access server is configured for Windows authentication, modify the registry on that server. If the remote access server is configured for RADIUS authentication, and you are using IAS, modify the registry on the IAS server.

**Caution**

- Do not edit the registry unless you have no alternative. The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Windows Server 2003 Resource Kit Registry Reference on the *Windows Server 2003 Deployment Kit* companion CD or at http://www.microsoft.com/reskit.

The AccountLockout subkey can be found in the following subkey:

HKLM\SYSTEM\CurrentControlSet\Services\RemoteAccess\Parameters

The AccountLockout subkey does not exist in the registry until you enable the Routing and Remote Access service or install the Internet Authentication Service.

To configure remote access account lockout, modify two entries in the AccountLockout subkey:

1. To enable account lockout, set **MaxDenials** to 1 or greater.

   **MaxDenials** sets the maximum number of failed attempts that can occur within the configured reset time before the account is locked out. By default, **MaxDenials** is set to zero, which disables account lockout.

2. To change the interval at which the failed attempts counter is reset, set the number of minutes in **ResetTime (mins)**.

   By default, the failed attempts counter is reset every 48 hours (a value of 0xb40, or 2,880 minutes). To modify this interval, enter the preferred number of minutes.

**Note**

- To manually reset a user account that has been locked out before the failed attempts counter is automatically reset, delete the following registry subkey, which corresponds to the user's account name: HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\RemoteAccess\Parameters\AccountLockout*domainname:username*.

For more information about remote access account lockout, see "Remote Access Technologies" in the *Networking Collection* of the *Windows Server 2003 Technical Reference*.

# Deploying a Dial-up Remote Access Server Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Deploying a dial-up remote access server involves three major tasks: configuring a Windows Server 2003–based server as a dial-up remote access server, configuring the LAN adapter to provide the server with a connection to the intranet, and configuring the appropriate level of encryption strength in the dial-up remote access policy. Figure 8.8 shows the process for deploying a dial-up remote access server solution.

**Figure 8.8 Deploying a Dial-up Remote Access Server Solution**

# Configuring a Dial-up Remote Access Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To provide dial-up access to your organization's intranet, configure a computer running Windows Server 2003 as a dial-up remote access server.

Before configuring the server as a dial-up remote access server, you must enable the Routing and Remote Access service, which is installed automatically with Windows Server 2003. Use the Routing and Remote Access Server Setup Wizard. For instructions on using the wizard, see "Remote access/VPN server role: Configuring a remote access/VPN server " in Help and Support Center for Windows Server 2003.

**Note**

- You can optionally implement Network Access Quarantine Control to quarantine each new remote access connection until the configuration of the client computer can be verified against network policy restrictions. For more information, see "Planning for Network Access Quarantine Control" and "Configuring Network Access Quarantine Control" earlier in this chapter.

With Routing and Remote Access enabled, configure the properties of a dial-up remote access server by using the Routing and Remote Access snap-in.

**To configure a server for dial-up remote access**

1. Open the **Routing and Remote Access** snap-in.

2. In the console tree, right-click the server name, and then click **Properties**.

3. On the **General** tab of the **Server Properties** dialog box, verify that the **Remote access server** check box is selected.

4. On the **Security** tab, set up authentication for dial-up remote access clients:

    a. Click **Authentication Methods**, and in the dialog box select the authentication methods that the server will accept for dial-up connections.

    **Note**

The server is configured by default to accept certain authentication methods. You can use remote access policies to control which authentication methods to accept. For more information about using Windows Server 2003 remote access policies, see "Introduction to remote access policies" in Help and Support Center for Windows Server 2003.

1. Under **Authentication Provider** on the **Security** tab, select the authentication provider to use for dial-up networking clients.

2. Under **Accounting Provider**, select and configure the accounting provider to use for recording dial-up connection accounting information.

1. On the **IP** tab, set up routing for remote access clients:

    a. Verify that the **Enable IP routing** and A**llow IP-based remote access and demand-dial connections** check boxes are selected.

    b. If you are using DHCP to obtain IP addresses for remote access clients, select **Dynamic Host Configuration Protocol (DHCP)**.

    -Or-

Select **Static address pool**, and then configure ranges of IP addresses that are dynamically assigned to dial-up networking clients.

If the static IP address pool consists of ranges of IP addresses for a separate subnet, either enable an IP routing protocol on the remote access server or add static IP routes for each range to your IP routing infrastructure. If the routes are not added, remote access clients cannot receive traffic from resources on the intranet.

# Configuring a Dial-up Connection to the Intranet

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A LAN adapter provides the connection from a dial-up remote access server to the intranet. To enable this connection, you must configure TCP/IP on the LAN adapter and, on the dial-up remote access server, configure the modem ports for remote access.

**Configuring TCP/IP on the LAN Adapter**
Configure the following TCP/IP settings on the LAN adapter that provides the connection from the dial-up remote access server to the intranet:

- The IP address and subnet mask assigned by a network administrator.
- The default gateway of a local router.
- The IP addresses of DNS and WINS servers.

**Configuring a Connection to Dial-up Networking Clients**
To enable multiple dial-up clients to connect to the intranet simultaneously, the dial-up solution must have a modem bank connected to a telecommunications provider. The modem bank adapter includes drivers that you install on the dial-up remote access server.

**Configuring Dial-in Ports for Remote Access**
With the modem bank adapter drivers installed, the modem bank appears as a device with multiple modem ports. Use the Routing and Remote Access snap-in to configure all of the active modem bank ports on the server for remote access.

**To configure the ports of a device for remote access**

1. Open the **Routing and Remote Access** snap-in.
2. In the console tree, right-click **Ports**, and then click **Properties**.
3. In the **Ports Properties** dialog box, select the device that you want to configure, and then click **Configure**.
4. In the **Configure Device** dialog box, select the appropriate routing connection options.

# Configuring Encryption for a Dial-up Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In the remote access policy that governs connections for remote access on the dial-up remote access server, use Routing and Remote Access to set the appropriate encryption level. For a procedure for entering encryption settings in a remote access policy, see "Configuring authentication and data encryption" in Help and Support Center for Windows Server 2003.

In the remote access policy for dial-up connections on the dial-up remote access server, choose one of the following encryption levels:

- To use MPPE with a 40-bit key, select **Basic**.
- To use MPPE with a 56-bit key, select **Strong**.
- To use MPPE with a 128-bit key, select **Strongest**.

For more information about using Windows Server 2003 remote access policies, see "Introduction to remote access policies" in Help and Support Center for Windows Server 2003.

# Additional Resources for Deploying Dial-up and VPN Remote Access Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information and tools related to this chapter.

# Deploying Remote Access Clients Using Connection Manager

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use Connection Manager, a component of the Microsoft® Windows® Server 2003 operating systems, to provide customized remote access to your network through a dial-up or a virtual private network (VPN) connection. By deploying remote access clients with the Connection Manager family of programs, which includes the Connection Manager Administration Kit (CMAK), Connection Point Services (CPS), and the Connection Manager client, you can configure the remote access experience for your users. This configuration can include providing a phone book in which users can find the most convenient dial-up access number.

**In This Chapter**

Overview of Remote Access Client Deployment

Providing Connection Manager Phone Book Support

Customizing Connection Manager

Implementing Your Connection Manager Solution

Example: Deploying Remote Access Clients

Additional Resources for Deploying Remote Access Clients Using Connection Manager

**Related Information**

- For information about designing and deploying Internet authentication, see "Deploying Internet Authentication Service (IAS)" in this book.
- For information about creating connections to branch offices and remote sites, see "Connecting Remote Sites" in this book.

**Note**

- For the purposes of this chapter, "phone book" and "Connection Manager phone book" refer to a list of Points of Presence (POPs) and other information configured by using the Connection Manager family of programs.

# Overview of Remote Access Client Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you have users who travel frequently or need to access your network from home or other locations, Connection Manager provides a way for you to customize a self-installing service profile for your users. The Connection Manager client allows users to either connect to your network directly or to create a VPN connection from a remote location. Using this managed remote access solution reduces administration by providing a single connection client for all remote access users.

Before you deploy a remote access client solution, you must design and deploy your remote access and VPN servers and related infrastructure. You must also deploy an authentication service, such as Internet Authentication Service (IAS), to enable authentication, authorization, and accounting. Many of the decisions that you make when you deploy your Connection Manager service profiles are based on the decisions that you make when you design your servers.

# Deploying Connection Manager Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The process for deploying Connection Manager includes designing phone books if you are configuring dial-up access, and optionally deploying phone book servers to provide phone book updates; customizing the Connection Manager service profile through the CMAKwizard; testing your remote access solution; and distributing your Connection Manager profile to users.

Figure 9.1 shows the process for deploying Connection Manager.

**Figure 9.1 Deploying Connection Manager**

# Remote Access Clients Background Information

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In order for users to take advantage of an organization's remote access solution, each client must be configured to connect to the remote access dial-up or VPN servers. You can either use the native connection features in Windows to configure clients or use a managed client solution, such as Connection Manager and its components, to create and distribute a custom service profile.

# Native Connection Capabilities and Limitations

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is possible for users to manually configure remote access connections using the native network connection capabilities in Windows. To connect to the remote access server using these native capabilities, the user configures the network settings on the client. These settings include:

- **Dial-up connections** The telephone number for your remote access server, user authentication method, encryption settings, and dialing scripts.

- **VPN connections** The host name or IP address for the VPN server, VPN type, user authentication method, and encryption settings.

The native connection capabilities are best suited for when there are few users connecting to the network. These connections are relatively simple to set up when there are a small number of clients; however, there are major disadvantages to this method when you are administering a large network with many remote access users, including:

- The procedure for manually configuring remote access clients varies between versions of Windows; therefore, you would need a separate set of procedures for each client operating system you support.

- Each client must be manually configured; either an administrator must configure each client individually, or the users must configure their own settings using operating system–specific instructions. Either approach can lead to a large resource drain in the IT department.

- If any telephone numbers change, either the administrator or the user must manually reconfigure the connection. For example, you might contract with a telecommunications supplier to provide multiple dial-up telephone numbers and worldwide access for users who travel. Similarly, you might choose to use VPN connections over Internet connections supplied by an Internet service provider (ISP), with multiple access numbers and worldwide Internet access. If any of these telephone numbers change, you need a way to notify the users.

Connection Manager provides a solution for these and other issues when you deploy a large number of remote access clients.

# Connection Manager Solutions

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Connection Manager family of programs is a set of optional components used to create a managed remote access solution. Connection Manager enables a network administrator to preconfigure remote access clients, add custom behavior and a custom appearance, and provide an updateable phone book that enables users to find the most convenient dial-up access number. The Connection Manager family of products includes:

- The Connection Manager client

  The Connection Manager client provides a simplified way of connecting to a remote network. Typically, the user only needs to enter a user name and password and select a phone number if applicable. The administrator configures all other settings before distributing the service profile.

- The Connection Manager Administration Kit (CMAK)

  CMAK allows the administrator to create and configure the service profile and creates a small, self-installing package. CMAK also allows the administrator to customize Connection Manager features such as branding, custom actions, and custom Help files, as well as enhanced security features.

- Connection Point Services (CPS)

  CPS allows you to create and maintain phone books. It consists of two parts:

  - Phone Book Administrator (PBA)

    PBA is a tool used to create and maintain phone book files, and to publish new or updated phone book files on the PBS server.

  - Phone Book Service (PBS)

    PBS distributes phone books to Connection Manager clients on request.

# Connection Methods

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Remote users connect to networks by using one of two methods: they either connect with *direct dial*, where they connect directly by using dial-up lines, or they use VPNs to connect over the Internet. When using a VPN to connect, remote users who do not have a pre-existing connection to the Internet must use a *double-dial* configuration, where they first dial an ISP number to access the Internet and then establish the VPN connection. Connection Manager can make this double dial process look like a single connection attempt to the end user.

**Direct Dial**

Users who connect to your network by using direct dial call directly into your network, using the dial-up phone numbers that your organization provides to connect to remote access dial-up servers. You can easily manage a small number of users calling a small number of phone numbers. However, if a large number of users are dialing into your network, or if your network can be reached through many phone numbers, Connection Manager and CPS are useful for managing remote access.

**VPN**

Organizations that offer VPN access to their remote users approach this in either one of two ways:

- Assume that the users have their own connections to the Internet.
- Provide users with an easy method to dial up the Internet and establish a subsequent VPN connection to the corporate network.

An organization can also contract with an ISP to supply a national or worldwide collection of phone numbers for Internet access. Connection Manager provides a method to expose these numbers from the ISP in a phone book and automatically establish the VPN connection after the ISP connection is complete. For more information about working with an ISP, see "Providing Connection Manager Phone Book Support" in this chapter. For more information about double-dial connections, see "Example: Deploying Remote Access Clients" in this chapter.

# User Authentication Methods

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The user authentication method that you implement depends on the operating systems that your clients are running and the level of security that you require for your network. For example, you might require passwords, certificates, or smart cards for user authentication, depending on your organization's security needs. For more information about user authentication methods, see "Designing an Authentication Strategy" in *Designing and Deploying Directory and Security Services* of this kit. For more information about deploying smart cards, see "Deploying Smart Cards" in *Designing and Deploying Directory and Security Services* of this kit.

# Virtual Private Network (VPN) Tunneling Protocols

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For VPN connections, you can require Point-to-Point Tunneling Protocol (PPTP) or Layer Two Tunneling Protocol (L2TP) connections, or you can allow users to attempt L2TP connections and use PPTP if they cannot connect using L2TP. If you require L2TP/IPSec authentication, you can use preshared keys or certificates. For more information about choosing a VPN strategy, see "Deploying Dial-up and VPN Remote Access Servers" in this book.

# Network Access Quarantine Control

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Network Access Quarantine Control, a new feature in the Windows Server 2003 family, delays normal remote access to a private network until the configuration of the remote access computer has been examined and validated by an administrator-provided script. Without Network Access Quarantine Control, only the credentials of the user are verified, and a user with the correct credentials can connect even if their configurations do not comply with corporate network policy. For example, a remote access user with valid credentials can connect to a network with a computer that does not have required antivirus software installed on it. Remote access client can use either a manually-configured connection or a Connection Manager profile. For more information about configuring Network Access Quarantine Control by using a Connection Manager profile, see "Incorporate Custom Actions" later in this chapter.

**Important**

- Network Access Quarantine Control allows an administrator to prevent computers with unsafe or undesirable configurations from connecting to a private network, not to protect a private network from malicious users who have obtained a valid set of credentials.

For more information about Network Access Quarantine Control, see "Deploying Dial-up and VPN Remote Access Servers" and "Deploying Internet Authentication Service (IAS)" in this book, and "IAS Network Access Quarantine Control" in Help and Support Center for Windows Server 2003.

# Providing Connection Manager Phone Book Support

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Use CPS to create, publish, and update Connection Manager phone books, which include all information relating to a POP, such as area code, phone number, and user authentication methods supported. The Connection Manager phone book also includes various network settings that you configure when you run the CMAK wizard.

Figure 9.2 shows the process for providing phone book support.

**Figure 9.2 Providing Connection Manager Phone Book Support**

For more information about security considerations when using CPS, see "Security information for Connection Point Services" in Help and Support Center for Windows Server 2003.

# Using PBA to Create and Maintain Phone Books

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

PBA in CPS allows you to create and maintain phone books for use with Connection Manager. By using CPS, you can ensure your remote access users have the most recent phone numbers to connect to your network.

**Note**

- If you are providing a VPN-only profile you do not need to create a phone book and can skip to "Customizing Connection Manager" later in this chapter.

Before using PBA, you must install it on a computer running either Windows Server 2003 or Microsoft® Windows® XP Professional. You install PBA by running Pbainst.exe from the VALUEADD\MSFT\MGMT\PBA folder on the Windows Server 2003 family CD-ROM or Windows XP Professional CD-ROM.

For information about how to administer phone books from the command line, see "Administer phone books" in Help and Support Center for Windows Server 2003.

**Creating, Publishing, and Maintaining Phone Books**

A phone book contains one or more Points of Presence (POPs), each of which includes a telephone number to access the network or the Internet. Connection Manager phone books allow the user to have a complete POP list, so they have more than one phone number to choose from when traveling or if there is a problem connecting to a specific number.

Before you begin adding POPs to the phone book, you can create a list of regions to organize the POPs. *Regions* allow the user to see a filtered list within their country or dependency. This reduces the number of POPs the Connection Manager client displays at one time, so the user chooses from a list of POPs targeted to their region. Use the **Region Editor** in PBA to create a new list of regions, or import regions from an existing .pbr file.

After you have gathered all the POPs contained in the phone book, use PBA to create your new phone book.

When you create a new phone book, PBA creates a phone book file (.pbk) and a region file (.pbr). When you finish creating the phone book, you need to publish it so that it is available on the PBS server.

**To publish the phone book**

1. Start the FTP service on the PBS server.
2. Enable the account that was created on the PBS server for phone book posting.
3. Start PBA, click the **Tools** menu, and then click **Publish Phone Book**.
4. In the **Options** dialog box, type the server address, user name, and password used to post the phone book to the server running PBS.
5. Click **Create** to create the .cab files in the release directory.
6. Enter the address of the PBS server and click **Post** to post the new release to the PBS server.
7. Disable the account on the PBS server.
8. Stop the FTP service on the PBS server.

Use PBA to edit your phone book when adding or changing telephone numbers, and then use the same procedure to re-publish the updated phone book.

**Updating Phone Books**

To ensure the client always has the most recent version of the phone book, leave the **Automatically download phone book updates** check box selected on the **Phone Book** page of the CMAK wizard.

If you have configured automatic phone book updates, after the client connects to the network, the client sends a request to PBS that includes the name of the phone book file and the version currently installed on the client. The server then replies with either a full or an incremental update, if one is required.

# Using an Outsourced Phone Book

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To provide a wider range of phone numbers, your organization might outsource your phone book to a telecommunications company or an ISP. If your telecommunications company or ISP uses CPS, you can import that company's phone book.

When negotiating with the ISP or telecommunications company, you should ask that company to provide a service profile that contains all its phone book information, including an update URL, and then use CMAK to merge this profile into your service profile.

If the company does not provide you with a service profile, request the phone book .(pbk) and region .(pbr) files for the phone book, as well as the update URL. Use these files to create a service profile, and merge it into the service profile you will send to your users.

If your telecommunications company or ISP does not use CPS, obtain the phone numbers in another format, such as a text file, and import this file into your phone book. For more information about importing phone book files using PBS, see "Add, edit, or delete POPs by command line" in Help and Support Center for Windows Server 2003.

For more information about merging service profiles, see "Merging Service Profiles" later in this chapter.

# Hosting Phone Books on a PBS Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You do not need to run PBS on a high-end computer because any computer capable of running Windows Server 2003 and Internet Information Services (IIS) can run PBS.

Just before publishing, ensure that the PBS server is using IIS to run FTP and the Web server service. This is necessary for PBS servers to receive posts from PBA and to provide updated files to clients. For more information about IIS, "Internet Information Services (IIS) 6.0 overview" in Help and Support Center for Windows Server 2003.

**Caution**

- For security reasons, do not allow anonymous FTP access to your PBS server. Also, only run the FTP service when you are actually publishing or updating a phone book. For more information about CPS security, see "Security information for Connection Point Services" in Help and Support Center for Windows Server 2003.

PBS servers can be located on your perimeter network or in the perimeter network of the ISP if you outsource phone book support. Because the phone book updates after connecting to your network, locate the PBS server such that the client has access to it after a successful connection to your network. For more information about security in perimeter networks, see "Securing Network Perimeters with ISA Server in this book.

# Customizing Connection Manager

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Use the CMAK wizard to create a custom service profile. You then distribute this .exe file to your users. When they double-click the file, it installs a service profile customized with the information you entered in the CMAK wizard. The Connection Manager client then allows users to dial in to your organization directly or to complete a VPN connection, based on the information provided in the CMAK wizard. Figure 9.3 shows steps in the process for customizing your service profile.

**Tip**

- You can install the CMAK wizard from **Management and Monitoring Tools** details in the Windows Components Wizard. For more information about installing the CMAK wizard, see "The Connection Manager Administration Kit Wizard" in Help and Support Center for Windows Server 2003.

**Figure 9.3 Customizing Connection Manager**

Before you run the CMAK wizard, make sure you know the following information, which is required to complete the wizard:

- The service name and a file name that you will use for the new profile and related files.
- A realm name, if your service requires it. A *realm name* is a prefix or suffix that Connection Manager automatically adds to the user name.
- Any existing service profiles that you plan to merge into the new profile. For more information about merging service profiles, see "Merging Service Profiles" later in this chapter.
- VPN Support information, including: the VPN server address(s) and whether or not the client will use the same passwords for the dial-up and VPN connection in a double-dial situation. For an example of configuring VPN Support information, see "Example: Deploying Remote Access Clients" later in this chapter. For information about configuring a VPN-only profile, see "Implementing VPN support" in Help and Support center for Windows Server 2003.
- VPN Entries network and security information. For more information about networks and security, see "Configuring Network and Security Settings" later in this chapter.
- Preshared key information, if needed for L2TP/IPSec VPN connections. If you are using a preshared key, encrypt it with a PIN that follows strong password rules. *Strong passwords* include a combination of uppercase and lowercase letters, numbers, and special characters so the password is protected from a dictionary attack or a database of popular passwords.
- The location of the phone book file that was created by PBA to include in this service profile and any text that should appear in the **More access numbers** box in the **Phone Book** dialog box.

- Phone book file name for downloading updates and the update URL to point to on the phone book server, if applicable.
- Dial-up Networking Entries and security information. For more information about networks and security, see "Configuring Network and Security Settings" later in this chapter.
- Routing table update information, if you are planning to implement *split-tunneling* where users can connect to both your internal network and the Internet simultaneously.
- Automatic Proxy Configuration settings, if you want Connection Manager to automatically update proxy settings for this connection.
- Custom Actions, which are any programs you want to start automatically before, during, or after users connect to your service. For more information about custom actions, see "Incorporate Custom Actions" later in this chapter.
- Branding information, including custom graphics, icons, menu items for the notification area shortcut, custom Help, and support information, if applicable. For more information about including branding information in your service profile, see "Branding Your Connection Manager Client" later in this chapter.
- Whether to include the latest version of Connection Manager with your service profile. This is a small file, so if you are not sure that all clients have the latest version of CM, include the latest version with your profile.
- A custom license agreement, if applicable. For more information about including a custom license agreement in your service profile, see "Branding Your Connection Manager Client" later in this chapter.
- Any additional files you want to include in this service profile.
- Any information you require for advanced customization, if applicable. For more information about advanced customization, see "Providing Advanced Customization" later in this chapter.

For a worksheet to assist you in completing the CMAK wizard, see "Preparation for Running the CMAK Wizard" (DNSRAC_1.doc) on the *Microsoft® Windows® Server 2003 Deployment Kit* companion CD (or see "Preparation for Running the CMAK Wizard" on the Web at http://www.microsoft.com/reskit).

For more specifics about customizing Connection Manager using CMAK, see "Preparing to run the CMAK wizard" and "Connection Manager Administration Kit" in Help and Support Center for Windows Server 2003.

# Merging Service Profiles

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Merging service profiles is especially useful for incorporating information from multiple phone books, including service types, POP names, and access numbers. You can also use it to consolidate different dial-up access numbers that are covered by more than one of your phone books. By merging existing service profiles into a single top-level service profile, you can present several dissimilar networks as a single, cohesive service.

You can merge multiple profiles so that the *top-level profile*, which is the service profile you distribute to users, behaves as if it has a single phone book, which contains all the POPs defined in each of the component profiles. For example, if you outsource your phone book through multiple ISPs, and each ISP provides you with a service profile containing its phone book(s), you can merge the profiles together within a top-level service profile that contains dial-up numbers for all the POPs from all the providers.

For an example of merging service profiles, see "Example: Deploying Remote Access Clients" later in this chapter.

# Configuring Network and Security Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Configure network and security settings by editing the appropriate networking entry from the **VPN Entries** page and/or the **Dial-Up Networking Entries** page of the CMAK wizard. From the **Edit VPN Entry** and the **Edit Dial-Up Networking Entry** dialog boxes, you can customize general network properties, TCP/IP settings, and security settings.

**Configuring General Network Properties**
Use the general network properties to disable file and print sharing and enable clients to log on to a network. For a dial-up connection, you can also enter a dial-up networking script.

**Configuring TCP/IP Settings**
Use the TCP/IP settings to change the Domain Name System (DNS) and Windows Internet Name Service (WINS) client configuration by either allowing the server to assign these addresses or manually configuring the DNS and WINS addresses for this profile. You can also choose to make this connection the default gateway for the client and to use IP header compression.

**Configuring Security Settings**
Use the security settings to select the authentication method for VPN or dial-up users and the VPN strategy for VPN clients. You can choose to use basic or advanced security settings for all computers or use a combination. If you choose a combination of both basic and advanced security settings, Connection Manager uses the advanced security settings for clients running on the operating systems that support them and basic security settings for clients running on operating systems that do not support advanced security settings.

# Incorporate Custom Actions

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Connection Manager has the ability to run custom actions at various points when establishing a connection. By providing custom actions, you can enhance the connection experience for your users. Use the CMAK wizard to include custom actions in your service profile to automatically start programs when users connect to your service. A *custom action* can be any batch file, executable file, or dynamic-link library (DLL). These custom actions can use programs that users have installed, or you can distribute the programs with your service profile.

Using the CMAK wizard, you can specify custom actions for each of the following points during the connection process.

- **Pre-initialization actions.** These actions occur immediately when the user starts the Connection Manager client.
- **Pre-connect actions.** These actions occur before the connection attempt.
- **Pre-dial actions.** These actions occur before every dialing attempt, including redials. (For dial-up connections only.)
- **Pre-tunnel actions.** These actions occur before tunneling. (For VPN connections only.)
- **Post-connect actions.** These actions occur immediately after the connection is established.
- **Disconnect actions.** These actions occur immediately after the user or server disconnects.
- **On cancel actions.** These actions occur whenever the user abandons a connection attempt.
- **On error actions.** These actions occur whenever the connections attempt fails due to an error.

You might want to use pre-connect actions to start an application before you connect, such as an e-mail program, or use a post-connect action to upload logs of connection activity or to download the latest virus signatures. An on error action could also be used to point the user to custom Help files for self-help information, potentially reducing help desk calls.

Several common custom actions are built into CMAK, such as:

- A post-connect action checks for phone book updates. This action is automatically included in your profile if you leave the **Automatically download phone book updates** check box selected on the **Phone Book** page of the CMAK wizard.
- A post-connect action obtains and installs routing tables for the target network. This action is automatically included in your profile if you enable the **Routing Table Update** feature.
- A post-connect action updates proxy settings of the client during the connection. This action is automatically included in your profile if you enable the **Automatic Proxy Configuration** feature.

The *Windows Server 2003 Technical Reference* also contains custom actions you can use to customize your profile:

**Profile update**
This includes the files Getcm.exe, which runs as a post-connect action that checks for and downloads an updated service profile, and Instcm.exe, which runs as a disconnect action that checks to see if an updated service profile has been downloaded and installs it.

**Certificate deployment**
This DLL (Cmgetcer.dll) allows Connection Manager to automatically obtain a certificate for L2TP/IPSec connections.

**Network Access Quarantine Control**

- This network policy requirements script runs as a post-connect action. The network policy requirements script performs validation checks on the remote access client computer to verify that it conforms to network policies. The script can be a

custom executable file or simple batch file.

When the script has run successfully and the connecting computer has satisfied all of the network policy requirements (as verified by the script), the script executes a notifier component (an executable) with the appropriate parameters. You can also configure your script to download the latest version of the script from a quarantine resource. If the script does not run successfully, it directs the remote access user to a quarantine resource such as an internal Web page, which describes how to install the components that are required for network policy compliance.

The notifier component sends a message to the quarantine-compatible remote access server that indicates a successful execution of the script. You can use your own notifier component or you can use Rqc.exe, which is provided on the *Windows Server 2003 Deployment Kit* companion CD. With these components installed, the remote access client computer uses the Connection Manager profile to perform its own network policy requirements check and indicate its success to the remote access server as part of the connection setup.

**Tip**

- Because Network Access Quarantine Control introduces a delay in obtaining normal remote access, applications that run immediately after the connection is complete might encounter problems. One way to minimize the delay is to separate your script into two scripts: one that runs as a pre-connect action and one that runs as a post-connect action.

For more information about Network Access Quarantine Control, see "IAS Network Access Quarantine Control" in Help and Support Center for Windows Server 2003, "Deploying Dial-up and VPN Remote Access Server" and "Deploying Internet Authentication Service (IAS)" in this book. For a sample notifier component, see the Windows SDK. For more information about the Windows SDK, see the Software Development Kit (SDK) information in the MSDN Library link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

In addition to these predefined custom actions, you can create your own custom actions to include in the service profile.

For security reasons, custom actions cannot be run when users log on to the network using dial-up networking unless certain registry keys have been set. For more information about custom actions, see "Incorporating custom actions" in Help and Support Center for Windows Server 2003.

# Branding Your Connection Manager Client

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Another important feature of CMAK is the ability to apply your own branding to the client by using your organization's graphics, icons, menu items for the notification area shortcut, Help, and license agreement. If you do not want to customize the appearance of the client, accept the defaults provided in CMAK.

**Using Custom Graphics and Icons**
You must specify whether to use the default bitmaps or your own graphics. Customize the user interface by including your company logo or another image that identifies your organization. You can replace the graphics in both the **Logon** dialog box and the **Phone Book** dialog box. The replacement graphic must be a bitmap (.bmp) file.

Provide custom icons for your service profile in the form of either one file containing icons in multiple sizes or one file for each icon in each size. Use the CMAK wizard to specify the icons.

**Customizing Connection Manager Help and License Agreement**
To offer your users customized Help and license agreement files, enter the appropriate file information in the CMAK wizard.

The default Help file is Cmmgr32.hlp. If you do not want to use the default Help, create your own .hlp file, and then use the CMAK wizard to replace the default Help with your .hlp file in the service profile. To include a license agreement, create a .txt file containing the agreement and enter the file name into the CMAK wizard when prompted. For more information about providing your users with custom Help, see "Providing custom Windows Help" in Help and Support Center for Windows Server 2003.

# Providing Advanced Customization

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The CMAK wizard guides you through most of the customization features that you need to build a service profile. However, you can provide additional customization by selecting the **AdvancedCustomization** check box in the **Ready to Build the Service Profile** page of the CMAK wizard.

You can also delete any section or key from the .cms or .cmp files by using the **Advanced Customization** page of the CMAK wizard.

**To delete a section**

1. On the **Advanced Customization** page of the CMAK wizard, in the **File name** box, select the appropriate file.
2. In the **Section name** box, select the section you want to delete.
3. Clear the **Key name** and **Value** boxes.
4. Click **Apply**.
5. Click **Yes** to confirm that you want to delete the entire section.

**To delete a key**

1. On the **Advanced Customization** page of the CMAK wizard, in the **File name** box, select the appropriate file.
2. In the **Section name** box, select the appropriate section.
3. In the **Key name** box, select the key you want to delete.
4. Clear the **Value** box.
5. Click **Apply**.
6. Click **Yes** to confirm that you want to delete the key.

**Caution**

- Use extreme care when deleting sections or keys from the .cms or .cmp files by using the **Advanced Customization** page of the CMAK wizard, particularly when you are editing an existing service profile.

For more information, including a comprehensive list of the service profile files and keys that you can customize through advanced customization, see "Advanced Customization" in Help and Support Center for Windows Server 2003.

The following procedures show four ways to use advanced customization to increase security for user connections.

**Tip**

- If the key names you want to customize do not appear in the drop down list, simply type them in the **Key name** text box.

**Removing the Save Password Option**

Edit the HideRememberPassword key to remove the **Save Password** check box from the Connection Manager user interface.

**To remove the Save Passwordcheck box from the Connection Manager user interface**

1. On the **Advanced Customization** page of the CMAK wizard, in the **File name** box, select *FileName***.cms**.

2. In the **Section name** box, select **Connection Manager**.

3. In the **Key name** box, type or select **HideRememberPassword**.

4. In the **Value** box, type **1**.

5. Click **Apply**.

   **Important**

   - In order for any advanced customization setting to be recorded, you must click **Apply** after entering each setting.

**Disabling ICS**
Edit the DisableICS key to disable Internet Connection Sharing (ICS) in Windows XP for this connection.

**To disable Internet Connection Sharing (ICS) from the Connection Manager user interface**

1. On the **Advanced Customization** page of the CMAK wizard, in the **File name** box, select *FileName***.cms**.

2. In the **Section name** box, select **Connection Manager**.

3. In the **Key name** box, type or select **DisableICS**.

4. In the **Value** box, type **1**.

5. Click **Apply**.

**Enabling ICF**
Edit the EnableICF key to turn on Internet Connection Firewall (ICF) in Windows XP for this connection.

**To enable ICF from the Connection Manager user interface**

1. On the **Advanced Customization** page of the CMAK wizard, in the **File name** box, select *FileName***.cms**.

2. In the **Section name** box, select **Connection Manager**.

3. In the **Key name** box, type or select **EnableICF**.

4. In the **Value** box, type **1**.

5. Click **Apply**.

**Hiding the Advanced Tab**
Edit the HideAdvancedTab key to hide the **Advanced** tab from the Connection Manager user interface in Windows XP for this connection. The **Advanced** tab is where users control ICF and ICS for the connection. You should only enable this key if you are using the DisableICS and EnableICF keys.

**To hide the Advanced tab from the Connection Manager user interface**

1. From the **Advanced Customization** page of the CMAK wizard, in the **File name** box, select *FileName***.cms**.

2. In the **Section name** box, select **Connection Manager**.

3. In the **Key name** box, type or select **HideAdvancedTab**.

4. In the **Value** box, type **1**.

5. Click **Apply**.

# Implementing Your Connection Manager Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you create your service profile(s), test your remote access solution in its entirety before distributing your service profile to the users.

Figure 9.4 shows the process for implementing your managed remote access client solution using Connection Manager.

**Figure 9.4 Implementing Your Connection Manager Solution**

# Testing Your Remote Access Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When testing your solution in a lab, recreate the actual user experience as closely as possible. It is likely that the client will be deployed on computers not directly under the control of your organization, such as a user's home computer. For this reason, it is necessary to test your service profile(s) using a standard set of applications and test on the same types of hardware that you will deploy to.

**Important**

- Test both the server and client portions of your remote access design.

Use the following guidelines to test your deployment:

- Load and run the client on each operating system you are supporting for remote access. If you are supporting both dial-up and VPN connections, test both of these types of connections on your test clients.
- Test custom actions in detail, using a standard set of application that users might have on their computers. Be sure your test is representative of the end-user experience.
- Make sure your phone books are updating. If phone books are not updating, check the URL that is pointing to the phone book server, check for firewall conflicts, and ensure that IIS is correctly configured on PBS server.
- Test your distribution method before announcing and rolling it out. For information about establishing a distribution method, see "Distributing Your Connection Manager Service Profiles" later in this chapter.

# Distributing Certificates

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you configured the security settings of the VPN Entries in the CMAK wizard to use L2TP/IPSec, you might need to distribute certificates to your users. The certification authority (CA) is generally set up as a Web server. You can either have your CA on the Internet or on your intranet.

**Internet Enrollment**
With Internet enrollment, users go to a public Web site to obtain their certificates. Internet enrollment is useful if you are using a CA that is provided by another company.

**Intranet Enrollment**
If certificates are optional but recommended, users can obtain their certificates after connecting to your intranet. Configure the service profile to attempt authentication by using L2TP first. This setting allows the client to attempt a connection using L2TP; if L2TP is not available, the client connects using PPTP. When you configure this setting, the client will first attempt to connect using L2TP each time the client connects. By using this setting, clients can connect the first time by using PPTP and get a certificate. After receiving the certificate, subsequent connections will use L2TP.

You can configure the Connection Manager Certificate Deployment Tool, Cmgetcer.dll, as a custom action. This tool enables the client to get a certificate from the certification authority.

For more information about certification authorities and certificates, see "Designing a Public Key Infrastructure" in *Designing and Deploying Directory and Security Services* of this kit.

# Educating Users About Security

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When distributing your service profiles, you should also inform users of their responsibilities in protecting the organization's resources. Educate your users about potential threats and how to avoid them, including:

- Enable a personal firewall (such as ICF in Windows XP).
- Use strong passwords on their remote computers.
- Never save passwords for any connection.

  To prevent users from saving their password for this connection, disable the **Save Password** check box on the Connection Manager client. For more information, see "Providing Advanced Customization" earlier in this chapter.
- Lock their computers when they are not actively using them. They do this by password-protecting the screen saver or through the **Ctrl-Alt-Delete** dialog box.
- Do not share VPN connections or run a VPN connection from an ICS host. Sharing the VPN connection allows all computers on the ICS network — using the VPN connection — to access your organization's network and resources using the VPN connection's credentials.

# Distributing Your Connection Manager Service Profiles

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

There are several ways to distribute your service profile, each with costs and benefits. Choose one of the following methods, or provide more than one method to give your users a choice.

**Distributing Service Profiles on CD or Floppy Disk**
You can distribute CDs or floppy disks containing your self-installing Connection Manager package. Connection Manager and the service profile fit on a floppy disk. However if you want to include other programs, such as anti-virus software, you might need more space than a floppy provides so a CD is a better choice.

The benefit of distributing this way is that you can physically give a copy to all users or send them easily through the mail. However, this solution might be costly and has little inherent security.

**Distributing Service Profiles by E-mail**
You can send a service profile through e-mail to your users. If you choose to send the service profile through e-mail, ensure that users are able to receive .exe files, because not all e-mail systems allow executable files as attachments.

**Distributing Service Profiles by Download**
You can set up a Web site where users can download the service profile. Desktop users can download to a floppy disk, and portable-computer users can download directly to their computers from a Web site inside your network.

It is also possible to make the service profile available by download from a Web site over the Internet. However, identify any security risks to your organization before posting your service profile on an Internet site.

**Pre-installing Service Profiles**
You can install the service profile on each client individually. The benefit of this method is that users are not required to install anything themselves, which can reduce user frustration and calls to your help desk. However, this method requires administrator or help desk resources during the initial installation, which might be a large resource hit during the roll out phase of your deployment. This method is useful when there are a small number of client computers or when all of the client computers and devices are controlled by your organization.

**Combining Distribution Methods**
You can also use a combination of distribution methods. For example, a company could distribute the Connection Manager service profiles on CD to users who work from their own computers from remote locations, provide downloads for local employees who have portable computers, and pre-install the service profile on any new portable computers before distribution.

# Example: Deploying Remote Access Clients

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A large company, Contoso Ltd., is redesigning remote access infrastructure. Contoso decides to use the Connection Manager family of products to provide managed remote access to their company network through both dial-up connections and VPN connections. The new VPN server allows both PPTP and L2TP/IPSec VPN connections.

Contoso contracts with an ISP, A. Datum Corporation, to provide bulk dial-up Internet access. Under the arrangement, A. Datum will provide single sign-on for users using their Contoso credentials. This is accomplished by using a Remote Authentication Dial-In User Service (RADIUS) proxy to forward connection requests to a Contoso RADIUS server using a realm name agreed to by both A. Datum and Contoso. For more information about deploying a RADIUS proxy and RADIUS server, see "Deploying Internet Authentication Service (IAS)" in this book.

Contoso has the following primary objectives for providing a remote access solution to its users:

- Allow local users to connect to the corporate intranet with direct dial using a local phone number, which dials directly into Contoso's remote access servers.
- Reduce costs by eliminating the need for toll free (1-800) dial-up access numbers for users traveling within the United States. The company has a contract with A. Datum to provide dial-up access numbers to the Internet, which will be used to carry VPN connections to the company.
- Provide all users with automatic phone book updates when dial-up access numbers change.

  Allow users to connect by making a VPN connection to the corporate Intranet over their existing connections to the Internet, such as digital subscriber line (DSL) and cable modem connections.

The company would also like to improve the connection experience for their users in the following ways:

- Provide a simplified method of setting up all types of connections on a variety of Windows operating systems.
- Provide a unified phone book for all access numbers.
- Provide a customized user interface for the connection client, including custom icons and graphics.
- Provide a single sign-on experience for double-dial VPN users by using a realm name and a RADIUS proxy.

The Connection Manager family of products provides Contoso with solutions to meet all of these goals.

# Contoso Prepares Phone Books

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before Contoso creates the Connection Manager service profile, they create the local phone book file (Contoso.pbk) and the region file (Contoso.pbr). These files contain the local phone numbers that allow users to dial directly into Contoso's corporate intranet.

The company also receives a phone book file (Adatum.pbk), a region file (Adatum.pbr), and an update URL (http://pbupdate.adatum.com) from A. Datum, the ISP. To incorporate the phone numbers from the ISP, Contoso creates a component service profile that it will merge into a top-level profile.

The company creates a phone book that includes all the direct-dial numbers for users to the company. Contoso performs the following steps to create the phone book:

1. Installs CPS and PBA. For more information about installing and running PBA, see "Providing Connection Manager Phone Book Support" earlier in this chapter.
2. Runs PBA.
3. Creates a new phone book named Contoso.
4. Uses the **Region Editor** to enter the regions for these numbers.
5. Adds POP entries and enters the information for each phone number.
6. Publishes the phone book.

To provide phone book updates, Contoso installs PBS on a computer running a member of the Windows Server 2003 family. The phone books from the ISP are already in the form of a phone book file (Adatum.pbk) and a region file (Adatum.pbr), so Contoso does not have to create any additional phone book files.

# Contoso Creates Service Profiles

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Contoso uses the "Preparation for Running the CMAK Wizard" worksheet to collect all the information necessary to run the CMAK wizard. This information is used to create a component profile, which includes the phone numbers and the update URL provided by the ISP, and the top-level profile, which is the service profile the company will distribute to its users.

# Preparing to Create the Component Profile

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A. Datum supplies Contoso with a phone book file (Adatum.pbk) and a region file (Adatum.pbr), as well as a phone book update URL. Contoso uses this information to create a component profile. Contoso also includes the realm name, @contoso.com, agreed to by both Contoso and A. Datum. The realm name identifies the Contoso user and allows A. Datum to forward the RADIUS messages to the RADIUS server for Contoso, as shown in Figure 9.5.

**Figure 9.5 Double-Dial Using RADIUS Proxy**

Figure 9.6 shows the worksheet that Contoso uses to create the component profile.

**Important**

- Figure 9.6 only shows the portions of the "Preparation for Running the CMAK Wizard" worksheet that Contoso customizes to create the component profile. To see the entire blank worksheet to help prepare to run the CMAK wizard, see "Preparation for Running the CMAK Wizard" (DNSRAC__1.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Preparation for Running the CMAK Wizard" on the Web at http://www.microsoft.com/reskit).

**Figure 9.6 Preparation for Running the CMAK Wizard: Component Profile**

| Include? (Y/N) | Implementation Information | | | | | Ready? (Y/N) |
|---|---|---|---|---|---|---|
| Y | Service Profile Source *(Choose one)* | | | | | Y |
| | | X | Create a new service profile | | | |
| | | | Edit an existing service profile | | | |
| | | | Existing profile name: | | | |
| Y | Service Name<br>*Use up to 35 characters, including spaces. Do not use any of the following: *\|/:<>\|[]* | | | A. Datum phone numbers | | Y |

# Preparing to Create the Top-Level Profile

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Contoso then creates its top-level profile, merging the component profile into the top-level profile, which is the service profile that Contoso will distribute to its users. Additional information about files included in this profile, such as CMProxy.txt and CMRoute.txt, is discussed in the following section.

Figure 9.7 through Figure 9.13 show the worksheet that Contoso uses to create the component profile and complete the CMAK wizard. Additional information about files included in this profile, such as CMProxy.txt and CMRoute.txt, is discussed in the following section.

**Important**

- Figure 9.7 through Figure 9.13 only show the portions of the "Preparation for Running the CMAK Wizard" worksheet that Contoso customizes to create the top-level profile. To see the entire blank worksheet to help you prepare to run the CMAK wizard, see "Preparation for Running the CMAK Wizard" (DNSRAC_1.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Preparation for Running the CMAK Wizard" on the Web at http://www.microsoft.com/reskit).

**Figure 9.7 Preparation for Running the CMAK Wizard: Top-Level Profile (page 1)**

| Include? (Y/N) | Implementation Information | | Ready? (Y/N) |
|---|---|---|---|
| Y | Service Profile Source *(Choose one)* | | Y |
| | [X] Create a new service profile | | |
| | [ ] Edit an existing service profile | | |

| | Check, if appropriate | | | |
| | X | Install Connection Manager 1.3 with this service profile. | | |
| Y | Ready to Build the Service Profile | | | Y |
| | You have completed all steps required to build your service profile. To further customize the information included in this profile, check the Advanced Customization box. | | | |
| | *Check, if appropriate.* | | | |
| | X | Advanced Customization | | |
| Y | Advanced Customization | | | Y |
| | For each file you want to modify, enter the file name, the section name, the name of the key that you want to modify, and the new value for the key. | | | |
| | First file to customize: | | | |
| | | Description | Remove "Save Password" option | |
| | | File name | Contoso.cms | |
| | | Section name | Connection Manager | |
| | | Key name | HideRememberPassword | |
| | | Value | 1 | |

**Figure 9.13 Preparation for Running the CMAK Wizard: Top-Level Profile (page 7)**

| Include? (Y/N) | Implementation Information | | | Ready? (Y/N) |
|---|---|---|---|---|
| | Second file to customize: | | | |
| | | Description | Disable ICS | |
| | | File name | Contoso.cms | |
| | | Section name | Connection Manager | |
| | | Key name | DisableICS | |
| | | Value | 1 | |
| | Third file to customize: | | | |
| | | Description | Enable ICF | |
| | | File name | Contoso.cms | |
| | | Section name | Connection Manager | |
| | | Key name | EnableICF | |
| | | Value | 1 | |
| | Fourth file to customize: | | | |
| | | Description | Hide Advanced Tab | |
| | | File name | Contoso.cms | |
| | | Section name | Connection Manager | |
| | | Key name | HideAdvancedTab | |
| | | Value | 1 | |

Based on the decisions to provide routing table updates, automatic proxy configuration, and custom graphics, Contoso creates

several files before running the CMAK wizard:

- A route update file, CMRoute.txt.

  This plain text file includes information required to add or delete routes in the following format:

  ```
  Command Destination maskNetmask Gatewaymetric Metric if Interface
  ```

  Certain parameters can contain the value of **default**. In those cases, the appropriate information from the client computer is used.

  The file CMRoute.txt contains the following text to make all locations in the address range 192.168.0.0/16 reachable through the VPN connection:

  ```
  ADD 192.168.0.0 MASK 255.255.0.0 default METRIC default IF default
  ```

  For more information about including routing table updates, see Including routing table updates in Help and Support Center for Windows Server 2003.

- A proxy setting file, CMProxy.txt.

  This plain text file includes information to ensure that the user has appropriate access to internal and external resources.

  The proxy setting file for Contoso, CMProxy.txt, includes the following information:

  ```
  [Automatic Proxy]
  AutoProxyEnable=1

  [Manual Proxy]
  ProxyEnable=1
  ProxyServer=Contosoproxy:80
  ProxyOverride=<local>
  ```

  For more information about using automatic proxy configuration, see Using automatic proxy configuration in Help and Support Center for Windows Server 2003.

- Bitmap (.bmp) files for each of the custom graphics.

  Contoso creates custom bitmap files for the logon bitmap (330 x 140 pixels) and the phone book bitmap (114 x 309 pixels).

- Icon (.ico) files for each of the custom icons.

  Contoso creates custom icon files for the program icon (32 x 32 pixels) and the title bar icon (16 x 16 pixels). Contoso leaves the default notification area icon to show the connection status in the notification area.

# Contoso Uses CMAK to Create the Service Profiles

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After completing these worksheets, the company completes the CMAK wizard using this information.

The company completes the following steps to run the CMAK wizard:

1. Install CMAK from the Windows Component Wizard.

2. Create the component profile based on the information gathered in the component profile worksheet (Figure 9.6).

3. Create the top-level profile, merging the component profile to include the phone book provided by the ISP. The top-level profile is completed by using the information gathered in the top-level profile worksheet (Figure 9.7 to Figure 9.13).

# Contoso Tests Its Remote Access Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After creating the top-level service profile, Contoso tests its entire remote access solution before rolling it out. To test both the client and server aspects of the remote access solution, Contoso installs the Connection Manager profile onto a computer running each operating system the company supports and runs each possible user scenario. The company tests for the following from the Connection Manager client of each operating system:

- A VPN connection to the company's VPN remote access server.
- A direct-dial connection to the company's dial-up remote access server. By reviewing the Connection Manager log file, Contoso also confirms that the phone books are updating from the update URL provided by the company.
- A double-dial connection to several phone numbers provided by the ISP to ensure that the RADIUS proxy is forwarding the RADIUS messages to the Contoso RADIUS server. By reviewing the Connection Manager log file, Contoso also confirms that the phone books are updating from the update URL provided by A. Datum.

# Distributing the Connection Manager Profile

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After thoroughly testing the entire remote access solution, Contoso distributes the Connection Manager service profile Contoso.exe to users at the company. Contoso uses a combination of distribution methods: the service profile is made available for download from the company's corporate network, and the service profile is preinstalled onto all new portable computers before distributing them.

The service profile can be downloaded from inside the corporate network and either installed on portable computers or saved to floppy disk and installed later on the user's home computer.

After the user has Contoso.exe on their computer, the user installs and sets up Connection Manager by using the following procedure.

**To install Contoso.exe**

1. Double-click **Contoso.exe**.
2. Click **Yes** when prompted to install Remote access to Contoso.
3. Click **My use only** to make the connection available to only the intended user and not all users of that computer. The user can also choose to add a shortcut to the connection on the desktop, and then click **OK**.
4. After the installation is complete, the user selects a primary and backup phone number or chooses to connect over their existing Internet connection.

   **Tip**

   - The user can create additional settings for home, travel, or other locations. Users create these customized settings by using the **New** button on the **General** tab of the **Remote access to Contoso Properties** dialog box and access them by using the **Use settings for** list on the **Remote access to Contoso** dialog box.

**To select a phone number**

1. Click **Properties** in the **Remote access to Contoso** dialog box.
2. On the **General** tab of the **Remote access to Contoso Properties** dialog box, click **Dial a phone number to connect**.
3. Click **Phone Book** to specify a phone number and a backup number.

**To use an existing connection to the Internet**

1. Click **Properties** in the **Remote access to Contoso** dialog box.
2. On the **General** tab of the **Remote access to Contoso Properties** dialog box, click **I am already connected to the Internet**.
3. The user clicks **OK** to return to the **Remote access to Contoso** dialog box.
4. Finally, the user enters their credentials and connects to the Contoso intranet.

# Additional Resources for Deploying Remote Access Clients Using Connection Manager

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Related Information**

- "Deploying Dial-up and VPN Remote Access Servers" in this book for information about designing and deploying a remote access server solution.
- "Deploying Internet Authentication Service (IAS)" in this book for information about designing and deploying Internet authentication.
- "Connecting Remote Sites" in this book for information about creating connections to branch offices and remote sites.
- The *Internetworking Guide* of the *Windows Server 2003 Resource Kit* (or see the Internetworking Guide on the Web at http://www.microsoft.com/reskit) for information about the Routing and Remote Access service and remote access issues, virtual private networks, and Connection Manager.
- "Deploying Internet Authentication Service (IAS)" in this book for more information about Network Access Quarantine Control.

**Related Tools**

- Certificate Deployment (Cmgetcer.dll)

  Cmgetcer.dll allows Connection Manager to automatically obtain a certificate for L2TP/IPSec connections. For more information about Cmgetcer.dll, in Help and Support Center for Windows Server 2003, click **Tools**, and then click Windows Resource Kit Tools Help.

- Profile Update (Getcm.exe and Instcm.exe)

  Getcm.exe runs as a post-connect action that checks for and downloads an updated service profile; Instcm.exe runs as a disconnect action that checks to see if an updated service profile has been downloaded and installs it. For more information about Getcm.exe and Instcm.exe, in Help and Support Center for Windows Server 2003, click **Tools**, and then click Windows Resource Kit Tools Help.

- Remote Access Quarantine Support Tools (RQC.exe and RQS.exe)

  IAS Network Access Quarantine Control provides phased network access for remote client computers. The Remote Access Quarantine Agent service is included when RQS.exe is installed on a remote access server. When you create the Connection Manager profile, you can include an administrator-provided script and RQC.exe. For more information about RQC.exe and RQS.exe, in Help and Support Center for Windows Server 2003, click **Tools**, and then click Windows Resource Kit Tools Help.

**Related Help Topics**

For best results in identifying Help topics by title, in Help and Support Center, under the **Search** box, click **Set search options**. Under **Help Topics**, select the **Search in title only** checkbox.

- "Administer phone books" in Help and Support Center for Windows Server 2003 for more information about how to administer phone books from the command line.
- "Add, edit, or delete POPs by command line" in Help and Support Center for Windows Server 2003 for more information about importing phone book files by using PBS.

- "Preparing to run the CMAK wizard" and "The Connection Manager Administration Kit Wizard" in Help and Support Center for Windows Server 2003 for more specifics about customizing Connection Manager by using CMAK.

- "Incorporating custom actions" in Help and Support Center for Windows Server 2003 for more information about custom actions.

- "Advanced Customization" in Help and Support Center for Windows Server 2003 for more information about advanced customization, including a comprehensive list of the service profile files and keys that you can customize.

- "IAS Network Access Quarantine Control" in Help and Support Center for Windows Server 2003 for more information about Network Access Quarantine Control.

- "Security information for Connection Point Services" in Help and Support Center for Windows Server 2003 for more information about phone book security.

- "Set up FTP accounts for known users" in Help and Support Center for Windows Server 2003 for more information about setting up FTP accounts for CPS.

# Connecting Remote Sites

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Routing and Remote Access service in the Microsoft® Windows® Server 2003 operating system supports remote site connectivity by using dial-up or virtual private network (VPN) connections. You can deploy either a temporary or persistent site-to-site (also known as router-to-router) connectivity solution in your network to achieve optimal scalability, security, and performance while reducing your connection costs.

# Overview of Remote Site Connectivity

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Many organizations have offices located in different geographical locations, requiring remote site connectivity. You can use the Windows Server 2003 Routing and Remote Access service to deploy a cost-effective and secure site-to-site solution.

Traditionally, organizations have used wide area network (WAN) site-to-site connection technologies, such as T-Carrier or Frame Relay, to connect remote sites across a private data network. However, these private lines are expensive. For example, the prices for T-Carrier services are based on both bandwidth and distance, which makes the connections relatively costly. In addition, T-Carrier typically requires a dedicated infrastructure, including a Channel Service Unit/Data Service Unit (CSU/DSU) and line-specific routers at each end of the connection.

In contrast, you can integrate the Windows Server 2003 Routing and Remote Access service solution into your organization's current network by using existing servers. With the site-to-site connections provided by the Routing and Remote Access service, you have two alternatives to conventional WAN links: a site-to-site dial-up connection or a site-to-site VPN connection. If you deploy a Routing and Remote Access solution to replace an existing WAN connection, or to implement a new connection, you can optimize cost savings by tailoring your connection type to your traffic volume. You can also customize security to fit your organization's requirements.

**Note**

- The Routing and Remote Access service can support both site-to-site connections between remote offices and remote access connections for individual computers. This chapter focuses on site-to-site connections.

Before you begin the design process to introduce a new site-to-site connection into your network, or modify an existing connection, inventory your existing hardware and software, and create or update a map of your current network. Updating your inventory and network configuration information facilitates both the design and the deployment phases. For a guide to conducting inventories and creating a network map, see "Planning for Deployment" in *Planning, Testing, and Piloting Deployment Projects* of this kit.

**Note**

- For a list of job aids that are available to assist you in deploying site-to-site connection technology, see "Additional Resources for Connecting Remote Sites" later in this chapter.

# Remote Site Connectivity Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To begin the design process for deploying a site-to-site connection, choose the remote site connection type and its configuration options that are most appropriate, and decide which security features to use to protect that connection. Next, decide how you want to integrate the remote site connection into your existing network infrastructure. Finally, prepare the servers that you plan to configure as routers. After you complete these design decisions, you are ready to deploy your remote site connection. The flowchart in Figure 10.1 outlines this process.

**Figure 10.1 Connecting Remote Sites**

# Remote Site Connectivity Background

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can design and deploy a remote site connection that is optimal for your organizational and network environment by using the connectivity, security, and network configuration options provided by the Routing and Remote Access service.

The following sections describe three typical remote site connection solutions — a Point-to-Point Tunneling Protocol (PPTP) VPN connection, a Layer Two Tunneling Protocol over Internet Protocol security (L2TP/IPSec) VPN connection, and a dial-up connection. For detailed information about each connection type and the range of available configuration and security options, see "Choosing the Remote Site Connection Type" and "Choosing Security Features" later in this chapter.

**PPTP VPN Solution**

Organizations with moderate to heavy traffic between a branch office and a main office and existing connections to the Internet might choose a PPTP–based site-to-site connection. In the example shown in Figure 10.2, a firewall creates a perimeter network at each end of the Internet tunnel. Windows Server 2003 also supports VPN functionality without the use of a firewall.

Microsoft Challenge Handshake Authentication Protocol version 2 (MS-CHAP v2), which provides a high-security protocol for password authentication, is a highly recommended method for authentication and encryption key generation for a site-to-site connection. Alternatively, you can use Extensible Authentication Protocol-Transport Layer Security Protocol (EAP-TLS), which provides an even stronger user-level authentication than the password-based MS-CHAP v2.

The main office site must have a permanent WAN link to its local Internet service provider (ISP), but the branch office site can use a dial-up WAN link to its local ISP. An on-demand connection that disconnects when the connection is idle ensures that the connection is not active when not in use. Reciprocal replication ensures that replication between domain controllers in separate sites takes place over the one-way initiated on-demand connection. Figure 10.2 depicts this solution.

**Figure 10.2 One-Way Initiated On-Demand Dial-up PPTP VPN Solution**

**L2TP/IPSec VPN Solution**

Organizations that need maximum security to support substantial two-way traffic between a large branch office and a headquarters office might choose an L2TP/IPSec VPN solution. A firewall creates a perimeter network at each end of the Internet tunnel. A persistent connection, enabled by a dedicated link to the ISP at both sites, allows around-the-clock traffic.

The recommended method for the computer-level authentication provided by L2TP/IPSec is the exchange of computer certificates by the calling and answering endpoints, which requires a certificate infrastructure provided by the certification authority (CA) server. EAP-TLS provides stronger user-level authentication than does the password-based MS-CHAP v2, because it requires a user certificate on the calling endpoint and a computer certificate on the answering endpoint. L2TP/IPSec uses IPSec as its encryption method. For a persistent connection, replication takes place across the site link at specified intervals — you do not need to configure reciprocal replication as you do for a one-way initiated on-demand connection. The example in Figure 10.3 depicts this solution.

**Figure 10.3 Persistent Two-Way Initiated L2TP/IPSec VPN Solution**

**Dial-up Solution**

Organizations with moderate traffic between a branch and a main office might choose to replace an existing leased WAN link with a dial-up WAN link or use a dial-up WAN link to create a new connection. Figure 10.4 shows an example of a site-to-site connection that uses an ISDN dial-up link. One common situation in which you might deploy a dial-up link is as a backup solution when a VPN link provides your primary connection. For more information about when to use a dial-up connection, see "Choosing a Dial-up or VPN Connection" later in this chapter.

A one-way initiated on-demand dial-up connection disconnects when the connection is idle for a specified period of time and thus provides efficient access for branch office users who need only intermittent access to the main office. A dial-up connection typically uses MS-CHAP v2as the user authentication method to authenticate the calling router together with Microsoft Point-to-Point Encryption (MPPE) for data encryption. Configuring reciprocal replication enables replication between domain controllers in separate sites over a one-way initiated on-demand connection. Figure 10.4 depicts this solution.

**Figure 10.4 One-Way Initiated On-Demand Dial-up Solution**

# Choosing the Remote Site Connection Type

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The first set of decisions that you need to make when designing remote site connectivity are about the connection type. The flowchart in Figure 10.5 shows the tasks required when choosing connection type options.

**Figure 10.5 Choosing a Remote Site Connection Type**

# Choosing a Dial-up or VPN Connection

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When considering your connection type options, your first decision is whether to use a dial-up (non-VPN) connection or a VPN connection.

# Routing and Remote Access Dial-up Connections

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Routing and Remote Access connections that run over a physical device (such as an ISDN adapter or analog modem) that is installed on both the calling and answering routers are known as *dial-up connections*. These connections differ from traditional WAN links in that they use existing telephone lines instead of leased lines. A dial-up connection differs from a VPN connection in that it does not cross the Internet.

Using existing phone lines can substantially reduce connection costs, especially where traffic volume between sites is low. Instead of paying for a permanent WAN connection 24 hours a day, you can configure the link to disconnect when no traffic crosses the connection for a specified period of time. For example, customers who use ISDN typically pay by the minute or by the byte, so configuring the call to hang up when the connection is idle reduces cost.

To keep data transmission secure, a dial-up connection uses private, dedicated lines or circuits across a carrier's network. In addition, the connection uses Point-to-Point Protocol (PPP) user authentication and MPPE for data encryption.

An organization might choose to deploy a dial-up connection if it has a small branch office that needs an occasional dial-up connection to a main office. For a dial-up link used as the main site-to-site connection, using ISDN is a viable option.

A larger organization that uses a VPN connection might also deploy an ISDN dial-up connection as a backup solution in case the Internet connection in either site is ever unavailable. You can use a Public Switched Telephone Network (PSTN) dial-up link as the backup if the primary link is Frame Relay with a committed information rate (CIR) of 56 Kbps. If the link for which you need a backup is faster than 56 Kbps CIR, using a PSTN dial-up connection as the backup is not feasible, because users accustomed to a faster connection will perceive the dial-up connection as too slow or inoperable. If the primary link is faster than 56 Kbps, instead use a synchronous circuit solution, such as ISDN or a leased-line circuit, for the backup.

In either of these situations, a dial-up connection provides a solution that is easy to deploy and cost-effective.

# Virtual Private Network Connections

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Routing and Remote Access connections that cross the Internet (or other shared network) are known as virtual private network (VPN) connections. A VPN connection typically uses a physical link to a local ISP. A VPN-based answering router always uses a permanent WAN link to an ISP, such as a T-Carrier, Frame Relay, DSL, or cable modem link. The answering router's permanent link to the Internet ensures that the router is available whenever a calling router attempts to establish a connection. This link requires a static IP address, which is assigned by your local ISP (or by InterNIC), on the answering router's Internet-connected interface. However, a VPN-based calling router might use a permanent WAN link to an ISP, or it might use a temporary link (such as a modem or adapter) to the ISP.

When traffic volume is high or permanent connectivity across long distances is required, using a VPN connection to transport data across the Internet is more cost-effective than using a dedicated WAN line or a dial-up connection.

To keep data transmission secure, a VPN connection uses PPP user authentication, routes packets encapsulated in a secure tunnel across the Internet, and uses MPPE or IPSec encryption to protect the data portion of the packet. This virtual point-to-point connection emulates a dedicated, private, physical point-to-point connection but lets you replace long-distance WAN links with local WAN links to your nearby ISP. The ISP does not install any VPN software on its equipment, nor is any VPN software installed on the intermediate routers that a VPN data packet crosses.

If you choose a VPN connection in which the calling router uses a temporary link to connect to its local ISP, the temporary link can be either a dial-up link or a PPP over Ethernet (PPPoE) link. The calling router first establishes the dial-up or PPPoE link to the ISP and then establishes the VPN tunnel across the Internet to the answering router. Many broadband ISPs use PPPoE. PPPoE links to the ISP are faster than dial-up links.

An example of an organization that might choose to deploy a VPN connection is a large enterprise with several large satellite offices that each need secure connection for high-volume traffic across the Internet to a headquarters office.

**Choosing PPTP or L2TP/IPSec**

If you choose a VPN site-to-site connection, you must next decide whether to use PPTP or L2TP/IPSec as the VPN technology. Table 10.1 lists some of the factors you need to consider in order to determine whether to deploy a PPTP or an L2TP/IPSec solution. For more information about the security options (user authentication, certificates, and encryption) described briefly in the table, see "Choosing Security Features" later in this chapter.

**Table 10.1 Comparing a PPTP Solution with an L2TP/IPSec Solution**

| Factor | Using PPTP | Using L2TP/IPSec |
|---|---|---|
| Windows version | PPTP is supported by Windows Server 2003, as well as the Microsoft® Windows® 2000 Server operating system, and the Microsoft® Windows NT® version 4.0 operating system with the Routing and Remote Access Service (RRAS). Most third-party VPN routers also support PPTP. | L2TP/IPSec is supported by Windows Server 2003 and Windows 2000 Server (with the Routing and Remote Access service). Most third-party VPN routers also support L2TP/IPSec. |
| User authentication | EAP-TLS or MS-CHAP v2 is recommended. | EAP-TLS or MS-CHAP v2 is recommended. |

| | | |
|---|---|---|
| Certificates | PPTP requires certificates only when using EAP-TLS for user authentication, in which case a user certificate for the calling router and a computer certificate for the authenticating server of the answering router are required. | • Using EAP-TLS user authentication with L2TP/IPSec requires a user certificate for the calling router and a computer certificate for the authenticating server of the calling router.<br>• For computer-level authentication, L2TP/IPSec supports computer certificates or preshared keys as the authentication method for IPSec. Computer certificate authentication is recommended and requires a computer certificate on both the calling and answering routers. |
| Encryption | For a PPTP-based VPN connection, choosing either EAP-TLS or MS-CHAP v2 for user authentication provides MPPE for data encryption. MPPE provides data confidentiality (encryption); that is, captured packets cannot be interpreted without the encryption key. | L2TP/IPSec generates its encryption keys by using IPSec. IPSec provides data confidentiality (encryption), replay protection, data integrity, and data origin authentication. |
| NATs | In most cases, you can locate PPTP-based calling routers behind a network address translator (NAT), so you can configure a small or home office (SOHO) network to share a single connection to the Internet. Most NATs include a NAT editor that can accurately translate PPTP-tunneled data. | With Windows Server 2003–based calling or answering routers, you can use IPSec NAT traversal (NAT-T) to create L2TP/IPSec connections across NATs. Using NAT-T requires running Windows Server 2003 on both the calling and answering routers. With NAT-T, hosts that are hidden behind a NAT can use IPSec to connect to a remote site. |
| Ease of deployment | When using MS-CHAP v2 (or MS-CHAP) for user authentication, PPTP is cost-effective and easier to deploy than L2TP/IPSec with computer certificates. | • When you use computer certificates as the authentication method, L2TP/IPSec requires a certificate infrastructure and, therefore, requires more administrative overhead to deploy and maintain than does PPTP used with password-based MS-CHAP v2. For optimal security, using certificates is the recommended method.<br>• Using preshared keys as the authentication method, L2TP/IPSec requires less administrative overhead (for initial setup but not for long-term administration) than using L2TP/IPSec with certificates but more administrative overhead than using PPTP. To ensure security, do not use preshared keys.[1] |

1. For more information about the advantages of computer certificates over preshared keys, see "Choosing Computer Certificates or Preshared Keys for Computer-Level Authentication" later in this chapter.

**Using Both a PPTP Connection and an L2TP/IPSec Connection**

You can deploy both a PPTP solution and an L2TP/IPSec solution at the same time. By default, a VPN router running Windows Server 2003 simultaneously supports both connection types. A VPN router running Windows 2000 Server supports both connection types if the router is not behind a NAT; however, Windows 2000 Server supports only PPTP — but not L2TP/IPSec — across a NAT.

You might want to use PPTP for some site-to-site connections and L2TP/IPSec for others. Table 10.2 lists some situations in which you might use PPTP or L2TP/IPSec for different connections on the same network.

**Table 10.2 Using PPTP and L2TP/IPSec for Different VPN Connections on the Same Network**

| VPN Connection Type | Typical Uses |
|---|---|

| | |
|---|---|
| PPTP | • To connect from calling routers that are running Windows NT 4.0 with RRAS.<br>• To connect from routers that are running Windows Server 2003 or Windows 2000 Server that do not have an installed computer certificate.<br>• To establish a VPN connection when you want to place Windows 2000 Server–based routers behind a Routing and Remote Access NAT or a third-party NAT. |
| L2TP/IPSec | • To connect from calling routers running Windows Server 2003 or Windows 2000 Server that have an installed computer certificate.<br>• To enable hosts that are hidden behind a NAT (because they use private addresses) to use IPSec to connect to a remote site. This is possible because NAT-T, which is enabled by default on Windows Server 2003–based computers, can create L2TP/IPSec connections across a NAT.<br>• To provide the highest security solution available.<br>• To connect from calling routers running Windows Server 2003 that use preshared keys (not recommended for security reasons). |

If you use both a PPTP and an L2TP/IPSec solution, you can create separate remote access policies that define different connection parameters for each connection type. For example, if you have PPTP VPN connections to two branch offices whose calling routers run Windows NT 4.0 with RRAS, you might want to create a more restrictive remote access policy for those connections than the remote access policy that you create for an L2TP/IPSec VPN connection to a branch office whose calling routers run Windows Server 2003 and use computer-level authentication. For more information about creating remote access policies for a site-to-site connection, see "Configure a Remote Access Policy" later in this chapter.

# Choosing an On-Demand or Persistent Connection

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can configure the calling router for any of the connection types — dial-up, PPTP VPN, or L2TP/IPSec VPN — with either an on-demand or a persistent connection. Table 10.3 describes and compares these connection type options.

**Table 10.3 Comparing On-Demand and Persistent Connections**

| Connection Type | Description | Use |
|---|---|---|
| On-demand connection | Establishes a connection when traffic is forwarded, and it terminates the connection when the link is not used for a specified period of time. | Use an on-demand connection if using the communications link incurs per-minute charges.<br><br>For an on-demand VPN connection, the initiating router can use either a permanent or a dial-up link to the Internet. The answering router must have a permanent link to the Internet to ensure that it is available when a calling router attempts to establish a connection. |
| Persistent connection | Sustains a connection for 24 hours a day. | Use a persistent connection in the following circumstances:<br>• When the cost of the connection is based on a flat fee, such as for a link to a local ISP for each site when sites are located in separate cities or for a connection between different sites within the same city.<br>• When data traffic is time-sensitive. For example, if you support mainframe terminal connectivity between sites, if the terminals must wait for an on-demand VPN connection to be activated, the connection attempt will time out before the session can be launched.<br><br>For a persistent VPN connection, both the calling and the answering router must use a permanent link to the Internet. |

For on-demand connections, to prevent the calling router from establishing unnecessary connections, you can use demand-dial filtering and dial-out hours:

- **Demand-dial filters.** To prevent a VPN calling router from initiating unnecessary connections, you can configure demand-dial filters to specify the types of IP traffic for which the router will or will not create a demand-dial connection. You can identify traffic to accept or reject based on source and destination addresses of incoming traffic and the protocol in use. It is recommended that you match the demand-dial filters to the IP packet filters configured on the demand-dial interface. If there is specific traffic that is not allowed across the demand-dial interface when it is connected, that same traffic should not be allowed to initiate a demand-dial connection using that interface. For example, if you have a packet filter that prevents ICMP traffic from being sent across the demand-dial interface, then you should configure a demand-dial filter to prevent ICMP traffic from initiating the demand-dial connection. For more information about matching demand-dial filters to IP packet filters, see "Integrate the VPN Server into a Perimeter Network" and "Configure IP Packet Filters and Demand-Dial Filters" later in this chapter.

- **Dial-out hours.** To prevent a dial-up or VPN calling router from initiating unnecessary connections, you can configure dial-out hours to specify the hours during which a calling router is either permitted to make a site-to-site connection or denied the connection. You can also configure remote access policies on the answering router to restrict the time periods when incoming demand-dial connections are allowed.

# Choosing a One-Way or Two-Way Initiated Connection

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can set up a site-to-site connection so that it can be initiated from only one location, or you can configure a connection that can be initiated from either side of the dial-up or VPN connection. Table 10.4 describes and compares these options.

**Table 10.4 Comparing One-Way and Two-Way Initiated Connections**

| Connection Type | Description | Use |
|---|---|---|
| One-way initiated connection | A one-way initiated connection is one in which one site contains only an answering router and the other site contains only a calling router. | Use an on-demand or persistent one-way initiated connection when users at a branch office need to connect to a headquarters office but not vice versa.<br>Use a persistent one-way initiated connection when you have 10 or more branch offices and users at each site need to access the other sites. When you use a two-way initiated connection for 10 or more connections, performance is too slow. |
| Two-way initiated connection | A two-way initiated connection is one in which a router at each site can function as both the answering router and as the calling router. | Use a two-way initiated connection when users at both locations need to access resources or people in the other location and you have 10 or fewer connections (if you have 10 or more connections, use a one-way initiated persistent connection). |

For both a one-way and a two-way initiated connection, use the properties of the router in the Routing and Remote Access snap-in to configure both the calling and the answering router as a local area network (LAN) router and as a demand-dial router.

# Choosing Security Features

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As described in "Choosing the Remote Site Connection Type" earlier in this chapter, security is one of the factors that you weigh when you choose a connection type. For all connection types, securing site-to-site communications requires making decisions about several additional security features. The flowchart in Figure 10.6 shows the tasks required when choosing these additional security features.

**Figure 10.6 Choosing Security Features**

# Integrate the VPN Server into a Perimeter Network

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 supports VPN functionality without the use of a firewall. However, many organizations use firewalls to implement a perimeter network (also known as a DMZ, demilitarized zone, and screened subnet) to increase security by protecting their internal network from intrusion through the Internet.

Only servers that provide resources to users over the Internet, such as Proxy, Web, and FTP servers, are located in the perimeter network. Traffic between dial-up routers does not cross the Internet. Therefore, you do not need to locate dial-up routers in a perimeter network. However, placing VPN routers in a perimeter network helps ensure that communications between sites are protected.

**VPN Router Placement in Relation to Firewall**

If your organization already uses a perimeter network, you can add your VPN router to the existing set of servers on the perimeter network. If not, consider adding a perimeter network to your infrastructure when you deploy a VPN site-to-site connection.

How you configure firewall filters and the filters on the VPN router depends on the position of the VPN router relative to the firewall. Although it is possible to place the VPN router in front of the firewall (with the VPN router attached to the Internet), the more common — and recommended — configuration for a site-to-site connection is to place the VPN router behind the firewall (attaching the firewall to the Internet). When you place the VPN router behind the firewall, you configure the firewall with input and output filters on the firewall's Internet and perimeter network interfaces to restrict traffic to the VPN server. These filters are configured the same for a site-to-site VPN server as for a remote access VPN server. For a description of these filters and how they function, see the instructions for configuring packet filters for a VPN server in "Deploying Dial-up and VPN Remote Access Servers" in this book.

For more information about VPN servers and firewalls, including configuration of PPTP and L2TP/IPSec packet filters both for VPN servers behind the firewall and for VPN servers in front of the firewall, see "VPN servers and firewall configuration" in Help and Support Center for Windows Server 2003.

**Match IP Packet Filters to Demand-Dial Filters**

At the same time that you plan where to place your VPN router in relation to a firewall and how to configure PPTP and L2TP/IPSec IP packet filters on the firewall, also plan how to configure demand-dial filters in conjunction with the IP packet filters configured on the demand-dial interfaces. Although IP packet filters and demand-dial filters serve different purposes, Microsoft recommends that you configure them together.

You use demand-dial filters, which are applied *before* a connection is made, to specify which types of traffic are allowed to create a connection in the first place. You use IP packet filters, which are applied *after* a connection is made, to specify what traffic is allowed into and out of an interface after a connection is established. To prevent the demand-dial connection for traffic that will be discarded by the IP packet filters, you need to match your demand-dial and IP packet filters.

For more information about configuring IP packet filters to match your demand-dial filters, see Demand-dial routing design considerations in Help and Support Center for Windows Server 2003.

# Choosing the Authentication Provider

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Site-to-site connections between remote offices require an authentication and accounting provider for:

- Authentication of calling router credentials and authorization of the site-to-site connection.
- Accounting services that record the creation and termination of each site-to-site connection.

When a connection is attempted, the answering router authenticates the credentials of the calling router by using one of two authentication providers: Windows or RADIUS. Your choice of authentication provider is determined by whether your solution involves a site-to-site only connection or a combined site-to-site and remote access connection:

- **For a site-to-site only connection, choose Windows.** When you choose Windows as the authentication, authorization, and accounting provider, the same Windows authentication process that validates user credentials when a user logs on also validates the calling router.
- **For a combined site-to-site and remote access connection, choose either Windows or RADIUS.** If the same answering router will support both a site-to-site connection and remote access users (such as home or mobile users), you can use either Windows or Remote Authentication Dial-in User Service (RADIUS) as your authentication provider. Servers running the Internet Authentication Service (IAS) component of Windows Server 2003 provide an Internet standards–compliant RADIUS server and proxy.

If you have more than one answering router or other types of access servers (such as wireless access servers), you can use a single RADIUS server to provide centralized authentication, authorization, and accounting for all answering routers and access servers instead of administering each answering router and access server separately. To simplify administration for a combined site-to-site and remote access connection, you can use IAS to store both site-to-site and remote access information.

In an Active Directorydomain, it is recommended that you use the Windows Server 2003 version of IAS as your RADIUS server. The IAS RADIUS server is tightly integrated with Windows Server 2003, Active Directory, and the Routing and Remote Access service. When you use RADIUS authentication, you configure each of participating answering router as a RADIUS client. After you configure both the answering router and the IAS server, the answering router uses remote access policies stored on the IAS server instead of those on the answering router.

Although it is possible to use RADIUS as the authentication provider for a site-to-site only connection, you do not need RADIUS. Deploying an IAS server is unnecessary administrative overhead for a demand-dial connection that connects two sites but does not support remote access users.

The credentials that the calling router passes to the answering router for verification are those of a user account, either in Active Directory or on the local computer. Authorization is granted based on the dial-in properties that you specify in the user account and on remote access policies configured on the answering router (or on the RADIUS server). For more information, see "Choosing Router User Accounts and Groups" and "Choosing a Remote Access Policy Type" later in this chapter.

The authentication provider that you choose also functions as the authorization provider. However, the Routing and Remote Access service does not require that you use the same provider for authentication and authorization that you use for accounting. You can use Windows for authentication and RADIUS for accounting, or vice versa. However, if you have multiple answering routers that support remote access users, consider using RADIUS for integrated authentication, authorization, and accounting, and, if you use IAS, to manage remote access policies.

For more information about RADIUS authentication, see "Checklist: Configuring IAS for dial-up and VPN accessChecklist: Configuring IAS for dial-up and VPN access" in Help and Support Center for Windows Server 2003. For more information about deploying IAS to perform centralized authentication, authorization, and accounting, see "Deploying Internet Authentication Service (IAS)" in this book.

# Choosing an Authentication Method

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For site-to-site connections, you must implement user-level authentication, and, for greater security, you might decide to implement computer-level authentication as well:

- User-level authentication — for all site-to-site connection types.
- Computer-level authentication — for L2TP/IPSec connections only.

# Choosing EAP-TLS or MS-CHAP v2 for User-Level Authentication

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

All site-to-site connection technologies require user-level authentication. The "user" to be authenticated is the calling router. To prevent a nonauthorized router from making a connection, the Routing and Remote Access service requires that the calling router requesting the connection be authenticated by the answering router.

The Routing and Remote Access service can use any of several PPP authentication methods to provide user-level authentication. For optimal security, choose one of the two strongest recommended PPP user authentication methods — EAP-TLS or MS-CHAP v2.

For more information about the other PPP authentication protocols (in addition to EAP-TLS and MS-CHAP v2) supported by Windows Server 2003, Windows 2000 Server, and Windows NT Server 4.0, see "Authentication methods" in Help and Support Center for Windows Server 2003.

**Certificate-based EAP-TLS**

EAP-TLS is a more secure protocol than MS-CHAP v2 for user-level authentication on a dial-up, PPTP VPN, or L2TP/IPSec VPN connection. EAP-TLS requires a certificate infrastructure, because it uses a user certificate for the calling router and a computer certificate for the authenticating server of the answering router. The identity of the authenticating server depends on the authentication provider:

- If Windows provides authentication, as is the case for a site-to-site only connection, the computer certificate is installed on the answering router. The answering router must be joined to the Active Directory domain.
- If RADIUS provides authentication, as might be the case if your answering router also supports remote access users, the computer certificate is installed on the RADIUS server. If the RADIUS server is an IAS server, it must be joined to the Active Directory domain. In this case, the answering router does not need to belong to the domain.

EAP-TLS is recommended for all connection types both because it is the strongest method for user authentication and because it provides mutual user authentication between calling and answering routers. The calling router submits a user certificate for authentication, and the answering router (or RADIUS server) submits a computer certificate for authentication. With EAP-TLS, the user account that the answering router uses to authenticate and authorize the calling router must be an Active Directory user account.

If you plan to use certificate-based EAP-TLS, you can use a third-party CA if the conditions in Table 10.5 are met.

**Table 10.5 Requirements for Using a Third-Party CA**

| Certificates Installed on Authenticating Server (Answering Router or RADIUS Server) | Certificates Installed on Calling Router |
|---|---|

| | |
|---|---|
| • Computer certificates must be installed in the Local Computer certificate store.<br>• Computer certificates must have a corresponding private key.<br>• The cryptographic service provider for the certificates must support secure channel (Schannel). (If not, the authenticating server cannot use the certificate and the certificate cannot be selected from the properties of the Smart Card or Other Certificate EAP type on the Authentication tab in the properties of a profile for a remote access policy.)<br>• Computer certificates must contain the Server Authentication certificate purpose (also known as an enhanced key usage [EKU]). An EKU is identified using an object identifier (also known as an OID). The object identifier 1.3.6.1.5.5.7.3.1 represents Server Authentication.<br>• Computer certificates must contain the fully qualified domain name (FQDN) of the computer account of the authenticating server computer in the Subject Alternative Name property.<br>• The root CA certificates of the CAs that issued the calling router user certificates must be installed in the Trusted Root Certification Authorities certificate store. | • User certificates must have a corresponding private key.<br>• User certificates must contain the Client Authentication EKU (the 1.3.6.1.5.5.7.3.2 object identifier).<br>• User certificates must be installed in the Current User certificate store.<br>• User certificates must contain the universal principal name (UPN) of the user account in the Subject Alternative Name property.<br>• The root CA certificates of the CAs that issued the authenticating server computer certificates must be installed in the Trusted Root Certification Authorities store. |

For examples of how to deploy EAP-TLS certificate-based user authentication for site-to-site connections, see Deploying certificate-based authentication for demand-dial routing in Help and Support Center for Windows Server 2003. For more information about certificate types and requirements, see Certificate Services in Help and Support Center for Windows Server 2003, and see "Designing a Public Key Infrastructure" in *Designing and Deploying Directory and Security Services* of this kit.

**Password-based MS-CHAP v2**

Like EAP-TLS, MS-CHAP v2 also provides mutual authentication between the calling router and the answering router. MS-CHAP v2 is a password-based authentication method in which the answering router uses either an Active Directory user account or a local user account to authenticate the calling router. MS-CHAP v2 is the recommended method for user authentication if a certificate infrastructure is not available.

If you use a local user account for MS-CHAP v2 authentication, the demand-dial routers do not need to join the Active Directory domain. Be sure to use strong passwords with MS-CHAP v2. In an Active Directory domain, you can use Group Policy settings to enforce the use of strong passwords.

**Advantages of EAP-TLS and MS-CHAP v2**

Although several weaker PPP authentication protocols are also available for user authentication, EAP-TLS and MS-CHAP v2 are the preferred methods because both provide the following benefits:

- **Mutual authentication.** With mutual authentication, the calling router is authenticated by the answering router, and the answering router is then authenticated by the calling router. This mutual authentication prevents an attacker from masquerading as the answering router, whereas other types of authentication verify only the identity of the calling router.

- **Encryption features.** In addition, for a dial-up or PPTP connection, EAP-TLS and MS-CHAP v2 provide the following encryption features. (L2TP/IPSec generates its encryption keys using IPSec and therefore does not need EAP-TLS or MS-CHAP v2 for encryption keys.)

    - **Stronger initial encryption keys.** MS-CHAP v2 uses both a unique session identifier and user credentials to generate encryption keys. EAP-TLS uses user certificates to verify user identity. (In contrast, MS-CHAP uses only the user name and password to create these keys, making it easier for attackers to determine the keys in use.)

    - **Different keys for sending and receiving data.** The calling router and answering router use separate keys to encrypt data and to send data. Using different keys makes it more difficult for attackers to determine which key is

used for encryption.

- **MPPE for encryption.** MPPE uses Rivest-Shamir-Adleman (RSA) RC4 stream ciphering with 40-bit, 56-bit, and 128-bit encryption keys. (RC4, developed by RSA Data Security, is a secret key cryptographic method that uses a variable-length key.) Encryption key strength is negotiated during connection establishment (as is authentication method). The client (calling router) and server (answering router) negotiate the strongest mutually allowable key size. If the answering router requires a larger key than that supported on the calling router, the answering router rejects the connection.

For more information about encryption for site-to-site connections, see "Choosing MPPE or IPSec Encryption" later in this chapter.

# Choosing Computer Certificates or Preshared Keys for Computer-Level Authentication

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The only site-to-site connection technology that provides computer-level authentication is an L2TP/IPSec VPN connection. Computer-level authentication occurs in one of two ways:

- **Computer certificates:** the exchange of computer certificates by the calling and answering routers. Computer-level authentication requires that you deploy a public key infrastructure (PKI). Although computer certificate authentication requires more administrative overhead for initial setup than does the use of preshared keys, it is the recommended method because it provides stronger computer authentication than the preshared keys method. Windows Server 2003 supports the automatic enrollment of certificates, which makes certificate deployment and management easier than using preshared keys over the long term.

- **Preshared keys:** the exchange of preshared keys during the establishment of the IPSec security association (SA). Support for preshared keys is new with Windows Server 2003, and it requires running Windows Server 2003 on both VPN routers. A preshared key is a text string that is configured on both the calling and the answering router. Because a preshared key is a weaker computer authentication method than certificate authentication, Microsoft recommends that you use preshared key authentication only during the time you are deploying a PKI to enable the use of certificates. Using preshared key authentication is not as secure as using computer certificates, but it requires less administrative overhead.

The IPSec Internet Key Exchange (IKE) protocol can use either certificate-based or preshared key authentication to negotiate security for the L2TP traffic.

For more information about creating a certificate infrastructure, see Certificate Services in Help and Support Center for Windows Server 2003, and see "Designing a Public Key Infrastructure" in *Designing and Deploying Directory and Security Services* of this kit. For more information about key exchange, see Internet Key Exchange in Help and Support Center for Windows Server 2003.

# Choosing MPPE or IPSec Encryption

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For site-to-site connections, the connection type and the user authentication protocol that you choose to deploy determine the data encryption method. Table 10.6 shows the available options.

**Table 10.6 Choosing a Data Encryption Method**

| Connection Type | Recommended User Authentication Protocol | Encryption Method |
|---|---|---|
| Dial-up connection | EAP-TLS or MS-CHAP v2 | MPPE |
| PPTP connection | EAP-TLS or MS-CHAP v2 | MPPE |
| L2TP connection | EAP-TLS or MS-CHAP v2 | IPSec |

Understanding the following features can help you decide how you want to manage encryption:

- **Link encryption versus end-to-end encryption.** MPPE provides *link encryption*. Link encryption encrypts data as it passes between the calling and answering routers. In addition to providing computer-level authentication, IPSec provides *end-to-end* encryption for data that passes between the sending and receiving nodes.

- **Encryption method used if VPN connection type is Automatic.** If you configure a VPN connection for an **Automatic** server type (the default), the connection first tries to use PPTP and its associated MPPE encryption, and then it tries to use L2TP and its associated IPSec encryption. If you configure the VPN connection to connect to a PPTP server, only MPPE encryption is used. If you configure the VPN connection to connect to an L2TP server, only IPSec encryption is used.

- **No encryption needed for link to ISP.** For VPN connections, you do not need to use encryption for the link between your site and the ISP, because no data is transmitted during the process that establishes this connection. After the connection to the ISP is made, the data that passes between the calling and answering routers is encrypted as it passes through the VPN tunnel.

You configure MPPE and IPSec encryption strengths on the **Encryption** tab for the properties of a remote access policy. For information about how to configure encryption in a remote access policy for a site-to-site connection, see "Configure a Remote Access Policy" later in this chapter. For general information about configuring encryption, see Add a remote access policy and Remote Access Policies Examples in Help and Support Center for Windows Server 2003.

Configure either MPPE or IPSec to use one of the encryption keys as shown in Table 10.7.

**Table 10.7 Encryption Strength by Connection Type**

| Encryption Strength | Dial-up or PPTP | L2TP/IPSec |
|---|---|---|
| **Basic** | 40-bit MPPE | 56-bit DES |
| **Strong** | 56-bit MPPE | 56-bit DES |
| **Strongest** | 128-bit MPPE | 3DES (three 56-bit keys) |

**Note**

- Windows NT 4.0 with the 128-bit version of Service Pack 4 (SP4) can support 128-bit MPPE, but it does not support 56-bit MPPE. Therefore, any Windows operating system earlier than Windows NT 4.0 SP4 is not recommended, because security enhancements for MS-CHAP and MPPE are not included.

# Choosing Router User Accounts and Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After a calling router is authenticated by using either Windows or RADIUS as the authentication provider, it must be authorized: that is, it must be given permission to establish a connection with the answering router. You use two interrelated sets of components to authorize access by the calling router: user accounts and (optionally) groups, and remote access policies.

Before you can successfully configure either the router user accounts or remote access policies (both described later in this chapter), you need to understand the relationship between the two. Configuring the router user account includes the option of choosing whether to use remote access policies to grant the calling router access to the answering router. You can grant or deny permission for the calling router to access the answering router either at the user account level or at the remote access policies level. The permission specified in the user account overrides the permission specified in a remote access policy. However, if you choose the **Control access through Remote Access Policy** option in the user account that the answering router uses to authenticate the calling router, the remote access policy permission specified on Properties page for the remote access policy governs whether the user account of the calling router is granted or denied access. This option is available only for accounts on stand-alone routers or members of a native mode Active Directory domain. For more information about remote access policies, see "Choosing a Remote Access Policy Type" later in this chapter.

To allow or reject connection attempts according to a variety of criteria, you can specify several remote access options in the user account of the calling router and multiple additional options by using remote access policies. This level of precision enhances the security of your site-to-site connection by providing great flexibility in how you can control access to the answering router and its network resources.

You can configure router user accounts individually for each router or by adding router accounts to an Active Directory group.

# Configuring Router User Accounts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Successfully configuring the router's user account includes the following tasks:

- Configure the router user account name to match the demand-dial interface name.
- Configure the authentication provider for the router.
- Choose an Active Directory user account or a local user account.
- Choose dial-in options for the router user account.
- Ensure that the calling router can establish a connection.

**Configure the Router User Account Name to Match the Demand-Dial Interface Name**

The name of a demand-dial interface configured on the answering router must match the name of the user account that the answering router uses to authenticate the calling router (unless, for a one-way initiated connection, you do not create a demand-dial interface on the answering router, instead configuring static routes in the calling router's user account). For example, if you have one headquarters site and multiple branch offices, on the headquarters answering router configure a separate demand-dial interface for the calling router at each branch-office site. This creates a one-to-one relationship between each calling router's user account name and the name of its corresponding demand-dial interface on the answering router.

**Caution**

- If the user account name does not match the name of the demand-dial interface, the answering router identifies the calling router as a remote access client rather than as a demand-dial router. In this case, the connection might not work correctly. For this reason, do not change the user account name without also changing the corresponding demand-dial interface name.

Table 10.8 shows an example configuration of the demand-dial interfaces and user accounts for a two-way initiated VPN connection. The example in Table 10.8 uses Active Directory user accounts for the routers. In some cases, you can alternatively use a local user account.

**Table 10.8 Example Configuration of Demand-Dial Interfaces and User Accounts for a Two-Way Initiated VPN Connection**

| Router | Demand-Dial Interface | User Account for Calling Router |
|---|---|---|
| Router located in Seattle<br><br>(Functions as both a calling and an answering router) | Interface Name: VPN_NewYork<br><br>Destination IP Address: 131.107.0.1<br><br>Credentials: VPN_Seattle<br><br>Password: PasswordOne | VPN_NewYork<br><br>PasswordTwo |
| Router located in New York<br><br>(Functions as both a calling and an answering router) | Interface Name: VPN_Seattle<br><br>Destination IP Address: 157.54.0.1<br><br>Credentials: VPN_NewYork<br><br>Password: PasswordTwo | VPN_Seattle<br><br>PasswordOne |

For a two-way initiated VPN connection, such as the example in Table 10.8, the name of the demand-dial interface for each router must match the user name in the remote router's user credentials so that each router knows that a requested connection is for a site-to-site connection rather than for a remote access connection. The destination address of the remote router is configured on the demand-dial interface so that each router knows what address to connect to for the site-to-site

connection. Each router uses the user account (the credentials and password of the remote router) to authenticate the remote router when it attempts to establish a connection.

Table 10.9 shows an example configuration of the demand-dial interfaces and user accounts for a one-way initiated dial-up connection in which two branch offices — Portland and Olympia — call the headquarters office in Seattle. In this case, because the connection is a one-way initiated connection, no demand-dial interface is required on the answering router. Therefore, the "rule" that the calling router's user account name must match the name of a demand-dial interface on the answering router does not apply. If you do not create a demand-dial interface on the answering router, you use the calling router's local or Active Directory user account to configure static routes that identify the network IDs of the calling router's site.

**Table 10.9 Example Configuration for a Dial-up One-Way Initiated Connection**

| Router | Demand-Dial Interface | Calling Router User Accounts |
|---|---|---|
| Answering router in Seattle | No demand-dial interface needed.<br><br>If you do not configure a demand-dial interface on the answering router, you must configure static routes specifying the network IDs of the calling router's site on the **Dial-in** tab of the calling router's user account. | DD_Olympia<br><br>PasswordOne<br><br>-and-<br><br>DD_Portland<br><br>PasswordTwo |
| Calling router in Olympia | Interface Name: DD_Seattle<br><br>Modem or adapter: Modem on COM1<br><br>Phone number: 555-0111<br><br>Credentials: DD_Olympia / PasswordOne | No user accounts needed, because the Seattle router does not call the routers in Olympia or Portland. |
| Calling router in Portland | Interface Name: DD_Seattle<br><br>Modem or adapter: Modem on COM2<br><br>Phone number: 555-0111<br><br>Credentials: DD_Portland / PasswordTwo | No user accounts needed, because the Seattle router does not call the routers in Olympia or Portland. |

**Configure the Authentication Provider for the Router**

The answering router uses the calling router's credentials to authenticate and authorize the calling router. As described earlier, if the answering router is configured for Windows authentication, as is the case for a site-to-site only connection, Windows security is used to authenticate the credentials of the calling router. If the answering router is configured for RADIUS authentication, as might be the case if the same answering router is used to support both a site-to-site connection and remote access users, the RADIUS server verifies the credentials of the calling router.

The user accounts and groups that Windows and IAS can use to authenticate and authorize site-to-site dial-up or VPN connection attempts are those available in Windows Server 2003 or Windows 2000 native-mode or mixed-mode Active Directory domains and Windows NT 4.0 domains.

**Choose an Active Directory User Account or a Local User Account**

The answering router must be able to access an Active Directory user account or a local user account to verify the calling router's credentials. In either case, because demand-dial routers make connections automatically, the user account that the answering router uses to authenticate and authorize the calling router must not prompt for human intervention.

**Active Directory user account**

If your demand-dial routers belong to an Active Directory domain, you use the Active Directory Users and Computers snap-in (rather than the Demand-Dial Interface Wizard) to create a user account for each calling router before you deploy a dial-up or VPN connection. When you create the router account, be sure to clear the **User must change password at next logon** check box and select the **Password never expires** check box.

If you use EAP-TLS user authentication with Windows as the authentication provider, the answering router must belong to the Active Directory domain, and you must create an Active Directory user account for the calling router. (If you use EAP-TLS user authentication with RADIUS as the authentication provider, you must join the IAS server to the Active Directory domain.)

If you use RADIUS authentication, the RADIUS server can use either an Active Directory user account or a local user account to

authenticate the calling router. If you use a Windows Server 2003 IAS server as your RADIUS server, Microsoft recommends that you use Active Directory accounts.

For information about how to create an Active Directory user account, see "Create a new user account" in Help and Support Center for Windows Server 2003.

**Local user account**

If you use Windows authentication and your demand-dial routers do not belong to an Active Directory domain, the answering router uses a local user account to authenticate the calling router. This user account is created locally on the answering router.

Instead of creating the user account for the calling router manually, you use the Demand-Dial Interface Wizard to create the account. When you run the Demand-Dial Interface Wizard on an answering router that is not joined to an Active Directory domain, the wizard adds a local account for the calling router when you select **Add a user account so a remote router can dial in** on the **Protocols and Security** page. The wizard clears the **User must change password at next logon** check box and selects the **Password never expires** check box on the user account object.

For information about using the Demand-Dial Interface Wizard, see "Configure the Routing and Remote Access Service and Demand-Dial Interfaces" later in this chapter, and see Add a demand-dial interface in Help and Support Center for Windows Server 2003.

If you use a local account and password, you must use MS-CHAP v2 rather than EAP-TLS for user authentication.

If you use RADIUS authentication, the RADIUS server can use a local user account to authenticate the calling router. If you use a Windows Server 2003 IAS server as your RADIUS server, however, using Active Directory accounts is recommended.

**Choose Dial-in Options for the Router User Account**

You use the **Dial-in** tab of the calling router's user account to specify the remote access permission as follows:

- **Allow access (for native-mode or mixed-mode domains).** Allows access when a connection is attempted. (When you use the Demand-Dial Interface Wizard to create a local account, the remote access permission is set to **Allow access** by default.) This option overrides the grant or deny remote access permission setting specified on the Properties page of any associated remote access policy. The remote access permission on the associated remote access policy is either **Deny remote access permission** or **Grant remote access permission**. Thus, for example, if you select **Allow access** on the router user account, and if you select **Deny remote access permission** on the remote access policy, the connection attempt succeeds.

- **Deny access.** Denies access when a connection is attempted. This option also overrides the remote access permission configured on the remote access policy.

- **Control access through Remote Access Policy (available only for native-mode domains).** With this option selected, the grant or deny remote access permission setting specified on the Properties page of any associated remote access policy is used. Thus, for example, if you select **Control access through Remote Access Policy** on the router user account, and if you select **Deny remote access permission** on the remote access policy, the connection attempt is blocked.

  **Note**

  - If the user account is in a Windows Server 2003 or Windows 2000 mixed-mode domain, the **Control access through Remote Access Policy** setting is not available, and you must set the remote access permission in each calling router's user account to **Allow access**.

Even when remote access permission is allowed, the connection attempt still can be denied on the basis of other user account properties, such as callback options configured on the **Dial-in** tab, or it can be denied on the basis of remote access policy conditions or profile settings. Authorization of the site-to-site connection is controlled by a combination of the account dial-in properties (which includes the account remote access permission), the policy remote access permission, and the profile constraints configured on the remote access policy.

You can configure the following settings on the user account **Dial-in** tab:

- **Verify Caller ID (for dial-up router only).** Typically, you use this option to increase security when accepting dial-in connections from telecommuters, but you can also use it for a calling router. Selecting this option requires that the calling router always call from the phone number that you type. Windows Server 2003 uses the caller ID functionality of

the modem and the phone connection to verify that the dial-up router is in fact using the correct number; if the number matches, the connection is allowed. This option is not available if the answering router is in a Windows NT 4.0 domain or a Windows Server 2003 or Windows 2000 mixed-mode domain.

**Note**

- For caller ID verification to work, the calling router, the answering router, and the phone system that connects them must all support caller ID. In addition to supporting the caller ID feature, the calling and answering routers must have the appropriate drivers to support the transmission of caller ID information to the Routing and Remote Access service.

- **Callback Options.** Typically, these options are used for managing individual dial-up remote access users rather than demand-dial calling router user accounts. However, you can also configure callback options for a dial-up demand-dial connection. For example, you can specify that the main office router call the branch office router back if the main office has fixed or low-cost long-distance rates and the branch office has higher long-distance rates.

- **Assign a static IP address (for dial-up or VPN routers).** Use this option to cause the remote router to assign a static IP address to this router when a connection is made. For more information about assigning IP addresses, see "IP Address Assignment for the Logical Interface" later in this chapter. You can increase security by specifying which IP address the router must use. This option is not available in a Windows NT 4.0 domain or a Windows Server 2003 or Windows 2000 mixed-mode domain.

  If the static IP address that you specify is not valid or is already in use by another calling router or by a remote access user, the answering router assigns a dynamic IP address to the calling router.

- **Apply static routes (for dial-up or VPN routers).** This option is designed for one-way initiated site-to-site connections. You select **Apply static routes** to add static IP routes (network IDs) for the calling router's site to the routing table of the answering router when a connection is made. This lets the answering router forward packets to all addresses on the calling router's intranet across the connection to the calling router. This option is not available if the answering router is in a Windows NT 4.0 domain or a Windows 2000 mixed-mode domain.

#### Ensure That the Calling Router Can Establish a Connection

To ensure that the router user account is not prevented from establishing a site-to-site connection, verify that the following options are configured as appropriate:

- When you create the calling router user account, clear the option **User must change password at next logon**. If you select **User must change password at next logon**, the site-to-site connection attempt fails, because changing the password while attempting to make the connection is an interactive process. For information about how to create a user account, see "Create a new user account" in Help and Support Center for Windows Server 2003.

- For a site-to-site connection, do not use the remote access account lockout feature. If the router user account is disabled (locked out by using the remote access account lockout feature), the connection attempt is rejected. For information about the remote access account lockout feature, see Remote access account lockout in Help and Support Center for Windows Server 2003.

- If you block the calling router from establishing a connection during certain times, make sure that the times specified are appropriate for your organization. If the router user account is not permitted to log on during the time specified for the site-to-site connection, the connection attempt is rejected. For information about how to use remote access policies to configure dial-in hours on an answering router in order to block incoming connections from a calling router at specific times of the day or week (such as at night or on weekends), see Configure dial-in constraints in Help and Support Center for Windows Server 2003.

# Configuring Router Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Adding demand-dial router user accounts to an Active Directory group reserved for demand-dial routers simplifies administration by letting you centrally manage the list of demand-dial routers on your network. If you decide to manage authorization by group rather than by each router's individual user account, you must set the remote access permission on each calling router's user account to either **Control access through Remote Access Policy** or **Allow access** and then create a remote access policy based on connection type and group membership.

For example, if multiple calling routers will use a VPN connection, you can create an Active Directory global group called VPN-Routers and add the user account of each calling router to that group.

Then, create a remote access policy with two conditions:

- Set **NAS-Port-Type** to **Virtual (VPN)**. A network access server (NAS) is a server that accepts point-to-point connections from a calling router, or other remote client, and then acts as a gateway to the network for the calling router; the NAS-Port-Type is the media type that a calling router uses to access the site of the answering router).

- Set **Windows-Group** to **VPN-Routers**.

Finally, configure the profile for the remote access policy, selecting an authentication method and encryption strength.

# Choosing a Remote Access Policy Type

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use remote access policy settings to validate a variety of connection settings *before* a connection is authorized and to specify a variety of connection restrictions *after* the connection is authorized. For example, you can use remote access policies to allow or reject connection attempts based on membership in an Active Directory group or by time of day or day of week; to require a specific authentication method and encryption strength; or to limit the connection based on bandwidth.

The computer on which you create a remote access policy is determined by which authentication provider you use for site-to-site connections. If you use Windows authentication, you create and manage remote access policies on each answering router. If you use RADIUS authentication, as you might if your answering router supports both a site-to-site connection and home or mobile users, you can configure and manage all remote access policies centrally on the IAS server that provides RADIUS authentication for multiple answering routers.

If you use RADIUS as the authentication provider in Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; or Windows Server 2003, Datacenter Edition, you can configure a RADIUS attribute to ignore the dial-in properties of a user account in the profile properties of a remote access policy. To support the multiple types of connections for which IAS provides authentication and authorization, you might need to disable the processing of user account dial-in properties. For more information about dial-in properties, see "Dial-in properties of a user accountDial-in properties of a user account" and "Add RADIUS attributes to a remote access policy" in Help and Support Center for Windows Server 2003.

You can use one of three types of remote access policies:

- **Common policy.** You can create a common policy, which uses typical settings for a particular access method.

- **Custom policy.** You can create a custom policy, which lets you specify a detailed configuration for a particular access method. If you want to manage authorization and connection parameters other than by group or by type of connection, you must configure custom remote access policies. For more information about each possible setting for remote access policy conditions and profiles for a custom policy, see "Elements of a remote access policyElements of a remote access policy" in Help and Support Center for Windows Server 2003.

- **Default policy.** If enforcing a high level of security is not important for your organization, you can use one of the existing default policies. Two default remote access policies are created when you enable and configure the Routing and Remote Access service on a demand-dial router or when you install IAS: The **Connections to Microsoft Routing and Remote Access server** policy and the **Connections to other access servers** policy. To use the **Connections to Microsoft Routing and Remote Access server** policy for a site-to-site connection, all you have to do is change the remote access permission on the policy's Properties page to **Grant remote accesspermission**.

For more information about using Windows Server 2003 remote access policies, see "Remote Access Policies" in Help and Support Center for Windows Server 2003. For more information about using remote access policies with an Internet Authentication Service (IAS) server, see "Deploying Internet Authentication Service (IAS)" in this book and see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

# Integrating the Remote Site Connection into Your Network

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you can successfully deploy a dial-up or VPN remote site connection on your network, you must decide how you want to integrate the connection into your existing network infrastructure. The flowchart in Figure 10.7 shows the tasks required to integrate the connection into your network.

**Figure 10.7 Integrating the Remote Site Connection into Your Network**

# Designing the Routing Infrastructure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Integrating a remote site connection into your existing routing infrastructure requires that you decide which choices you want to make about the following tasks:

- Adding static routes
- Using routing protocols
- Servicing Internet traffic
- Enabling multicast connectivity between sites

# Adding Static Routes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In some cases, instead of using routing protocols to dynamically update routing tables, you must configure one or more static routes on the intranet interfaces and demand-dial interfaces of the demand-dial routers in your site-to-site deployment. A static route, which creates a specific path to a destination IP address in an IP network, is one of a set of routes in a routing table that are permanent until changed by a network administrator or by an automatically scheduled auto-static update.

The following topics provide the information that you need to manage static routes for a site-to-site connection:

- Static routes for a site-to-site connection
- Auto-static updates
- Using on-subnet or off-subnet address ranges

**Static Routes for a Site-to-Site Connection**

You might need to create one or more the following types of static routes for your site-to-site connection:

- **LAN interface at both sites.** On both the calling and the answering router, configure a static route or routes on the LAN interface that connects the router to the local intranet. Include a static route for each subnet on the local area network.

  Alternatively, you can use a routing protocol instead of configuring static routes. For more information about using routing protocols, see "Using Routing Protocols" later in this chapter.

- **Demand-dial interface for the remote site.** On the calling router, configure a static route or routes on the demand-dial interface that connects the router to the remote site. Include a static route for each subnet in the answering router's network that you want users to be able to access (or you can use the default route).

  Alternatively, for a persistent site-to-site connection only, you can enable a routing protocol on the demand-dial interface instead of configuring static routes. For more information about using routing protocols, see "Using Routing Protocols" later in this chapter.

- **Demand-dial interface for the local ISP.** On the calling router — for a VPN connection in which the branch office router uses a temporary link to a local ISP only — you must configure a static host route on the demand-dial interface that connects to the local ISP. The destination that you specify for this static host route is the IP address of the answering router's Internet-connected interface; this IP address is assigned to the answering router by its local ISP (or by InterNIC).

- **Router user account.** For a one-way connection in which the answering router is a standalone router or a member of a native-mode Active Directory domain, you can omit creating a demand-dial interface on the answering router. In this case, you must configure a static route or routes in the calling router's user account that identify the network IDs of the calling router's site.

For information about how to configure these static routes, see "Configure Static Routes" later in this chapter. For general information about the difference between using static routes or routing protocols, see the discussion of developing routing strategies in "Designing a TCP/IP Network" in this book.

**Auto-static Updates**

You can add the static routes that correspond to the network IDs available across a demand-dial interface either manually or by using auto-static updates. An auto-static update is a one-time, one-way transfer of routing information. In contrast to the periodic announcements issued by routing protocols, an administrator must either issue a command to initiate a manual auto-static update or must schedule auto-static updates by running the update as a scheduled task.

When instructed, a demand-dial interface that is configured for auto-static updates sends a request across an active connection to request all of the routes of the router on the other side of the connection. In response to the request, all of the routes of the requested router are automatically entered as static routes in the routing table of the requesting router.

**Using On-Subnet or Off-Subnet Address Ranges**
If any of the static address ranges that you configure in the IP properties of the answering router is an off-subnet address range, you must add routes to the routing infrastructure in order for the *logical interfaces* of calling routers to be reachable. During the PPP negotiation, each router typically assigns an IP address to the logical interface of the other router. When a site-to-site connection is made, each router sends traffic to the other router using the logical interface that corresponds to the dial-up, PPTP, or L2TP port of the connection. For more information about how each router assigns an IP address to the other, see "IP Address Assignment for the Logical Interface" later in this chapter.

The method used to ensure the reachability of the logical interfaces in a site-to-site connection depends on how you configure each router to obtain IP addresses for calling routers (and for remote access clients, if your network also supports them). You use either an on-subnet or an off-subnet address range for these IP addresses.

**On-subnet address range**
An on-subnet address range is an address range of the subnet to which the answering router is attached. An on-subnet address range provides the IP address for a logical interface whenever the router is configured to use Dynamic Host Configuration Protocol (DHCP) to obtain IP addresses, a DHCP server is available, and the manually configured pool (or pools) of IP addresses are within the range of addresses of the attached subnet. If you use an on-subnet address range, no additional routing configuration is required.

**Off-subnet address range**
An off-subnet address range is an address range that represents a different subnet than the subnet to which the router is attached. Off-subnet addressing uses a separate subnet address space that is unique to the intranet. An off-subnet address range provides the IP address for a logical interface whenever the router is manually configured with a pool of IP addresses for a separate subnet.

If you use an off-subnet address range, you must add the route or routes that summarize the off-subnet address range to the intranet routing infrastructure so that traffic destined to the logical interfaces of connected routers are forwarded from the originating node to the local dial-up or VPN router and then sent by it to the appropriate connected remote router. You can add the routes that summarize the off-subnet address range to the routing infrastructure by using one of the following methods:

- Add static routes for the off-subnet address range that point to the dial-up or VPN router's intranet interface to the neighboring router. Configure the neighboring router to propagate this static route to other routers in the site by using the dynamic routing protocol used in your site.

- If the dial-up or VPN router uses Open Shortest Path First (OSPF) and participates as a dynamic router, you must configure the router as an autonomous system boundary router (ASBR) so that the static routes of the off-subnet address range are propagated to the other OSPF routers in the site.

If your site consists of a single subnet, and you use an off-subnet address range, you must do one of the following:

- Configure each intranet host for a persistent route (or routes) that points to the dial-up or VPN router's intranet interface. The route (or routes) expresses the off-subnet address range.

  In the Routing and Remote Access snap-in, you must configure address ranges with a starting and ending address. To simplify the set of routes needed to express the off-subnet address ranges, express each range as an IP address with a subnet mask. For more information about using an IP address and a mask to express an address range, see Expressing an IP address range with a mask in Help and Support Center for Windows Server 2003.

- Configure each intranet host with the IP address of the intranet-connected interface of the dial-up or VPN router as its default gateway.

Therefore, if your site consists of a single subnet, it is more efficient to use an on-subnet address range.

# Using Routing Protocols

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you use the Routing Information Protocol version 1 or 2 (RIPv1 or RIPv2) or the OSPF routing protocol in your site, you can add and configure the RIP or OSPF routing protocol components of the Routing and Remote Access service so that a demand-dial router participates in the propagation of routing information as a dynamic router. As an efficient alternative to manually configuring static routes, you can use routing protocols on each LAN interface and on each demand-dial interface that is used for a persistent site-to-site connection. You must configure dynamic routing protocols for each new router so that it can participate in the dynamic routing architecture and share its subnets.

If you use a routing protocol other than RIP or OSPF, such as the Cisco proprietary Interior Gateway Routing Protocol (IGRP) or Enhanced Interior Gateway Routing Protocol (EIGRP), configure the neighboring Cisco router for RIP or OSPF on the interface connected to the subnet that contains the dial-up or VPN router, and then configure IGRP or EIGRP on all other interfaces. You must also configure the neighboring Cisco router to redistribute the IGRP or EIGRP routes into the OSPF or RIP routing tables.

Do *not* use routing protocols across an on-demand site-to-site connection. The periodic announcements that most routing protocols use to propagate routing information cause one demand-dial router to call another each time an announcement occurs. For example, RIPv1, by default, announces routing information every 30 seconds. If your router incurs a long-distance charge every 30 seconds, the phone bill that results defeats the cost savings that an on-demand link is designed to provide. Instead, add routes for network IDs that are available across the demand-dial interface as static routes to the routing tables of demand-dial routers.

# Servicing Internet Traffic

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Depending on the immediate task at hand, users in an organization that includes more than one site might want to access people or resources at the remote site, or they might want to access the Internet. You can use a demand-dial router to handle both types of traffic. If you do use the demand-dial router to enable users to access the Internet, you must decide whether you want users at a branch office to access the Internet through the main office or to access the Internet directly from the branch office.

**For security, route branch office Internet traffic through the main office**
If you deploy Microsoft® Internet Security and Acceleration (ISA) Server at the main office, and you want branch office Internet traffic to be protected by this system, configure branch office Internet traffic to go over the dial-up or VPN connection to the ISA server at the main office. ISA Server is an integrated firewall and Internet caching server that can also act as a VPN router to provide Internet access that is both secure and fast. For information about deploying ISA Server, see "Deploying ISA Server" in this book.

**For performance, route branch office Internet traffic directly to the Internet**
To give branch office users faster access to the Internet than is possible if the Internet traffic must travel to the main office and back, configure branch office Internet traffic to go directly out to the Internet through the demand-dial router. In addition, if you use an on-demand connection rather than a persistent connection, you must provide direct access to the Internet through the demand-dial router rather than over the link to the main office. Configuring client computers to allow users in the branch office to access the Internet directly through the demand-dial router is known as *split tunneling*.

For information about handling each alternative, see "Configure Internet Access Through the Calling Router" later in this chapter.

# Enabling Multicast Connectivity Between Sites

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An increasing number of organizations use multicast communication for such multiple-user applications as video conferencing, collaborative computing, and distance learning. Computers running Windows Server 2003 can both send and receive IP multicast traffic. The Routing and Remote Access service includes the Windows Server 2003 Internet Group Management Protocol (IGMP) routing protocol component, which you can configure with IGMP router mode and IGMP proxy mode to enable the exchange of multicast packets between remote sites. The IGMP Router and Proxy routing protocol is not itself a multicast routing protocol.

When you make your demand-dial routers multicast-capable, they can listen for all multicast traffic over all site-to-site connections, they can listen for IGMP Membership Report messages, and they can update the TCP/IP multicast forwarding table so that routers can determine where to forward incoming multicast traffic.

For a site-to-site connection, use the Routing and Remote Access snap-in to enable IGMP with IGMP proxy mode on the demand-dial interface on both the calling router and the answering router, and to enable IGMP with IGMP router mode on all other interfaces internal to the site.

For more information about IP multicasting, see "Designing a TCP/IP Network" in this book and the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit). For more information about multiple supported multicast configurations, see the *Internetworking Collection* of the *Windows Server 2003 Technical Reference* (or see the Internetworking Collection on the Web at http://www.microsoft.com/reskit).

# Planning IP Address Assignment and Name Resolution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The DHCP and name resolution issues that you must consider when planning how to integrate a site-to-site connection into your existing network include:

- Client IP address assignment
- IP address assignment for the logical interface
- Using IP addresses to avoid name resolution issues
- Using name resolution when accessing other services on a VPN router

# Client IP Address Assignment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Typically, when you have slower WAN links or when you have dial-up links, you place a DHCP server on each side of a remote site connection. Installing the DHCP service on a calling router or other server at a branch office lets branch office clients obtain IP addresses from that server.

However, a DHCP server located in one subnet can support other subnets. If no DHCP server is located at the branch office, when a client at the branch office requests an address, the calling router can forward the client's request across the dial-up or VPN link to the DHCP server in the main office, which then leases the client an address. For this to work, ensure the following:

- The calling router contains the DHCP Relay Agent (the DHCP Relay Agent component is added with the internal interface by default).
- The calling router is configured with the DHCP server's IP address.
- The site-to-site connection is a persistent connection.

For an on-demand connection, if the DHCP Relay Agent is installed on a branch office router, this can cause the router to dial the main office router (for a non-VPN dial-up connection) or the local ISP (for a VPN connection that uses a dial-up link to the ISP) every time a DHCP packet is sent by a computer in the branch office network. Therefore, if you deploy an on-demand connection, install the DHCP service in the branch office and uninstall the DCHP Relay Agent on the calling router.

For more information about deploying DHCP, see "Deploying DHCP" in this book.

# IP Address Assignment for the Logical Interface

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When a calling router initiates a connection, the router creates a temporary logical interface (also known as a *virtual interface* or a *virtual network adapter*) and requests that the answering router assign an IP address to this logical interface. The answering router then creates a logical interface and requests an IP address for itself from the calling router. The logical interface on the calling router connects to the logical interface on the answering router to form the demand-dial connection. The IP address assignment for each demand-dial interface lasts for the duration of the connection. These IP addresses can be either private or public IP addresses. If both requests are successful, the logical interface on the PPP connection for each router is assigned an IP address from the other router. This is known as a *numbered connection*. In the absence of a numbered connection, a site-to-site connection can also use an unnumbered connection.

**Numbered Connection**

A numbered IP address assignment can occur in one of the following ways:

- **Dynamic IP addresses allocated by a DHCP server.** The answering router obtains the IP address to assign to a calling router from a DHCP server. This is the default method for IP address assignment. If no DHCP server is available, the router uses an address from the Automatic Private IP Addressing (APIPA) range 169.254.0.1–169.254.255.254. You must install a DHCP server on each network that contains an answering router.

- **Dynamic IP addresses allocated from a static address pool configured on the answering router.** The answering router obtains the IP address from a static pool of addresses. If you configure a static address pool, be sure to use only IP addresses that are not in a range that your DHCP server might assign to another computer and that are not already assigned to specific computers. The pool can be ranges of addresses that are a subset of addresses from the IP network to which the server is attached or from a separate subnet. As described earlier, if the static IP address pool address ranges represent a different subnet, ensure that routes to the address ranges exist on the routers of your intranet so that traffic to the logical interface of a calling router is forwarded to the remote server.

- **Static IP address specified in the calling router user account.** You configure a static IP address on the router user account **Dial-in** tab for both the calling and the answering router. In this case, when a calling router initiates a connection, creates a temporary logical interface, and requests that the answering router assign an IP address to this logical interface, the answering router assigns the IP address specified in the calling router's user account. The answering router then creates a logical interface and requests an IP address for itself from the calling router. The calling router assigns the IP address specified in the answering router's user account.

**Unnumbered Connection**

Site-to-site connections in Windows Server 2003 and Windows 2000 do not require a numbered connection (Windows NT 4.0 RRAS connections do require a numbered connection). If one of the routers rejects the request for an IP address during the connection establishment process between a calling and an answering router (because no addresses are available to assign, probably due to a misconfiguration), a connection is still established. In this case, the logical interface on the PPP connection does not have an assigned IP address. This is known as an *unnumbered connection*.

The routing protocols provided with Routing and Remote Access cannot operate over unnumbered connections. Therefore, you must use static routing if you use unnumbered connections.

# Using IP Addresses to Avoid Name Resolution Issues

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you configure a demand-dial interface for a dial-up calling router, you provide the phone number of the answering router with which this router establishes a connection. In this case, name resolution is not an issue.

For VPN connections, however, the corresponding entry on the demand-dial interface is the destination address of the answering router. In this case, name resolution can be an issue, because you can provide either the Domain Name System (DNS) name or the IP address of the answering router. Microsoft recommends that you provide the IP address rather than the answering router name when you configure a demand-dial interface so that resolution of the name to the IP address by means of a DNS or Windows Internet Name Service (WINS) server is not needed.

If you do use names for demand-dial interfaces, make sure that an appropriate DNS record exists on the DNS server that hosts the public namespace that is visible to Internet users and computers, or on the DNS server of your ISP, so that the DNS names of your answering routers can be resolved.

# Using Name Resolution When Accessing Other Services on a VPN Router

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In some organizations, you might want users to be able to access other services, such as file shares, on the answering VPN router. For this type of configuration, if you specify the DNS name rather than the IP address in the demand-dial interface, and the name resolves to the public IP address of the answering router, traffic sent to the services running on the router is sent in clear text (unencrypted) across the Internet. It is not encapsulated, encrypted, and sent using the VPN connection, which can compromise security.

A related problem is that if you configure packet filters on the answering router to allow only traffic over a VPN connection, all other traffic is discarded. Attempts to connect to services running on the answering router fail in this situation, because traffic attempting to connect to those services is not sent over the site-to-site VPN connection.

If the site DNS and WINS servers do not contain a record mapping the name of the VPN router to its public IP address, traffic to services running on the VPN router is always sent across the VPN connection. To ensure that the name of the VPN router is always resolved to the private or site IP address of the VPN router, disable DNS dynamic update and NetBIOS over TCP/IP (NetBT) on the Internet-connected interface (or interfaces) of the VPN router from the properties of the Internet connection in Network Connections as follows:

- **Prevent DNS name resolution.** To prevent a VPN router from dynamically registering the public IP address of its Internet interface on the site DNS servers, on the Internet interface of the router, configure the properties of **Internet Protocol (TCP/IP)** by clicking the **Advanced** button, selecting the **DNS** tab, and then clearing the **Register this connection's addresses in DNS** check box.

- **Prevent WINS name resolution.** To prevent a VPN router from dynamically registering the public IP address of its Internet interface on the site WINS servers, on the Internet interface of the router, configure the properties of **Internet Protocol (TCP/IP)** by clicking the **Advanced** button, selecting the **WINS** tab, and then selecting the option **Disable NetBIOS over TCP/IP**.

  **Note**

  - By default, the Routing and Remote Access Wizard clears **Register this connection's addresses in DNS** and selects **Disable NetBIOS over TCP/IP**. Be sure not to change these defaults if you want users to be able to access services such as file shares on the answering VPN router.

For more information about name resolution, see "Deploying Domain Name System (DNS)" and "Deploying WINS" in this book.

# Planning Active Directory Integration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Integrating a remote site connection into an Active Directory–based network requires you to decide which choices you want to make about the following tasks:

- Put a domain controller at the branch office.
- Use one domain to include geographically remote sites.
- Use scheduled replication or reciprocal replication.
- Join demand-dial routers to the Active Directory domain.

**Putting a Domain Controller at the Branch Office**
If you deploy a persistent site-to-site connection between a branch office and a main office, you might not need a domain controller at the branch office. Branch office users can access a domain controller in the main office when they log on to their computers or use other Active Directory services.

For an on-demand connection, install a domain controller at the remote site.

**Using One Domain to Include Geographically Remote Sites**
You can include a main office and a branch office in one Active Directory domain. However, geographically remote sites must not share the same address space and must have separate Active Directory sites. You must create a separate Active Directory site for the branch office and create a child object for the branch office, providing the appropriate network ID and subnet mask for the branch office site.

For more information about deploying Active Directory, see "Deploy Active Directory" later in this chapter.

**Using Scheduled Replication or Reciprocal Replication**
Typically, domain controllers have a constantly available connection so that all domain controllers obtain a steady flow of updated directory information. If you have domain controllers in sites that are connected by a site-to-site connection, you must ensure that replication takes place. Directory updates can be exchanged through a site-to-site connection in one of two ways:

- **Scheduled replication.** On a persistent site-to-site connection, you can schedule replication to take place at specified intervals.
- **Reciprocal replication.** For a one-way initiated on-demand connection in which no constantly available connection exists between domain controllers in the two sites, you must enable reciprocal replication. With reciprocal replication, all replication occurs simultaneously between the domain controllers in the two sites, and the connection is closed when replication is complete. Reciprocal replication maximizes the efficiency of directory information exchange while minimizing connection time and eliminating timeout errors that can occur if the main site domain controller requests changes from the branch site domain controller when the connection is not available. You can configure reciprocal replication on a site link or on a connection.

For more information, see "Configure Replication for Active Directory" later in this chapter.

**Joining Demand-Dial Routers to the Active Directory Domain**
In an Active Directory domain, you can choose either to join a demand-dial router computer to the domain or not to, based on the following factors:

- If your answering router uses Active Directory user accounts to authenticate and authorize a calling router, you must join the answering and calling routers to the domain.
- If you use EAP-TLS user authentication with Windows as the authentication provider, you must join the answering router (which is the authenticating server) to the Active Directory domain. If you use EAP-TLS user authentication with RADIUS as the authentication provider, you must join the IAS server (which is the authenticating server) to the Active Directory

domain. With RADIUS authentication, the answering router does not need to be joined to the domain. (Use Windows authentication for a site-to-site only connection. You might use RADIUS authentication for a site-to-site connection if the answering router also supports remote access users.)

- If you use L2TP/IPSec with computer certificates, the demand-dial routers are not required to join the Active Directory domain. However, the Windows Server 2003 PKI uses Active Directory, if it is installed, to store certificates, certificate revocation lists, and delta certificate revocation lists and to publish root CA certificates and cross-certificates. Using Active Directory makes this information easy to locate from anywhere on the network. (If you use L2TP/IPSec with preshared keys, you are not required to join the VPN routers to the Active Directory domain.)

For more information about planning and deploying Active Directory for an organization with multiple branch office sites, see the Active Directory Branch Office Planning Guide link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

For more information about deploying Active Directory domains and sites and Active Directory replication between sites, see "Designing the Site Topology" in *Designing and Deploying Directory and Security Services* of this kit.

# Preparing for Server Configuration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you have existing Windows NT 4.0 or Windows 2000 site-to-site connections, you must decide whether to upgrade your routers to Windows Server 2003 and migrate to the Windows Server 2003 Routing and Remote Access service, or whether to continue to support your current configuration. Before you install the Routing and Remote Access service on your demand-dial routers, you must decide how many routers you need, and you must make sure that the computers meet Windows Server 2003 requirements.

For more information about creating hardware and software inventories, see "Planning for Deployment" in *Planning, Testing, and Piloting Deployment Projects* of this kit. The flowchart in Figure 10.8 shows the tasks required when preparing to configure the router server.

**Figure 10.8 Preparing for Server Configuration**

# Migrating Routers from Windows NT 4.0 or Windows 2000

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you have an existing site-to-site connection between remote offices using Windows NT 4.0–based or Windows 2000–based servers and plan to upgrade most of your network to Windows Server 2003, Windows Server 2003 can support your existing Routing and Remote Access or RRAS servers. Alternatively, you can take advantage of the new features in Windows Server 2003 by upgrading your demand-dial routers.

The following topics can help you decide whether to upgrade your demand-dial routers:

- New features
- Migrating router settings

**New Features**

In Windows NT Server 4.0, routing and remote access are separate services. In Windows 2000 Server and Windows Server 2003, these functions are combined in the single Routing and Remote Access service. Table 10.10 lists new features available in Windows Server 2003 and Windows Server 2000.

**Table 10.10 New Features for Dial-up or VPN Site-to-Site Connections Since Windows NT Server 4.0 RRAS**

| Windows Release | New Features |
|---|---|
| Windows 2000 Server | • **L2TP/IPSec.** An L2TP/IPSec VPN tunnel provides stronger security than a PPTP VPN tunnel.<br>• **Remote access policies.** This feature gives administrators more flexibility in setting remote access permissions and connection restraints.<br>• **MS-CHAP v2.** This type of password–based user authentication provides a stronger alternative to MS-CHAP. (MS-CHAP v2 is also available in Windows NT 4.0 SP4.)<br>• **EAP.** Support for EAP lets you use installable authentication methods, such as EAP-TLS certificate-based user authentication, which is stronger than password-based user authentication. |

| | |
|---|---|
| Windows Server 2003 | • **Improved wizards and snap-in.** The Routing and Remote Access and Demand-Dial Interface wizards and the Routing and Remote Access snap-in are easier to use.<br><br>• **Intranet and Internet-connected interface improvements.** By default, the Routing and Remote Access service now disables dynamic update on the intranet interface and disables dynamic update and NetBIOS over TCP/IP on the Internet-connected interface to ensure correct name resolution of the router and to ensure access to services running on the router.<br><br>• **Preshared keys.** Support for configuring preshared keys using the Routing and Remote Access snap-in provides an alternative to computer certificates in L2TP/IPSec authentication.<br><br>• **NAT/Basic Firewall configuration.** You can use Manage Your Server to configure the NAT/Basic Firewall component of Routing and Remote Access. NAT integration with static and dynamic packet filtering lets you configure NAT interfaces to work with Basic Firewall or with incoming or outgoing static packet filters.<br><br>• **NAT-T.** IPSec NAT traversal (NAT-T) lets you create L2TP/IPSec connections from a calling or answering router that is located behind one or more NATs.<br><br>• **PPPoE.** Support for PPPoE lets a small business use NAT/Basic Firewall and their broadband Internet connection to connect a branch office to their local ISP. Using PPPoE for an on-demand connection is faster than using a dial-up link to connect to the ISP. |

**Migrating Router Settings**

When you upgrade from Windows NT 4.0 or Windows 2000 to Windows Server 2003, you retain all IP-based routing configuration, including demand-dial, RIP, OSPF, and DHCP Relay Agent settings. However, Windows Server 2003 does not support the NetWare routing protocol Internetwork Packet Exchange (IPX). If you upgrade from Windows NT 4.0 to Windows Server 2003, and IPX settings are detected, you are provided the option not to upgrade after all.

# Planning Server Capacity

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Table 10.11 provides capacity planning information that you can use to help determine how many demand-dial servers you need to deploy and how much data throughput your site-to-site connection can support.

**Table 10.11 Capacity Planning**

| Factor | Capacity |
|---|---|
| Number of connections | For two-way connections, one answering router supports 10 simultaneous calling router connections before performance begins to degrade.<br>• For one-way connections, one answering router supports 100 simultaneous calling router connections before performance begins to degrade. |
| Data throughput | The amount of data throughput that a site-to-site connection can support depends, in part, on what resources the users are using on the network. Other factors that affect data throughput include:<br>• **IPSec offload card.** You can increase data throughput for L2TP/IPSec by installing an IPSec offload card. Using an IPSec offload card and a dual processor lets a server process more than 50 Mbps of fully encrypted data. To install an IPSec offload card, follow the manufacturer's instructions.<br>• **Compression.** Using Microsoft Point-to-Point Compression (MPPC) decreases data throughput. To increase data throughput, turn off MPPC. You can turn off MPPC by using one of the following methods:<br>  • **To clear compression on a specific demand-dial interface.** In Routing and Remote Access, in the console tree, click **Network Interfaces**, right-click the demand-dial interface on which you want to clear compression, and then click **Properties**. On the demand-dial interface Properties page, click the **Networking** tab, click **Settings**, and then in the **PPP Settings** dialog box, clear the check box **Enable software compression**.<br>  • **To clear compression for all types of PPP connections.** In Routing and Remote Access, in the console tree, right- click the demand-dial server icon, click **Properties**, click the **PPP** tab, and then clear the check box **Software compression**. This disables compression both for site-to-site connections and for remote access connections. |

# Planning Server Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The following information can help you plan how to set up your server before you deploy the remote site connection:

- Meeting server requirements
- Disabling unused services
- Planning physical and administrative security

# Meeting Server Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Table 10.12 lists the minimum hardware and software requirements for a demand-dial router.

**Table 10.12 Hardware and Software Requirements for a Demand-Dial Router**

| Component | Requirement |
|---|---|
| Processor | Pentium 233 MHz processor (550 MHz recommended) |
| Memory | 128 MB RAM (256 MB recommended) |
| Hard drive | 4 GB hard drive |
| LAN adapter | A network adapter connected to the intranet. The adapter must have a driver that displays the Designed for Windows logo. The server must have multiple network adapters or a single network adapter configured with multiple IP addresses. |
| WAN adapter | • **For a dial-up site-to-site connection:** An ISDN adapter, analog modem, or other physical device that is connected to the line that connects the two sites.<br>• **For a VPN site-to-site connection:** A network adapter that is connected to the Internet, either directly or through a perimeter network. Typically, this is a T-Carrier or Frame Relay adapter, or a DSL or cable modem. |
| Software | The Windows Server 2003 operating system. Windows Server 2003 includes the Routing and Remote Access service, which you must enable. |

Before you deploy a dial-up or VPN router, install and configure the required hardware and the appropriate drivers, and test whether each one functions properly. To determine if the hardware in your organization is certified and compatible, see the Windows Catalog link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Disabling Unused Services

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Disabling services that you do not use on your demand-dial server has two advantages: It returns resources to the server that other components can use, and it makes your backend network more secure by shutting off services that are potential entry points for attackers trying to break into your network.

The following is a list of services that you might be able to disable on a server that you plan to use as a demand-dial router:

- Distributed File System (DFS)
- Distributed Transaction Coordinator
- Fax Services
- File Replication service (FRS)
- Indexing Service
- Internet Connection Sharing (ICS)
- Intersite Messaging
- Kerberos Key Distribution Center
- License Logging Service
- Print Spooler
- Task Scheduler
- Telnet
- Windows Installer

**Important**

- Do not disable the remote registry service. If you disable it, the demand-dial router cannot operate correctly.

# Planning Physical and Administrative Security

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To prevent the intentional or unintentional modification of your router configuration, use the following guidelines to secure your routers:

- Keep router computers physically secure from unauthorized users or intruders, for example, by placing them in a locked room.
- Delegate administration rights and permissions for the Routing and Remote Access service to a limited number of individuals.
- Assign administrator rights to an Active Directory group whose role is to administer remote site connections, and add only authorized users to that group. You can easily update changes to the group membership, whereas, if you do not use a group, you must administer each Administrator account separately on each Routing and Remote Access server.
- On both the calling router and the answering router, rename the local Administrator account and use strong passwords for the account.

# Deploying a Site-to-Site Connection

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you make all the necessary design decisions, you can deploy a remote site connection for your organization. The flowchart in Figure 10.9 shows the tasks that can help you to successfully deploy a site-to-site connection.

**Figure 10.9 Deploying a Site-to-Site Connection**

If you want to try a test deployment to prepare for your production deployment, see "Perform a Test Deployment in Your Lab" later in this chapter. If you are ready to connect two sites in your production environment now, see "Deploy a Remote Site Connection" later in this chapter.

# Perform a Test Deployment in Your Lab

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

By reading the design sections earlier in this chapter, you can develop a good idea about which remote site connectivity features are appropriate for your organization. However, before you deploy any technology in your production network, it is a good practice to perform a test deployment in a lab first. Testing in a lab familiarizes you with how the technology works and gives you the opportunity to experiment with different features when alternatives are available.

When testing how to deploy a remote site connection, evaluate the following key issues in a lab setting before deciding how to deploy the technology in your production environment:

- Whether to deploy a dial-up connection, a PPTP VPN, or an L2TP/IPSec VPN.
- Whether to deploy an on-demand connection or a persistent connection.
- Whether to deploy a one-way initiated connection or a two-way initiated connection.
- If you plan to deploy a VPN connection, what type of perimeter network you want to use.
- Whether to use certificate-based EAP-TLS or password-based MS-CHAP v2 for user-level authentication.
- If you plan to deploy an L2TP/IPSec VPN connection (the only connection type that offers computer-level authentication), whether to use computer certificates or preshared keys.
- Whether the encryption method, such as a dial-up or PPTP VPN connection using MPPE encryption or an L2TP/IPSec VPN using IPSec for encryption, influences your decision about which connection type to use.
- Whether to use an Active Directory account (and join your routers to the Active Directory domain) or use a local account for your router user accounts.
- Which dial-up options to set in the router user account.
- Whether to use a default remote access policy, a common policy, or a custom policy.
- Which static IP addresses and which static routes are needed.
- Which routing protocol or protocols are needed.
- Whether your demand-dial routers will support Internet traffic.
- Whether to enable multicast connectivity between your sites.
- Whether to deploy a DHCP server in each site.
- Whether to deploy a domain controller in each site.

For a tool to assist you in evaluating some of the remote connectivity features presented in this list, see "Example: Contoso Connects Remote Sites" (DNSREM_1.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Example: Contoso Connects Remote Sites" on the Web at http://www.microsoft.com/reskit). This job aid shows you how to deploy a PPTP VPN and a dial-up connection in a lab environment.

For additional test lab deployment examples, including information about deployments that include certificates and L2TP/VPN connections, see "Routing Scenarios" and "Virtual Private Network Implementation Examples" in Help and Support Center for Windows Server 2003.

# Deploy a Remote Site Connection

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To connect remote sites using a site-to-site link, you must decide which of the design options described earlier in this chapter you want to deploy. Use the "Choose Optional Tasks You Need" column in Figure 10.10 to mark which optional tasks you will perform for your deployment.

**Figure 10.10 Deployment Tasks for a Site-to-Site Connection Worksheet**

Site-to-Site Connection Deployment Steps

| Prepared By | | Date | |
|---|---|---|---|

Instructions: Perform the deployment tasks in the sequence shown here. Enter an X in the second column to choose the optional tasks needed for your deployment.

| Task # | Choose Optional Tasks You Need (X) | Task Description |
|---|---|---|
| 1 | | Deploy Active Directory.[1] |
| 2 | | Deploy a certificate infrastructure.[1] |
| 3 | | Deploy an IAS server for RADIUS authentication.[1] |
| 4 | | Configure Active Directory user accounts and groups.[1] |
| 5 | Required | Configure the WAN adapter (modem/interface). |
| 6 | Required | Configure the intranet connection. |
| 7 | | Join the router to the domain.[1] |
| 8 | | Place the router in your perimeter network.[1] |
| 9 | | For L2TP/IPSec, install computer certificates.[1] |
| 10 | | For EAP-TLS, install computer and user certificates.[1] |
| 11 | Required | Configure the Routing and Remote Access service and demand-dial interfaces. |
| 12 | | Configure remote access policies on the answering router or IAS server.[2] |
| 13 | Required | Configure a persistent connection or a disconnect interval. |
| 14 | Required | Configure static routes. |
| 15 | | Configure routing protocols.[1] |
| 16 | | Configure Internet access through the calling router.[1] |
| 17 | | Configure IP multicasting.[1] |
| 18 | | Configure the authentication provider.[2] |
| 19 | | Configure authentication methods.[2] |
| 20 | | Configure ports.[2] |
| 21 | | Configure dial-out or dial-in hours.[2] |
| 22 | | Configure IP packet filters and demand-dial filters.[1] |
| 23 | Required | Initiate the connection. |
| 24 | Required | Test connectivity. |
| 25 | | Configure replication.[1] |

[1] If you do not perform this task, this feature is not deployed for your site-to-site connection.
[2] If you do not perform this task, the default configuration is used for your site-to-site connection.

For a copy of Figure 10.10 that you can use to record which deployment options you need for your site-to-site deployment, see "Site-to-Site Connection Deployment Steps" (DNSREM_2.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Site-to-Site Connection Deployment Steps" at http://www.microsoft.com/reskit). You can also use this worksheet as a guide for the sequence in which you must perform the tasks.

# Deploy Active Directory

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

How you manage Active Directory and domain controllers in a branch office varies depending on the size, complexity, and structure of your overall network. If you do *not* plan to deploy a domain controller in the branch office location, Microsoft recommends that you establish a persistent connection between the two sites. If you do plan to locate a domain controller in the remote site with which you want to establish a site-to-site connection, you must place it in a subnet separate from the computers at the main site and create a separate Active Directory site for the branch office subnet.

**To deploy a domain controller for a new branch office site**

**Note**

- This procedure assumes that both sites belong to the same Active Directory domain.

1. Install the Windows Server 2003 operating system on a computer at the main office, promote it to a domain controller, and then confirm that it successfully replicates with the existing domain controllers.

2. Log on as a member of either the Domain Administrators or Enterprise Administrators security group of the forest root domain, open Active Directory Sites and Services, right-click Sites, select New Site, type a name for the new branch office site, and then, under Link Name, select the appropriate site link (such as DEFAULTIPSITELINK).

3. Right-click the server object of the new branch office domain controller from its current location (which might be under Default-First-Site-Name), click Move, and then, in the Move Server dialog box, click the new site that you just created.

4. Right-click Subnets, click New, and then click Subnet to create a new child for the new remote site, providing the appropriate network ID and subnet mask.

   **Note**

   - If, until now, your domain has had only one site, you must create two child objects under **Subnets** — one for the main office site and one for the branch office site, each with its own network ID and subnet mask.

5. If necessary to optimize network performance, make the domain controller a global catalog.

6. Ship the new domain controller to the remote site.

7. Install a LAN adapter connected to the branch office intranet, and then, on the LAN adapter's **Internet Protocol (TCP/IP) Properties** page, configure an IP address, subnet mask, and gateway appropriate for the branch office subnet.

The domain controllers in the main and branch offices cannot replicate yet, because the demand-dial connection does not exist yet. For information about how to configure replication after a connection exists, see "Configure Replication for Active Directory" later in this chapter.

# Deploy a Certificate Infrastructure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you plan to use EAP-TLS as your authentication protocol for user-level authentication on a dial-up, PPTP VPN, or L2TP/IPSec VPN connection, or if you plan to use L2TP/IPSec with computer certificates for your VPN connection, or if you plan to do both, you must have a certificate infrastructure in place in your network.

For information about creating a certificate infrastructure, see Certificate Services in Help and Support Center for Windows Server 2003, and see "Designing a Public Key Infrastructure" in *Designing and Deploying Directory and Security Services* of this kit.

# Deploy an IAS Server for RADIUS Authentication

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For a site-to-site only connection, you use Windows authentication and do not need to deploy an IAS server. However, if you use the same answering router for both a site-to-site connection and a remote access connection that supports mobile or home users, you might decide to use RADIUS authentication instead. If you plan to use RADIUS authentication and Windows Server 2003 IAS, you must have an IAS server available in your network. Deploying an IAS server is the same for both dial-up and VPN site-to-site connections.

**To enable RADIUS authentication**

1. Install an IAS server. To ensure that RADIUS authentication and accounting services remain available, configure both a primary IAS server and one or more backup (secondary) IAS servers to provide redundancy and fault tolerance.

2. Register the IAS servers in the appropriate Active Directory domain.

3. Configure the primary IAS server with RADIUS clients corresponding to your answering routers.

4. Configure each answering router with the RADIUS servers of your primary and secondary RADIUS servers.

5. After you enable the Routing and Remote Access service, configure remote access policies that reflect your dial-up or VPN connection requirements on the primary IAS server. For more information, see "Configure the Routing and Remote Access Service and Demand-Dial Interfaces" and "Configure a Remote Access Policy" later in this chapter.

6. Configure logging methods for user authentication and accounting requests.

7. Copy the IAS configuration (including the remote access policies) from the primary IAS server to the secondary IAS server.

For more information about installing an IAS server and using it for RADIUS authentication, see "Deploying Internet Authentication Service (IAS)" in this book, and see Checklist: Configuring IAS for dial-up and VPN access in Help and Support Center for Windows Server 2003.

# Configure Active Directory User Accounts and Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Note**

- If you plan to use local accounts, do not perform these steps. Instead, use the Demand-Dial Interface Wizard to create a user account for the calling router locally on the answering router.

Each calling router must have a user account, which the answering router uses to authenticate the calling router. If you have more than one calling router and if you joined your routers to the Active Directory domain, you can add each router user account to an Active Directory group to simplify administration.

Use the following procedures to accomplish these tasks:

- Create Active Directory user accounts for routers.
- Add router user accounts to an Active Directory group.

**Create Active Directory User Accounts for Routers**

If you plan to use Active Directory user accounts for demand-dial routers, you manually create an Active Directory user account for each calling router (you can use the Demand-Dial Interface Wizard to create the user account only if you use a local user account).

**To create an Active Directory user account for a router**

1. Open the Active Directory Users and Computers snap-in, and create a user account for the calling router (for a two-way connection, create a user account for the calling router in both sites). The name of the account must match the name of a corresponding demand-dial interface on the remote router.
2. To ensure that connectivity occurs, clear the **User must change password at next logon** check box and select the **Password never expires** check box on the **Account** tab on the property sheet for the user account object.
3. On the user account **Dial-in** tab, select one of the following options:
   - **Allow access.** This option overrides the grant or deny remote access permission setting specified on the Properties page of any associated remote access policy.
   - **Control access through Remote Access Policy.** This option ensures that the grant or deny remote access permission setting specified on the Properties page of any associated remote access policy is used.

**Add Router User Accounts to an Active Directory Group**

If you use Active Directory user accounts for demand-dial routers, you can add the router user accounts to a group to simplify administering them and to simplify configuring remote access policies.

**To add router user accounts to a group**

1. Open the Active Directory Users and Computers snap-in, create an Active Directory group to contain the user accounts of the calling routers. Use an appropriate name, such as **BranchOfficeRouters**.
2. Add the user accounts of the calling routers to the group.

# Configure the WAN Adapter

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

On the demand-dial router at each site, use the following procedures, as appropriate, to configure the WAN adapter for a dial-up connection, the WAN adapter for a dedicated link to an ISP, or (if needed) to configure the DNS server IP address.

**To configure the WAN adapter for a dial-up connection**

1. On the demand-dial router at each site, install the WAN adapter. This WAN adapter is a modem, an ISDN adapter, or other physical device connected to one of the following:

    - For a non-VPN dial-up connection, the line that links the two sites.
    - For a VPN with a dial-up connection to the local ISP, the line that links the branch office router to its local ISP.

2. Provide the phone number and the authorized user name and password. Leave the **Domain** field blank. The phone number is one of the following:

    - For a non-VPN dial-up connection, the phone number of the answering router.
    - For a VPN that uses a modem, ISDN, or PPPoE dial-up connection to its local ISP, the phone number of the local ISP.

**To configure the WAN adapter for a dedicated link from a VPN router to an ISP**

1. On the demand-dial router at each site, install the Internet-connected WAN adapter. This WAN adapter is a DDS, T1, Fractional T1, or Frame Relay adapter.

2. On the WAN adapter's **Internet Protocol (TCP/IP) Properties** page, configure the following:

    a. The public IP address and subnet mask allocated to you by your ISP (or by the InterNIC).

    b. The default gateway of the firewall (if you plan to have the router connect to a perimeter network) or of the ISP router (if you plan to have the router connect directly to the Internet).

**To configure the DNS server IP address (if needed)**

- If you have a VPN connection, configure the DNS server IP address on the Internet-connected interface of the calling router if either of the following is true:

    - If you use the DNS name of the answering router (instead of its IP address), you must specify the DNS server IP address in the Internet-connected interface of the calling router. Because the Routing and Remote Access Wizard clears the **Register this connection's addresses in DNS** check box (on the **DNS** tab) and selects **Disable NetBIOS over TCP/IP** (on the **WINS** tab), you must configure the DNS server IP address on the VPN Internet-connected interface after you run the wizard.

    - If the branch office calling router will provide users access to the Internet (in addition to supporting site-to-site traffic to the main office), you must specify the DNS server IP address in the Internet-connected interface of the calling router. For more information about configuring access to the Internet, see "Configure Internet Access Through the Calling Router" later in this chapter.

# Configure the Intranet Connection

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Configure the intranet interface on the demand-dial router at each site.

**To configure the connection to the local intranet**

1. Install a LAN adapter connected to the intranet.

2. On the LAN adapter's **Internet Protocol (TCP/IP) Properties** page, configure the following:

    a. The public or private IP address and subnet mask that your network administrator assigned.

    b. The IP addresses of the DNS and WINS name servers for your organization's intranet.

3. Typically, leave the default gateway value on the LAN adapter blank to avoid default route conflicts with the default route pointing to the Internet.

    **Note**

    - If a router is positioned between the demand-dial router that you are configuring and the intranet, the Routing and Remote Access Wizard might not be able to add the demand-dial router to the list of valid remote access servers in the Active Directory. One workaround to this problem is to temporarily configure the default gateway on the LAN adapter. To do this, enter a value for the default gateway, run the Routing and Remote Access and Demand-Dial Interface wizards (as described later), and then remove the default gateway from the LAN adapter.

Do not configure the intranet interface of the router to be a DHCP client. However, an answering router can still use DHCP to obtain IP addresses for calling routers, and vice versa.

# Join the Router to the Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you install the Windows Server 2003 operating system on the computers that you want to use as the calling and answering routers, you can join the routers to the Active Directory domain.

If you have a calling router that is located in the branch office, and you already have a domain controller in the branch office, join the router computer to the domain there.

If you do not have a domain controller at the branch office yet, you can install the Windows Server 2003 operating system on the computer that you want to use as the calling router while that computer is located in the main office, join the computer to the domain, and then ship it to the branch office.

**Note**

- Alternatively, you can set up the routers to dial in once, install Active Directory on the computer in the branch office that you want to use as the domain controller, replicate, and then join the routers to the domain.

# Place the Router in Your Perimeter Network

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For optimal security, place both the answering router and the calling router in a perimeter network at their respective sites. For more information about VPN routers and perimeter networks, see "VPN servers and firewall configuration" in Help and Support Center for Windows Server 2003.

# Install Computer Certificates for L2TP/IPSec

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you use an L2TP/IPSec site-to-site connection, you must install a computer certificate on both the answering router and on the calling router. You must have a certification authority (CA) in your network to issue these certificates.

You can install a computer certificate for L2TP/IPSec by using one of three methods:

- Configure the automatic enrollment of computer certificates in a Windows Server 2003 domain system container by using Group Policy.
- Use the Certificates snap-in to request a computer certificate.
- Use your Web browser to connect to the CA Web enrollments pages to request a certificate.

**Note**

- It is also possible to use a preshared key to provide authentication for IPSec security associations for an L2TP/IPSec connection. However, using computer certificates is the recommended method.

For information about how to create a certificate infrastructure and install computer certificates, see Certificate Services in Help and Support Center for Windows Server 2003, and see "Designing a Public Key Infrastructure" in *Designing and Deploying Directory and Security Services* of this kit. For more information about configuring a preshared key, see Configure a pre-shared key for a demand-dial routing interface in Help and Support Center for Windows Server 2003.

# Install Computer and User Certificates for EAP-TLS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you use EAP-TLS as the user authentication method for your site-to-site connection, you must install a computer certificate on the authentication server of the answering router and a user certificate on the calling router. These steps are the same for a dial-up router and for a VPN router.

For information about how to deploy certificates required by EAP-TLS, see Deploying certificate-based authentication for demand-dial routing in Help and Support Center for Windows Server 2003.

# Configure the Routing and Remote Access Service and Demand-Dial Interfaces

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Use the following procedures to enable the Routing and Remote Access service and to establish a site-to-site connection:

- Enable Routing and Remote Access.
- Configure the demand-dial interface for the remote site connection.
- Configure an additional demand-dial interface for a temporary ISP link.

**Enable Routing and Remote Access**

When you run the Routing and Remote Access Wizard to enable the Routing and Remote Access service, the choices you make are the same for dial-up routing and for VPN routing.

**To enable the Routing and Remote Access service**

**Note**

- You can skip step 1 if either of the following is true:
  - If this server uses local authentication or authenticates against a RADIUS server.
  - If you have administrative rights to add the computer account of the Routing and Remote Access server to the **RAS and IAS Servers** security group. The wizard automatically adds the computer to **RAS and IAS Servers**.

1. Enable the router as follows:

Ask your domain administrator to add the router's computer account to the **RAS and IAS Servers** security group for this domain by using the Active Directory Users and Computers snap-in or the **netsh ras add registeredserver** command.

If this router must access other domains, ask your domain administrator to add the router's computer account to the **RAS and IAS Servers** security group of the other domains.

Restart the router for the change to take effect immediately.

1. Open **Routing and Remote Access**, select the computer on which you want to enable the Routing and Remote Access service (probably the computer you are currently working on), and then, on the **Action** menu, select **Configure and Enable Routing and Remote Access** to start the Routing and Remote Access Wizard. Complete the wizard pages as shown in Table 10.13.

**Table 10.13 Enabling the Routing and Remote Access Service**

| Wizard Page | Action |
|---|---|
| Configuration | Select **Secure connection between two private networks**. |
| Demand-Dial Connections | Select **Yes** (to use demand-dial routing to access remote networks). |

| | |
|---|---|
| IP Address Assignment | Choose one of the following alternative options: Select **Automatically** to use DHCP if you want to assign addresses automatically without using a specified range of addresses. -or- Select **From a specified range of addresses** if you want to specify an address range (recommended):<br>1. On the **Address Range Assignment** screen, select **New**, and then type values for the following:<br>• **Starting address**<br>• **Ending address**<br>You can use public or private address ranges. Based on what you specify for the starting and ending addresses, the **Number of addresses for the IP address pool** field is prepopulated for you. **Note.** For example, for a two-way connection, you might specify the range 192.168.10.1–192.168.10.2 on the calling router and the range 192.168.0.220–192.168.0.221 on the answering router. In this case, if the calling router initiates the connection, the calling router assigns 192.168.10.1 to itself, and it assigns 192.168.10.2 to the answering router.<br>2. If the static IP address pool address range is an off-subnet address range, ensure that the routes to the address range exist in the routers of your intranet. |

When the Routing and Remote Access Wizard completes, you might see the message "Windows was unable to add this computer to the list of valid remote access servers in the Active Directory. Before you can use this computer as a remote access server, the domain administrator must complete this task." If you see this message, click **OK**. Later, after you complete the Demand-Dial Interface Wizard (described next), you will add the computer account to the RAS and IAS Servers security group.

**Configure the Demand-Dial Interface for the Remote Site Connection**

- The Demand-Dial Interface Wizard appears automatically after the Routing and Remote Access Wizard completes.

**To configure the demand-dial interface for a remote site connection**

- Complete the wizard pages for the Demand-Dial Interface Wizard as shown in Table 10.14.

**Table 10.14 Configuring the Demand-Dial Interface for a Remote Site Connection**

| Wizard Page | Action |
|---|---|
| Interface Name | Type a name for the remote router that matches the user account name that you created earlier for the remote router. |

| | |
|---|---|
| Connection Type | Choose one of the following alternative options:<br><br>**Connect using a modem, ISDN adapter, or other physical device**. Select this option to establish a device-to-device dial-up connection.<br><br>• On the **Select a device** screen, select the modem or adapter this interface will use from the prepopulated list.<br><br>• On the **Phone Number** screen, if this is a calling router, type the phone number of the router this interface will call. (If this is an answering router that is not also a calling router, you can leave this blank.)<br><br>-or-<br><br>**Connect using virtual private networking (VPN)**. Select this option to establish a VPN connection over the Internet.<br><br>• On the **VPN Type** screen, select one of the following:<br><br>  • **Automatic** (accepts either PPTP or L2TP connections)<br><br>  • **Point to Point Tunneling Protocol (PPTP)**<br><br>  • **Layer Two Tunneling Protocol (L2TP)**<br><br>• On the **Destination Address** screen, if this is a calling router, type the IP address of the remote router this interface will connect to. (If this is an answering router, you can leave this field blank.)<br><br>Do *not* select the third option, **Connect using PPP over Ethernet (PPPoE)**, because PPPoE is used to link to the local ISP, not to create a device-to-device dial-up link or a VPN tunnel. |
| Protocols and Security | • Select **Route IP packets on this interface** (the default).<br><br>• If this is an answering router that is not joined to an Active Directory domain, add a local account by selecting **Add a user account so a remote router can dial in**. This creates a local user account on the demand-dial router. (Do *not* select this option if you earlier created an Active Directory user account for the answering router to use to authenticate the calling router.) |
| Static Routes for Remote Networks | To add one or more static routes to define the permanent route between this network and the remote network, click **Add**, and then, in the **Static Route** dialog box, do the following:<br><br>• **Destination** — Type the network ID of the remote site.<br><br>• **Network Mask** — Type the subnet mask for the network ID of the remote site.<br><br>• **Metric** — Select an appropriate number for the metric. |
| Dial In Credentials (for an answering router) | Type and confirm a password for the local user account. **Note.** This page appears *only* if this is an answering router and if you chose **Add a user account so a remote router can dial in** on the **Protocols and Security** page earlier in the wizard (to use a local account rather than an Active Directory account for router authentication). Notice that the prepopulated **User name** provided is the same name as that used for the demand-dial interface. |

| | |
|---|---|
| Dial Out Credentials (for a calling router) | Specify the dial-out credentials that this interface will use to connect to the remote router:<br>• **User name** — Type the name of the user account for the calling router that matches the name of the corresponding demand-dial interface on the answering router.<br>• **Domain** — Type the domain name; typically, both sites belong to the same domain.<br>• **Password** and **Confirm Password** — Type the password.<br>**Note.** If this is an answering router that is not also a calling router, you do not need to provide this information; however, the wizard requires that you fill in this page, so type any name, domain, and password. |

If the Routing and Remote Access Wizard (which ran before the Demand-Dial Interface Wizard) was unable to add the computer to the list of valid remote access servers in Active Directory, you saw the error message "Windows was unable to add this computer to the list of valid remote access servers in the Active Directory. Before you can use this computer as a remote access server, the domain administrator must complete this task." To enable the computer to function as a remote access server, add the computer account for the router to the RAS and IAS Servers security group. For information about how to add a computer account to a group, see Add a computer account to a group in Help and Support Center for Windows Server 2003. If you did not see the error message indicating that the computer had not been added to the valid remote access servers in Active Directory, you do not need to perform this step.

After at least one demand-dial interface exists, you can run the Demand-Dial Interface Wizard at any time to add additional demand-dial interfaces by right-clicking **Network Interfaces** in console tree, and then clicking **New Demand-dial Interface**. You run the wizard again for the following reasons:

- To add other branch office sites, repeat the steps in this procedure for each additional demand-dial interface you want to create.
- To establish a temporary link to the local ISP at the branch office in order to create a demand-dial interface for that link, perform the steps as described in the next section.

#### Configure an Additional Demand-Dial Interface for a Temporary ISP Link

If this is a VPN connection, and you connect your branch office to its local ISP through a temporary link, you must run the Demand-Dial Interface Wizard a second time to create a demand-dial interface for this physical link to the ISP. This link to the ISP can be a dial-up link or a PPPoE link.

### Note

- If you are deploying a non-VPN dial-up link, or a VPN connection between two sites, each of which connects to its local ISP through a dedicated link, do not perform these steps. Instead, perform the steps in "Configure the Demand-Dial Interface for the Remote Site Connection" earlier in this chapter.

#### To configure a demand-dial interface for a temporary link to the ISP

- Open Routing and Remote Access, right-click **Network Interfaces**, click **New Demand-dial Interface**, and then complete the wizard pages for the Demand-Dial Interface Wizard as shown in Table 10.15.

**Table 10.15 Configuring an Additional Demand-Dial Interface for a Temporary Link to the ISP**

| Wizard Page | Action |
|---|---|
| Interface Name | Type an appropriate name, such as **Dial_ISP**. |

| | |
|---|---|
| Connection Type | Choose one of the following alternative options:<br><br>Select **Connect using a modem, ISDN adapter, or other physical device**. Select this option to create a dial-up link to your local ISP.<br><br>• On the **Select a device** screen, select the modem or adapter that this interface will use from the prepopulated list.<br><br>• On the **Phone Number** screen, type the phone number of your local ISP.<br><br>-or-<br><br>Select **Connect using PPP over Ethernet (PPPoE)**. Select this option to create a PPPoE link to your local ISP.<br><br>• On the **Service Name** screen, type the name of the service in the text box provided. (If you leave this text box blank, Windows will automatically detect and configure your service when you connect.)<br><br>Do *not* select the third option, **Connect using virtual private networking (VPN)**, because this demand-dial interface is for the link to the ISP, not for a VPN tunnel. |
| Protocols and Security | Select **Route IP packets on this interface** (do *not* select **Add a user account so a remote router can dial in**). |
| Static Routes for Remote Networks | To add a static host route for the IP address allocated to the answering router by the answering router's ISP (or by InterNIC):<br><br>• **Destination** — Type the IP address of the answering router's Internet-connected interface.<br><br>• **Network Mask** — Type 255.255.255.255<br><br>• **Metric** — Select an appropriate number for the metric. |
| Dial-In Credentials | This page does not appear. |
| Dial-Out Credentials | Specify the dial-out credentials that this interface will use to connect to the local ISP:<br><br>• **User name** — Type the name of the user account that has permission to access the local ISP (this is *not* the router user account).<br><br>• **Domain** — leave this field blank.<br><br>• **Password** and **Confirm password** — Type the password.<br><br>**Note.** Open Active Directory Users and Computers, and then, on the **Dial-in** tab of the user object's **Properties** page for the user account that has permission to access the local ISP, select **Allow access**. |

# Configure a Remote Access Policy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use a remote access policy to validate a variety of connection settings before a connection is authorized, and to specify a variety of connection restrictions after the connection is authorized.

**Configure the Default Policy or Create a New Policy**

Configuring the Routing and Remote Access service on a demand-dial router or installing IAS on a computer running Windows Server 2003 creates two default remote access policies. You can use the **Connections to Microsoft Routing and Remote Access server** default policy for your site-to-site connection. However, if you want more precise control over connection requirements than the default policy provides, you can create a common or a custom remote access policy.

**To enable the default policy**

**Note**

- Do not perform these steps if you plan to create a common or custom remote access policy, described next.

1. To enable the default policy, do one of the following:

   - If you use Windows authentication, on the answering router open Routing and Remote Access, and, if necessary, double-click Routing and Remote Access and the server name. (Use Windows authentication for a site-to-site only connection.)

   - If you use RADIUS authentication, on the IAS server open Internet Authentication Service, and, if necessary, double-click Internet Authentication Service. (Use either Windows or RADIUS authentication if the answering router for the site-to-site connection also supports remote access users.)

2. In the console tree, click **Remote Access Policies**. In the details pane, right-click the default policy **Connections to Microsoft Routing and Remote Access server**, and then click **Properties**.

3. Select **Grant remote access permission**. (The default selection is **Deny remote access permission**.)

**To add a common or custom remote access policy**

**Note**

- Do not perform these steps if you plan to use the default policy, described earlier.

1. To add a common or custom remote access policy, do one of the following:

   - If you use Windows authentication, open Routing and Remote Access, and, if necessary, double-click Routing and Remote Access and the server name.

   - If you use RADIUS authentication, open Internet Authentication Service, and, if necessary, double-click Internet Authentication Service.

2. In the console tree, right-click **Remote Access Policies**, and then click **New Remote Access Policy**. Use the New Remote Access Policy wizard to create a common policy, as shown in Table 10.16, or to create a custom policy, as shown in Table 10.17.

**Table 10.16 Creating a Common Remote Access Policy by Using the New Remote Access Policy Wizard**

| Wizard Page | Action |
|---|---|
| Policy Configuration Method | Select **Use the wizard to set up a typical policy for a common scenario**, and then type an appropriate name for the policy, such as **Authenticate BranchOfficeRouters**. |
| Access Method | Select **VPN** or **Dial-up**, as appropriate. |
| User or Group Access | Click **Group**, click **Add**, and then type the group name you created earlier, such as **BranchOfficeRouters**. |
| Authentication Methods | Either accept the default method, **MS-CHAP v2**, or choose **Extensible Authentication Protocol (EAP)** and specify its type (either **MD5-Challenge** or **Smart card or other certificate**). |
| Policy Encryption Level | Select **Strongest encryption**, and clear any other selections. |

**Table 10.17 Creating a Custom Remote Access Policy by Using the New Remote Access Policy Wizard**

| Wizard Page | Action |
|---|---|
| Policy Configuration Method | Select **Set up a custom policy**, and then type an appropriate name for the policy, such as **Authenticate BranchOfficeRouters**. |
| Policy Conditions | **If this is a dial-up (non-VPN) connection**:<br>1. Click **Add**.<br>2. Select **Windows-Groups**, click **Add** twice, and then specify the group name you created earlier (such as **BranchOfficeRouters**). Click **OK** twice to return to the **Policy Conditions** page.<br>3. Click **Add**, and select **NAS-Port-Type.** Click **Add**, and select the appropriate device type, such as **Async (Modem)**, **ISDN Async V.100**, **ISDN Async V.120**, or **ISDN Sync**. Then click **Add**.<br>4. Click **Add**, select **Authentication Type**, click **Add**, select either **MS-CHAP v2** or **EAP**, and then click **Add**.<br>5. Select and configure any other attributes for which you want to specify a setting.<br>-or-<br>**If this is a VPN connection**:<br>1. Click **Add**.<br>2. Select **Windows-Groups**, click **Add** twice, and then specify the group name you created earlier (such as **BranchOfficeRouters**). Click **OK** twice to return to the **Policy Conditions** page.<br>3. Click **Add**, select **NAS-Port-Type**, click **Add**, select **Virtual VPN**, and then click **Add**.<br>4. Click **Add**, select **Tunnel-Type**, click **Add**, select either **Point-to-Point Tunneling Protocol** or **Layer 2 Tunneling Protocol** (as appropriate), and then click **Add**.<br>5. Click **Add**, select **Authentication-Type**, select either **MS-CHAP v2** or **EAP**, and then click **Add**.<br>6. Select and configure any other attributes for which you want to specify a setting. |
| Permissions | Select **Grant remote access permission**. |

| | |
|---|---|
| Profile | If you want to change the defaults, click **Edit Profile**, and then make the desired changes. For example, click **Edit Profile**, select the **Encryption** tab, select **Strongest encryption**, and clear any other selections. |

# Configure a Persistent Connection or a Disconnect Interval

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

By default, the wizards configure a site-to-site connection to be an on-demand rather than a persistent connection, and the idle time before disconnecting the on-demand connection is set to **Never**. You can change these defaults.

**To configure a persistent connection or a disconnect interval**

1. On the calling router, open the Routing and Remote Access snap-in.

2. In the console tree, under the desired router, click **Network Interfaces**. Right-click the appropriate demand-dial interface in the details pane, and then click **Properties**.

3. Click the **Options** tab, and then, under **Connection type**, do one of the following:

   - If you want a connection that disconnects, accept the default **Demand dial** (on-demand) option, and then configure the **Idle time before hanging up** by using the drop-down list to select, for example, **10 minutes**.

   - If you want a connection that is always available, select **Persistent connection**.

4. Specify values for **Redial attempts** and **Average redial interval**.

# Configure Static Routes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can configure several types of static routes for a site-to-site connection. You can add static routes manually or, when requesting routes from the remote router, by using auto-static updates.

**Create Static Routes for a Site-to-Site Connection**

For a site-to-site connection, you can use Routing and Remote Access to create the following types of static routes.

- LAN interface. If you do not use routing protocols for the local intranet, you must create one or more static routes for locations on the local intranet.
- Demand-dial interface for the remote site connection. Although you were prompted to provide a static route for the network ID of the remote site when you ran the Demand-Dial Interface Wizard, you might need to recreate this static route in the future. Alternatively, for a persistent site-to-site connection only, you can enable a routing protocol instead of using static routes.
- Demand-dial interface for a link to a local ISP. If you created an additional demand-dial interface for a link to the local ISP, you were prompted to provide a static host route for the IP address of the answering router's Internet-connected interface when you ran the Demand-Dial Interface Wizard. You might need to recreate this static host route in the future.
- Router user account. For a one-way initiated connection in which the answering router is a standalone router or a member of a native-mode Active Directory domain, you can omit creating a demand-dial interface on the answering router, but, in this case only, you must create one or more static routes on the calling router's user account that identify the network IDs of the calling router's site.

Use the following procedures to accomplish these tasks:

- Create static routes on the LAN or demand-dial interfaces.
- Create static routes on the router user account.

**Create static routes on the LAN or demand-dial interfaces**

For each static route you create, fill out the **Static Route** dialog box as shown in Table 10.18. For information about how to add static routes, see Add a static route in Help and Support Center for Windows Server 2003.

**Table 10.18 Configuring the Static Route Dialog Box for a Site-to-Site Connection**

| Interface | Action |
|---|---|
| LAN interface<br><br>(Calling and answering routers) | Specify values for the following fields:<br>• **Interface.** Select **Local Area Connection**.<br>• **Destination.** Type the network ID of the local site.<br>• **Network mask.** Type the subnet mask of the local site.<br>• **Gateway.** Do *not* specify a default gateway on the LAN interface.<br>• **Metric.** Select a number representing the appropriate metric.<br><br>(The check box **Use this route to initiate demand-dial connections** is unavailable.) |

| | |
|---|---|
| Demand-dial interface for the remote site [1]<br><br>(Calling router only) | Specify values for the following fields:<br><br>• **Interface.** Select the demand-dial interface for the connection to the remote site.<br><br>• **Destination.** Type the network ID of the remote site. (Alternatively, you can use the default route.)<br><br>• **Network mask.** Type the subnet mask of the remote site.<br><br>• **Gateway.** This field is unavailable.<br><br>• **Metric.** Select a number representing the appropriate metric. To prevent this static route from causing problems with RIP or OSPF, give it a higher cost than the cost of the static route configured on the LAN interface.<br><br>Select the following check box:<br><br>• **Use this route to initiate demand-dial connections.** |
| Demand-dial interface for the local ISP (if any) [1]<br><br>(Calling router only) | Specify values for the following fields:<br><br>• **Interface.** Select the demand-dial interface for the link to the local ISP.<br><br>• **Destination.** Type the IP address (static host route) of the answering router's Internet-connected interface.<br><br>• **Network mask.** 255.255.255.255<br><br>• **Gateway.** This field is unavailable.<br><br>• **Metric.** Select a number representing the appropriate metric. To prevent this static route from causing problems with RIP or OSPF, give it a higher cost than the cost of the static route configured on the LAN interface.<br><br>Select the following check box:<br><br>• **Use this route to initiate demand-dial connections.** |

1. You might have already created one or more static routes for one or both of these demand-dial interfaces when you ran the Demand-Dial Interface Wizard.

**Create static routes on the router user account**

For a one-way connection, you can create a demand-dial interface on the answering router, but this is not required. If you do not create a demand-dial interface on the answering router, you must create a static route or routes that identify the network IDs of the calling router's site on the calling router's user account.

For information about how to configure static routes on either a local user account or on an Active Directory user account, see Configure static routes for a dial-in user in Help and Support Center for Windows Server 2003. When performing the steps in that Help topic, you are prompted to provide a value for **Destination**. Type a network ID of the calling router's site.

**Configure Auto-static Updates**

You can use auto-static updates to request all of the routes of the router on the other side of a site-to-site connection. Auto-static updates are supported when you use RIP for IP, but not OSPF.

For more information about how to manually configure auto-static updates, see Perform manual auto-static updates in Help and Support Center for Windows Server 2003.

For more information about how to schedule auto-static updates, see Perform scheduled auto-static updates in Help and

Support Center for Windows Server 2003.

# Configure Routing Protocols

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Instead of manually configuring static routes, you can use routing protocols for the following:

- On each LAN interface.
- On each demand-dial interface that is used for a persistent site-to-site connection.

If you use routing protocols, you must configure each new LAN interface or demand-dial interface to use the protocols, because, typically, each interface is connected to a different subnet.

**To configure routing protocols for a persistent site-to-site connection**

- For information about how to deploy the IP unicast routing protocols supported by Routing and Remote Access, see RIP for IP and OSPF in Help and Support Center for Windows Server 2003.

# Configure Internet Access Through the Calling Router

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

At a branch office, you can configure the calling router to grant users access to the Internet in addition to sending traffic to the main site over the site-to-site connection. Choose one of the following scenarios if you want to configure access to the Internet:

- Access the Internet through the main office — for greater security.
- Access the Internet directly — for faster performance.

**For Security, Access the Internet Through the Main Office**

To access the Internet through the main office, use the following steps to add a default (0.0.0.0/0.0.0.0) route to the demand-dial interface used for the dial-up or VPN connection. The default route ensures that all IP packets that cannot find specific routes on the private branch office network are sent to the Internet-connected interface of the demand-dial router at the main office. You might use this alternative if you use ISA Server at the main office.

**To use the calling router to access the Internet through the main office**

1. On the branch office demand-dial router, open the **Routing and Remote Access** snap-in.
2. In the console tree, expand the router you want to configure, expand **IP Routing**, right-click **Static Routes**, and then select **New Static Route**.
3. In the **Static Route** dialog box, configure the following:
   a. In the **Interface** box, select the demand-dial interface used for the dial-up or VPN connection to the main office.
   b. In the **Destination** box, type **0.0.0.0**
   c. In the **Network Mask** box, type **0.0.0.0**
   d. In the **Metric** box, accept the default value (**1**).
   e. Select **Use this route to initiate demand-dial connections**.
   f. Click **OK**.

**For Performance, Access the Internet Directly**

To access the Internet directly from the branch office, you have two options, depending on how the branch office connects to the local ISP:

- The branch office uses a dial-up connection to its local ISP.
- The branch office uses a demand-dial connection to its local ISP.

**Option 1: The branch office uses a dial-up connection to its local ISP**

This method, which is more common and requires configuring only one static route, assumes that the branch office uses a dial-up connection to the local ISP in conjunction with the demand-dial connection to the main office.

**To use the calling router to access the Internet directly if the branch office uses a dial-up connection to its local ISP**

1. On the branch office demand-dial router, open the **Routing and Remote Access** snap-in.
2. In the console tree, expand the router you want to configure, expand **IP Routing**, right-click **Static Routes**, and then

select **New Static Route**.

3. In the **Static Route** dialog box, configure the following:

    a. In the **Interface** box, select the demand-dial interface used for the dial-up or VPN connection to the main office.

    b. In the **Destination** box, type the network ID of the main office network.

    c. In the **Network Mask** box, type the network mask for the main office network ID.

    d. In the **Metric** box, accept the default value (**1**).

    e. Select **Use this route to initiate demand-dial connections**.

    f. Click **OK**.

**Option 2: The branch office uses a demand-dial connection to its local ISP**

This method, which is less common and requires configuring two static routes, assumes that the branch office uses a demand-dial connection to the local ISP in conjunction with the demand-dial connection to the main office.

**To use the calling router to access the Internet directly if the branch office uses a demand-dial connection to its local ISP**

1. On the branch office demand-dial router, open the **Routing and Remote Access** snap-in.

2. In the console tree, expand the router you want to configure, expand **IP Routing**, right-click **Static Routes**, and then select **New Static Route**.

3. In the **Static Route** dialog box, configure the following:

    a. In the **Interface** box, select the demand-dial interface used for connecting the branch office to its ISP.

    b. In the **Destination** box, type **0.0.0.0**.

    c. In the **Network Mask** box, type **0.0.0.0**.

    d. In the **Metric** box, accept the default value (**1**).

    e. Select **Use this route to initiate demand-dial connections**.

    f. Click **OK**.

4. In the console tree, right-click **Static Routes**, and then select **New Static Route**.

5. In the **Static Route** dialog box, configure the following:

    a. In the **Interface** box, select the demand-dial interface used for the dial-up or VPN connection to the main office.

    b. In the **Destination** box, type the network ID of the main office network.

    c. In the **Network Mask** box, type the network mask for the main office network ID.

    d. In the **Metric** box, accept the default value (**1**).

    e. Select **Use this route to initiate demand-dial connections**.

    f. Click **OK**.

# Configure IP Multicasting

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can configure your site-to-site connection to support IP multicast applications.

**To configure demand-dial routers for IP multicasting**

1. For both the calling and the answering router, in the Routing and Remote Access snap-in, expand **IP Routing**, right-click **General**, click **New Routing Protocol**, and then click **IGMP Router and Proxy**.

2. Right-click **IGMP**, click **New Interface**, select the interface you want to enable, and then configure the interface as follows:

   a. Select **Enable IGMP** (the default), and then do the following:

      If this is the demand-dial interface, select **IGMP proxy**.

      If this is an intranet interface, select **IGMP router**.

   b. Typically, for **IGMP protocol version**, you can accept **Version 3** (the default).

3. If needed, modify the default IGMP router settings. In most cases, no changes are needed.

   For more information about how to modify these settings, if analysis of your network indicates that you do need to modify them, see Configure IGMP router settings in Help and Support Center for Windows Server 2003.

# Configure the Authentication Provider

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After the Routing and Remote Access and Demand-Dial Interface wizards complete, Windows authentication and Windows accounting are selected by default. You can change these defaults from Windows authentication and Windows accounting to RADIUS authentication and RADIUS accounting, or you can choose separate providers for authentication and accounting. For a deployment that supports only a site-to-site connection, use Windows authentication and Windows accounting. However, you can change these defaults if the same answering router will support both the site-to-site connection and remote access users, and you want to use RADIUS as either the authentication provider or the accounting provider.

Use the following procedures to accomplish these tasks:

- Configure the authentication provider on the answering router.
- Configure the accounting provider on the answering router.

**To configure the authentication provider on the answering router**

1. Configure either Windows authentication or RADIUS authentication.

   For information about how to configure Windows or RADIUS authentication, see Use Windows Authentication or "Use RADIUS authentication" in Help and Support Center for Windows Server 2003.

2. If you select RADIUS authentication, add the answering router as a RADIUS client on the IAS server.

   For information about how to add the answering router as a RADIUS client, see "Configure RADIUS Clients" in Help and Support Center for Windows Server 2003.

**To configure the accounting provider on the answering router**

1. Select either Windows accounting or RADIUS accounting.

   For information about how to select the accounting method you want to use, see Use Windows Accounting or "Use RADIUS accounting" in Help and Support Center for Windows Server 2003.

2. If you select RADIUS accounting, add the answering router as a RADIUS client on the IAS server.

   For information about how to add the answering router as a RADIUS client, see "Configure RADIUS Clients" in Help and Support Center for Windows Server 2003.

# Configure Authentication Methods

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

By default, the answering router is configured to accept EAP-TLS, MS-CHAP v2, and MS-CHAP as the authentication methods. To increase security, use either EAP-TLS alone or EAP-TLS along with MS-CHAP v2. Alternatively, you can use MS-CHAP v2 with passwords for user authentication.

**To configure the authentication method on the answering router**

1. On the answering router, specify which authentication method or methods to accept.

   By default, the answering router is configured to accept EAP-TLS, MS-CHAP v2, and MS-CHAP.

   - To increase security, clear the MS-CHAP selection, and, if you plan to use EAP-TLS only, also clear the MS-CHAP v2 selection.

     -or-

   - To use MS-CHAP v2 with passwords for user authentication, clear the EAP-TLS selection.

   For information about how to add or clear authentication methods, see Enable authentication protocols in Help and Support Center for Windows Server 2003.

2. If you select EAP-TLS authentication, be sure to perform the steps in "Install Computer and User Certificates for EAP-TLS" earlier in this chapter.

# Configure Ports in Routing and Remote Access

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If needed, you can change the default values for **Ports** in Routing and Remote Access.

**To configure ports**

- Fill out the **Configure Device** dialog box as shown in Table 10.19. For information about how to configure ports for your site-to-site connection, see Enable routing on ports in Help and Support Center for Windows Server 2003.

**Table 10.19 Using the Configure Device Dialog Box to Configure Ports**

| Option | Action |
|---|---|
| **Remote access connections (inbound only)** | Select this option if you want to allow connections from individual remote access users in addition to connections from a remote router. |
| **Demand-dial routing connections (inbound and outbound)** | Select this option if you want to enable a site-to-site demand-dial connection. This is the default. |
| **Demand-dial routing connections (outbound only)** | This option is available only for a PPPoE connection to the Internet. Select this option if you want this router to function only as a calling router. |
| **Phone number for this device** | If you configure a value for **Called-Station-ID** in the remote access policy associated with this connection, you must manually type a value for this field:<br>• If this is a dial-up connection, type the phone number that was entered in the **Called-Station-ID** remote access policy attribute.<br>• If this is a VPN connection, type the IP address of the VPN server's Internet-connected interface (entered in the **Called-Station-ID** remote access policy attribute). |
| **Maximum ports** | For PPTP or L2TP/IPSec VPN routers only, change the default number of ports. For optimal scalability, use 10 or fewer ports. |

# Configure Dial-out or Dial-in Hours

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For on-demand connections, you can specify time limits for dial-out or dial-in hours.

**To configure dial-out hours on a calling router**

- Configure dial-out routers on the calling router to prevent connections at unwanted times.

  For information about how to use Routing and Remote Access to configure dial-out hours on the demand-dial interface of a calling router to block outgoing connections at specific times of the day or week (such as at night or on weekends), see Configure dial-out hours in Help and Support Center for Windows Server 2003.

**To configure dial-in hours on an answering router**

- Configure dial-in hours on the answering router to specify when the calling router can access the answering router.

  For information about how to use remote access policies to configure dial-in hours on an answering router to block incoming connections at specific times of the day or week (such as at night or on weekends), see Configure dial-in constraints in Help and Support Center for Windows Server 2003.

# Configure IP Packet Filters and Demand-Dial Filters

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For an on-demand VPN connection, you can specify IP packet filters and demand-dial filters.

Use the following procedures to accomplish these tasks:

- Configure IP packet filters on the Internet interface
- Match IP demand-dial filters to IP packet filters on the demand-dial interface

**Configure IP Packet Filters on the Internet Interface**
You can configure PPTP or L2TP/IPSec input and output filters on the Internet-connected interface of a VPN router to allow only PPTP or only L2TP/IPSec traffic to travel between the two sites.

How you configure firewall filters and filters on the VPN router depends on the relative position of the VPN router and firewall. For information about configuring filters for a VPN site-to-site server, see "Deploying Dial-up and VPN Remote Access Servers" in this book, and see "VPN servers and firewall configuration," Add PPTP Filters, and Add L2TP over IPSec Filters in Help and Support Center for Windows Server 2003.

**Configure IP Demand-Dial Filters and Match Them to IP Packet Filters on the Demand-Dial Interface**
You can configure demand-dial filters to specify which types of traffic are allowed to create a site-to-site connection. By matching demand-dial filters to the IP packet filters, you can also prevent a calling router from establishing a demand-dial connection for traffic that IP packet filters are configured to discard.

For information about how to configure demand-dial filters and to match them to IP packet filters, see Configure demand-dial filters and Demand-dial routing design considerations in Help and Support Center for Windows Server 2003.

# Initiate the Connection

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

First, ensure that both routers are enabled for dial-up access, and then initiate the connection.

**To confirm that a router has permission to initiate an on-demand connection**

1. Open Active Directory Users and Computers, and then on the **Dial-in** tab of the user account of the router's **Properties** page, confirm that either **Allow access** or **Control access through Remote Access Policy** is selected.

2. If **Control access through Remote Access Policy** is selected, open the Routing and Remote Access snap-in and confirm that the remote access permission setting on the Properties page of the associated Remote Access Policy is set to **Grant remote access permission**.

**To initiate the on-demand connection on the calling router**

- On the calling router, in the **Routing and Remote Access** snap-in, click **Network Interfaces**, right-click the demand-dial interface for which you want to initiate a connection, and then click **Connect**.

If the calling router uses a dial-up connection to the local ISP, the local ISP assigns the router a temporary IP address. You can confirm that this IP address exists by typing **ipconfig** at a command prompt.

# Test Connectivity

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Use the following procedures to test the remote site connection:

- **Test network connectivity.** To test network connectivity, ping a client computer at the main office from a client computer in the branch office.

- **Test application connectivity.** To test application connectivity, map a network drive to a client computer at the main office from a client computer in the branch office. For example, map a drive to *ClientComputerName*\c$.

- **Force replication between domain controllers in both sites.** If you have a domain controller in both sites, use the following procedure to test replication:

  1. Open Active Directory Users and Computers, and create a new user account called, for example, *TestReplication*.

  2. Use the Active Directory **Replicate Now** option to test that replication takes place over the site-to-site connection.

     For information about how to force replication between the two sites, see Force replication over a connection in Help and Support Center for Windows Server 2003.

  3. Confirm that the new user account exists on domain controllers located in both sites.

# Configure Replication for Active Directory

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Configure Replication**
If you installed an Active Directory domain controller in the branch office, you must ensure that replication takes place continually. How you do this depends on whether this is a persistent connection or an on-demand connection.

Use the following procedures to accomplish these tasks:

- Configure a replication interval for a persistent connection
- Configure reciprocal replication for a one-way initiated on-demand connection

**Configure a Replication Interval for a Persistent Connection**
If this is a persistent connection, you can schedule replication to occur after a specified interval.

Use the Active Directory Sites and Services snap-in to configure a replication interval. For information about how to specify a replication interval, see Configure site link replication frequency in Help and Support Center for Windows Server 2003.

**Configure Reciprocal Replication for a One-Way Initiated On-Demand Connection**
If this is a one-way initiated on-demand connection, you must configure reciprocal replication using the Active Directory Service Interfaces (ADSI) Edit tool.

Install ADSI Edit, a Windows Support tool, on a domain controller in the main office or in the branch office. For information about how to install Windows Support Tools, which include ADSI Edit, in Help and Support Center for Windows Server 2003, click **Tools**, and then click Install Windows Support Tools.

**Caution**

- If you use the ADSI Edit snap-in and incorrectly modify the attributes of Active Directory objects, you can cause serious problems that might require you to reinstall Windows Server 2003. Microsoft cannot guarantee that problems resulting from the incorrect modification of Active Directory object attributes can be solved. Modify these attributes at your own risk.

**To enable reciprocal replication on a site link for a one-way initiated on-demand connection**

1. On a domain controller, type **adsiedit.msc** in the Run dialog box to open the ADSI Edit snap-in.
2. Expand the **Configuration** container, expand the **Sites** container, expand the **Inter-Site Transports** container, and then click **CN=IP**.
3. In the details pane, right-click the site link object for the sites for which you want to enable reciprocal replication, and then click **Properties**.
4. In the **Attributes** box, double-click **Options**.
5. In the **Integer Attribute Editor** dialog box, take one of the following actions:
   a. If the **Value** box displays **<not set>**, type **2**.
   b. If a value is displayed, convert the integer value to a binary value and use the binary OR operation to combine that value with the binary value **0010**, and then type the integer value of the result in the **Value** box.

      For a job aid that includes a table of examples showing how to perform this operation, see "Example: Contoso Connects Remote Sites" (DNSREM_1.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Example: Contoso Connects Remote Sites" on the Web at http://www.microsoft.com/reskit).

Alternatively, you can enable reciprocal replication on a connection, instead of on a site link.

**To confirm reciprocal replication over a one-way initiated on-demand connection**

1. On the branch office domain controller, create a user account called TestReplication.

2. On the calling router in the branch office, establish a connection to the answering router in the main office.

3. Wait 15 to 20 minutes, and then open Active Directory Users and Computers on a domain controller in the main office. If your connection is working correctly, the TestReplication user account will be listed.

4. To confirm that replication did in fact take place over the one-way initiated site-to-site connection, perform the following steps:

    a. On both the calling router and the answering router, type **ipconfig** at a command prompt. If, when you ran the Routing and Remote Access wizard, you chose the recommended option to configure IP address assignment from a specified range of addresses, the output of both **ipconfig** commands will include IP addresses from the specified address ranges.

    b. On the branch office domain controller, type **tracert** at a command prompt. If, when you ran the Routing and Remote Access wizard, you configured IP address assignment from a specified range of addresses, the output of the **tracert** command will include an IP address from the specified range that the answering router assigns to the calling router.

# Additional Resources for Connecting Remote Sites

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information related to this chapter.

# Deploying a Wireless LAN

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Wireless connectivity offers users a high degree of mobility and provides another networking option when traditional wired networks are impractical. The Microsoft® Windows® Server 2003 operating system provides the networking services needed to deploy a secure and manageable wireless local area network (WLAN) infrastructure within an enterprise environment. The deployment of WLANs — the primary wireless networking support for an enterprise environment provided by Windows Server 2003 and the Microsoft® Windows® XP operating system — is detailed in this chapter.

**In This Chapter**

Overview of Deploying a Wireless LAN

Adapting the Network Infrastructure for a WLAN

Designing a Wireless Network Access Solution

Implementing a WLAN Test Environment

Additional Resources for Deploying a Wireless LAN

**Related Information**

- For more information about the Internet Authentication Service (IAS), see "Deploying Internet Authentication Service (IAS)" in this book and the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

- For information about designing a certificate infrastructure, see "Designing a Public Key Infrastructure" in *Designing and Deploying Directory and Security Services* of this kit.

- For more information about implementing the Active Directory® directory service, see "Designing the Active Directory Infrastructure" in *Designing and Deploying Directory and Security Services*.

# Overview of Deploying a Wireless LAN

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To provide authorization and authentication, automatic IP address assignment, and name resolution for wireless users, your networking infrastructure should include the following services:

- Active Directory directory service
- Remote Authentication Dial-In User Service (RADIUS) servers and proxies
- A certificate infrastructure, also known as a *public key infrastructure* (*PKI*)
- Dynamic Host Configuration Protocol (DHCP) services
- Domain Name System (DNS) services

These services together provide the security, availability, and scalability needed for an enterprise WLAN solution. Before you begin designing and deploying an enterprise WLAN, all of the supporting components and services in your networking infrastructure should be in place.

All of the components required for an enterprise WLAN solution are included with Windows Server 2003 and Windows XP. Windows Server 2003 includes DHCP, DNS, and Certificate Services, and support for RADIUS (through the Internet Authentication Service [IAS]), the IEEE 802.1X standard, and certificate authentication. Windows XP with wireless network adapters provides support for wireless devices such as laptops and personal digital assistants (PDAs), the IEEE 802.1X standard, and certificate authentication.

**Note**

- Though the WLAN components are included in the Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; and Windows® Server 2003, Datacenter Edition operating systems, there are differences in the levels of features supported and the capabilities. For information about differences in these services among the Windows Server 2003 operating systems, see Help and Support Center for Windows Server 2003.

After designing your enterprise WLAN and deploying the networking components and services needed for the WLAN, you will be able to maintain a secure and manageable wireless network by using supported features such as the Wireless Zero Configuration (WZC) service included in Windows XP and Windows Server 2003, RADIUS-based 802.1X authentication, and interoperability with other networking services.

# Process for Deploying a Wireless LAN

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In deploying a wireless LAN, adapt your existing network infrastructure for a WLAN before designing the wireless network access solution — that is, deciding where to locate wireless access points (APs) and how to deploy them; designing wireless security and unauthenticated access; optionally designing a public space WLAN; and designing for better manageability. Before embarking on a full-scale WLAN deployment, implement a WLAN test environment and test your wireless networking solution. Figure 11.1 shows the major steps in the process for deploying a WLAN.

**Figure 11.1 Deploying a Wireless LAN**

# WLAN Technology Background

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The WLAN solution provided by Windows XP and Windows Server 2003 is based on IEEE standards 802.11 and 802.1X.

**IEEE 802.11** IEEE 802.11, the standard for WLANs, specifies a technology that operates in the 2.4 through 2.5 GHz Industrial, Scientific, and Medical (ISM) band and has a maximum bit rate of 2 megabits per second (Mbps). IEEE 802.11b supports two additional speeds, 5.5 Mbps and 11 Mbps, in the ISM band.

**Note**

- The latest IEEE standard, IEEE 802.11a, specifies a technology that operates in a 5.725 through 5.875 GHz band with a maximum bit rate of 54 Mbps.

The 802.11 standard defines an *access point* (AP) as a device that functions as a transparent bridge between the wireless clients and the existing wired network. The AP contains at least one interface to connect to the existing wired network, and transmitting equipment to connect with the wireless clients. The AP also contains IEEE 802.1D bridging software, thereby acting as a transparent bridge between wireless and wired data-link layers.

**IEEE 802.1X** The 802.1X standard defines port-based network access control to provide authenticated network access for Ethernet networks. This port-based network access control uses the physical characteristics of the switched LAN infrastructure to authenticate devices attached to a LAN port. Access to the port can be denied if the authentication process fails. Although this standard is designed for wired Ethernet networks, it applies to 802.11 WLANs as well.

# Adapting the Network Infrastructure for a WLAN

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In adapting your network infrastructure for a WLAN, verify you have the required components; eliminate any potential single points of failure; and define IP addressing and subnets needed to support your wireless clients. Figure 11.2 shows the process for adapting your existing network infrastructure for a WLAN.

**Figure 11.2 Adapting the Network Infrastructure for a WLAN**

# Verifying Required Components

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To support a secure wireless solution, your existing network infrastructure must include the following components:

- Active Directory, to store account properties and validate password-based credentials.
- DHCP services, to provide automatic IP configuration to wireless clients.
- DNS services, to provide name resolution.
- RADIUS support, to provide centralized connection authentication, authorization, and accounting.
- A certificate infrastructure, also known as a PKI, to issue and validate the certificates required for Extensible Authentication Protocol–Transport Level Security (EAP-TLS) and Protected EAP (PEAP)–TLS authentication. TLS can use either smart cards or registry-based user certificates for authenticating the wireless client.
- For PEAP-Microsoft Challenge Handshake Authentication Protocol version 2 (MS-CHAP v2) authentication, computer certificates for the RADIUS servers and root CA certificates of the issuing CAs on the wireless clients (if needed).

Windows Server 2003 provides all of these components, with some variations in the levels of features supported and capabilities in different editions of the operating system (Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition). For information about differences in these services among the different editions of Windows Server 2003, see Help and Support Center for Windows Server 2003.

After verifying that your existing network infrastructure includes the appropriate components, update the design to support your WLAN.

**Active Directory: Planning Groups and Group Policy for Wireless Access**
Active Directory contains the user and computer accounts that are used for authentication and authorization of wireless users. It also contains the Group Policy settings that govern wireless connections — for example, information regarding autoenrollment for the user and computer certificates that are installed on wireless clients, and the Wireless Network (IEEE 802.11) Policies settings that specify preferred networks, Wired Equivalent Privacy (WEP) settings, and IEEE 802.1X settings for wireless connections.

To plan for the configuration of Active Directory for your wireless clients, identify the user and computer accounts for wireless users, and add them to a group that will be used in conjunction with a remote access policy to manage wireless access. You must also determine how to set the remote access permission on the user and computer accounts.

**Note**

- For a native-mode domain, you can use universal groups and nested global groups. For example, you might create a universal group named WirelessUsers that contains global groups of wireless user and computer accounts for intranet access.

For information about designing group policies for a WLAN, see "Designing a Group Policy Infrastructure" in *Designing a Managed Environment* of this kit.

For information about configuring Active Directory for a WLAN, see "Implementing a WLAN Test Environment" later in this chapter. For information about the design and deployment of Active Directory, see "Designing the Active Directory Infrastructure" in *Designing and Deploying Directory and Security Services*.

**Note**

- You can configure a computer running Windows Server 2003 or the Microsoft® Windows® 2000 Server operating system as an Active Directory domain controller. To configure a Windows 2000 Server–based computer as an Active Directory domain controller for wireless access, you must install Service Pack 3 (SP3) or later.

**DNS: Identifying Zones Where Wireless Clients Will Register**
In DNS, identify the DNS zones where the wireless computers will register DNS address records, and ensure that the zones are configured for dynamic updates. Optionally specify that the DNS zones are Active Directory–integrated zones, which provide secured updates, and that the DNS zones are updated by DHCP. For information about configuring DNS zones, see "Deploying Domain Name System (DNS)" in this book.

**DHCP: Creating Scopes and Leases for Wireless Clients**
On the DHCP server, you must configure the scope and lease duration differently for wireless clients than for clients connected to the wired LAN.

A DHCP *scope* is the full, consecutive range of possible IP addresses for a network, which typically defines a single physical subnet where DHCP services are offered. A DHCP *lease duration* is the specified time during which the IP addresses within the DHCP scope can be leased.

Define separate scopes for your wired subnets and your wireless subnets, so that you can configure the lease duration differently for the clients requiring DHCP services on your WLAN than for the clients on your wired LAN.

The default lease duration for a DHCP scope is eight days. This might be optimal for clients on your wired network. Because wireless clients do not release their addresses when the wireless user roams to a new subnet, you should decrease the lease duration substantially for wireless clients. By setting a shorter lease duration for wireless clients, you free IP addresses for reuse throughout the day instead of leaving the addresses unavailable for as long as eight days. When determining the optimal lease duration for the wireless clients in your environment, keep in mind the additional processing load that the shorter lease duration places on your DHCP server.

For more information about configuring scopes and lease durations on a DHCP server, see "Deploying DHCP" in this book.

**RADIUS: Verifying Support for 802.1X and EAP-TLS**
Verify that the RADIUS servers, such as IAS, support EAP-TLS and PEAP-MS-CHAP v2 authentication. Optionally, verify that the RADIUS servers support the use of the NAS-Port-Type attribute in their Access-Request messages. IAS uses the NAS-Port-Type attribute to identify the wireless connection types.

Computers running Windows Server 2003 or Windows 2000 Server IAS can be used for RADIUS support. A Windows 2000 IAS server must have Service Pack 3 (SP3) or later installed.

### Notes

- You can configure IAS in Windows Server 2003, Standard Edition, with a maximum of 50 RADIUS clients and a maximum of 2 remote RADIUS server groups. You can define a RADIUS client by using a fully qualified domain name or an IP address, but you cannot define groups of RADIUS clients by specifying an IP address range. If the fully qualified domain name of a RADIUS client resolves to multiple IP addresses, the IAS server uses the first IP address returned in the DNS query.

- With IAS in Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition, you can configure an unlimited number of RADIUS clients and remote RADIUS server groups. In addition, you can configure RADIUS clients by specifying an IP address range.

By using IAS as your RADIUS server and Active Directory as your directory service, you can provide a single sign-on solution. IAS uses Active Directory as its user accounts database. The same set of credentials is used to control network access (authenticating and authorizing access to a network), to log the user on to an Active Directory domain, and to control access to resources in the domain.

The RADIUS server must support the EAP-TLS authentication protocol, which is used in certificate-based security environments. In addition, EAP-TLS is required if you are using smart cards for network access authentication. The RADIUS server also must support the PEAP-MS-CHAP v2 authentication protocol, which is used in password-based security environments.

**Certificate Infrastructure: Verifying Support for EAP-TLS and PEAP-MS-CHAP v2**
To support EAP-TLS authentication, verify that the certificate infrastructure supports issuing user and computer certificates to wireless client computers and issuing computer certificates to your RADIUS servers.

To support PEAP-MS-CHAP v2 authentication, verify that your RADIUS servers have the appropriate computer certificates installed, and that each wireless client computer has the root certification authority (CA) certificates of the issuers of the

computer certificates of the RADIUS servers installed.

You can use a third-party CA to issue certificates for wireless access, as long as the certificates that you install fulfill the requirements for TLS authentication.

For more information about certificate requirements, see the discussion of deploying a certificate infrastructure in "Implementing a WLAN Test Environment" later in this chapter. For information about designing and deploying a certificate infrastructure, see "Designing a Public Key Infrastructure" in *Designing and Deploying Directory and Security Services*.

# Eliminating Single Points of Failure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To ensure that wireless clients can continue to be authenticated on the network and can access resources and applications, eliminate single points of failure in your network infrastructure by including:

- Redundant services (such as Active Directory domain controllers) on separate subnets.
- Clustered DHCP services, in the event that one of the cluster nodes fails.
- DNS on all domain controllers, in the event that a DNS server fails.
- Redundant RADIUS servers and proxies, to provide fault tolerance for RADIUS-based authentication.
- Redundant switches and routers, in the event that a switch or router fails.
- Redundant network paths between switches and routers.

# Defining IP Addressing and Subnets

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Determine how many additional IP addresses your wireless clients will require, and whether or not to define additional subnets.

**To determine the number of additional IP addresses that you will need for wireless access:**

1. Calculate the number of additional IP addresses that wireless users will require:

    a. Determine the average number of wireless clients currently using your corporate network at any given time.

    b. Add to this the estimated number of additional concurrent wireless clients your network will need to support in the future.

2. Estimate the number of APs (and associated IP addresses) that you will need for wireless network access. For information about how to determine how many wireless APs to deploy, see "Designing Wireless AP Location" later in this chapter.

Based on the number of IP addresses that you will add to accommodate your WLAN, decide whether or not to add additional subnets.

Creating separate subnets for your wireless networking components offers many benefits, including:

- Wired network components do not have to draw from the same pool of existing IP addresses as your wireless clients.
- IP addresses for wireless clients are easier to identify, which assists in easier management and troubleshooting.
- Separate subnets give you increased control over DHCP lease times.
- You can associate each of your physical subnets (both wireless and wired) with sites within Active Directory, which enables you to assign network access policies to the specific subnets.
- If all APs are on the same subnet, you can provide seamless network-layer roaming for the wireless clients. *Network-layer roaming* allows a wireless client to associate with a new AP within the same subnet, in the same wireless network. When crossing subnets, applications that cannot handle a change of address, such as some e-mail applications, might fail.

**Note**

- Network-layer roaming is to be distinguished from *general roaming,* which allows a wireless client to associate with a new AP within the same wireless network. In network-layer roaming, the wireless client associates with a new AP on the same subnet, within the same wireless network.

**Example: An Enterprise Corporation Designs Subnets and IP Addressing for a WLAN**
IEEE 802.11 APs are designed with Ethernet ports and use TCP/IP as a networking protocol. Thus, an enterprise corporation designed their network so that the wireless APs in the building are all attached to the same separate subnet, which is connected to a router.

To avoid using IP addresses from existing subnets, they assigned all of the wireless components to a separate subnet. Because they used a separate subnet for wireless components, the wireless components did not adversely affect the available number of host addresses allocated on previously configured wired subnets.

To keep track of the allocation of IP addresses, they created the IP address numbering scheme shown in Table 11.1. The corporation adopted this numbering convention for all of their buildings that have wireless network connectivity.

**Table 11.1 Example IP Address Allocation for IP Subnet 172.16.50.0/24**

| IP Address | Device |
| --- | --- |
| 172.16.50.1 | Router |
| 172.16.50.2–172.16.50.10 | Servers (terminal, proxy, IAS, and so forth) |
| 172.16.50.11–172.16.50.*x* | Wireless APs |
| 172.16.50.*x*+*1*–172.16.50.254 | Wireless clients |

Under this addressing scheme, addresses were assigned in the following manner:

- Within the IP subnet 172.16.50.0/24, they assigned the router connecting to the rest of the network the first IP address of 172.16.50.1.
- They assigned other devices — such as terminal servers, proxy servers, and IAS servers — addresses from 172.16.50.2 through 172.16.50.10.
- They assigned the wireless APs sequential IP addresses starting with 11. To make it easier to keep track of the wireless APs, they assigned IP addresses that were 10 digits higher than the wireless AP number. For example, Wireless AP 1 was assigned 172.16.50.11, Wireless AP 2 was assigned 172.16.50.12, and so forth.

As is usual practice, they assigned static IP addresses to the APs and any servers on the subnet. To prevent the DHCP server from allocating a static IP address to a wireless client, they created a DHCP scope for the wireless subnet that did not include the assigned servers and APs (the scope range was 172.16.50.*x*+*1* through 172.16.50.254).

They located all APs in a building on the same subnet, which allowed network-layer roaming throughout the building. This also made IP addressing by DHCP servers more manageable. The DHCP server assigned wireless clients dynamic IP addresses.

# Designing a Wireless Network Access Solution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In designing your wireless network access solution, determine where to locate wireless APs and plan how to deploy the APs; design security for wireless access; if needed, design for unauthenticated access and for a public space WLAN; and, finally, optimize your design for manageability. Figure 11.3 shows the process for designing your wireless network access solution.

**Figure 11.3 Designing Your Wireless Network Access Solution**

# Designing Wireless AP Location

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After designing and verifying that the services needed for your network infrastructure to support an enterprise WLAN are in place, begin the design process for the location of the wireless APs.

To determine where to locate your wireless APs:

- Identify the areas of coverage for wireless users.
- Determine how many wireless APs to deploy.
- Determine where to place wireless APs.
- Select the channel frequencies for wireless APs.

# Identifying the Areas of Coverage for Wireless Users

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To identify the areas of coverage for wireless users:

1. Obtain or create scaled architectural drawings of each floor for each building, in each geographic location in your organization that has wireless users.

2. On the drawing, identify the offices, conferences rooms, lobbies, or other areas where you want to provide wireless coverage.

   It might be useful to enable wireless coverage for a building in its entirety rather than for specific locations within the building. For example, this can prevent connectivity problems that might result from undocking a laptop from an office for use in a different part of your building.

3. Indicate any devices that interfere with the wireless signals.

   Any device that operates on the same frequencies as your wireless devices (in the 2.4 through 2.5 GHz ISM range) might interfere with the wireless signals. Devices that operate on the same frequency include:

   - Existing Bluetooth-enabled devices
   - Microwave ovens
   - Some models of cordless telephones
   - Wireless video cameras
   - Medical equipment

4. Indicate any building construction materials that interfere with wireless signals.

   Metal objects used in the construction of a building can affect the wireless signal. For example, the following common objects interfere with signal propagation:

   - Support girders
   - Elevator shafts
   - Rebar reinforcement in concrete
   - Heating and air-conditioning ventilation ducts
   - Wire mesh that reinforces plaster or stucco in walls

**Note**

- *Radio frequency attenuation* (the reduction of signal strength), shielding, and reflection can affect how you deploy your APs. Refer to the manufacturer of your APs for information regarding the different scenarios that might increase the radio frequency attenuation. Testing software is available with most APs to check for signal strength, error rate, and data throughput. This can be very beneficial during the deployment of your APs.

# Determining How Many Wireless APs to Deploy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To determine how many wireless APs to deploy, following these guidelines:

- Include enough wireless APs to ensure that wireless users have sufficient signal strength from anywhere in the area of coverage.

  Wireless APs typically have an indoor range within a 150-foot radius. Include enough wireless APs to ensure signal overlap between the wireless APs.

- Determine the maximum number of simultaneous wireless users per coverage area.

- Estimate the data throughput that the average wireless user requires.

Add additional wireless APs to:

- Improve wireless client network bandwidth capacity.

- Increase the number of wireless users supported within a coverage area

  Based on the total data throughput of all users, determine the number of users that you can connect through a wireless AP. Obtain a clear picture of throughput before deploying the network or making changes. Some wireless vendors provide an 802.11 simulation tool, which you can use to model traffic in a network and view throughput levels under various conditions.

- Ensure redundancy, in the event that a wireless AP fails.

# Determining Where to Place Wireless APs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is important to locate the APs close enough together to provide ample wireless coverage but far enough apart to not interfere with each other and increase the error rate. The actual distance needed between any two APs depends upon the combination of the type of AP, the type of AP antenna, and the construction of the building, as well as on sources of signal degradation, shielding, and reflection. For specifications and guidelines for placing wireless APs, see the manufacturer's documentation for the APs and the antennas used with them.

Maintain the best average ratio of wireless clients to APs. The greater the number of wireless clients that are associated with the AP, the lower the effective data transmission rate. Too many wireless clients attempting to use the same AP degrade the effective throughput or available bandwidth for each wireless client. By adding APs, you can increase throughput. To increase the number of APs per wireless client, you must increase the number of APs in a given coverage area. You can move APs closer together up to a point before they start to interfere with each other.

To determine where to place the wireless APs:

1. On the architectural drawings, place wireless APs so that each wireless AP is no further than 300 feet from an adjacent wireless AP.

2. To test the wireless AP placement, perform a site survey:

   - Temporarily place wireless APs in the locations specified on the architectural drawings.

   - Using a laptop equipped with an 802.11 wireless adapter and site survey software (site survey software ships with most wireless adapters), determine the signal strength within each coverage area.

3. In coverage areas where signal strength is low, make any of the following adjustments:

   - Reposition existing APs to increase the signal strength for that coverage area.

   - Reposition or eliminate devices that interfere with signal strength (such as Bluetooth devices or microwave ovens).

   - If possible, reposition or eliminate metal obstructions that interfere with signal propagation (such as filing cabinets and appliances).

   - Add additional wireless APs to compensate for the weak signal strength.

     It is important to remember that radio frequency is three-dimensional. It can be conceptualized as a sphere of signal.

   - Purchase antennas to meet the requirements of your building infrastructure.

     For example, to eliminate interference between APs located on adjoining floors in your building, you can purchase directional antennas that flatten the signal (forming a donut-shaped signal distribution) to increase the horizontal range and decrease the vertical range.

4. Update the architectural drawings to reflect the final number and placement of the wireless APs.

**Example: An Enterprise Corporation Determines AP Location**
An enterprise corporation used information from the manufacturer of its APs and from internal testing to determine the best locations for their APs when using IEEE 802.11b. They determined that a 30-foot radius for each AP (with 60 feet between adjacent APs) would provide the best coverage without interference between the APs.

To assist them in designing AP locations, the IT staff created a plan view of the building, with one drawing per floor. The floor plans displayed the location, name, IP address, and channel information for each AP. Based on the information in the floor plans, the IT staff determined that they could locate their APs in the plenum area between the lowered ceiling and the next floor up, which simplified troubleshooting for the AP equipment.

# Selecting Channel Frequencies for Wireless APs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Direct communication between an 802.11 wireless network adapter and an AP occurs over a common channel corresponding to a frequency range in the S-Band ISM frequency range. You set the channel in the AP, and the wireless network adapter automatically tunes to the channel of the AP with the strongest signal. The wireless network adapter continues communication with the AP until the signal gets weak, at which time it attempts to locate another AP with a stronger signal.

To reduce interference between wireless APs, ensure that wireless APs with overlapping signals use unique channel frequencies. The 802.11b standard reserves 14 frequency channels for use with wireless APs. Within the United States, the Federal Communications Commission (FCC) allows channels 1 through 11. In most of Europe, you can use channels 1 through 13. In Japan, you have only one choice: channel 14.

Figure 11.4 shows the 11 802.11b frequency channels available in the United States. Notice that the 802.11b signals overlap with adjacent channel frequencies. As a result, you can only use three channels (in the United States, channels 1, 6, and 11) without causing interference between adjacent APs.

**Figure 11.4 Channel Overlap for 802.11b APs in the United States**

To select the channel frequencies for the wireless APs:

1. Identify any wireless networks owned by other organizations in the same building. Find out the placement of their wireless APs and the channel frequencies assigned to the APs.

   Radio waves travel through floors and ceilings, so APs located near each other on different floors need to be set to non-overlapping channels. If another organization located on a floor adjacent to your organization's offices has a wireless network, the wireless APs for that organization might interfere with the wireless APs in your network. Contact the other organization to determine the placement and frequencies of their wireless APs so that you can ensure that any of your own wireless APs that provide overlapping coverage use a different channel frequency.

2. Identify overlapping wireless signals on adjacent floors within your own organization.

3. After identifying overlapping coverage areas outside and within your organization, assign channel frequencies for your wireless APs.

   a. Assign channel 1 to the first wireless AP.

   b. Assign channels 6 and 11 to any wireless APs that overlap coverage areas with the first wireless AP, to ensure that those APs do not interfere with one another.

   c. Continue assigning channel frequencies to the wireless APs, ensuring that any two wireless APs with overlapping coverage are assigned different channel frequencies.

**Example: An Enterprise Corporation Determines IEEE 802.11b Channels**

An enterprise corporation occupies multiple floors in a building. Because of this, they had to pay attention to both the horizontal and vertical dimensions when determining which IEEE 802.11b channel to assign to each AP. For example, if a certain spot on the first floor used channel 1, they assigned channel 6 to the same location on the second floor, and assigned

channel 11 to the same location on the third floor. They did not use channel 1 again until the fourth floor.

Figure 11.5 illustrates the selection of channels for the wireless APs on a building floor. The wireless AP channels were selected to ensure that no two overlapping areas of coverage have the same channel (frequency).

**Figure 11.5 Example of 802.11b Channel Allocation**

# Planning the Deployment of APs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After determining where to locate APs, you need to make additional decisions about how you will deploy the APs. These decisions affect the types of equipment required, where the equipment should be located, and how the equipment will be installed

**Will you install the APs on the walls of your building or in the plenum area?**
If you place your APs in the plenum area, you must determine the best method for powering the APs. Consult with the AP manufacturer to determine how to meet the power requirements for the APs. Some wireless APs can receive electrical power through the Ethernet cable.

The plenum area is regulated by fire codes. Therefore, for plenum placement, you must purchase APs that are fire-rated.

**Will you preconfigure APs before installing them or configure them remotely?**
Preconfiguring the APs before installing them on location can speed up the deployment process and can save labor costs, because less skilled workers can perform the physical installation. You can preconfigure APs by using the console port (serial port), Telnet, or a Web server that is integrated with the AP. If you will use a terminal server for console configuration of APs, decide where to locate the terminal server. Regardless of whether you decide to preconfigure the APs, make sure that you can access them remotely, particularly if you deploy many APs. This enables you to configure or upgrade the APs remotely by using scripts.

The terminal server can be located on the same subnet as the APs, or elsewhere.

It is helpful to physically locate the terminal server in the same wiring closet as the hub or patch panel connecting the AP. With this arrangement, you can pull together the Ethernet and console (serial) wires at the same time. This is only possible if the wires are run to and from the same place. You can then complete the configuration of many APs from a central location.

**What model of antenna will you use for the APs?**
For example, in a building with multiple floors, an omnidirectional antenna — which propagates the signal equally in all directions except the vertical — might work best. For information about which type of antenna will work best for your WLAN deployment, see the documentation for your APs.

**What model of AP will you purchase?**
The AP must be able to be configured as a RADIUS client and must support Wired Equivalent Privacy (WEP) and 802.1X authentication.

**Example: An Enterprise Corporation Mounts APs in the Plenum Area**
An enterprise corporation learned that mounting its APs in the plenum area would resolve some of the issues raised during their pilot test of their wireless network deployment.

For instance, users often disconnected data and power cables from the APs in order to plug their portable computers into the network. The unavailable APs prompted many service calls to the Help desk.

In addition, the IT staff found that by mounting APs in the plenum area, they could install APs in doorways and halls, avoiding users' offices. Though the initial installation cost was higher, they believe the placement will pay off in the long term in decreased user interference during working hours.

The enterprise corporation worked closely with the manufacturer of the APs to ensure that all procedures were followed and that the wireless APs were fire-rated for plenum placement.

# Designing for Wireless Security

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In designing security for your wireless LAN, choose the appropriate level of basic security available under IEEE 802.11 and 802.1X. Then, to close inherent security risks associated with wireless networking, require authorization and authentication of wireless clients before they exchange data with the network attached to the wireless APs, and encrypt the data sent between wireless clients and APs.

**Choosing the Right Basic Security for Your WLAN**
IEEE 802.11 open system or shared key authentication does not scale appropriately for a large, infrastructure mode wireless network (corporate offices and public places, such as airports and malls). In a large enterprise environment, you should not deploy 802.11 without also deploying 802.1X and RADIUS support.

To ensure the highest level of security for a WLAN in a corporate enterprise environment, use 802.1X with EAP-TLS authentication, a PKI, and RADIUS. The wireless clients must support 802.1X in a WLAN deployment using EAP-TLS.

Microsoft 802.1X Authentication Client provides 802.1X support for computers running any of the following Windows operating systems: Microsoft® Windows® 2000, Windows® 98, and Windows NT® version 4.0 Workstation.

**Note**

- The Microsoft 802.1X Authentication Client is only available for Windows® 98 and Windows NT® version 4.0 Workstation to customers who have Microsoft Premier Support.

Windows XP provides 802.1X support and additional wireless support, including automatic wireless configuration.

**Closing Inherent Security Risks for WLANs**
While providing convenience, wireless networking technologies and wireless APs present security risks. In wireless networks, the signals can be intercepted because the data is broadcast using an antenna. Furthermore, if the signals are not encrypted, an eavesdropper outside the premises can view the packets sent on a wireless network.

Wireless networking technologies and wireless APs present two security risks:

- Any person with a compatible wireless network adapter can associate with your wireless APs and attach to your network.
- Because wireless networking signals use radio waves to send and receive information, anyone within a certain distance of a wireless AP can detect and receive all data sent to and from the wireless AP.

**Enforcing authorization and authentication**
To counter the first security risk, wireless APs must require authentication and authorization of the wireless client before data can be sent to, and received from, the network attached to the wireless AP.

The solution is to use the combination of an 802.1X-enabled wireless client, such as Windows XP; an IEEE 802.1X-enabled and RADIUS-capable wireless AP; and EAP-capable RADIUS servers such as Windows Server 2003 IAS.

With this combination, wireless APs can send connection requests and accounting messages to central RADIUS servers. The RADIUS servers have access to a user accounts database, such as Active Directory, and a set of rules for granting authorization, such as IAS remote access policies. The RADIUS server processes the wireless AP connection request, and either accepts or rejects it.

**Encrypting data**
To counter the second security risk, encrypt the data sent between the wireless clients and the wireless APs. The method of encryption defined by the IEEE 802.11b standard is Wired Equivalent Privacy (WEP). To provide per-session strong cryptographic keys for WEP encryption, use EAP-TLS, PEAP-TLS, or PEAP-MS-CHAP v2 as the authentication method. IAS has been enhanced to support both PEAP-MS-CHAP v2 and EAP-TLS.

EAP-TLS, as defined in RFC 2716, is the TLS authentication scheme as an EAP type. TLS is used in certificate-based security environments. EAP-TLS is a secure channel (SChannel) authentication protocol that provides for mutual authentication, integrity-protected cipher-suite negotiation, and key exchange between the two endpoints by means of public key cryptography.

PEAP-MS-CHAP v2 provides a secure wireless authentication solution for small businesses without requiring a certificate infrastructure (PKI) and the installation of a user or computer certificate on each wireless client. With PEAP, you can use a password-based authentication method to securely authenticate wireless connections. PEAP creates an encrypted channel before the password-based authentication occurs. Therefore, password-based authentication exchanges such as occur in MS-CHAP v2 are not subject to offline dictionary attacks.

**Note**

- PEAP with MS-CHAP v2 is provided with Windows XP Service Pack 1 (SP1) and later, Windows Server 2003, and Microsoft 802.1X Authentication Client.

# Designing Unauthenticated Access

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Unauthenticated EAP-TLS access can be useful in both corporate and public space environments.

In a corporate environment, this feature can be used to grant guest access to visitors such as consultants. The unauthenticated users are redirected to a specific virtual LAN (VLAN), which provides only limited network access, such as access to the Internet.

In a public space environment, a wireless Internet service provider (ISP) can use this feature to give potential subscribers access to a restricted VLAN with local information. When the person subscribes for Internet access, the ISP provides connectivity to the Internet.

EAP-TLS unauthenticated access provides a means to grant guest access for a wireless client that does not have a certificate installed. EAP-TLS supports one-way authorization or unauthenticated access when a client does not send credentials. If a network access client does not provide credentials, IAS determines whether unauthenticated access is enabled in the remote access policy that matched the connection attempt.

Windows Server 2003 and IAS support unauthenticated wireless connections. For more information about unauthenticated wireless access, see "Wireless access" in Help and Support Center for Windows Server 2003.

# Designing a Public Space WLAN

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you plan to deploy a public space WLAN in a venue such as an airport or shopping mall, you need to design your WLAN to meet some additional requirements.

- Plan for a single wireless network infrastructure that multiple service providers can share and access.

  A single wireless network infrastructure eliminates radio frequency interference. Because of the finite number of non-overlapping channels available in 802.11b, multiple wireless network infrastructures in the same location cause interference among wireless APs with overlapping channel frequencies.

- Make sure that the APs support VLANs, the capability for beaconing multiple Service Set Identifiers (SSIDs, also known as *network names*), and the capability for binding each SSID to a separate VLAN.

  Enhanced APs are necessary in a public space WLAN deployment. VLAN support enables the AP to route the wireless client to the correct network path. The capability for beaconing multiple SSIDs enables multiple service providers to share the same wireless network infrastructure. After the wireless client associates with the correct SSID, the AP must bind that SSID to the correct VLAN in order to route the network traffic to the correct destination. The AP maintains a table that maps each SSID to its respective VLAN number. The public space WLAN also must allow non-802.1X wireless clients access. To support this, you must assign a VLAN number for all non-802.1X wireless clients. The VLAN number routes the non-802.1X clients to a VLAN that is configured to provide non-802.1X clients with 802.1X credentials.

- To provide security, you need an IEEE 802.1X and RADIUS-capable wireless AP, and an EAP-capable RADIUS server such as Windows Server 2003 IAS.

- You might need to provide billing and accounting for services provided to customers connecting through the public space WLAN.

  A public space WLAN must provide a means for charging for services provided, typically by an ISP, to customers connecting through the public space WLAN. An ISP can charge the customer for this service in several ways. It can bill for the total time connected, the quantity of data transferred, or a combination of the two methods.

  You can configure the same IAS server that is used for the authorization of wireless users to capture this connection data and save it to an accounting log file. The log file contains the connection time, the amount of data transferred during a session, and other data that can be used to produce billing records for ISP customers. Database exporting can convert the log files into a format that can be read and interpreted to provide the billing records. IAS for Windows Server 2003 can also be configured to send accounting information to a SQL server database.

  In addition, third-party software is available to create billing solutions.

- Provide sufficient bandwidth to support the volume of users likely to use a public space WLAN.

  In designing a public space WLAN, consider how many users need to connect simultaneously through each AP. For example, if you design for an average bandwidth of 56 kilobits per second (Kbps), approximating a 56K modem, more users will be able to associate with the network than if you design the average bandwidth to be more than 56 Kbps.

Figure 11.6 shows the infrastructure for a public space WLAN with 802.1X designed for an airport. This public space WLAN enables ISPs to provide Internet access for general and corporate users with wireless devices that are 802.11b-capable.

**Figure 11.6 Example of a Public Space WLAN Infrastructure in an Airport**

**Example: Public Space WLAN Access**
A user with a computer running Windows XP (with the Wireless Zero Configuration [WZC] service and IEEE 802.1X) starts his computer. The wireless adapter attempts to authenticate with an AP, but can only associate with VLAN 0 since it has no authorization for VLAN 1, the ISP network for the airport. When associated with VLAN 0, the wireless device is directed to the airport's ISP Web server.

The Web server queries the user about access to the Internet or another company's network. As a free service, the ISP's Web site provides local travel information, including arrival and departure times and restaurants. If the user chooses to set up an account, the ISP creates the account for billing purposes and provides the wireless user with a certificate to join VLAN 1.

The wireless user now has a certificate and can access VLAN 1. The user is authenticated using IAS, which simultaneously creates or appends a log file. The log file and new user account are both used for billing purposes. The wireless user is granted permission to access the Internet.

If the user decides to access his own corporate network across the Internet, a virtual private network (VPN) connection can be created from the wireless client to a VPN server in the perimeter network.

### Notes

- As an alternative to a VLAN, a public space wireless network can support IP filtering. This requires the use of APs that are capable of IP filtering and can be configured to restrict access to only the IP addresses for the ISP's certificate, DHCP, and Web servers. These servers provide the minimum connectivity and services that are required in order to obtain authenticated access.

- If an AP is associated with repeatedly when you use IP filtering for authentication, the AP can consume the allotted quantity of IP addresses that the DHCP server has set aside, preventing additional wireless clients from obtaining an IP address. Although the infrastructure for IP filtering is less costly, because IP filtering saves a switch and a server, IP filtering is less secure. For these reasons, it is better to use a VLAN than IP filtering for a public space wireless network.

# Designing for Manageability

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For a large wireless deployment to be practical, it must be easy to manage. The combination of Windows XP and Windows Server 2003 allows for efficient management of your wireless network.

For optimal manageability of your wireless network, ensure that your wireless clients use Windows XP, which provides support for automatic switching between APs during roaming and support for zero configuration through the WZC. Although you can use other Windows operating systems with Microsoft 802.1X Authentication Client, they do not support zero configuration.

**Automatic Switching Between APs During Roaming**

Windows XP supports automatic switching between APs when roaming, autodetection of wireless networks, 802.1X, and automatic wireless configuration.

Windows XP has improved and built upon the wireless support for clients that Windows 2000 provides. In Windows 2000, *media sense capability* (the capability for detecting an attached network) is used to control the configuration of the network stack and inform the user and applications when the network is unavailable. With Windows XP, media sense capability is used to enhance the wireless roaming experience. This is done by detecting a move to a new AP and then forcing re-authentication and DHCP renewal to ensure appropriate network access during roaming. Windows XP in addition supports autodetection of a wireless network, and automatic wireless configuration with the Wireless Zero Configuration (WZC) service.

**Distributing Certificates Through Autoenrollment**

An IAS server, which acts as a RADIUS server and proxy, also supports EAP–TLS. Because both Windows XP and IAS in Windows Server 2003 support EAP-TLS, the combination gives you support for a strong authentication method and a per-session key management system. To ease deployment, you can distribute the computer and user certificates used for authentication through certificate autoenrollment. *Autoenrollment* is the automatic requesting and issuing of certificates based on Group Policy settings.

Table 11.2 lists the types of certificates (user, computer, or both) for which autoenrollment is supported with each combination of client and server operating system. When using any other clients, such as Windows NT or Windows 98, you must manually enroll each client or use a scripted solution.

**Table 11.2 Support for Autoenrollment of Certificates Provided in Windows**

| Client | Server | Computer | User |
|---|---|---|---|
| Windows XP or Windows Server 2003 | Windows Server 2003 | ● | |
| Windows XP or Windows Server 2003 | Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition | ● | ● |
| Windows XP or Windows Server 2003 | Windows 2000 Server | ● | |
| Windows 2000 | Windows Server 2003 | ● | |
| Windows 2000 | Windows 2000 Server | ● | |

For more information about the design and deployment of IAS, see "Deploying Internet Authentication Service (IAS)" in this book.

**Taking Advantage of Autoconfiguration**

The addition of the Wireless Zero Configuration (WZC) service in Windows XP improves the manageability of your wireless network. The WZC service dynamically selects the wireless network to which to attempt connection based either on your preferences or on default settings. When a more preferred wireless network becomes available, the WZC service automatically selects and connects to that network. If none of the preferred wireless networks is found nearby, the WZC service configures the wireless adapter so that there is no accidental connection until the wireless client roams within the range of a preferred network.

To improve the roaming experience by automating the process of configuring the network adapter to associate with an

available network, Microsoft partnered with 802.11 wireless adapter vendors. The wireless network adapter scans for available networks and passes them to Windows XP, which then configures the wireless network adapter with an available network. If you are not using a WZC-capable network adapter, you must configure the network adapter manually by using the configuration software that the manufacturer provides.

For improved manageability of your wireless network, ensure that your wireless clients are using Windows XP so the WZC service is available. Windows Server 2003 also provides this service, which is known in Windows Server 2003 as the Wireless Configuration service. The Microsoft 802.1X Authentication Client does not provide WZC and roaming support.

**Managing APs Remotely**

For better manageability, design your network so that you can manage your APs from a remote location. You can remotely manage APs by using the AP console port (serial port) and an asynchronous terminal server, a Telnet session, or a Web server that is integrated with the AP.

To configure an AP for network access by an asynchronous terminal server, use the two unused pairs of Ethernet cable to return the serial communication lines to the data closet where they can be connected to an asynchronous terminal server. This enables you to configure an AP remotely if necessary. If you arrange to switch power off remotely, you can also restart APs remotely when they are not responding to a signal from an Ethernet or console port.

Using these methods, you will be able to completely manage APs remotely except when an AP fails and must be repaired or replaced.

**Using Active Directory-based Wireless Network Policies**

To centrally manage the configuration of secure wireless connections for wireless client computers, you can create Active Directory-based wireless network policies that specify the types of networks that users can access, preferred networks, WEP settings, IEEE 802.X settings, and other settings for wireless connections. The settings are configured in Group Policy, in Wireless Network (IEEE 802.1) Policies. The wireless network policy is replicated to computers that are associated with the computer configuration Group Policy object. Users do not need to enter the configurations or select settings.

For example, you can configure the following items in the Wireless Network (IEEE 802.11) Policies settings:

- Types of networks that users can access

  For example, you might restrict users' access to an AP (infrastructure) network only, or to a computer-to-computer (ad hoc) network only.

- Network name (SSID)

- WEP settings

- Enabling of network access control using IEEE 802.1X

- Authentication methods and settings

The Wireless Network (IEEE 802.1) Policies settings are only supported by wireless clients running Windows XP (SP1 and later) and Windows Server 2003.

For information about:

- Opening the Group Policy Object Editor, see "Ways to open Group Policy Object Editor" in Help and Support Center for Windows Server 2003. (Click the **Index** button, and in the keyword box type **Group Policy Object Editor**; then select **opening**.)

- Adding and defining wireless network policies, see "Define Active Directory-based wireless network policies" in Help and Support Center for Windows Server 2003.

- Designing wireless network policies, see "Deploying Security Policy" in *Designing a Managed Environment*.

# Implementing a WLAN Test Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before embarking on a full-scale WLAN deployment on your enterprise network, perform a trial deployment on a WLAN test network in your lab to familiarize yourself with how the technology works and resolve any issues that arise before deploying the enterprise WLAN. After setting up your WLAN test environment, perform a limited test to ensure that all components are working together under a simplified certificate infrastructure. Then expand the test environment, testing your Group Policy design and a three-tier CA infrastructure. Figure 11.7 shows the process for implementing a WLAN test environment.

**Figure 11.7 Implementing Your WLAN Test Environment**

# Setting Up Your WLAN Test Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Keep your initial WLAN test deployment simple so that you can focus on successfully installing and configuring the essential components. To simplify your initial test:

- Test a basic, single-tier PKI.

  When you deploy your enterprise WLAN, it is recommended that you provide the extra security of a three-tiered certificate infrastructure in which the root CA is offline. For guidelines for designing a certificate infrastructure, see "Designing a Public Key Infrastructure" in *Designing and Deploying Directory and Security Services*.

- Omit using Group Policy in your initial test.

  In your production deployment, you will want to use Group Policy to preconfigure and control the following Wireless Network (IEEE 802.11) Policies settings for Windows XP (SP1 and later) and Windows Server 2003 wireless clients:

  - Types of networks that users can access

    For example, you might restrict users' access to an AP (infrastructure) network only, or to a computer-to-computer (ad hoc) network only.

  - Network name (SSID)

  - Wireless network key (WEP) settings

  - Enabling of network access control using IEEE 802.1X

  - Authentication methods and settings

In your initial test deployment, install and configure the following components and services:

- Wireless APs
- Active Directory
- DNS and DHCP
- A single-tier PKI
- At least one RADIUS server (IAS)
- Wireless clients

After successfully deploying your initial WLAN test environment, add the use of Group Policy and deploy a WLAN with a three-tier PKI in your lab, and confirm that your WLAN still functions properly, to prepare for a successful production deployment.

# Configuring Wireless APs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Configure your wireless APs according to the manufacturer's specifications.

To provide secure wireless connectivity, the APs must support WEP and 802.1X authentication.

Because your WLAN uses 802.1X and RADIUS, you do not need to manually enter the WEP keys: They are generated automatically during the EAP-TLS and PEAP-MS-CHAP v2 authentication process. (Most APs include the option for manually entering the WEP keys on the AP, which you can do if needed for the test deployment.)

In configuring the AP, you enter a value for the RADIUS shared secret, which you will later enter on the IAS server when you add the AP as a RADIUS client on the IAS server.

# Configuring Active Directory for the WLAN

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Your test deployment must include at least one Active Directory–based domain controller.

Perform the following configuration tasks in Active Directory:

- Configure the remote access permission on wireless user and computer accounts.
- Create a group for wireless user and computer accounts. You will create a remote access policy for the group.
- Register the IAS server in Active Directory.

**Configuring the Remote Access Permission**

To grant wireless user accounts and wireless computer accounts permission to access the network remotely, set the remote access permission in the computer and user accounts.

**To configure the remote access permission on wireless user and computer accounts**

1. On a domain controller (or on a member server on which the Active Directory snap-ins are installed), open Active Directory Users and Computers.
2. To configure each wireless user account with the permission to access the network remotely, right-click the user object in the **Users** folder, click **Properties**, click the **Dial-in** tab, and then under **Remote Access Permission (Dial-in or VPN)**, select either **Control access through Remote Access Policy** (for native-mode domains) or **Allow access** (for mixed-mode domains).
3. To configure each computer account with the permission to create wireless connections, right-click the computer object in the **Computers** folder, click **Properties**, click the **Dial-in** tab, and then under **Remote Access Permission (Dial-in or VPN)**, select either **Control access through Remote Access Policy** (for native-mode domains) or **Allow access** (for mixed-mode domains).

**Create a Group for Wireless Users and Computers**

Create an Active Directory group to contain wireless users and computers. Later in the test deployment, you will create a group-based remote access policy for wireless connections and specify the group.

**To create a group for wireless users and computers**

1. Open Active Directory Users and Computers.
2. Create a group for wireless users. For the test deployment, accept the default group scope — that is, create a global group.

   For information about how to add a group, see "Creating user and group accounts" in Help and Support Center for Windows Server 2003.
3. Add each user account for wireless users and each computer account to be used for wireless access as a group member.

   For information about how to add a member to a group, see "Changing group memberships" in Help and Support Center for Windows Server 2003.

   **Tip**

   - If you are unable to add computer objects when adding members to a group, use the **Object Types** button in the **Select Users, Contacts, Computers, or Groups** dialog box to add computers to the types of objects that you can

add to a group.

**Register the IAS Server in Active Directory**

The next step in setting up your WLAN test environment is to use the IAS snap-in to register the IAS server in Active Directory. The following procedure registers the IAS server by using the Internet Authentication snap-in.

**To register the IAS server in Active Directory**

1. Open the Internet Authentication Service snap-in on the IAS computer.

2. Right-click **Internet Authentication Service (Local)** for the IAS server, and then click **Register Server in Active Directory**.

3. When asked if you want to authorize this computer to read users' dial-in properties for this domain, click **OK**.

   **Note**

   - This procedure registers the IAS server only in its member domain, which is all that you need for your test deployment. For your production deployment, you will need to register the IAS server in its member domain, trusted domains, and so on. For information, see "Enable the IAS server to read user accounts in Active Directory" in Help and Support Center for Windows Server 2003.

# Configuring DNS and DHCP

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To support wireless computers in your test lab, your test deployment must include one or more servers running the DNS and DHCP services.

Configure the DNS and DHCP services as follows:

1. On the DNS server:

    a. Ensure that the DNS zone in which the wireless computers will register DNS address records is configured for dynamic updates.

    b. Optionally, specify that the DNS zone is an Active Directory-integrated zone, which provides secured updates, and that the DNS zone is to be updated by DHCP.

2. On the DHCP server, configure a separate scope and lease duration for your wireless client computers.

    The DHCP scope should not include the static IP addresses of your APs or any of your servers.

    For more information about configuring DHCP for your wireless deployment, see "Adapting the Network Infrastructure for a WLAN" earlier in this chapter. For information about configuring scopes and lease durations on a DHCP server, see "Deploying DHCP" in this book.

# Deploying a Certificate Infrastructure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For your initial test lab deployment, use a simple certificate infrastructure. To be able to integrate the certificate services with Active Directory in your test environment (and, later, to use Group Policy to provide easier management of wireless clients), you must install the CA as an enterprise CA. After installing your enterprise root CA, you can install a computer certificate on the IAS server and install user and computer certificates on your wireless computers.

To set up the certificate infrastructure for your initial test environment, perform the following tasks:

- Install a single-tier CA.
- Install a computer certificate on the IAS server.
- Install user and computer certificates on wireless computers.

**Installing a Single-Tier CA**

To keep your initial test deployment simple, install a single-tier CA.

**To install a single-tier CA in your test environment**

- Install the enterprise root CA either on the domain controller or on a separate member server in your test environment.

  You must be logged on as a member of both the Enterprise Admins group and the Domain Admins group for the root domain.

  For installation instructions, see "Install an enterprise root certification authority" in Help and Support Center for Windows Server 2003. For your test lab deployment, you do not need to add certificate templates to the CA or configure the CA to allow subjects to request a certificate based on a template.

**Installing a Computer Certificate on the IAS Server**

On the IAS server, install a computer certificate from the issuing CA, which, in the single-tier CA infrastructure that you will deploy in your WLAN test environment, is the enterprise root CA. For your test lab deployment, use the Certificates Request Wizard located in the Certificates snap-in to obtain a computer certificate.

Start by creating a Certificates console on the IAS server that contains the Certificates - Local Computer snap-in, which you will use to request the computer certificate.

**To install a computer certificate on the IAS Server**

1. Create a Certificates console on your IAS server that contains the Certificates - Local Computer snap-in. For the test lab deployment, name the console Certificates.

   For information about how to add a snap-in to manage certificates, see "Manage certificates for a computer" in Help and Support Center for Windows Server 2003. To perform this task, you must be a member of the Domain Admins group (or a member of the Administrators group on the local computer).

2. Use the Certificates console to request a computer certificate for the IAS server.

   To install a computer certificate, click **Certificates - Local Computer** in the console tree, and select **Computer** as the certificate type (unless your IAS server is also a domain controller, in which case your only option is to select **Domain Controller**). For more information about how to use the Certificates console to request a certificate, see "Request a certificate" in Help and Support Center for Windows Server 2003.

For more information about using the Certificates Request Wizard for installing computer certificates, in addition to two alternative methods, see "Computer certificates for certificate-based authentication" in Help and Support Center for Windows

Server 2003.

**Verifying that the computer certificates meet IAS requirements**

Each computer certificate installed on an IAS server must meet the following requirements:

- The certificate must be installed in the Local Computer certificate store.
- The cryptographic service provider for the certificate must support the secure channel (Schannel) security package. If not, the IAS server cannot use the certificate, and the certificate is not available for selection in the properties of the **Smart Card or other certificate** EAP type in the remote access policy.

The computer certificate for the IAS server must meet additional requirements. The following procedure tells how to verify each requirement.

**To verify that the computer certificate for the IAS server meets all requirements**

1. From the **Certificates** console, double-click the certificate to open it.
2. On the **General** tab, confirm that **You have a private key that corresponds to this certificate** appears.
3. On the **Details** tab, under **Field**, click **Enhanced Key Usage**, and then confirm that there is an object identifier for Server Authentication (1.3.6.1.5.5.7.3.1).
4. On the **Details** tab, under **Field**, click **Subject Alternative Name**, and then confirm that the fully qualified domain name (FQDN) of the computer account for the IAS server (for example, **DNS Name=*IASServerName.TestDomainName*.com**) appears.
5. On the **Certification Path** tab, confirm that a valid certification path appears and that the statement **This certificate is OK** appears.

**Verifying the root CA certificate**

The root CA certificate of the CA that will issue the wireless client computer and user certificates must be installed in the Trusted Root Certification Authorities certificate store. The following procedure tells how to verify this.

**To verify that the root CA is in the Trusted Root Certification Authorities store**

1. From the Certificates console, expand **Certificates - Local Computer**, expand **Trusted Root Certification Authorities**, and then click **Certificates**.
2. In the **Details** pane, confirm that the name of your test lab enterprise root CA appears in the **Issued To** list.

   If the root CA is not in the list, you might need to refresh the display. To do this, **click Action**, and then click **Refresh**.

**Installing User and Computer Certificates on Wireless Clients**

When EAP-TLS is in use, as in your test lab deployment, wireless clients should have both a computer certificate and a user certificate in order to be authenticated to the network. When PEAP-MS-CHAP-v2 is in use, the root CA certificates of the issuing CAs for the computer certificates on the RADIUS servers must be installed on the wireless clients. You can do this manually by importing the root CA certificate on each wireless client, or you can publish the root CA certificate using Group Policy.

For your test lab deployment, use the Certificate Request Wizard located in the Certificates snap-in on the wireless client computer to obtain both a computer certificate and a user certificate for each wireless computer in your test lab.

**Before you begin**

- Connect the wireless client directly to the wired network that contains the CA infrastructure.

  The connection is required in the test environment in order for the wireless client to receive computer and user certificates. In your enterprise environment, this step might not be necessary, depending upon how you decide to deploy certificates.

If you connect the wireless client to the wired network, you can install the user certificate on the wireless client by using the Certificates - Current User snap-in (as described in the procedure), by using autoenrollment, by submitting a certificate request over the Web, or by implementing a CAPICOM program or script. If you prefer not to make a temporary connection between the wireless client and the wired network, you can install the certificate from a floppy disk.

**Note**

- CAPICOM is a COM client, supporting Automation, that performs cryptographic functions (the CryptoAPI) using Microsoft® ActiveX® controls and COM objects.

**To install user and computer certificates on a wireless client**

1. Create a single console that contains two snap-ins, for managing computer certificates and user certificates. For the test deployment, name the console Certificates.

   a. Install the snap-in for computer accounts under the name **Certificates - Local Computer**.

      For information about how to install a snap-in for managing computer certificates, see "Manage certificates for a computer" in Help and Support Center for Windows Server 2003.

   b. Install the snap-in for user accounts under the name **Certificate - Current User**.

      For information about how to install a snap-in for managing user certificates, see "Manage certificates for your user account" in Help and Support Center for Windows Server 2003.

   To install both snap-ins, log on under a user account with administrative credentials for the local computer. (You can install the user certificates snap-in but not the computer certificates snap-in if you log on under a user account in the test domain.)

   **Note**

   - For the initial test deployment, to receive computer and user certificates, the wireless client must be connected directly to the wired network that has the CA infrastructure.

2. Use the **Certificates - Local Computer** snap-in to request a computer certificate for the wireless client.

   For instructions telling how to use the Certificates console to request a computer certificate, see "Request a certificate" in Help and Support Center for Windows Server 2003.

   The Help topic provides instructions for requesting a *user* certificate. To request a *computer* certificate, instead of clicking **Certificates - Current User** in the console tree, click **Certificates - Local Computer**. Then, when prompted for a certificate type, select **Computer**.

3. Use the **Certificates - Current User** snap-in to request a user certificate.

   For instructions telling how to use the Certificates console to request a user certificate, see "Request a certificate" in Help and Support Center for Windows Server 2003. When prompted for a certificate type, select **User**.

**Verifying that the certificates meet all requirements**

After installing the computer and user certificates, perform the following procedures to verify that the certificates meet all requirements for the client to perform properly over a wireless connection.

**To verify that the computer certificate for the wireless client meets requirements**

1. Verify that the computer certificate is installed in the Local Computer certificate store (required for EAP-TLS

authentication).

After verifying the correct certificate store, verify the certificate configuration.

2. From the **Certificates** console, double-click the certificate to open it.

3. On the **General** tab, confirm that the statement **You have a private key that corresponds to this certificate** appears.

4. On the **Details** tab, under Field :

    a. Click **Enhanced Key Usage**, and confirm that the object identifier for Client Authentication is 1.3.6.1.5.5.7.3.2.

    b. Click **Subject Alternative Name**, and confirm that the FQDN of the wireless computer account (for example, **DNS Name=*LaptopName.TestDomainName*.com**) appears.

5. On the **Certification Path** tab:

    a. Confirm that a valid certification path appears.

    b. Confirm that the statement **This certificate is OK** appears.

**To verify that the user certificate for the wireless client meets requirements**

1. Verify that the user certificate is installed in the Current User certificate store (required for EAP-TLS authentication).

2. From the **Certificates** console, double-click the certificate to open it

3. On the **General** tab, confirm that **You have a private key that corresponds to this certificate** appears.

4. On the **Details** tab, under **Field**, confirm the following items:

    a. Click **Enhanced Key Usage**, and confirm that the object identifier for Client Authentication is 1.3.6.1.5.5.7.3.2.

    b. Click **Subject Alternative Name**, and confirm that the universal principal name (UPN) of the user account (**PrincipalName=*WirelessUserName@TestDomainName*.com**, for example) appears.

5. On the **Certification Path** tab:

    a. Confirm that a valid certification path appears.

    b. Confirm that the statement **This certificate is OK** appears.

# Configuring the RADIUS (IAS) Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you configure your RADIUS server, open Active Directory Users and Computers and verify that your IAS server is a member of the RAS and IAS Servers group.

Configure your RADIUS (IAS) server by performing the following tasks:

1. Add each wireless AP to the IAS server as a RADIUS client.

2. Create a remote access policy for wireless clients.

**Adding APs as RADIUS Clients**

On the IAS server, add each wireless AP as a RADIUS client. You will need to type the RADIUS shared secret that you configured earlier on the wireless AP.

**To add a wireless AP as a RADIUS client on the IAS server**

1. Open the Internet Authentication Service snap-in.

2. In the console tree, right-click the **RADIUS Clients** folder, and then click **New RADIUS Client**.

3. In the **Friendly name** field, type a name for the AP.

4. In the **Client address (IP or DNS)** field, type the IP address of the wireless AP. Then click **Next**.

5. If the remote access policy for wireless users is designed for a specific model of wireless AP (for example, a remote access policy that contains vendor-specific attributes), in the **Client Vendor** list, select the manufacturer's name.

   If you do not know the manufacturer, accept the default value, **RADIUS Standard**.

6. In the **Shared secret** and **Confirm shared secret** fields, type the shared secret value that you assigned when you configured the AP.

**Creating a Remote Access Policy for Wireless Clients**

To give wireless users access to the network, create a remote access policy for wireless clients, and then configure that policy for the highest level of encryption. To use IAS, you must be logged on using an account that has administrative credentials.

**To add a remote access policy for wireless clients**

1. Open the Internet Authentication Service snap-in.

2. In the console tree, right-click **Remote Access Policies**, and then click **New Remote Access Policy**.

3. Complete the New Remote Access Policy Wizard using the information provided in Table 11.3. Accept default settings when no information is specified.

   **Table 11.3 Adding a Remote Access Policy for Wireless Users**

| Wizard Page | Action |
|---|---|
| Policy Configuration Method | For **Policy Name**, type an appropriate name, such as WLAN Test Policy. |

| | |
|---|---|
| Access Method | Select **Wireless**. |
| User or Group Access | Click **Group**, and then click **Add**.<br><br>In the **Select Groups** dialog box, type the name of the group that you created for wireless users, and then click **Check Names** to confirm that the name you typed is correct. |
| Authentication Methods | Select **Smart Card or other certificate**. |

**To configure encryption for the new remote access policy**

1. In the console tree of the Internet Authentication Service snap-in, right-click the newly created wireless access policy, and then click **Properties**.

2. Verify that **Grant remote access permission** is selected, and then click **Edit Profile**.

# Configuring the Wireless Adapter on Wireless Clients

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

On each wireless client, you can manually configure the wireless adapter to recognize the wireless network that the client must access in order to gain wireless connectivity. However, this is generally not necessary, because Windows XP will sense the wireless network and prompt the user via the notification bar. Once the user selects the network name, the network is automatically added to the preferred networks list.

**To manually configure the client computer's wireless adapter to recognize the AP**

1. On the wireless computer, log on under a user account with administrative credentials on the local computer, and open **Network Connections**.

2. Right-click the wireless adapter icon, and click **Properties** to display properties for the wireless network adapter.

3. To configure TCP/IP for the wireless adapter, on the **General** tab, type the static IP address for your DNS server.

4. On the **Wireless Networks** tab, confirm that the name of the wireless network that you added appears in the **Available Networks** list.

5. Disable the network adapter that connects the client computer to the wired network, and then disconnect the client computer from the wire that connects it to the network.

# Testing Your Limited WLAN Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To test the deployment of your wireless network, roam the entire coverage area for your wireless network, associating with one AP after another. Use your floor plan (with the APs marked on it) to mark the areas that provide adequate coverage and those that require more troubleshooting. You should be able to roam around the building, associating with one AP after another, and test applications.

As you roam through coverage areas, perform the following tests to ensure that your wireless network will provide strong, uninterrupted coverage for wireless clients:

- Use the client software that the adapter manufacturer provided for the wireless device to determine that the wireless client associates with the nearest AP.

  If the wireless client does not readily associate with the closest AP when you move from one AP's coverage area to the next, turn the network adapter's radio off and back on using software provided by the adapter manufacturer. This forces the wireless adapter to find the strongest signal, which usually is the closest AP.

  The wireless client's ability to associate with an AP is determined by the error rate of the data packets and the signal strength. If the coverage from the first AP is still strong, the wireless transceiver receives few bad packets and maintains its association. If the closest AP is failing to associate with the wireless client, restarting the radio of the wireless network adapter forces the wireless adapter to find the strongest signal, which usually is the closest AP.

- Check the statistics for error rates and signal strength to be sure that they are within limits. Check the AP for throughput to determine whether the data transfer rate is adequate.

The following troubleshooting tools also can be useful when testing and deploying your WLAN:

- Use the Wireless Monitor MMC snap-in, included with Windows Server 2003, to gather and view statistical and configuration information for wireless APs and the Windows Server 2003 wireless client.

- Use a spectrum analyzer to determine the location and strength of interfering signals as you move from one signal area to another. A *spectrum analyzer* measures radio frequency radiation from low to high frequencies across a frequency spectrum. These signals are plotted on a graph that shows their strength and frequency. If necessary, you can shield or move any devices that are causing interference.

- Use a *protocol analyzer* to document usage intervals and traffic load. You can use Network Monitor or third-party tools to capture 802.11 packets sent between a wireless client and a wireless AP. With a protocol analyzer, you can capture 802.11 packets, but cannot view the contents of the encrypted payloads.

# Expanding Your WLAN Test Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After successfully deploying and testing a simple wireless network, you can add more complex features — such as Group Policy settings to more easily deploy and manage wireless clients, and a three-tier CA infrastructure to provide greater security for your enterprise WLAN.

Each time that you add a new component or feature, test your new deployment before expanding your test deployment further.

**Configuring Group Policy Settings**
For your initial test deployment, you configured your wireless clients without creating the Active Directory-based wireless network policies that enable you to preconfigure and replicate the wireless client configuration to all wireless clients. Wireless network policies are created by configuring Wireless Network (IEEE 802.11) Policies settings in Group Policy.

In addition, you did not use Group Policy to configure autoenrollment, which enables you to install certificates for the wireless clients automatically.

Instead, you manually configured some of the wireless client settings and used the Certificates console on the client computer to request the computer certificate. (Alternatively, you could have used Web enrollment to request the user or computer certificate.)

However, in your production WLAN deployment, you will want to use Group Policy to provide easier deployment and management of wireless clients and to enable autoenrollment for the installation of the certificates. Before embarking on an enterprise deployment of your WLAN, configure and test Group Policy settings to enable these features.

**Note**

- To support automatic computer certificate allocation, the issuing CA must be an enterprise CA server running either Windows 2000 or Windows Server 2003. To support automatic user and computer certificate allocation, the issuing CA must be an enterprise CA server running either Windows Server 2003, Enterprise Edition or Windows Server 2003, Data Center Edition.

When you configure Group Policy settings to support your WLAN, decide whether you want to manage wireless connections through the domain or create a separate organizational unit (OU) for this purpose. Using an OU might be more efficient than entering Group Policy settings for the domain, which includes both wired and wireless clients.

**Note**

- If you need to force a Group Policy update on the wireless client during your testing, you can use Gpupdate command-line tool. For Gpupdate parameters, see "Command-line reference" in Help and Support Center for Windows Server 2003.

For more information about:

- Designing OUs, see "Designing the Active Directory Logical Structure" in *Designing and Deploying Directory and Security Services*.
- Designing group policies, see "Designing a Group Policy Infrastructure" in *Designing a Managed Environment*.
- Deploying autoenrollment, see "Planning for autoenrollment deployment" in Help and Support Center for Windows Server 2003.
- The appropriate way to open Group Policy Object Editor for a specific type of object, see "Ways to open the Group Policy Object Editor Ways to open Group Policy Object Editor" in Help and Support Center for Windows Server 2003. (Click the **Index** button, and in the keyword box type **Group Policy Object Editor**; then select **opening**.)
- Adding and defining wireless network policies, see "Define Active Directory-based Wireless Network Policies" in Help and

Support Center for Windows Server 2003.

**Installing a Three-Tier CA**

When you deploy your enterprise WLAN, it is recommended that you provide the extra security of a three-tier certificate infrastructure in which the root CA is offline. Therefore, after you finish deploying and testing your WLAN test environment with a single-tier CA, and then introducing Group Policies and retesting, it is a good practice to install a test version of the CA infrastructure that you plan to implement in your enterprise environment in your lab before doing so in your production environment.

For information about designing and deploying a certificate infrastructure, see "Designing a Public Key Infrastructure" in *Designing and Deploying Directory and Security Services*.

# Deploying Windows Firewall

Updated: June 8, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To protect your network from the growing number of malicious attacks, you need to adopt a defense-in-depth strategy. A defense-in-depth strategy incorporates a variety of network security technologies into your security architecture and implements those technologies in a layered structure that extends from your perimeter network (outer layer) to every computer in your organization (inner layer). By providing host firewall protection on the innermost layer of your network, Windows Firewall, a new security component in Microsoft® Windows Server™ 2003 with Service Pack 1 (SP1), can be an effective part of your defense-in-depth security strategy.

**In This Chapter**

Overview of Windows Firewall Deployment

Step-by-Step Guide for Using Windows Firewall

Deploying Windows Firewall with Group Policy

Deploying Windows Firewall During an Unattended Installation

Deploying Windows Firewall with a Netfw.inf File

# Overview of Windows Firewall Deployment

Updated: June 8, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

By default, Windows Firewall is turned off (disabled) in Windows Server 2003 with Service Pack 1 (SP1). In addition, when Windows Firewall is turned on, all unsolicited incoming Internet Protocol version 4 (IPv4) and Internet Protocol version 6 (IPv6) traffic that uses UDP or TCP is blocked. Therefore, to deploy Windows Firewall you must turn on (enable) Windows Firewall and configure Windows Firewall settings so that unsolicited incoming traffic is allowed to reach the programs and services that are acting as servers, listeners, or peers.

The Security Configuration Wizard (SCW) is the recommended tool for deploying Windows Firewall in small, medium, and large organizations. SCW is an optional component that must be installed through **Add or Remove Programs** in Control Panel. SCW guides you through the process of creating a security policy, based on the roles performed by a given server. Once a policy is created, it can be edited or applied to one or more similarly configured servers. For more information, see Configuring Windows Firewall with SCW on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48116).

In addition to SCW, there are several other deployment tools that are suitable for small-scale and large-scale deployments of Windows Firewall.

**Small-Scale Deployments**
If you are deploying Windows Firewall to a small number of servers, you can use Windows Firewall in Control Panel to turn on Windows Firewall and configure Windows Firewall settings on a server-by-server basis. This deployment method is not efficient if you are deploying more than a few servers, and can result in inconsistencies among your server configurations. Therefore, this deployment method is recommended only for small organizations or for servers that require special configuration settings. For more information about deploying Windows Firewall by using Windows Firewall in Control Panel, see the Step-by-Step Guide for Using Windows Firewall.

**Large-Scale Deployments**
If you are deploying Windows Firewall to a large number of servers, you can use one of the following tools to automate the startup and configuration of Windows Firewall.

**Windows Firewall Group Policy Settings**
Windows Server 2003 with SP1 includes several new Group Policy settings that allow you to configure Windows Firewall using domain-based or local Group Policy. Using the Windows Firewall Group Policy settings is the recommended method for deploying Windows Firewall in organizations that use Active Directory. For more information about deploying Windows Firewall with Group Policy, see Deploying Windows Firewall with Group Policy.

**Unattended Installation Answer File**
Windows Server 2003 with SP1 includes several new answer file entries that allow you to enable or disable Windows Firewall and configure Windows Firewall settings. This deployment solution is recommended if your organization does not use Active Directory or Group Policy and you are rolling out slipstream installations of Windows Server 2003. For more information about using an answer file to deploy Windows Firewall, see Deploying Windows Firewall During an Unattended Installation.

**Netfw.inf Information File**
Windows Server 2003 with SP1 includes a Netfw.inf file that you can use to configure Windows Firewall settings while you are installing SP1 or while you are performing a slipstream installation of Windows Server 2003 with SP1. The Netfw.inf file is primarily used by original equipment manufacturers (OEMs) in a manufacturing environment, but it can also be used in a corporate environment during a large-scale rollout. For more information, see Deploying Windows Firewall with a Netfw.inf File.

# Step-by-Step Guide for Using Windows Firewall

Updated: June 8, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Set up Windows Firewall for the first time using a four-step process: review Windows Firewall limitations, turn on Windows Firewall, configure Windows Firewall exceptions, and configure advanced settings.

This step-by-step guide shows you how to start and configure Windows Firewall for the first time on a computer that is running Windows Server 2003 with Service Pack 1 (SP1).

**Steps for Using Windows Firewall**

Step 1: Review Windows Firewall limitations.

Step 2: Turn on Windows Firewall.

Step 3: Configure exceptions.

Step 4: Configure advanced settings.

Do not use this guide if you are:

- Using domain-based Group Policy to configure Windows Firewall.
- Using an automated installation technology to configure Windows Firewall during setup, such as a Netfw.inf file or an answer file.
- Using Security Configuration Wizard (SCW) to configure Windows Firewall.

**Note** SCW is the recommended method for starting and configuring Windows Firewall. For more information, see Configuring Windows Firewall with SCW on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48116).

**Step 1: Review Windows Firewall limitations.**

It is recommended that you use Windows Firewall on all of your servers; however, there are a few server configurations on which you cannot run Windows Firewall. To determine whether Windows Firewall is appropriate for your server configuration, see Known issues for managing resets, startup, and shutdown on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48117).

In addition, Windows Firewall is designed to be a supplemental security solution; it should be part of a security architecture that implements a variety of security technologies. For more information, see Best practices for managing Windows Firewall on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48221) and Windows Firewall Technical Reference on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=42729).

You might not want to start Windows Firewall if a server requires you to open numerous ports or allow a large number of applications and services to receive unsolicited traffic. Because a significant volume of network traffic will be allowed to pass through Windows Firewall anyway, by disabling Windows Firewall, you eliminate the operational overhead associated with Windows Firewall configuration and maintenance. You also avoid any performance impact related to Windows Firewall. However, you should closely evaluate the design of any client or server that requires you to open numerous ports. Clients and servers that are configured for numerous roles or to provide numerous services can be a critical point of failure in your organization and might indicate poor infrastructure design.

**Step 2: Turn on Windows Firewall.**

Windows Firewall is turned off by default on Windows Server 2003. When you turn on Windows Firewall, you must also start the Windows Firewall/Internet Connection Sharing service, if it is not already running. If the Windows Firewall/Internet Connection Sharing service is not started, and you attempt to start Windows Firewall, a **Windows Firewall** dialog box will appear in the graphical user interface asking if you want to start the service.

To turn on Windows Firewall, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority. If the computer is joined to a domain, members of the Domain Admins group might be able to perform this procedure.

**To turn on Windows Firewall using Windows Firewall in Control Panel**

1. Open Control Panel, and double-click **Windows Firewall**.

   If a **Windows Firewall** dialog box displays a message asking if you want to turn on the Windows Firewall/Internet Connection Sharing service, click **OK**.

2. On the **General** tab, click **On**.

3. Click **OK**.

If a Windows Firewall setting appears dimmed in the graphical user interface, and you see **For your security, some settings are controlled by Group Policy** at the top of the **General** tab, the setting might be managed by Group Policy. In this case, you should not use this step-by-step guide.

If all Windows Firewall settings appear dimmed, and you see **You must be a computer administrator to change these settings** at the top of the **General** tab, you do not have administrative rights to configure Windows Firewall. For more information about administrative rights, see Default local groups on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=43150) and Default groups on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=43151). For more information about turning on Windows Firewall, see Enabling and disabling Windows Firewall on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48118).

**Step 3: Configure exceptions.**
When you turn on Windows Firewall for the first time, all unsolicited incoming TCP/IP traffic is blocked on all network connections. This means that any programs or system services that are acting as servers, listeners, or peers will be unable to receive traffic through TCP and UDP ports. To allow programs and system services to receive unsolicited traffic through these ports, you must add the program or system service to the Windows Firewall exceptions list. In some cases, if you cannot add a program or system service to the exceptions list, you must determine which port or ports the program or system service uses and add the port or ports to the Windows Firewall exceptions list.

To configure exceptions, do the following:

**Use Windows Firewall notifications to add programs to the exceptions list**

By default, Windows Firewall displays a **Windows Security Alert** dialog box whenever a program attempts to listen for incoming traffic and the incoming traffic is blocked. If you are a member of the Administrators group, the **Windows Security Alert** dialog box will display the option to keep blocking the program or unblock the program. Unblocking a program adds the program to the exceptions list and allows unsolicited incoming traffic to reach the program.

To add programs to the exceptions list, do the following when you see a **Windows Security Alert** dialog box:

1. Verify that the program listed in **Name** is a program that you installed and that it is not a malicious program (malware) or spyware.

2. Hover your cursor over the program name to see the path and file name for the program's executable (.exe) file. Verify that the path and file name are correct.

3. If the program is legitimate (not malware or spyware) and you want it to receive unsolicited incoming traffic, click **Unblock**.

   If the program is a malicious program, click **Keep Blocking**. You should immediately remove any malicious programs from your computer.

   If you are unsure, but you think it might be a legitimate program, click **Ask Me Later**. Windows Firewall will continue to block the program, but will prompt you again later.

Windows Firewall displays a **Windows Security Alert** dialog box only when a program is running and attempting to listen for incoming traffic. If a program is not running or does not attempt to listen for incoming traffic, Windows Firewall does not display a **Windows Security Alert** dialog box. You might see several **Windows Security Alert** dialog boxes over the course of several minutes or several hours as programs and system services start up on your server. You should respond to each of these dialog boxes to be sure add all required programs to the Windows Firewall exceptions list.

For more information, see Managing Windows Firewall Notifications on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48222), Add a program to the exceptions list on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48119), and Add a port to the exceptions list on the Microsoft Web site

(http://go.microsoft.com/fwlink/?LinkId=48120).

**Use the Windows Firewall Settings Technical Reference to determine which programs and ports to add to the exceptions list**

Use the Windows Firewall Settings Technical Reference to find out how to configure program and port exceptions for your specific server configuration. The Windows Firewall Settings Technical Reference provides Windows Firewall configuration settings for server roles, system services, remote administration tools, and optional components.

| **Note** |
| --- |
| If you do not know which server roles or optional components are installed on your server, or you do not know which system services or remote administration tools your server uses, you should use SCW to configure Windows Firewall settings. |

For more information, see Windows Firewall Settings on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=43155).

For detailed instructions about adding a program to the exceptions list, see Add a program to the exceptions list on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48119).

For detailed instructions about adding a port to the exceptions list, see Add a port to the exceptions list on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48120).

**Step 4: Configure advanced settings.**
To optimally configure Windows Firewall for your server, you must understand and configure the following:

**Windows Firewall profiles**

Windows Firewall settings can be configured in two profiles: a domain profile and a standard profile. This step-by-step guide has helped you configure settings in one profile only. For more information, see Managing Windows Firewall profiles on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48121).

**Windows Firewall scope settings**

When you configure a program, port, or system service exception, you must also configure scope settings for the exception. Scope settings control from which addresses unsolicited traffic is allowed to originate. For more information about scope settings, see Configuring scope settings on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48122).

**ICMP settings**

By default, Windows Firewall blocks all incoming Internet Control Message Protocol (ICMP) traffic and some outgoing ICMP traffic. This can prevent you from using certain troubleshooting tools, including the **ping** command. For more information about ICMP settings, see Configuring ICMP settings on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48224).

**Log file settings**

Windows Firewall has a log file that you can use to troubleshoot and monitor Windows Firewall. By default, the log file is disabled. For more information, see Using the Security Log on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48229) and Interpreting the Windows Firewall Log on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48228).

**Windows Firewall exceptions**

Although you have added program, system service, and port exceptions to the exceptions list, it is likely you still need to add (or remove) exceptions for your server to function optimally. For more information about exceptions, see Managing Program, Port, and System Service Exceptions on the Microsoft Web site (http://go.microsoft.com/fwlink/?linkid=43261).

For more information about Windows Firewall, see Windows Firewall Help on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=33577).

# Deploying Windows Firewall with Group Policy

Updated: June 8, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For organizations that use Active Directory, the recommended method for deploying and managing Windows Firewall is to use the new Windows Firewall Group Policy settings. When you use Group Policy to configure Windows Firewall, administrators will be unable to use the **Netsh firewall** command or Windows Firewall in Control Panel to configure the Windows Firewall settings that are managed through Group Policy. In other words, any Windows Firewall settings that are managed through Group Policy appear dimmed and are not accessible through Windows Firewall in Control Panel and cannot be configured through the **Netsh firewall** command.

You can configure Windows Firewall Group Policy settings in either the domain profile or the standard profile. The domain profile settings are used whenever the computer is joined to a network that contains the domain controllers for the domain in which the computer's computer account resides. The standard profile settings are used whenever the computer is joined to a network that does not contain the domain controllers for the domain in which the computer's computer account resides. Both the domain profile and standard profile contain the same set of Windows Firewall settings.

For more information about the Windows Firewall Group Policy settings, see "Windows Firewall Tools and Settings" in the Windows Firewall Technical Reference on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=42729). For more information about using Group Policy settings to deploy Windows Firewall in Windows XP with Service Pack 2 (SP2), see "Managing Windows XP Service Pack 2 Features Using Group Policy" on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=31974). Although the article is written specifically for Windows XP with SP2, most of the concepts and information apply to deployments of Windows Firewall in Windows Server 2003 with SP1.

Deploying Windows Firewall

# Deploying Windows Firewall During an Unattended Installation

Updated: June 8, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The answer file for unattended installations of Windows Server 2003 with Service Pack 1 (SP1) has been updated to include a section for configuring Windows Firewall. You can use the new Windows Firewall parameters to turn on Windows Firewall and configure Windows Firewall settings if you are deploying clean installations of Windows Server 2003 with SP1. You cannot use an answer file to perform an unattended installation if you are installing SP1 on a computer that already has Windows Server 2003 installed.

| **Note** |
| --- |
| If you use an unattended installation answer file to automate the configuration of Windows Firewall settings, the settings that you specify in the answer file are deleted and are not reapplied when you restore Windows Firewall default settings. However, if you use a Netfw.inf to configure Windows Firewall settings, the settings specified in Netfw.inf are reapplied to the computer when you restore Windows Firewall default settings. If you want to restore the Windows Firewall settings that you configured during an unattended installation with an answer file, you must configure the settings manually. |

For more information about using the Windows Firewall parameters in an unattended installation answer file, see "Windows Firewall Tools and Settings" in the Windows Firewall Technical Reference on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=42729). For more information about the Windows Firewall parameters that are available for use in an unattended installation answer file, see "Unattended Installation Tools and Settings" in the Unattended Installation Technical Reference on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=42729).

Deploying Windows Firewall

# Deploying Windows Firewall with a Netfw.inf File

Updated: June 8, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use the Netfw.inf file to turn on Windows Firewall and configure Windows Firewall settings during an installation of Windows Server 2003 with Service Pack 1 (SP1). The Netfw.inf file is typically used by original equipment manufacturers (OEMs) in a manufacturing setting, but it can also be used in a corporate environment during a large-scale rollout of SP1; however, unattended installation is the preferred method for deploying Windows Firewall in a corporate environment.

| **Note** |
| --- |
| If you use a Netfw.inf file to automate the configuration of Windows Firewall settings, the settings that you specify in Netfw.inf are reapplied to the computer when you restore Windows Firewall default settings. Any Windows Firewall settings that you specify in an answer file, such as Unattend.txt, are deleted and are not restored. If you want to restore the Windows Firewall settings that you configured during installation with an answer file, you must configure the settings manually. |

For more information about using the Netfw.inf file to deploy Windows Firewall, see "Windows Firewall Tools and Settings" in the Windows Firewall Technical Reference on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=42729).

# Designing and Deploying Directory and Security Services

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Welcome to *Designing and Deploying Directory and Security Services* of the *Microsoft Windows Server 2003 Deployment Kit*.

Whether you are designing a new Active Directory logical structure, deploying Active Directory for the first time, upgrading an existing Windows environment to Windows Server 2003 Active Directory, or restructuring your current environment to a Windows Server 2003 Active Directory environment, Part I of this book will assist you in meeting all of the Active Directory design and deployment goals for your organization.

You also need to make important decisions early in your deployment regarding the design and deployment of Windows Server 2003 distributed security services for authentication, access control, and, increasingly, certificate use. Part II of this book will assist you in preparing the design and planning documents needed to create a sound foundation of distributed security services.

This book contains the following chapters:

Part I: Designing and Deploying Directory Services

Planning an Active Directory Deployment Project

Designing the Active Directory Logical Structure

Designing the Site Topology

Planning Domain Controller Capacity

Enabling Advanced Windows Server 2003 Active Directory Features

Deploying the Windows Server 2003 Forest Root Domain

Deploying Windows Server 2003 Regional Domains

Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory

Upgrading from Windows 2000 Domains to Windows Server 2003 Domains

Restructuring Windows NT 4.0 Domains to an Active Directory Forest

Restructuring Active Directory Domains Between Forests

Restructuring Active Directory Domains Within a Forest

Part II: Deploying Distributed Security Services

Planning a Secure Environment

Designing an Authentication Strategy

Designing a Resource Authorization Strategy

Designing a Public Key Infrastructure

Planning a Smart Card Deployment

# Planning an Active Directory Deployment Project

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you deploy the Microsoft® Windows® Server 2003 Active Directory® directory service in your environment, you can take advantage of the centralized, delegated administrative model and single sign-on capability that Active Directory provides. After you identify the current environment and deployment goals for your organization, you can create the Active Directory deployment strategy that meets your organization's needs. Testing the deployment in an isolated lab environment and refining the deployment in selected pilot areas of your production environment help to ensure a smooth deployment throughout your organization.

**In This Chapter**

Overview of Planning an Active Directory Deployment Project

Determining Your Active Directory Design and Deployment Strategy

Testing and Verifying the Deployment Process

Additional Resources for Planning an Active Directory Deployment Project

**Related Information**

- For more information about planning, testing, and piloting a deployment project, see "Designing a Test Environment" and "Planning and Testing for Application Deployment" in *Planning, Testing, and Piloting Deployment Projects* in this kit.
- For more information about deploying Windows Server 2003 Domain Name System (DNS), see "Deploying DNS" in *Deploying Network Services* in this kit.
- For more information about Group Policy, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

# Overview of Planning an Active Directory Deployment Project

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Active Directory in the Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; and Windows® Server 2003, Datacenter Edition operating systems allows organizations to simplify user and resource management while creating a scalable, secure, and manageable infrastructure. You can use Active Directory to manage your network infrastructure, including branch office, Microsoft® Exchange Server, and multiple forest environments.

Although the guidelines presented in this book are appropriate for almost all network operating system (NOS) management deployments, the guidelines have been tested and validated specifically for environments that contain fewer than 100,000 users and fewer than 1,000 sites, with network connections of a minimum of 28.8 kilobits per second (Kbps). If your environment does not meet these criteria, consider using a consulting firm that has experience deploying Active Directory in more complex environments.

Deploying Active Directory provides the following benefits to your organization:

- **Simplified administration and resource management.** You can delegate administration to all levels of an organization, and you can use Group Policy to centralize administration.
- **Increased network security and single sign-on for users.** Active Directory supports multiple authentication protocols and X.509 certificates, and provides support for smart cards.
- **Interoperability with other directory services.** Active Directory provides standards-based, open interfaces that interoperate with other directory services and applications, such as e-mail applications.
- **Features that reduce administration costs, increase security, and provide additional functionality.** Application directory partitions allow you to configure application-specific data replication settings on domain controllers. When you raise domain or forest functional levels to Windows Server 2003, you can do the following:
    - Rename domains and domain controllers
    - Establish two-way forest trusts
    - Restructure forests
    - Improve replication
    - Remove some limitations in environments with a large number of sites

Although the Windows Server 2003 Active Directory design and deployment strategies that are presented in this book are based on extensive lab and pilot-program testing and successful implementation in customer environments, you might have to customize your Active Directory design and deployment to better suit specific, complex environments. For more information about deploying Active Directory in a branch office environment, see the *Active Directory Branch Office Planning Guide*. For more information about deploying Active Directory in an Exchange environment, see *Best Practice Active Directory Design for Exchange 2000*. For more information about deploying Active Directory in a multiple forest environment, see *Multiple Forest Considerations*. To download these guides, see the Active Directory link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources, and then click "Planning & Deployment Guides."

This book also provides flowcharts, job aids, and deployment examples to help you optimize your Active Directory design and deployment process.

# Process for Planning an Active Directory Deployment Project

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To plan a Windows Server 2003 Active Directory deployment project, first determine your design and deployment strategy, and then test and verify your design and deployment. Figure 1.1 shows the process for planning your Active Directory deployment project.

**Figure 1.1 Planning an Active Directory Deployment Project**

# Active Directory Background Information

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you design and deploy Windows Server 2003 Active Directory, become familiar with the Active Directory deployment project cycle, as well as Active Directory–related terms that are required for the Windows Server 2003 Active Directory deployment process.

# Active Directory Deployment Project Cycle

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An Active Directory deployment project involves three phases: a design phase, a deployment phase, and an operations phase. During the design phase, the design team creates a design for the Active Directory logical structure that best meets the needs of each division in the organization that will use the directory service. After the design is approved, the deployment team tests the design in a lab environment and then implements the design in the production environment. Because testing is performed by the deployment team and potentially affects the design phase, it is an interim activity that overlaps both design and deployment. When the deployment is complete, the operations team is responsible for maintaining the directory service.

Lab testing and the implementation of a pilot program continue throughout the lifetime of the Active Directory deployment.

Figure 1.2 shows the relationship between the phases of the Active Directory project cycle relative to the lifetime of the deployment project.

**Figure 1.2 Relationship Between Active Directory Project Cycle Phases**

# Terms and Definitions

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The following terms are important to understanding the Windows Server 2003 Active Directory deployment process.

**Active Directory domain**
An administrative unit in a computer network that, for management convenience, groups several capabilities, including:

- **Network-wide user identity.** Domains allow user identities to be created once and referenced on any computer that is joined to the forest in which the domain is located. Domain controllers that make up a domain are used to store user accounts and user credentials, such as passwords or certificates, securely.

- **Authentication.** Domain controllers provide authentication services for users and supply additional authorization data, such as user group memberships. These services can be used to control access to resources on the network.

- **Trust relationships.** Domains extend authentication services to users in other domains in their own forest by means of automatic bidirectional trusts, and to users in domains in other forests by means of either manually created external trusts or forest trusts.

- **Policy administration.** The domain is a scope of administrative policies, such as password complexity and password reuse rules.

- **Replication.** The domain defines a partition of the directory tree that provides data that is adequate to provide the required services and that is replicated between the domain controllers. In this way, all domain controllers are peers in a domain and are managed as a unit.

**Active Directory forest**
A collection of one or more Active Directory domains that share a common logical structure, directory schema, and network configuration, as well as automatic two-way transitive trust relationships. Each forest is a single instance of the directory and defines a security boundary.

**Active Directory functional level**
A setting in Windows Server 2003 Active Directory that enables advanced domain-wide or forest-wide Active Directory features.

**Migration**
The process of moving an object from a source domain to a target domain, while preserving or modifying characteristics of the object to make it accessible in the new domain.

**Domain restructure**
A migration process that involves changing the domain structure of a forest. A domain restructure can involve either consolidating or adding domains, and can take place between forests or within a forest.

**Domain consolidation**
A restructuring process that involves eliminating Microsoft® Windows NT® 4.0 domains or Active Directory domains by merging their contents with the contents of other domains.

**Domain upgrade**
The process of upgrading the directory service of a domain to a later version of the directory service. This includes upgrading the operating system on all domain controllers and raising the Active Directory functional level where applicable.

**In-place domain upgrade**
The process of upgrading the operating system on all domain controllers that are based on Windows NT 4.0 or on the Microsoft® Windows® 2000 operating system and raising the functional level of the domain if applicable, while leaving domain objects, such as users and groups, in place.

**Regional domain**
A child domain that is created based on a geographic region in order to optimize replication traffic.

# Determining Your Active Directory Design and Deployment Strategy

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you perform a high-level assessment of your current environment and determine your Active Directory deployment goals, you can determine the deployment strategy that works best for your environment. Figure 1.3 shows the steps for defining the Active Directory deployment process.

**Figure 1.3 Determining Your Design and Deployment Strategy**

The Active Directory deployment strategy that you apply varies according to your existing network configuration. For example, if your organization currently runs Windows 2000, you can simply upgrade your operating system to Windows Server 2003. If your organization currently runs Windows NT 4.0 or a non-Windows network operating system, however, you must design an Active Directory infrastructure before you upgrade to Windows Server 2003.

Your deployment process might involve restructuring existing domains, either within an Active Directory forest or between Active Directory forests. You might need to restructure your existing domains after you deploy Windows Server 2003 Active Directory or after organizational changes or corporate acquisitions. You can also restructure domains from a Windows NT 4.0 environment to an Active Directory forest in order to upgrade your production environment to Windows Server 2003.

Table 1.1 lists the possible starting points and goals for a Windows Server 2003 Active Directory deployment and the corresponding deployment steps and topics in this guide that apply to each.

**Table 1.1 Current Environment, Goals, and Corresponding Topics for Deploying Windows Server 2003 Active Directory**

| Environment | Deployment goals | Corresponding topics |
|---|---|---|
| New organization | Create forest, domain, Domain Name System (DNS), and OU design. | Designing the Active Directory Logical Structure (http://go.microsoft.com/fwlink/?LinkId=132452) |
| Create a site and site link design. | Designing the Site Topology (http://go.microsoft.com/fwlink/?LinkId=132453) | |
| Assess hardware requirements. | Planning Domain Controller Capacity (http://go.microsoft.com/fwlink/?LinkId=132455) | |
| Deploy the forest root domain. | Deploying the Windows Server 2003 Forest Root Domain (http://go.microsoft.com/fwlink/?LinkId=132457) | |

| | | |
|---|---|---|
| Deploy regional domains. | Deploying Windows Server 2003 Regional Domains (http://go.microsoft.com/fwlink/?LinkId=132461) | |
| Raise the domain and forest functional levels. | Enabling Advanced Windows Server 2003 Active Directory Features (http://go.microsoft.com/fwlink/?LinkId=132462) | |
| Windows NT 4.0 | Create forest, domain, DNS, and OU design. | Designing the Active Directory Logical Structure (http://go.microsoft.com/fwlink/?LinkId=132452) |
| Create a site and site link design. | Designing the Site Topology (http://go.microsoft.com/fwlink/?LinkID=132453) | |
| Assess hardware requirements. | Planning Domain Controller Capacity (http://go.microsoft.com/fwlink/?LinkId=132455) | |
| Deploy the forest root domain. | Deploying the Windows Server 2003 Forest Root Domain (http://go.microsoft.com/fwlink/?LinkId=132457) | |
| Deploy regional domains. | Deploying Windows Server 2003 Regional Domains (http://go.microsoft.com/fwlink/?LinkId=132461) | |
| Upgrade in-place Windows NT 4.0 domains that will remain part of your Active Directory domain structure. | Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory (http://go.microsoft.com/fwlink/?LinkId=132466) | |
| Restructure other Windows NT 4.0 domains. | Restructuring Windows NT 4.0 Domains to an Active Directory Forest (http://go.microsoft.com/fwlink/?LinkId=132467) | |
| Raise the domain and forest functional levels. | Enabling Advanced Windows Server 2003 Active Directory Features (http://go.microsoft.com/fwlink/?LinkId=132462) | |
| Windows 2000 | Upgrade Windows 2000 domain controllers. | Upgrading from Windows 2000 Domains to Windows Server 2003 Domains (http://go.microsoft.com/fwlink/?LinkId=132484) |
| Raise the domain and forest functional levels. | Enabling Advanced Windows Server 2003 Active Directory Features (http://go.microsoft.com/fwlink/?LinkId=132462) | |

Table 1.2 lists the goals and corresponding topics that apply to restructuring domains either within or between forests.

**Table 1.2 Goals and Corresponding Topics for Restructuring Active Directory Domains**

| Action | Deployment goals | Corresponding topics |
| --- | --- | --- |
| Restructure domains within a forest | Create forest, domain, DNS, and OU design. | Designing the Active Directory Logical Structure (http://go.microsoft.com/fwlink/?LinkId=132452) |
| Create a site and site link design. | Designing the Site Topology (http://go.microsoft.com/fwlink/?LinkID=132453) | |
| Use a tool such as the Active Directory Migration Tool (ADMT) to restructure domains within a forest. | Restructuring Active Directory Domains Within a Forest (http://go.microsoft.com/fwlink/?LinkId=132486) | |
| Restructure domains between forests | Create forest, domain, DNS, and OU design. | Designing the Active Directory Logical Structure (http://go.microsoft.com/fwlink/?LinkId=132452) |
| Create a site and site link design. | Designing the Site Topology (http://go.microsoft.com/fwlink/?LinkID=132453) | |
| Use a tool such as ADMT to restructure domains between forests. | Restructuring Active Directory Domains Between Forests (http://go.microsoft.com/fwlink/?LinkId=132488) | |

# Determining Your Active Directory Design Requirements

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If your network environment is currently operating without a directory service, or if you need to modify your current Active Directory infrastructure, complete the design process for your Active Directory infrastructure. You must complete a comprehensive design of your Active Directory logical structure before you deploy Active Directory. Thoroughly preparing your Active Directory design is essential to a cost-effective deployment.

**Logical Structure Design**
Before you deploy Windows Server 2003 Active Directory, you must plan for and design the Active Directory logical structure for your environment. The Active Directory logical structure determines how your directory objects are organized, and provides an effective method for managing your network accounts and shared resources. When you design your Active Directory logical structure, you define a significant part of the network infrastructure of your organization.

To design the Active Directory logical structure, determine the number of forests that your organization requires, and then create designs for domains, DNS, and organizational units.

**Site Topology Design**
After you design the logical structure for your Active Directory infrastructure, you must design the site topology for your network. The site topology is a logical representation of your physical network. It contains information about the location of Active Directory sites, the Active Directory domain controllers within each site, and the site links that support Active Directory replication between sites.

**Domain Controller Capacity Planning**
To ensure efficient Active Directory performance, you must determine the appropriate number of domain controllers for each site and verify that they meet the hardware requirements for Windows Server 2003. Careful capacity planning for your domain controllers ensures that you do not underestimate hardware requirements, which can cause poor domain controller performance and application response time.

**Advanced Active Directory Features**
Functional levels in Windows Server 2003 Active Directory allow you to enable new features, such as improved group membership replication, deactivation and redefinition of attributes and classes in the schema, and forest trust relationships that require that all domain controllers within the participating domain or forest run Windows Server 2003. Part of the Active Directory design process involves identifying the domain and forest functional levels that your organization requires. To implement these Windows Server 2003 Active Directory features in your organization, you must first deploy Windows Server 2003 Active Directory and then raise the forest and domain to the appropriate functional level.

# Determining Your Active Directory Deployment Requirements

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The structure of your existing environment determines your strategy for deploying Windows Server 2003 Active Directory. If you are creating an Active Directory environment and you do not have an existing domain structure, you must complete your Active Directory design before you begin creating your Active Directory environment. Then you can deploy a new forest root domain and deploy the rest of your domain structure according to your design.

**Windows Server 2003 Forest Root**
To deploy Active Directory, you must first deploy a Windows Server 2003 forest root domain. To do this, you must configure DNS, deploy forest root domain controllers, configure the site topology for the forest root domain, and configure operations master roles.

**Windows Server 2003 Regional Domains**
If you are creating one or more new regional domains in a Windows Server 2003 forest, you must deploy each regional domain after you deploy your forest root domain. To do this, you must delegate a DNS zone and deploy domain controllers for each regional domain.

**Windows NT 4.0 Domain Upgrade to Windows Server 2003**
When you perform an in-place domain upgrade of Windows NT 4.0 domains, you can begin to use Active Directory without making any modifications to your existing domain structure.

Alternatively, if you do not want to retain your existing domain structure, you can restructure your Windows NT 4.0 domains to a Windows Server 2003 forest. For more information about restructuring your Windows NT 4.0 domains to a Windows Server 2003 forest, see "Determining Your Restructure Requirements" later in this chapter.

**Windows 2000 Domain Upgrade to Windows Server 2003**
Upgrading your Windows 2000 domains to Windows Server 2003 domains is an efficient, straightforward way to take advantage of additional Windows Server 2003 features and functionality. Upgrading from Windows 2000 to Windows Server 2003 requires minimal network configuration and has little impact on user operations.

# Determining Your Restructure Requirements

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As part of your Active Directory deployment, you might choose to restructure your environment. Before doing so, you must determine when and how you want to restructure your environment. Organizations with an existing Windows NT 4.0 domain structure might perform an in-place upgrade of some domains and restructure others. In addition, you might decide to reduce the complexity of your environment by either restructuring domains between forests or restructuring domains within a forest after you deploy Active Directory.

**Windows NT 4.0 Domain Restructure to a Windows Server 2003 Forest**
Because of its greater scalability, a Windows Server 2003 Active Directory environment requires fewer domains than a Windows NT 4.0 environment. Instead of performing an in-place upgrade of your Windows NT 4.0 domains, it might be more efficient to consolidate a number of smaller Windows NT 4.0 account and resource domains into a few, larger Active Directory domains.

**Interforest Active Directory Domain Restructure**
When you restructure domains *between* Windows Server 2003 forests, you can reduce the number of domains in your environment and, therefore, reduce administrative complexity and overhead. When you migrate objects between forests as part of the restructuring process, both the source and target domain environments exist simultaneously. This enables you to roll back to the source environment during the migration, if necessary.

**Intraforest Active Directory Domain Restructure**
When you restructure Windows Server 2003 domains *within* a Windows Server 2003 forest, you can consolidate your domain structure and, therefore, reduce administrative complexity and overhead. Unlike the process for restructuring Windows Server 2003 domains between forests, when you restructure domains within a forest, the migrated accounts no longer exist in the source domain.

Table 1.3 lists the differences between an interforest and an intraforest domain restructure.

**Table 1.3 Differences Between Interforest and Intraforest Domain Restructures**

| Migration Consideration | Interforest Restructure | Intraforest Restructure |
|---|---|---|
| **Object preservation** | Objects are cloned rather than migrated. The original object remains in the source location to maintain user access to resources. | Objects are migrated and no longer exist in the source location. |
| **SID history maintenance** | Maintaining SID history is optional. | SID history is required. |
| **Password retention** | Password retention is optional. | Passwords are always retained. |
| **Local profile migration** | You must use tools such as ADMT to migrate local profiles. | For workstations that run Windows 2000 and later, local profiles are migrated automatically because the user's GUID is preserved. However, you must use tools such as ADMT to migrate local profiles for workstations that run Windows NT 4.0 and earlier. |
| **Closed sets** | You do not need to migrate accounts in closed sets. | You must migrate accounts in closed sets. |

# Example: Establishing an Active Directory Deployment Strategy

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To illustrate the Active Directory deployment process, the chapters in this book show an example of how a fictitious company, Contoso Pharmaceuticals, deploys Active Directory in its environment. The Contoso environment consists of four domains, all of which are running Windows 2000 Active Directory. Figure 1.4 shows the current domain structure for the Contoso corporation.

**Figure 1.4 Contoso Corporation Domain Structure**

After reviewing its existing environment and identifying its deployment goals, Contoso established the following Active Directory deployment strategy:

- Upgrade Windows 2000 domains to Windows Server 2003 domains.
- Enable advanced Active Directory features by raising the domain and forest functional levels to Windows Server 2003.

After upgrading all Windows 2000 domains to Windows Server 2003 domains, Contoso will restructure the africa.concorp.contoso.com domain within the forest to consolidate it with the emea.concorp.contoso.com domain.

The Contoso corporation is acquiring a company called Trey Research, which is currently running a Windows NT 4.0–based environment, as shown in Figure 1.5.

**Figure 1.5 Current Environment for Trey Research**

Contoso established the following Active Directory deployment strategy for their Trey Research acquisition:

- Design the Active Directory logical structure to create forest, domain, DNS, and organizational unit designs for the new Windows Server 2003 environment.
- Design the site topology to create the required sites, site links, and site link bridges.
- Plan domain controller capacity to determine the hardware requirements for the new Windows Server 2003 environment.
- Deploy trccorp.treyresearch.net as the forest root domain.
- Deploy three regional domains. Different teams can create these domains simultaneously.
    - Upgrade the EAST domain to Windows Server 2003 to become east.trccorp.treyresearch.net.
    - Create two new Windows Server 2003 regional domains called asia.trccorp.treyresearch.net and

west.trccorp.treyresearch.net.

- Restructure the BOSTON, MAIL-APPS, PROD-APPS, and OFFICE-APPS domains to the east.trccorp.treyresearch.net Windows Server 2003 domain by using ADMT.

- Raise the domain and forest functional levels to Windows Server 2003.

Figure 1.6 shows the interim environment for Trey Research.

**Figure 1.6 Interim Environment for Trey Research**

At a later time, Contoso determined that a single domain would be more cost-effective for the Europe, Middle East, and Asia region, so the final step in the deployment process is to restructure asia.trccorp.treyresearch.net into the emea.concorp.contoso.com domain in the Contoso forest by using ADMT.

Figure 1.7 shows the domain structure for the Contoso corporation after the acquisition of Trey Research and the Windows Server 2003 Active Directory deployment process is complete.

**Figure 1.7 Final Environment for Contoso and Trey Research**

# Testing and Verifying the Deployment Process

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In any Active Directory deployment, you can minimize the impact on normal business operations by testing design assumptions and verifying the deployment process in a pilot program. As you create the first draft of your Active Directory design, begin to test and verify. Testing and verifying begin during the design phase and continues through the deployment and operations phase.

Figure 1.8 shows the process for testing and verifying your Active Directory design and deployment.

**Figure 1.8 Testing and Verifying the Active Directory Design and Deployment**

# Testing the Design and Deployment in a Lab Environment

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Lab testing is the first evaluation of the Active Directory design. During lab testing, you confirm the assumptions made by the design architects.

As the first draft of the Active Directory design approaches completion, begin testing specific design assumptions in the deployment process in a lab environment. By testing the deployment process in your lab, you can discover potential design problems that affect the deployment process and provide feedback to the design team to correct problems before the deployment.

Ensure that the test lab environment is isolated from the rest of your organization's production network and represents, on a small scale, the hardware and operating system configuration of the computers in your organization. Include enough domain controllers in the lab environment to support a representative sample of your site design, including intrasite and intersite replication partners, site links, and realistic replication intervals.

Include user and group accounts and other resources that are exclusively designated for testing. Ensure that your test environment provides access to test configurations of external services, such as mainframe or Internet access, as required. Retain the lab permanently to test new procedures and train the deployment team.

The deployment team can use the lab environment to learn the specifics of your deployment process and to gain familiarity with the deployment and migration tools that are used during the Active Directory deployment.

Typically, the design assumption tests and the deployment process tests are performed by different teams. Table 1.4 lists the lab tests and the team members who perform the tests in the lab.

**Table 1.4 Lab Tests and Corresponding Team Members**

| Test Process | Lab Tests | Team Members |
|---|---|---|
| Test design assumptions | Analyze Active Directory replication and site topology. | Design team, site topology owner, and deployment team. |
| Test application and desktop compatibility. | Design team. | |
| Test deployment process | Test disaster recovery. | Forest owner and deployment team. |
| Test account and resource migration. | Forest owner and deployment team. | |
| Evaluate delegation, administration, and management. | Forest owner. | |

# Testing Design Assumptions

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

During the design process, the design team makes assumptions that are incorporated into the Active Directory design, such as Active Directory replication and application compatibility. After the team completes a preliminary draft of the design, it must prove these assumptions in the lab environment.

To test the design assumptions in the lab environment, the design team must:

- Analyze Active Directory replication site topology.
- Develop a test plan, and then test application and desktop compatibility.

**Analyze Active Directory Replication and Site Topology**

The site topology design specifies the maximum replication latency. This is the length of time that is required to replicate changes throughout the forest. The design team must make sure that forest-wide replication latency is less than or equal to the maximum replication latency specified in the design. The team must perform a worst-case test that is based on the maximum number of hops that are assumed in the design. The team must observe the time that is required for replication convergence when a domain controller or communications link fails.

**To analyze Active Directory intersite replication site failover**

1. Identify the domain controllers that are responsible for intersite replication by using Active Directory Sites and Services.
2. Disconnect domain controllers or disable communications links that are used in intersite replication.
3. Allow the Knowledge Consistency Checker (KCC) to automatically configure new replication topology.
4. Identify the domain controllers that are now responsible for intersite replication.
5. Reconnect the domain controllers or enable communications links.
6. Verify that the intersite replication topology returns to the original state, as identified in step 1.

**Verify Application and Desktop Compatibility**

The design team must also determine the compatibility between applications, desktop operating systems, and Active Directory. Typically, the aspects of application testing that are affected by an Active Directory migration or upgrade include applications that run on servers and client computers, in addition to remote access usage.

Verify the application and desktop compatibility design assumptions by creating a list of all critical applications. Have design team members test each application to make sure that it operates correctly in a migrated environment.

When you verify application and desktop compatibility, verify that:

- Existing server applications, such as those that currently run on a Windows NT 4.0 backup domain controller (BDC), can run on Windows Server 2003–based member servers and domain controllers.

  For example, some server applications that run on BDCs take advantage of Shared Local Groups. To run these server applications on a Windows Server 2003–based domain controller, verify that the applications run correctly by using Active Directory domain local groups.

- Server applications that run on a mixture of Windows Server 2003–based and Windows NT 4.0–based servers can interoperate with one another.

  For example, verify that a Windows Server 2003–based server running Microsoft® SQL Server™ can interact with a Windows NT 4.0–based server running the same application.

- Existing desktop applications run correctly when the domain infrastructure is migrated to Windows Server 2003 Active Directory.

- Existing applications that use integrated Windows security run correctly when the domain infrastructure is migrated to Windows Server 2003 Active Directory.

If you find that a server application cannot be migrated to a Windows Server 2003–based domain controller, you can try to reinstall the application or a later version of the application on a Windows Server 2003–based member server. If the application cannot run on a server that runs Windows Server 2003, you can continue to run the application on the server that runs Windows NT 4.0 or Windows 2000.

Provide feedback to the design team that the server application's domain cannot be upgraded in-place or consolidated and must remain until a version of the application that can run on a Windows Server 2003–based domain controller is available. As a long-term deployment goal, transition any applications that currently run on domain controllers to member servers.

# Testing Deployment Processes

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In a lab environment before the pilot program begins, the deployment team must test specific tasks that are essential to the Active Directory deployment process, such as testing account and resource migration from Windows NT 4.0 to Windows Server 2003 Active Directory.

To verify the deployment process in the lab environment:

- Test disaster recovery.
- Test account and resource migration.
- Evaluate delegation, administration, and management.

**Test Disaster Recovery**

Test disaster recovery in your lab environment to validate that users can log on within an acceptable response time until a failed domain controller is restored and to determine the time that is required to restore the failed domain controller.

To implement a disaster recovery process in your Active Directory deployment, back up the System State data on at least two domain controllers in the lab environment. After you back up the data, you need to test the validity of the backup tape and the restore process. Test the following scenarios:

- Perform a non-authoritative restore of the domain controller whose directory services database contains corrupted data.
- Perform an authoritative restore of a domain controller to restore Active Directory data that has been deleted.

Make sure that the tests represent the slowest connection speeds in your environment and the largest number of user accounts.

For example, when you determine the time that is required to restore a failed domain controller, make sure to test the restore of System State data from your backup for any domain controller that is the only one in a site that is connected with a data rate of 128 Kbps or less. In addition, test the restore of System State data from your backup for any domain controller in a domain that contains more than 20,000 user accounts.

When a domain controller is connected to other domain controllers with a data rate that is equal to or greater than 128 Kbps, test your process for installing Active Directory on a new domain controller and letting Active Directory replication repopulate the Active Directory database.

For more information about testing disaster recovery, see the Active Directory Disaster Recovery (.doc) link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Test Account and Resource Migration**

To test the deployment process for account and resource migration, use the procedures in the chapter for the restructure process that you are planning. Organizations that are planning to restructure Windows NT 4.0 domains can also perform the following tests of their restructure process:

**To test the deployment process for account and resource migration**

1. In two or more production Windows NT 4.0 account domains, create new backup domain controllers (BDCs).
2. Remove the new BDCs from the production network.
3. Install the new BDCs in the lab environment.
4. Promote the new BDCs to primary domain controllers (PDCs).
5. Perform in-place upgrades and restructure the account domains in your lab.

6. Perform account and resource migrations by using a migration tool such as ADMT.

7. Verify that migrated accounts have access to resources and retain user profiles.

**Evaluate Delegation, Administration, and Management**
Evaluate the delegation, administration, and management processes by creating the organizational unit structure that is specified by your Active Directory design. Delegate control of organizational units to specific group accounts that are used for administration. Use these steps to verify the success of the delegation:

**To verify successful delegation of control of OUs to specific groups**

1. Log on as a user who belongs to the group account to which you delegated control.

2. Perform administration tasks on objects within the organizational unit (for example, modify the properties of a user in an account organizational unit).

3. Try, and subsequently fail, to perform administrative tasks on organizational units to which the administration group does not have delegated control.

# Verifying the Deployment in a Pilot Program

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In the lab environment, you verify that the deployment process works *outside* of your production environment on accounts and resources that approximate your production environment. If your environment runs Windows 2000 Active Directory, use your existing pilot program to verify your Windows Server 2003 deployment. In the pilot deployment program, identify a *controlled* subset of the accounts (users, groups, and services) and resources that exist in the production environment. Perform the deployment process on the identified accounts and resources.

The goals of the pilot program include:

- Extend testing into a subset of the production environment.
- Provide a test environment for other design and deployment groups, such as Exchange 2000 deployment.
- Verify process and procedures for network and operating system infrastructure updates.
- Verify proper operation of application updates.
- Evaluate the impact of monitoring solutions on the network infrastructure and the servers that are being monitored.
- Discover any potential problems in the deployment process that are caused by complexities that could not be modeled in the lab environment.
- Revise the deployment process to correct any problems that you discovered before the production deployment.

In your pilot deployment, begin with users who are involved in the deployment project, and then include users who are representative of your user population.

**To create a pilot deployment program in your environment**

1. Create ***forest_root_domain*** (where *forest_root_domain* is the name of an empty Active Directory forest root domain that was created by appending "-test" to the same name as the production forest root domain).
2. Create ***regional_domain*** (where *regional_domain* is the regional domain name in the pilot program) by appending "-test" to a production regional domain.
3. Establish the appropriate trust relationships between ***regional_domain*** and ***winnt_domain*** (where *winnt_domain* is a Windows NT 4.0 account or resource domain).
4. Migrate selected accounts and resources from ***winnt_domain*** to ***regional_domain***.
5. Verify that users and administrators can minimally perform the same tasks that they performed before the migration (such as resource access, account administration, and resource administration).

**Important**

- When you migrate production users to the pilot, leave the user accounts enabled in the production and the pilot environments. By leaving the user accounts enabled in the production environment, you provide a fallback plan if any problems occur in the pilot environment.

# Example: Creating a Pilot Deployment Program for Trey Research

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Contoso corporation and Trey Research created a pilot deployment program for the Active Directory deployment. Table 1.5 lists the names that they provided for their pilot deployment.

**Table 1.5 Example of a Pilot Deployment Program**

| Domain | Name |
|---|---|
| forest_root_domain | trccorp-test.treyresearch.net |
| regional_domain | east-test.trccorp-test.treyresearch.net |
| winnt_domain | BOSTON for account domain<br>OFFICE-APPS for resource domain |

Figure 1.9 illustrates the pilot deployment configuration.

**Figure 1.9 Pilot Deployment Configuration**

# Completing the Pilot Deployment Program

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you finish the pilot deployment program, retain the pilot deployment environment and use it as a staging environment for your production deployment. Continue to use the pilot forest to verify new deployment processes, such as adding new applications or schema extensions, installing operating systems, creating Group Policy objects, or restructuring organizational units.

As noted earlier, provide a fallback plan by leaving user accounts enabled in both the original production environment and the pilot deployment environment. Keep users in the pilot deployment environment to do their production work; do not migrate the accounts from the pilot deployment environment to the production forest. Instead, if you decide to move pilot users to another production forest, migrate them from their original production environment. This ensures that all users in the production forest have consistent accounts and makes troubleshooting easier.

# Example: Completing the Pilot Deployment Program for Trey Research

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Figure 1.10 shows a comparison between the design of the Active Directory pilot forest and the production forest deployment.

**Figure 1.10 Comparison of the Pilot Forest and the Production Forest**

# Additional Resources for Planning an Active Directory Deployment Project

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information and tools related to this chapter.

# Active Directory Maximum Limits - Scalability

Updated: March 12, 2015

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

This topic describes Active Directory scalability and other limitations, as well as recommendations that apply when you are designing or implementing an Active Directory infrastructure. These limitations include the following:

- Maximum Number of Objects
- Maximum Number of Security Identifiers
- Maximum Number of entries in Discretionary and Security Access Control Lists
- Group Memberships for Security Principals
- FQDN Length Limitations
- File Name and Path Length Limitations
- Additional Name Length Limitations
- Maximum Number of GPOs Applied
- Trust Limitations
- Maximum Number of Accounts per LDAP Transaction
- Recommended Maximum Number of Users in a Group
- Recommended Maximum Number of Domains in a Forest
- Recommended Maximum Number of Domain Controllers in a Domain
- Recommended Maximum Kerberos Settings

**Maximum Number of Objects**

Each domain controller in an Active Directory forest can create a little bit less than 2.15 billion objects during its lifetime.

Each Active Directory domain controller has a unique identifier that is specific to the individual domain controller. These identifiers, which are called Distinguished Name Tags (DNTs), are not replicated or otherwise visible to other domain controllers. The range of values for DNTs is from 0 through 2,147,483,393 ($2^{31}$ minus 255). As objects are created on a domain controller, a unique value is used. A DNT is not reused when an object is deleted. Therefore, domain controllers are limited to creating approximately 2 billion objects (including objects that are created through replication). This limit applies to the aggregate of all objects from all partitions (domain NC, configuration, schema, and any application directory partitions) that are hosted on the domain controller.

Because new domain controllers start with low initial DNT values (typically, anywhere from 100 up to 2,000), it may be possible to work around the domain controller lifetime creation limit—assuming, of course, that the domain is currently maintaining less than 2 billion objects. For example, if the lifetime creation limit is reached because approximately 2 billion objects are created, but 500 million objects are removed from the domain (for example, deleted and then permanently removed from the database through the garbage collection process), installing a new domain controller and allowing it to replicate the remaining objects from the existing domain controllers is a potential workaround. However, it is important that the new domain controller receives the objects through replication and that such domain controllers not be promoted with the Install from Media (IFM) option. Domain controllers that are installed with IFM inherit the DNT values from the domain controller that was used to create the IFM backup.

At the database level, the error that occurs when the DNT limit is reached is "Error: Add: Operations Error. <1> Server error: 000020EF: SvcErr: DSID-0208044C, problem 5012 (DIR_ERROR), data -1076."

| **Note** |
| --- |
| KB article 2548145 includes a hotfix to correct a problem where the size of the Active Directory database can increase rapidly on a domain controller that hosts the DNS server role, with most of the growth contributed by deleted DNS records. To remove those records, the garbage collection task processes a maximum of 5000 records in a single database transaction (also known as MAX_DUMPSTER_SIZE), and will continue to re-schedule itself until it is done. The hotfix does not change the garbage collection process; it only changes behavior in the DNS Server component and how it deals with deletions of dnsNode objects. For more information about garbage collection, see How the Active Directory–Data Store Really Works (Inside NTDS.dit)–Part 4. |

Beginning with Windows Server 2012, you can check a rootDSE operational attribute named **approximateHighestInternalObjectID** to determine the actual highest DNT in use on a domain controller. The following script can be used to retrieve this attribute value:

```
$ossupported = $false

# max possible DNTs
$maxdnts = [System.Math]::Pow(2, 31) - 255

# connect rootDSE
$root = [ADSI]"LDAP://rootDSE"

# get operational attribute dsaVersionString
$root.RefreshCache("dsaVersionString")

# get version string usable in System.Version
$osverstring = $root.dsaVersionString[0].Substring(0,
$root.dsaVersionString[0].IndexOf(" "))

try
{
    $osver = New-Object System.Version $osverstring

    # we need at least W2K12 DC to see the approximateHighestInternalObjectID exposed
    if ($osver.Major -gt 6)
    { $ossupported = $true }

    elseif ($osver.Major -eq 6)
    { $ossupported = ($osver.Minor -ge 2) }
}

catch
{ Write-Host "ERROR: Could not evaluate DC OsVer!"  }

if ($ossupported)
{
    # get operational attribute approximateHighestInternalObjectID
    $root.RefreshCache("approximateHighestInternalObjectID")

    Write-Host "Approx highest committed DNT:
$($root.approximateHighestInternalObjectID[0])"

    Write-Host "DNTs left for new assignments: $($maxdnts -
$root.approximateHighestInternalObjectID[0]) from $maxdnts"
}

else
{ Write-Host "approximateHighestInternalObjectID not exposed (DC OsVer: $osverstring)"
}
```

**Maximum Number of Security Identifiers**

Beginning with Windows Server 2012, the maximum number of security identifiers that can be created over the life of a domain is increased to 2,147,483,647 RIDs. This increase is part of a series of improvements made to how RIDS are issued and monitored. For more information, see Managing RID Issuance.

In Windows Server 2008 R2 and earlier operating systems, there is a limit of approximately 1 billion security identifiers (SIDs) over the life of a domain. This limit is due to the size of the global relative identifier (RID) pool of 30 bits that makes each SID (that is assigned to user, group, and computer accounts) in a domain unique. The actual limit is $2^{30}$ or 1,073,741,823 RIDs. Because RIDs are not reused—even if security principals are deleted—the maximum limit applies, even if there are less than 1 billion security principals in the domain.

| **Note** |
| --- |
| RIDs are assigned in blocks of 500 by default from the domain controller that holds the RID operations master role in each domain. If a domain controller is demoted, the unused RIDs that were allocated to the domain controller are not returned to the global RID pool and are therefore no longer available for use in the domain. |

Beginning in Windows Server 2012, an artificial ceiling is introduced when the number of available RIDs reaches within 10 percent of the limit for the global RID space. When within one percent of the artificial ceiling, domain controllers that request RID pools will log Directory-Services-SAM warning event 16656 to their System event log. For more information, see Managing RID Issuance.

In Windows Server 2008 R2 and earlier operating systems, when all the available RIDs are assigned for a domain, the Directory Service log in the Application and Service Logs of Event Viewer also displays Event ID 16644 from an event log source of the Security Accounts Manager (SAM) that reads "The maximum domain account identifier value has been reached. No further account-identifier pools can be allocated to domain controllers in this domain." If you run Dcdiag when all the available RIDs are assigned for a domain, you see the error message "The DS has corrupt data: rIDAvailablePool value is not valid."

A partial work-around to this limitation is to create an additional domain to hold accounts and then migrate accounts to the new domain. However, you must create a trust relationship to migrate accounts in advance of reaching the limit. Creating a trust requires the creation of a security principal, which is also known as a trust user account. For more information about this limit, see articles 316201 (http://go.microsoft.com/fwlink/?LinkID=115211) and 305475 (http://go.microsoft.com/fwlink/?LinkId=115212) in the Microsoft Knowledge Base.

| **Note** |
| --- |
| The Active Directory database does not set limits on the number of objects in a container, such as organizational units (OUs). You might experience limits when you work with multiple thousands of objects. These limits are configured to help provide a certain level of application or service availability. For example, the Active Directory Users and Computers snap-in is configured by default to display a maximum of 2,000 objects per container. You can adjust this value by using the **Filter Options** settings on the **View** menu. There are also adjustable Lightweight Directory Access Protocol (LDAP) policies that are set by default to improve domain controller performance. These policies are described in article 315071 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkID=135481). |

**Maximum Number of entries in Discretionary and Security Access Control Lists**

The limitation for the number of entries in a discretionary access control list (DACL) or a security access control list (SACL) of an Active Directory object using the ntSecurityDescriptor attribute comes from a limitation in the size of the access control list (ACL), which is 64K. Since access control entries (ACEs) vary in size, the actual number of entries (SIDs) is approximately 1,820. For additional details, see How Security Descriptors and Access Control Lists Work (http://go.microsoft.com/fwlink/?LinkId=214683).

**Group Memberships for Security Principals**

Security principals (that is, user, group, and computer accounts) can be members of a maximum of approximately 1,015 groups. This limitation is due to the size limit for the access token that is created for each security principal. The limitation is not affected by how the groups may or may not be nested. For more information, see article 328889 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkID=115213). For a detailed discussion of access token limitations, see Addressing Problems Due to Access Token Limitation (http://go.microsoft.com/fwlink/?LinkId=146571).

For more information about how a domain controller creates the data structure that is used for authorization decisions, see:

- [MS-PAC]: Privilege Attribute Certificate Data Structure (http://msdn.microsoft.com/en-us/library/cc237917(PROT.13).aspx)
- 3.3.5.3.2 Initial Population of the PAC (http://msdn.microsoft.com/en-us/library/cc233956(PROT.13).aspx)
- 3.3.5.4.3 Domain Local Group Membership (http://msdn.microsoft.com/en-us/library/cc233950(PROT.13).aspx)

**FQDN Length Limitations**
Fully qualified domain names (FQDNs) in Active Directory cannot exceed 64 characters in total length, including hyphens and periods (.). For example, the following host name has 65 characters; therefore, it is not valid in an Active Directory domain:

server10.branch-15.southaz.westernregion.northamerica.contoso.com

This is an important limitation to keep in mind when you name domains. This limitation is due to the MAX_PATH length of 260 characters that the Win32 application programming interfaces (APIs) define, in combination with the way in which Group Policy objects (GPOs) are stored in the SYSVOL share. For more information, see article 245809 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkID=115219). For more information about naming limitations, see article 909264 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkID=106629).

**File Name and Path Length Limitations**
The physical files that Active Directory components use, such as SYSVOL, database (NTDS.DIT), and log file paths, are constrained by the MAX_PATH length of 260 characters, as defined by the Win32 APIs. When you are determining where to place your SYSVOL and database files during Active Directory installation, avoid nested folder structures that make the full file path to the SYSVOL folder, database, and log files longer than 260 characters. For more information, see article 245809 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkId=115219).

**Additional Name Length Limitations**
There are additional limitations regarding name lengths in Active Directory. The following limits are described in article 909264 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkID=106629):

- NetBIOS computer and domain names are limited to 15 characters.
- Domain Name System (DNS) host names are limited to 24 characters.
- OU names are limited to 64 characters.

**Name Length Limits from the Schema**
Default limits on attribute names for Active Directory objects that are imposed by the schema include the following. These items provide examples of schema-limited name attributes:

- Display names are limited to 256 characters. For more information, see Display-Name Attribute (http://go.microsoft.com/fwlink/?LinkId=153705).
- Common names are limited to 64 characters. For more information, see Common-Name Attribute (http://go.microsoft.com/fwlink/?LinkId=153706).
- The **SAM-Account-Name** attribute (also known as the pre–Windows 2000 user logon name) is limited to 256 characters in the schema. However, for the purpose of backward compatibility the limit is 20 characters. For more information, see SAM-Account-Name Attribute (http://go.microsoft.com/fwlink/?LinkId=153707).

**Name Length Limitations for LDAP Simple Bind Operations**
During binds to the directory, simple LDAP bind operations limit the distinguished name (also known as DN) of the user to 255 total characters. If you attempt a simple LDAP bind with more than 255 characters, you might experience authentication errors, such as the following:

```
Error <49>: ldap_simple_bind_s() failed: Invalid Credentials
Server error: 80090308: LdapErr: DSID-0C0903AA, comment: AcceptSecurityContext error,
data 57, v1771
Error 0x80090308 The token supplied to the function is invalid
```

You can avoid this issue by ensuring that the applications, scripts, and utilities that attempt to bind to your directory use secure LDAP binds. You can also avoid this issue by reducing the depth of the OU structure or the length of the OU names. For example, the following distinguished name is 261 characters:

```
CN=BobKelly,OU=CorporateVicePresidents,OU=CorporateOfficers,OU=ViewOfPugetSoundOffices,
OU=TopFloor,OU=Building1557,OU=CorporateCampus,OU=Redmond,OU=Washington,OU=NorthWestern
,OU=UnitedStatesOfAmerica,OU=NorthAmerica,DC=BusinessGroup,DC=humongousinsurance,DC=com
```

If the OU named CorporateVicePresidents is shortened to CVP, the distinguished name for the user account BobKelly is only 242 characters.

**Maximum Number of GPOs Applied**
There is a limit of 999 Group Policy objects (GPOs) that you can apply to a user account or computer account. This does not mean that the total number of policy settings on the system is limited to 999. Rather, a single user or computer will not be able to process more than 999 GPOs. This limit exists for performance reasons.

**Trust Limitations**
Trust limitations arise from the number of trusted domain objects (TDOs), the length of trust paths, and the ability of clients to discover available trusts. Limitations that apply include the following:

- Kerberos clients can traverse a maximum of 10 trust links to locate a requested resource in another domain. If the trust path between the domains exceeds this limit, the attempt to access the domain fails.
- When a client searches out a trust path, the search is limited to the trusts that are established directly with a domain and the trusts that are transitive within a forest.
- Previous testing shows that the increased time to complete TDO-related operations, such as authentication across domains, deteriorates performance noticeably if the Active Directory implementation in an organization contains more than 2,400 TDOs.

For more information about trust limitations, see "Practical Limitations of Trusts" in How Domain and Forest Trusts Work (http://go.microsoft.com/fwlink/?LinkID=35356).

**Maximum Number of Accounts per LDAP Transaction**
When you write scripts or applications that perform LDAP transactions, the recommended limit is to perform no more than 5,000 operations per LDAP transaction. An LDAP transaction is a group of directory operations (such as add, delete, and modify) that are treated as one unit. If your script or application performs more than 5,000 operations in a single LDAP transaction, you are at risk of running into resource limits and an operational time-out. If that happens, all the operations (changes, additions, and modifications) in the transaction are rolled back, which means that you lose all those changes.

As an example, if you are using Active Directory Service Interfaces (ADSI) to write a script, the SetInfo method completes a transaction. For more information about ADSI Methods, see Active Directory Service Interfaces (http://go.microsoft.com/fwlink/?LinkID=4487).

As another example, when you use the System.DirectoryServices (S.DS) namespace in the Microsoft .NET Framework, the DirectoryEntry.CommitChanges method completes an LDAP transaction. For more information about the DirectoryEntry.CommitChanges method, see DirectoryEntry.CommitChanges () (http://go.microsoft.com/fwlink/?LinkId=115220).

| **Note** |
| --- |
| Regardless of the method that you use for LDAP transactions, you should plan to send less than 5,000 directory operations in a single transaction. To learn more about the LDAP data structure that commits changes, see LDAPMod (http://go.microsoft.com/fwlink/?LinkId=115221). |

**Recommended Maximum Number of Users in a Group**
For Windows 2000 Active Directory environments, the recommended maximum number of members in a group is 5,000. This recommendation is based on the number of concurrent atomic changes that can be committed in a single database transaction.

Starting with Windows Server 2003, the ability to replicate discrete changes to linked multivalued properties was introduced as a technology called Linked Value Replication (LVR). To enable LVR, you must increase the forest functional level to at least Windows Server 2003 interim. Increasing the forest functional level changes the way that group membership (and other linked multivalued attributes) is stored in the database and replicated between domain controllers. This allows the number of group memberships to exceed the former recommended limit of 5,000 for Windows 2000 or Windows Server 2003 at a forest functional level of Windows 2000.

So far, testing in this area has yet to reveal any new recommended limits to the number of members in a group or any other linked multivalued attribute. Production environments have been reported to exceed 4 million members, and Microsoft scalability testing reached 500 million members.

**Important**

Increasing the forest functional level to Windows Server 2003 interim or higher does not modify the way that existing group members are stored or replicated. To do that, you must remove the members that were added to the group before the forest functional level was increased to Windows Server 2003 and then add them back again to the appropriate groups. Any group members that you either add or remove after the forest functional level is increased will be LVR enabled, even if the group contains other members that are not LVR enabled.

For more information about linked attributes, see Linked Attributes (http://go.microsoft.com/fwlink/?LinkId=142909). For more information about the replication process, see How the Active Directory Replication Model Works (http://go.microsoft.com/fwlink/?LinkId=142908).

**Recommended Maximum Number of Domains in a Forest**

For Windows 2000 Server, the recommended maximum number of domains in a forest is 800. For Windows Server 2003, the recommended maximum number of domains when the forest functional level is set to Windows Server 2003 (also known as forest functional level 2) is 1,200. This restriction is a limitation of multivalued, nonlinked attributes in Windows Server 2003. For more information, see "Maximum Database Record Size" in How the Data Store Works (http://go.microsoft.com/fwlink/?LinkId=134791).

**Recommended Maximum Number of Domain Controllers in a Domain**

To ensure reliable recovery of SYSVOL, we recommend a limit of 1200 domain controllers per domain.

If any Active Directory domain in your network is expected to exceed 800 domain controllers and those domain controllers are hosting Active Directory–integrated Domain Name System (DNS) zones, review article 267855 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkId=115222).

For more information about FRS limitations, see the FRS Technical Reference (http://go.microsoft.com/fwlink/?LinkId=115302).

**Recommended Maximum Kerberos Settings**

The maximum recommended size for a Kerberos ticket is 48,000 bytes, which is configured through the **MaxTokenSize** REG_DWORD value in the registry (**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Lsa\Kerberos\Parameters**) or through Group Policy, as described in KB article 938118.

**Note**

The maximum allowed value of MaxTokenSize is 65,535 bytes. If you are using Kerberos for IPSEC key management, the limit of 65,536 bytes. However, because of HTTP's base64 encoding of authentication context tokens, we do not recommend that you set the maxTokenSize registry entry to a value larger than 48,000 bytes. Starting with Windows Server 2012, the default value of the MaxTokenSize registry entry is 48,000 bytes.

For additional information about Kerberos tickets, including error conditions that can occur when Kerberos ticket size limits are set too low or too high, see Additional Resources for Troubleshooting Kerberos (http://go.microsoft.com/fwlink/?LinkId=134740).

# Designing the Active Directory Logical Structure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Designing your Microsoft® Windows® Server 2003 Active Directory® directory service logical structure involves defining the structure of and relationships between the forests, domains, and organizational units that you plan to deploy. Carefully designing your Active Directory logical structure enables you to minimize the time and effort required to implement Active Directory in your organization. In this way, you can establish an efficient structure that best meets the administrative needs of your organization.

**In This Topic**

Overview of Designing the Active Directory Logical Structure

Identifying the Deployment Project Participants

Creating a Forest Design

Creating a Domain Design

Designing a DNS Infrastructure to Support Active Directory

Designing Organizational Units for Delegation of Administration

Additional Resources for Designing the Active Directory Logical Structure

**Related Information**

- For more information about Active Directory concepts, see the *Active Directory Collection* of the *Windows Server 2003 Technical Reference* (or see the Active Directory Collection on the Web at http://www.microsoft.com/reskit).

# Overview of Designing the Active Directory Logical Structure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Active Directory in Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; and Windows® Server 2003, Datacenter Edition enables organizations to create a scalable, secure, and manageable infrastructure for user and resource management and to support directory-enabled applications.

A well-designed Active Directory logical structure provides the following benefits:

- Simplified management of Windows networks that contain large numbers of objects.
- A consolidated domain structure and reduced administration costs.
- The ability to delegate administrative control over resources as appropriate.
- Reduced impact on network bandwidth.
- Simplified resource sharing.
- Optimal search performance.
- Low total cost of ownership.

A well-designed Active Directory logical structure facilitates the efficient integration of features such as Group Policy, enabling desktop lockdown, software distribution, and user, group, workstation, and server administration, into your system. In addition, a carefully designed logical structure facilitates the integration of services such as Microsoft® Exchange 2000, public key infrastructure (PKI), and domain-based distributed file system (DFS).

If your organization is currently operating in a non-Microsoft operating system or Microsoft® Windows NT® version 4.0 operating system environment, designing an Active Directory logical structure before deploying Active Directory enables you to optimize your deployment process in order to best take advantage of Windows Server 2003 Active Directory features.

**Note**

- For a list of the job aids that are available to assist you in designing your Active Directory logical structure, see "Additional Resources for Upgrading from Windows 2000 Domains to Windows Server 2003 Domains" later in this chapter.

# Process for Designing the Active Directory Logical Structure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To design the Active Directory logical structure, a design team must first identify the requirements of the organization, and, based on this information, decide where to place the forest and domain boundaries. Then, the design team decides how to configure the DNS environment to meet the needs of the forest. Finally, the team identifies the organizational unit (OU) structure that is required in order to delegate management of resources in your organization.

Figure 2.1 shows the process for designing the logical structure.

**Figure 2.1 Designing the Active Directory Logical Structure**

# Active Directory Logical Structure Background Information

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you design your Active Directory logical structure, it is important to understand the Active Directory logical model. Active Directory is a distributed database that stores and manages information about network resources, as well as application-specific data from directory enabled applications. Active Directory allows administrators to organize elements of a network (such as users, computers, devices, and so on) into a hierarchical containment structure. The top-level container is the forest. Within forests are domains, and within domains are organizational units. This is called the logical model because it is independent of the physical aspects of the deployment, such as the number of domain controllers required within each domain and network topology.

Figure 2.2 shows the relationship between forests, domains, and organizational units.

**Figure 2.2 Relationship Between Active Directory Forests, Domains, and OUs**

**Active Directory forest**

A forest is a collection of one or more Active Directory domains that share a common logical structure, global catalog, directory schema, and directory configuration, as well as automatic two-way transitive trust relationships. Each forest is a single instance of the directory and defines a security boundary.

**Security boundary** A boundary that defines a container for which no administrator external to the container can take control away from administrators within the container. For example, a forest is a security boundary. No administrators from outside the forest can control access to information inside the forest unless first given permission to do so by the administrators within the forest. By contrast a domain is not a security boundary because within a forest it is not possible for administrators from one domain to prevent a malicious administrator from another domain from accessing data in their domain.

**Active Directory domain**

A domain is a partition in an Active Directory forest. Partitioning data enables organizations to replicate data only to where it is needed. In this way, the directory can scale globally over a network that has limited available bandwidth. In addition, the domain supports a number of other core functions related to administration, including:

- Network-wide user identity. Domains allow user identities to be created once and referenced on any computer joined to the forest in which the domain is located. Domain controllers that make up a domain are used to store user accounts and user credentials such as passwords or certificates securely.

- Authentication. Domain controllers provide authentication services for users and supply additional authorization data, such as user group memberships, which can be used to control access to resources on the network.

- Trust relationships. Domains can extend authentication services to users in domains outside their own forest by means of trusts.

- Replication. The domain defines a partition of the directory containing sufficient data to provide domain services and replicates it between the domain controllers. In this way, all domain controllers are peers in a domain and are managed as a unit.

**Active Directory organizational units**
OUs can be used to form a hierarchy of containers within a domain. Organizational units are used to group objects for administrative purposes, such as the application of Group Policies or delegation of authority. Control over an OU and the objects within it is determined by the access control lists (ACLs) on the OU and on the objects in the OU.

**Delegation of authority** To facilitate the management of large numbers of objects, Active Directory supports the concept of delegation of authority. By means of delegation, owners can transfer full or limited authority over objects to other users or groups. Delegation is important because it helps to distribute the management of large numbers of objects across a number of people trusted to perform management tasks.

**Active Directory Logical Structure Design Process**
Designing your Active Directory logical structure involves defining the relationships between the containers in your directory. These relationships might be based on administrative requirements, such as delegation of authority, or they might be defined by operational requirements, such as the need to control replication. In general, forests are used as security boundaries, domains are used to control replication, and OUs are used to delegate administration.

Figure 2.3 shows the distribution of users in a fictitious multinational organization. In this example, a single Active Directory forest contains all of the users, computers, devices, and other entities within the organization. The organization started with a domain for their corporate headquarters (Corp) and then, to control replication across the entire world-wide network, the organization created three additional domains (North America, South America, and Europe) as partitions of the forest. To support further delegation, the organization subdivided the North America domain into three OUs: West, Central, and East.

**Figure 2.3 Delegation of Administration Within an Organization**

# Identifying the Deployment Project Participants

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The first step in establishing an Active Directory deployment project is to establish the design and deployment project teams who will be responsible for managing the design phase and deployment phase of the Active Directory project cycle. In addition, you must identify the individuals and groups who will be responsible for owning and maintaining the directory after the deployment is completed. Figure 2.4 shows the process for identifying the Active Directory deployment project participants.

**Figure 2.4 Identifying Active Directory Project Participants**

The design and deployment teams that you establish consist of individuals who understand the various needs of the organization. This includes members of IT groups in your organization who are responsible for network engineering and network planning with respect to directory services. It is important that the project teams include forward-looking IT managers who are responsible for the future growth of your networking environment, as well as individuals who are familiar with the Active Directory deployment process.

It is also important to include in the project teams individuals, called *owners*, who will be responsible for maintaining the directory when the deployment process is complete. After Active Directory is deployed, the owners ensure that service levels are maintained and are responsible for the day-to-day maintenance of the directory. Owners are usually IT managers who oversee the groups or teams of network administrators that perform the hands-on work.

# Defining Project-Specific Roles

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An important step in establishing the project teams is to identify the individuals who are to hold project-specific roles. These include the executive sponsor, the project architect, and the project manager. These individuals are responsible for running the Active Directory deployment project.

After you appoint the project architect and project manager, these individuals establish channels of communication throughout the organization, build project schedules, and identify the individuals who will be members of the project teams, beginning with the various owners.

**Executive sponsor**
Deploying an infrastructure such as Active Directory can have a wide-ranging impact on an organization. For this reason, it is important to have an executive sponsor who understands the business value of the deployment, supports the project at the executive level, and can help resolve conflicts across the organization.

**Project architect**
Each Active Directory deployment project requires a project architect to manage the Active Directory design and deployment decision-making process. The architect provides technical expertise to assist with the process of designing and deploying Active Directory.

### Note

- If no existing personnel in your organization have directory design experience, you might want to hire an outside consultant who is an expert in Active Directory design and deployment.

The responsibilities of the Active Directory project architect include:

- Owning the Active Directory design.
- Understanding and recording the rationale for key design decisions.
- Ensuring that the design meets the business needs of the organization.
- Establishing consensus between design, deployment, and operations teams.
- Understanding the needs of Active Directory–integrated applications, such as Exchange 2000, and the impact they have on the Active Directory design.

The final Active Directory design must reflect a combination of business goals and technical decisions. Therefore, the project architect must review design decisions to ensure that they are in alignment with business goals.

**Project manager**
The project manager facilitates cooperation across business units and between technology management groups. Ideally, the Active Directory deployment project manager is someone from within the organization who is familiar with the operational policies of the IT group and the design requirements for the groups that are preparing to deploy Active Directory. The project manager oversees the entire deployment project, beginning with design and continuing through implementation, and makes sure that the project stays on schedule and within budget. The responsibilities of the project manager include:

- Providing basic project planning, such as scheduling and budgeting.
- Driving progress on the Active Directory design and deployment project.
- Ensuring that the appropriate individuals are involved in each part of the design process.
- Serving as single point of contact for the Active Directory deployment project.

- Establishing communication between design, deployment, and operations teams.
- Establishing and maintaining communication with the executive sponsor throughout the deployment project.

# Establishing Owners and Administrators

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In an Active Directory deployment project, individuals who are *owners* are held accountable by management for making sure that deployment tasks are completed and that Active Directory design specifications meet the needs of the organization. Owners do not necessarily have access to or manipulate the directory infrastructure directly. *Administrators* are the individuals responsible for completing the required deployment tasks. Administrators have the network access and permissions necessary to manipulate the directory and its infrastructure.

The role of the owner is strategic and managerial. Owners are responsible for communicating to administrators the tasks required for the implementation of the Active Directory design, such as the creation of new domain controllers within the forest. The administrators are responsible for implementing the design on the network according to the design specifications.

In larger organizations, different individuals fill owner and administrator roles; however, in some smaller organizations, the same individual might act as both the owner and the administrator.

**Service and Data Owners**

Managing Active Directory on a daily basis involves two types of owners:

- Service owners. Service owners are responsible for the planning and long-term maintenance of the Active Directory infrastructure, and ensuring that the directory continues to function, and that the goals established in service level agreements are maintained.

- Data owners. Data owners are responsible for the maintenance of the information stored in the directory. This includes user and computer account management and management of local resources, such as member servers and workstations.

It is important to identify the Active Directory service and data owners early on so that they can participate in as much of the design process as possible. Because the service and data owners are responsible for the long-term maintenance of the directory after the deployment project is finished, it is important for these individuals to provide input as to organizational needs and to be familiar with how and why certain design decisions were made. Service owners include the forest owner, the Active Directory DNS owner, and the site topology owner. Data owners include OU owners.

**Service and Data Administrators**

The operation of Active Directory involves two types of administrators: service administrators and data administrators. Service administrators implement policy decisions made by service owners and handle the day-to-day tasks associated with maintaining the directory service and infrastructure. This includes managing the domain controllers that are hosting the directory service; managing other network services, such as DNS, that are required for Active Directory; controlling the configuration of forest-wide settings; and ensuring that the directory is always available.

Service administrators are also responsible for completing ongoing Active Directory deployment tasks that are required after the initial Windows Server 2003 Active Directory deployment process is complete. For example, as demands on the directory increase, service administrators create additional domain controllers, and establish or remove trusts between domains as needed. For this reason, the Active Directory deployment team needs to include service administrators.

You must be careful to assign service administrator roles only to trusted individuals in the organization. Because these individuals have the ability to modify the system files on domain controllers, they can change the behavior of Active Directory, enabling them to gain access to and modify any resource in the forest. You must ensure that the service administrators in your organization are individuals who are familiar with the operational and security policies that are in place on your network and who understand the need to enforce those policies.

Data administrators are users within a domain who are responsible for maintaining data that is stored in Active Directory, such as user and group accounts, and maintaining computers that are members of their domain. Data administrators control subsets of objects within the directory and have no control over the installation or configuration of the directory service.

Data administrator accounts are not provided by default. After the design team determines how resources are to be managed for the organization, domain owners must create data administrator accounts and delegate them the appropriate permissions based on the set of objects for which the administrators are to be responsible.

It is best to limit the number of service administrators in your organization to the minimum number required to ensure that

the infrastructure continues to function. The majority of administrative work can be completed by data administrators. Service administrators require a much wider skill set because they are responsible for maintaining the directory and the infrastructure that supports it. Data administrators only require the skills necessary to manage their portion of the directory. Dividing work assignments in this way results in cost savings for the organization because only a small number of administrators need to be trained to operate and maintain the entire directory and its infrastructure.

For example, a service administrator needs to understand how to add a domain to a forest. This includes how to install the software to convert a server into a domain controller and how to manipulate the DNS environment so that the domain controller can be merged seamlessly into the Active Directory environment. A data administrator only needs to know how to manage the specific data that they are responsible for, such as the creation new user accounts for any new employees in their department.

**Service and Data Owners for Active Directory**
Deploying Active Directory requires coordination and communication between many different groups involved in the operation of the network infrastructure. These groups should appoint service and data owners who are responsible for representing the various groups during the design and deployment process.

Once the deployment project is complete, these service and data owners continue to be responsible for the portion of the infrastructure managed by their group. In an Active Directory environment these owners are:

**Forest Owner**
The forest owner is typically a senior IT manager in the organization, who is responsible for the Active Directory deployment process and who is ultimately accountable for maintaining service delivery within the forest after the deployment is complete. The forest owner assigns individuals to fill the other ownership roles by identifying key personnel within the organization who are able to contribute necessary information about network infrastructure and administrative needs. The forest owner is responsible for:

- The deployment of the forest root domain to create the forest.
- The deployment of the first domain controller in each domain to create the domains required for the forest.
- The memberships of the service administrator groups in all domains of the forest.
- The creation of the design of the OU structure for each domain in the forest.
- The delegation of administrative authority to OU owners.
- Changes to the schema.
- Changes to forest-wide configuration settings.
- The implementation of certain Group Policies, including
    - Domain user account policies, such as password complexity and account lockout.
    - Policies that apply to domain controllers.
    - Any other Group Policies that are applied at the domain level.

The forest owner has authority over the entire forest. It is the forest owner's responsibility to set policy and to select the individuals who are service administrators. The forest owner is a service owner.

**Active Directory DNS Owner**
The Active Directory DNS owner is an individual who has a thorough understanding of the existing DNS infrastructure and the existing namespace of the organization.

The Active Directory DNS owner is responsible for:

- Serving as a liaison between the design team and the IT group that currently owns the DNS infrastructure.
- Providing the information about the existing DNS namespace of the organization, to assist in the creation of the new

Active Directory namespace.

- Working with the deployment team to make sure that the new DNS infrastructure is deployed according to the specifications of the design team and that it is working properly.

- Managing the Active Directory DNS infrastructure including the DNS services and DNS data.

The Active Directory DNS owner is a service owner.

**Site Topology Owner**
The site topology owner is familiar with the physical structure of the network of the organization, including the mapping of individual subnets, routers, and the areas of the network that are connected by means of slow links. The site topology owner is responsible for the following tasks:

- Understanding the physical network topology and how it affects Active Directory.

- Understanding how the Active Directory deployment will impact the network.

- Determining the sites that need to be created.

- Updating server objects for domain controllers when a subnet changes.

- Creating site links.

The site topology owner is a service owner.

**OU Owner**
The OU owner is responsible for managing data stored in the directory. This individual needs to be familiar with the operational and security policies that are in place on the network. OU owners can only perform tasks that have been delegated to them by the service administrators and they can only perform those tasks on the OUs to which they are assigned. Some tasks that the OU owner might be assigned include the following:

- Performing all account management tasks within their assigned OU.

- Managing workstations and member servers that are members of their assigned OU.

- Delegating authority to local administrators within their assigned OU.

The OU owner is a data owner.

# Building Project Teams

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Active Directory project teams are temporary groups that are responsible for completing Active Directory design and deployment tasks. When the Active Directory deployment project is complete, the owners assume responsibility for the directory and the project teams can disband.

The size of the project teams varies according to the size of the organization. In smaller organizations, a single person can cover multiple areas of responsibility on a project team and be involved in more than one phase of the deployment. Larger organizations might require larger teams with different individuals, or even different teams, covering the different areas of responsibility. The size of the teams is not important as long as all areas of responsibility are assigned and the design goals of the organization are met.

# Identifying Potential Forest Owners

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Identify the groups within your organization that own and control the resources necessary to provide directory services to users on the network. These groups are considered potential forest owners.

The separation of service and data administration in Active Directory makes it possible for the infrastructure IT group or groups of an organization to manage the directory service, while local administrators in each group manage the data that belongs to their own groups. Potential forest owners have the required authority over the network infrastructure to deploy and support Active Directory.

For organizations that have one centralized infrastructure IT group, the IT group is generally the forest owner and therefore the potential forest owner for any future deployments. Organizations that include a number of independent infrastructure IT groups have a number of potential forest owners. If your organization already has an Active Directory infrastructure in place, then any current forest owners are also potential forest owners for new deployments.

Select one of the potential forest owners to act as the forest owner for each forest that you are considering for deployment. These potential forest owners are responsible for working with the design team to determine whether or not their forest will actually be deployed or if an alternate course of action, such as joining another existing forest, is a better use of the available resources and still meets their needs. The forest owner or owners in your organization are members of the Active Directory design team.

# Establishing a Design Team

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Active Directory design team is responsible for gathering all of the information needed to make decisions about the Active Directory logical structure design. The responsibilities of the design team include:

- Determining how many forests and domains are required and what the relationships are between the forests and domains.
- Working with data owners to ensure that the design meets their security and administrative requirements.
- Working with the current network administrators to ensure that the current network infrastructure supports the design and the design will not adversely affect existing applications deployed on the network.
- Working with representatives of the security group of the organization to ensure that the design meets established security policies.
- Designing OU structures that permit appropriate levels of protection and the proper delegation of authority to the data owners.
- Working with the deployment team to test the design in a lab environment to ensure that it functions as planned, and modifying the design as needed to address any problems that occur.
- Creating a site topology design that meets the replication requirements of the forest while preventing overload of available bandwidth. For more in formation about designing the site topology, see "Designing the Site Topology" in this book
- Working with the deployment team to ensure that the design is implemented correctly.

The design team includes the following members:

- Potential forest owners
- Project architect
- Project manager
- Individuals who are responsible for establishing and maintaining security policies on the network

During the logical structure design process, the design team identifies the other owners. These individuals must start participating in the design process as soon as they are identified.

After the deployment project is handed off to the deployment team, the design team is responsible for overseeing the deployment process to ensure that the design is implemented correctly. The design team also makes changes to the design based on feedback from testing.

# Establishing a Deployment Team

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Active Directory deployment team is responsible for testing and implementing the Active Directory logical structure design. This involves the following tasks:

- Establishing a test environment that sufficiently emulates the network environment.
- Testing the design by implementing the proposed forest and domain structure in a lab environment to verify that it meets the goals of each role owner.
- Developing and testing any migration scenarios proposed by the design in a lab environment.
- Making sure that each owner signs off on the testing process to ensure that the correct design features are being tested.
- Testing the deployment operation in a pilot environment.

When the design and testing tasks are complete, the deployment team:

- Creates the forests and domains according to the Active Directory logical structure design.
- Creates the sites and site link objects as needed based on the site topology design.
- Ensures that the DNS infrastructure is configured to support Active Directory and that any new namespaces are integrated into the existing namespace of the organization.

The Active Directory deployment team includes the following members:

- Forest owner
- Active Directory DNS owner
- Site topology owner
- OU owners

The deployment team works with the service and data administrators during the deployment phase to ensure that members of the operations team are familiar with the new design. This helps to ensure a smooth transition of ownership when the deployment operation is completed. At the completion of the deployment process, the responsibility for maintaining the new Active Directory environment passes to the operations team.

# Document the Design and Deployment Teams

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Document the names of and contact information for the people who will participate in the design and deployment of Active Directory. Identify who will be responsible for each role on the design and deployment teams. Initially this list includes the potential forest owners, the project manager, and the project architect. When you determine the number of forests that you will deploy, you might need to create new design teams for additional forests. Note that you will need to update your documentation as team memberships change and as you identify the various Active Directory owners during the design process.

For a worksheet to assist you in documenting your Active Directory design and deployment team members, see "Design and Deployment Team Information" (DSSLOGI_1.doc) on the *Microsoft® Windows® Server 2003 Deployment Kit* companion CD (or see "Design and Deployment Team Information" on the Web at http://www.microsoft.com/reskit).

# Example: Identifying Deployment Project Participants

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Contoso Pharmaceuticals Corporation decided to deploy Windows Server 2003 Active Directory in their environment. They established a design team to begin the forest planning and deployment process. This team included IT personnel who were familiar with the existing network, all of the potential forest owners, the individuals who manage the corporate namespace, and the owners and administrators who will be responsible for the directory after the deployment project is complete. Some members of the Active Directory logical structure design team will be identified as the design process progresses. Figure 2.5 shows the worksheet that Contoso corporation completed to document the design team members who will begin the deployment process.

**Figure 2.5 Example of a Design and Deployment Team Information Worksheet**

# Creating a Forest Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Creating a forest design involves first identifying the groups within your organization that have the resources available to host an Active Directory forest, and then defining your forest design requirements. Finally, you need to determine the number of forests that you require in order to meet the needs of your organization.

Figure 2.6 shows the process for creating a forest design.

**Figure 2.6 Creating a Forest Design**

# Identifying Forest Design Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In order to create a forest design for your organization, you must identify the business requirements that your directory structure needs to accommodate. This involves determining how much autonomy the groups in your organization need to manage their network resources, and whether each group needs to isolate their resources on the network from other groups.

Active Directory enables you to design a directory infrastructure that accommodates multiple groups within an organization that have unique management requirements, and to achieve structural and operational independence between groups as needed.

Groups in your organization might have some of the following types of requirements:

- **Organizational structure requirements.** Parts of an organization might participate in a shared infrastructure to save costs, but require the ability to operate independently from the rest of the organization. For example, a research group within a large organization might need to maintain control over all of their own research data.

- **Operational requirements.** One part of an organization might place unique constraints on the directory service configuration, availability, or security, or use applications that place unique constraints on the directory. Examples are found in:

    - Military organizations.

    - Hosting scenarios.

    - Organizations that maintain a directory that is available both internally and externally (publicly accessible by users on the Internet).

- **Legal requirements.** Some organizations have legal requirements to operate in a specific way, such as by restricting access to certain information as specified in a business contract. Failure to meet these requirements can result in loss of the contract and possibly legal action. These requirements commonly apply to the following types of organizations:

    - Financial institutions that need to maintain private client financial records.

    - Defense contractors that are working on classified military projects.

    - Government organizations that maintain top secret data.

Part of identifying your forest design requirements involves identifying the degree to which groups in your organization can trust the potential forest owners and their service administrators, and identifying the autonomy and isolation requirements for each group in your organization.

# Service Administrator Scope of Authority

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you choose to participate in an Active Directory forest, you must trust the forest owner and the service administrators. The forest owners are responsible for selecting and managing the service administrators; therefore, when you trust a forest owner, you also trust the service administrators that the forest owner manages. These service administrators have access to all of the resources in the forest. Before making the decision to participate in a forest, it is important to understand that the forest owner and the service administrators will have full access to your data. You cannot prevent this access.

All service administrators in a forest have full control over all data and services on all computers in the forest. Service administrators have the ability to do the following:

- Correct errors on ACLs of objects. This enables the service administrator to read, modify, or delete objects regardless of the ACLs that are set on those objects.
- Modify the system software on a domain controller to bypass normal security checks. This enables the service administrator to view or manipulate any object in the domain, regardless of the ACL on the object.
- Use the Restricted Groups security policy to grant any user or group administrative access to any computer joined to the domain. Service administrators can thus obtain control of any computer joined to the domain, regardless of the intentions of the computer owner.
- Reset passwords or change group memberships for users.
- Gain access to other domains in the forest by modifying the system software on a domain controller. Service administrators can affect the operation of any domain in the forest, view or manipulate forest configuration data, view or manipulate data stored in any domain, or view or manipulate data stored on any computer joined to the forest.

For this reason, groups that store data in OUs in the forest and that join computers to a forest must trust the service administrators. In order for a group to join a forest, it must choose to trust all service administrators in the forest. This involves ensuring that:

- The forest owner can be trusted to act in the interests of the group, and does not have reason to act maliciously against the group.
- The forest owner appropriately restricts physical access to domain controllers. Domain controllers within a forest cannot be isolated from one another. It is possible for an attacker who has physical access to a single domain controller to make offline changes to the directory database, and by so doing interfere with the operation of any domain in the forest, view or manipulate data stored anywhere in the forest, or view or manipulate data stored on any computer joined to the forest. For this reason, physical access to domain controllers must be restricted to trusted personnel.
- You understand and accept the potential risk that trusted service administrators can be coerced into compromising the security of the system.

Some groups might determine that the collaborative and cost-saving benefits of participating in a shared infrastructure outweigh the risks that service administrators will misuse or will be coerced into misusing their authority. These groups can share a forest and use OUs to delegate authority. However, other groups might not accept this risk because the consequences of a compromise in security are too severe. Those groups require separate forests.

# Autonomy vs. Isolation

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can design your Active Directory logical structure to achieve either of the following:

- **Autonomy**.Autonomy involves independent but not exclusive control of a resource. When you achieve autonomy, administrators have the authority to manage resources independently; however, administrators with greater authority exist who also have control over those resources and can take control away if necessary. You can design your Active Directory logical structure to achieve the following types of autonomy:
    - **Service autonomy.** This type of autonomy involves control over all or part of service management.
    - **Data autonomy.** This type of autonomy involves control over all or part of the data stored in the directory or on member computers joined to the directory.
- **Isolation.** Isolation involves independent and exclusive control of a resource. When you achieve isolation, administrators have the authority to manage a resource independently and no other administrators can take control of the resource away. You can design your Active Directory logical structure to achieve the following types of isolation:
    - **Service isolation.** This type of isolation prevents administrators other than those specifically designated to control service management from controlling or interfering with service management.
    - **Data isolation.** This type of isolation prevents administrators other than those specifically designated to control or view data from controlling or viewing a subset of data in the directory or on member computers joined to the directory.

Administrators who require only autonomy accept that other administrators who have equal or greater administrative authority have equal or greater control over service or data management. Administrators who require isolation have exclusive control over service or data management. Creating a design to achieve autonomy is generally less expensive than creating a design to achieve isolation.

In Active Directory, administrators can delegate both service administration and data administration in order to achieve either autonomy or isolation between organizations. The combination of service management, data management, autonomy, and isolation requirements of an organization impact the Active Directory containers that are used to delegate administration.

# Isolation and Autonomy Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The number of forests that you need to deploy is based on the autonomy and isolation requirements of each group within your organization. In order to identify your forest design requirements, you must identify the autonomy and isolation requirements for all groups in your organization. Specifically, you must identify the need for data isolation, data autonomy, service isolation, and service autonomy. You must also identify areas of limited connectivity in your organization.

**Data Isolation**

Data isolation involves exclusive control over data by the group or organization that owns the data. It is important to note that service administrators have the ability to take control of a resource away from data administrators, and data administrators do not have the ability to prevent service administrators from accessing the resources that they control. Therefore, you cannot achieve data isolation when another group within the organization is responsible for service administration. If a group requires data isolation, that group must also assume responsibility for service administration.

Because data stored in Active Directory and on computers joined to Active Directory cannot be isolated from service administrators, the only way for a group within an organization to achieve complete data isolation is to create a separate forest for that data. Organizations for which the consequences of an attack by a malicious or coerced service administrator are substantial might choose to create a separate forest to achieve data isolation. Legal requirements typically create a need for this type of data isolation. For example:

- A financial institution is required by law to limit access to data that belongs to clients in a particular jurisdiction to users, computers, and administrators located in that jurisdiction. Although the institution trusts service administrators that work outside the protected area, if the access limitation is violated, the institution will no longer be able to do business in that jurisdiction. Therefore, the financial institution must isolate data from service administrators outside that jurisdiction. Note that encryption is not always an alternative to this solution. Encryption might not protect data from service administrators.

- A defense contractor is required by law to limit access to project data to a specified set of users. Although the contractor trusts service administrators who control computer systems related to other projects, a violation of this access limitation will cause the contractor to lose business.

  **Note**

  - If you have a data isolation requirement, then you must decide whether you need to isolate your data from service administrators or from data administrators and ordinary users. If your isolation requirement is based on isolation from data administrators and ordinary users, then you can use ACLs to isolate the data. For the purposes of this design process, isolation from data administrators and ordinary users is not considered a data isolation requirement.

**Data Autonomy**

Data autonomy involves the ability of a group or organization to manage its own data, including making administrative decisions about the data and performing any required administrative tasks, without the need for approval from another authority.

Data autonomy does not prevent service administrators in the forest from accessing the data. For example, a research group within a large organization might want to be able to manage their project-specific data themselves, but not need to secure the data from other administrators in the forest.

**Service Isolation**

Service isolation involves exclusive control of the Active Directory infrastructure. Groups that require service isolation require that no administrator outside of the group can interfere with the operation of the directory service.

Operational or legal requirements typically create a need for service isolation. For example:

- A manufacturing company has a critical application that controls equipment on the factory floor. Interruptions in the service on other parts of the network of the organization cannot be allowed to interfere with the operation of the factory floor.

- A hosting company provides service to multiple clients. Each client requires service isolation so that any service interruption that affects one client does not affect the other clients.

**Service Autonomy**
Service autonomy involves the ability to manage the infrastructure without a requirement for exclusive control. This means that a group wants to make changes to the infrastructure, such as adding or removing domains, modifying the DNS namespace, or modifying the schema, without the approval of the forest owner.

Service autonomy might be required for a group within an organization that wants to be able to control the service level of Active Directory by adding and removing domain controllers as needed, or that needs to be able to install directory enabled applications that require schema extensions.

**Limited Connectivity**
If a group within your organization owns networks that are separated by devices that restrict or limit connectivity between networks, such as firewalls and Network Address Translation (NAT) devices, this can impact your forest design. When you identify your forest design requirements, be sure to note the locations where you have limited network connectivity. This information is required to enable you to make decisions regarding the forest design.

# Documenting the Forest Design Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The design team must document the isolation and autonomy requirements for service and data administration for each group in the organization that intends to use Active Directory. The team must also note any areas of limited connectivity that might affect the deployment of Active Directory.

For a worksheet to assist you in documenting your forest design requirements, see "Forest Design Requirements" (DSSLOGI_2.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Forest Design Requirements" on the Web at http://www.microsoft.com/reskit).

**Example: Documenting the Forest Design Requirements**
The Pharmaceuticals group of Contoso Corporation needs to keep their data confidential; therefore, they require complete administrative control over their information. They need to write a justification so that the design team understands their administrative requirements.

Figure 2.7 shows the forest design requirements worksheet that the design team created in conjunction with the Pharmaceuticals group.

**Figure 2.7 Example of Forest Design Requirements Worksheet**

Forest Design Requirements

| | | | |
|---|---|---|---|
| Prepared By | Maria Hammond | Date | 2/19/03 |
| Group | Pharmaceuticals Division | | |

Instructions: Complete the indicated information for the contacts in the group.

| Name | Role | E-mail | Phone |
|---|---|---|---|
| Yan Li | Pharmaceuticals Division IT Manager | yan@contoso.com | x164 |
| Lori Kane | Pharmaceuticals Division IT Analyst | lorik@contoso.com | x743 |
| Jay Adams | Pharmaceuticals Division IT Analyst | jay@contoso.com | x386 |
| Toby Nixon | Pharmaceuticals Division IT Analyst | toby@contoso.com | x224 |

In the area below, list the design requirements. Add check marks to the columns indicating the isolation and autonomy requirements for your decisions.

| | DI | DA | SI | SA | LC |
|---|---|---|---|---|---|
| The Pharmaceuticals Division maintains confidential research data. Only members of the division should be granted access to the information stored in the forest. Administrative access must be controlled. | x | | | | |
| The computers containing research data are on a network that is separated from the organization's network by a firewall. | | | | | x |
| Pharmaceuticals Division administrators must have complete autonomy to manage the information while the data must be isolated from administrators outside of the division. | x | | | | |

# Determining the Number of Forests Required

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In order to determine the number of forests that you must deploy, you need to carefully identify and evaluate the isolation and autonomy requirements for each group in your organization and map those requirements to the appropriate forest design models.

Note that if you are coming from a Windows NT 4.0 environment, the decision process for creating your Active Directory logical structure design is different than the decision process for deploying Windows NT 4.0 Master User Domains (MUDs). It is not always appropriate for you to attempt to model your existing Windows NT 4.0 infrastructure when creating your Active Directory forest design.

When determining the number of forests to deploy for your organization, consider the following points:

- Isolation requirements limit your design choices. Therefore, if you identify isolation requirements, be sure that the groups actually require data isolation and that data autonomy is not sufficient for their needs. Ensure that the various groups in your organization clearly understand the concepts of isolation and autonomy.

- Negotiating the design can be a lengthy process, and it can be difficult for groups to come to agreement about ownership and utilization of available resources. Ensure that you allow enough time for the groups in your organization to conduct adequate research to identify their needs. Set firm deadlines for design decisions and get consensus from all parties on the established deadlines.

- Determining the number of forests to deploy involves balancing costs against benefits. A single forest model is the most cost-effective option and requires the least amount of administrative overhead. Although a group in the organization might prefer autonomous service operations, it might be more cost-effective for the organization to subscribe to service delivery from a centralized, trusted IT group, allowing the group to own data management without creating the added costs of service management. Balancing costs against benefits might require input from the executive sponsor.

  A single forest is the easiest configuration to manage and allows for maximum collaboration within the environment because:

  - All objects in a single forest are listed in the global catalog. Therefore, no synchronization across forests is required.

  - Management of a duplicate infrastructure is not required.

- Co-ownership of a single forest by two separate and autonomous IT organizations is not recommended. In the future, the goals of the two IT groups might change, so that they can no longer accept shared control.

- Outsourcing service administration to more than one outside partner is not recommended. Multinational organizations that have groups in different countries or regions might choose to outsource service administration to a different outside partner for each country or region. Because multiple outside partners cannot be isolated from one another, the actions of one partner can affect the service of the other, which makes it difficult to hold the partners accountable to their service level agreements.

- Only one instance of an Active Directory domain should exist at any time. Microsoft does not support cloning, splitting, or copying domain controllers from one domain in an attempt to establish a second instance of the same domain. For further information about this limitation, see the following section, "Restructuring Limitations."

# Forest Design Models

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can apply one of the following three forest design models in your Active Directory environment:

- Organizational forest model
- Resource forest model
- Restricted access forest model

It is likely that you will need to use a combination of these models in order to meet the needs of all the different groups in your organization.

**Organizational Forest Model**
In the organizational forest model, user accounts and resources are contained in the forest and managed independently. The organizational forest can be used to provide service autonomy, service isolation, or data isolation, if the forest is configured to prevent access to anyone outside the forest.

If users in an organizational forest need to access resources in other forests, or vice versa, trust can be established between one organizational forest and the other forests, as shown in Figure 2.8. This makes it possible for administrators to grant access to resources in the other forest.

**Figure 2.8 Organizational Forest Model**

Every Active Directory design includes at least one organizational forest.

**Resource Forest Model**
In the resource forest model, a separate forest is used to manage resources. Resource forests do not contain user accounts other than those required for service administration and those required to provide alternate access to the resources in that forest if the user accounts in the organizational forest become unavailable. Forest trusts are established so that users from other forests can access the resources contained in the resource forest, as shown in Figure 2.9.

**Figure 2.9 Resource Forest Model**

Resource forests provide service isolation that is used to protect areas of the network that need to maintain a state of high availability. For example, if your company includes a manufacturing facility that needs to continue to operate when there are problems on the rest of the network, you can create a separate resource forest for the manufacturing group.

**Restricted Access Forest Model**

In the restricted access forest model, a separate forest is created to contain user accounts and data that must be isolated from the rest of the organization. Restricted access forests provide data isolation in a situation for project data for which the consequences of compromise are severe. Figure 2.10 shows a restricted access forest model.

**Figure 2.10 Restricted Access Forest Model**

Users from other forests cannot be granted access to the restricted data because no trust exists. In this model, users have an account in an organizational forest for access to general organizational resources and a separate user account in the restricted access forest for access to the classified data. These users must have two separate workstations, one connected to the organizational forest and the other connected to the restricted access forest. This protects against the possibility that a service administrator from one forest can gain access to a workstation in the restricted forest.

In extreme cases, the restricted access forest might be maintained on a separate physical network. Organizations that work on classified government projects sometimes maintain restricted access forests on separate networks in order to meet security requirements.

# Mapping Design Requirements to Forest Design Models

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Most groups in your organization can share a single organizational forest that is managed by a single IT group and that contains the user accounts and resources for all of the groups that share the forest. This shared forest, called the *initial organizational forest*, is the foundation of the forest design model for the organization.

Because the initial organizational forest can host multiple groups in the organization, the forest owner must establish service level agreements with each group so that all parties understand what is expected of them. This protects both the individual groups and the forest owner by establishing agreed-upon service expectations.

If not all of the groups in your organization can share a single organizational forest, you must expand your forest design to accommodate the needs of the different groups. This involves identifying the design requirements that apply to the groups, based on their needs for autonomy and isolation and whether or not they have a limited-connectivity network, and then identifying the forest model that you can use to accommodate those requirements. Use Table 2.1 to identify the forest design model scenario that best meets your needs based on the autonomy, isolation, and connectivity factors that you identified. After you identify your forest design scenario, determine whether you need to make any additional decisions in order to meet your design requirements.

**Note**

- If a factor is listed as N/A, it is not a consideration because other requirements also accommodate that factor.

**Table 2.1 Scenarios Based on Isolation and Autonomy Design Requirements**

| Limited Connectivity | Data Isolation | Data Autonomy | Service Isolation | Service Autonomy | Scenario |
|---|---|---|---|---|---|
| No | No | Yes | No | No | Scenario 1: Join an existing forest for data autonomy. |
| No | No | N/A | No | Yes | Scenario 2: Use an organizational forest or domain for service autonomy. |
| No | No | N/A | Yes | N/A | Scenario 3: Use an organizational or resource forest for service isolation. |
| N/A | Yes | N/A | N/A | N/A | Scenario 4: Use an organizational or restricted access forest for data isolation. |
| Yes | No | N/A | No | No | Scenario 5: Use an organizational forest or reconfigure the firewall for limited connectivity. |
| Yes | No | N/A | No | Yes | Scenario 6: Use an organizational forest or domain and reconfigure the firewall for service autonomy with limited connectivity. |
| Yes | No | N/A | Yes | N/A | Scenario 7: Use a resource forest and reconfigure the firewall for service isolation with limited connectivity. |

**Scenario 1: Join an Existing Forest for Data Autonomy**

You can meet a requirement for data autonomy simply by hosting the group in OUs in an existing organizational forest. Delegate control over the OUs to data administrators from that group to achieve data autonomy. For more information about delegating control by using OUs, see "Designing Organizational Units for Delegation of Administration" later in this chapter.

**Scenario 2: Organizational Forest or Domain for Service Autonomy**

If a group in your organization identifies service autonomy as a requirement, it is recommended that you first reconsider this requirement. Achieving service autonomy creates more management overhead and additional costs for the organization. Ensure that the requirement for service autonomy is not simply for convenience and that you can justify the costs involved in

meeting this requirement.

You can meet a requirement for service autonomy by doing one of the following:

- Creating an organizational forest. Place the users, groups, and computers for the group that requires service autonomy into a separate organizational forest. Assign an individual from that group to be the forest owner. If the group needs to access or share resources with other forests in the organization, then they can establish a trust between their organizational forest and the other forests.

- Using organizational domains. Place the users, groups, and computers in a separate domain in an existing organizational forest. This model provides for domain-level service autonomy only, and not full service autonomy or service or data isolation. Other groups in the forest must trust the service administrators of the new domain to the same degree that they trust the forest owner. For this reason, this approach is not recommended.

  For more information about using organizational domains, see "Using the Organizational Domain Forest Model" later in this chapter.

**Scenario 3: Organizational or Resource Forest for Service Isolation**
You can meet a requirement for service isolation by doing one of the following:

- Using an organizational forest. Place the users, groups, and computers for the group that requires service isolation into a separate organizational forest. Assign an individual from that group to be the forest owner. If the group needs to access or share resources with other forests in the organization, then they can establish a trust between their organizational forest and the other forests.

- Using a resource forest. Place resources and service accounts into a separate resource forest, keeping user accounts in an existing organizational forest. If necessary, alternate accounts can be created in the resource forest to access resources in the resource forest in the event that the organizational forest becomes unavailable. The alternate accounts must have the authority required to log on to the resource forest and maintain control of the resources until the organizational forest is back on line.

  Establish a trust between the resource and organizational forests so that the users can access the resources in the forest while using their regular user accounts. This configuration enables centralized management of user accounts, while allowing users to fall back to alternate accounts in the resource forest in the event that the organizational forest becomes unavailable.

Considerations for service isolation include the following:

- Forests created for service isolation can trust domains from other forests, but must not include users from other forests in their service administrators groups. If users from other forests are included in administrative groups in the isolated forest, the security of the isolated forest potentially can be compromised because the service administrators in the forest do not have exclusive control.

- As long as domain controllers are accessible on a network, they are subject to attacks (such as denial of service attacks) from computers on that network. You can do the following to protect against the possibility of an attack:

  - Host domain controllers only on networks that are considered secure.

  - Limit access to the network(s) hosting the domain controllers.

- Service isolation requires the creation of an additional forest. Evaluate whether the cost of maintaining the infrastructure to support the additional forest outweighs the costs associated with loss of access to resources due to an organizational forest being unavailable.

**Scenario 4: Organizational or Restricted Access Forest for Data Isolation**
You can achieve data isolation by doing one of the following:

- Using an organizational forest. Place the users, groups, and computers for the group that requires data isolation into a

separate organizational forest. Assign an individual from that group to be the forest owner. If the group needs to access or share resources with other forests in the organization, then establish a trust between the organizational forest and the other forests. Only the users who require access to the classified information exist in the new organizational forest. Users have one account that they use to access both classified data in their own forest and unclassified data in other forests by means of trust relationships.

- Using a restricted access forest. This is a separate forest that contains the restricted data and the user accounts that are used to access that data. Separate user accounts are maintained in the existing organizational forests that are used to access the unrestricted resources on the network. No trusts are created between the restricted access forest and other forests in the enterprise. You can further restrict the forest by deploying the forest on a separate physical network so that it cannot connect to other forests. If you deploy the forest on a separate network, users must have two workstations: one for accessing the restricted forest and one for accessing the nonrestricted areas of the network.

Considerations for creating forests for data isolation include the following:

- Organizational forests created for data isolation can trust domains from other forests, but users from other forests must not be included in any of the following:

    - Groups responsible for service management or groups that can manage the membership of service administrator groups.

    - Groups that have administrative control over computers that store protected data.

    - Groups that have access to protected data, or groups that are responsible for the management of user or group objects that have access to protected data.

  If users from another forest are included in any of these groups, then a compromise of the other forest might lead to a compromise of the isolated forest and to disclosure of protected data.

- Other forests can be configured to trust the organizational forest created for data isolation so that users in the isolated forest can access resources in other forests. However, users from the isolated forest must never interactively log on to workstations in the trusting forest. The computer in the trusting forest can potentially be compromised by a malicious administrator and can be used to capture the logon credentials of the user.

  **Note**

    - To prevent servers in a trusting forest from impersonating users from the isolated forest and then accessing resources in the isolated forest, the forest owner can disable delegated authentication or use the constrained delegation feature. For more information about delegated authentication and constrained delegation, see "Delegating authentication" on the Microsoft Web site.

- You might need to establish a firewall between the organizational forest and the other forests in the organization to limit users' access to information outside of their forest.

- Although creating a separate forest enables data isolation, as long as the domain controllers in the isolated forest and computers that host protected information are accessible on a network, they are subject to attacks launched from computers on that network. Organizations that decide that the risk of attack is too high, or that the consequence of an attack or security violation is too great, need to limit access to the network(s) hosting the domain controllers and computers hosting protected data by using technologies such as firewalls and Internet Protocol security (IPSec). In extreme cases, they might choose to maintain the protected data on an independent network that has no physical connection to any other network in the organization.

  **Note**

    - If any network connectivity exists between a restricted access forest and another network, then the possibility exists for data in the restricted area to be transmitted to the other network.

**Scenario 5: Organizational Forest or Reconfigured Firewall for Limited Connectivity**
To meet a limited connectivity requirement, you can do one of the following:

- Place users into an existing organizational forest and then open the firewall enough to allow Active Directory traffic to pass through. For more information about configuring firewalls for use with Active Directory, see the Active Directory in Networks Segmented by Firewalls link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

- Use an organizational forest. Place the users, groups, and computers for the group for which connectivity is limited into a separate organizational forest. Assign an individual from that group to be the forest owner. The organizational forest provides a separate environment on the other side of the firewall. The forest includes user accounts and resources that are managed within the forest, so that users do not need to go through the firewall to accomplish their daily tasks. Specific users or applications might have special needs that require the ability to pass through the firewall to contact other forests. You can address those needs individually by opening the appropriate interfaces in the firewall, including those necessary for any trusts to function. For more information about configuring firewalls for use with Active Directory, see the Active Directory in Networks Segmented by Firewalls link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Scenario 6: Organizational Forest or Domain and Reconfigured Firewall for Service Autonomy with Limited Connectivity**
If a group in your organization identifies service autonomy as a requirement, it is recommended that you first reconsider this requirement. Achieving service autonomy creates more management overhead and additional costs for the organization. Ensure that the requirement for service autonomy is not simply for convenience and that you can justify the costs involved in meeting this requirement.

If limited connectivity is an issue and you have a requirement for service autonomy, then you can do one of the following:

- Use an organizational forest. Place the users, groups, and computers for the group that requires service autonomy into a separate organizational forest. Assign an individual from that group to be the forest owner. The organizational forest provides a separate environment on the other side of the firewall. The forest includes user accounts and resources that are managed within the forest, so that users do not need to go through the firewall to accomplish their daily tasks. Specific users or applications might have special needs that require the ability to pass through the firewall to contact other forests. You can address those needs individually by opening the appropriate interfaces in the firewall, including those necessary for any trusts to function. For more information about configuring firewalls for use with Active Directory, see the Active Directory in Networks Segmented by Firewalls link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

- Place the users, groups, and computers in a separate domain in an existing organizational forest. This model provides for domain-level service autonomy only, and not full service autonomy or service or data isolation. Other groups in the forest must trust the service administrators of the new domain to the same degree that they trust the forest owner. For this reason, this approach is not recommended. For more information about using organizational domains, see "Using the Organizational Domain Forest Model" later in this chapter.

You also need to open the firewall enough to allow Active Directory traffic to pass through. For more information about configuring firewalls for use with Active Directory, see the Active Directory in Networks Segmented by Firewalls link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources..

**Scenario 7: Resource Forest and Reconfigured Firewall for Service Isolation with Limited Connectivity**
If limited connectivity is an issue and you have a requirement for service isolation, then you can do one of the following:

- Use an organizational forest. Place the users, groups, and computers for the group that requires service isolation into a separate organizational forest. Assign an individual from that group to be the forest owner. The organizational forest provides a separate environment on the other side of the firewall. The forest includes user accounts and resources that are managed within the forest, so that users do not need to go through the firewall to accomplish their daily tasks. Specific users or applications might have special needs that require the ability to pass through the firewall to contact other forests. You can address those needs individually by opening the appropriate interfaces in the firewall, including those necessary for any trusts to function. For more information about configuring firewalls for use with Active Directory, see the Active Directory in Networks Segmented by Firewalls link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

- Use a resource forest. Place resources and service accounts into a separate resource forest, keeping user accounts in an existing organizational forest. It might be necessary to create some alternate user accounts in the resource forest to maintain access to the resource forest in the event that the organizational forest becomes unavailable. The alternate accounts must have the authority required to log on to the resource forest and maintain control of the resources until the organizational forest is back on line.

  Establish a trust between the resource and organizational forests so that the users can access the resources in the forest while using their regular user accounts. This configuration enables centralized management of user accounts, while allowing users to fall back to alternate accounts in the resource forest in the event that the organizational forest becomes unavailable.

Considerations for service isolation include the following:

- Forests created for service isolation can trust domains from other forests, but must not include users from other forests in their service administrators groups. If users from other forests are included in administrative groups in the isolated forest, the security of the isolated forest potentially can be compromised because the service administrators in the forest do not have exclusive control.

- As long as domain controllers are accessible on a network, they are subject to attacks (such as denial of service attacks) from computers on that network. You can do the following to protect against the possibility of an attack:

  - Host domain controllers only on networks that are considered secure.

  - Limit access to the network(s) hosting the domain controllers.

- Service isolation requires the creation of an additional forest. Evaluate whether the cost of maintaining the infrastructure to support the additional forest outweighs the costs associated with loss of access to resources due to an organizational forest being unavailable.

  Specific users or applications might have special needs that require the ability to pass through the firewall to contact other forests. You can address those needs individually by opening the appropriate interfaces in the firewall, including those necessary for any trusts to function. For more information about configuring firewalls for use with Active Directory, see the Active Directory in Networks Segmented by Firewalls link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Using the Organizational Domain Forest Model

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In the organizational domain forest model, several autonomous groups each own a domain within a forest. Each group controls domain-level service administration, which enables them to manage certain aspects of service management autonomously while the forest owner controls forest-level service management.

Because a domain is not a security boundary, it cannot be used for service or data isolation. For this reason, it is important to ensure that service or data isolation are not requirements for the groups in the organization. In an organizational domain forest model, a malicious service administrator in one domain can access any other domain within the forest.

If you have an existing Windows NT 4.0 environment that is based on organizational domains, it is not recommended that you reproduce this configuration in an Active Directory forest. The Active Directory forest does not have the same administrative and security boundaries that exist in a Windows NT 4.0 environment.

Figure 2.11 shows an organizational domain forest model.

**Figure 2.11 Organizational Domain Forest Model**

**Note**

- Because the organizational domain forest model is not recommended, additional design information is not provided.

**Domain-Level Service Autonomy**

The organizational domain forest model enables the delegation of authority for domain-level service management. Table 2.2 lists the types of service management that can be controlled at the domain level.

**Table 2.2 Types of Service Management That are Controlled at the Domain Level**

| Type of Service Management | Associated tasks |
|---|---|
| Management of domain controller operations | • Creating and removing domain controllers.<br>• Monitoring the functioning of domain controllers.<br>• Managing services that are running on domain controllers.<br>• Backing up and restoring the directory. |

| | |
|---|---|
| Configuration of domain-wide settings | • Creating domain and domain user account policies, such as password, Kerberos, and account lockout policies.<br>• Creating and applying domain-wide Group Policies. |
| Delegation of data-level administration | • Creating OUs and delegating administration.<br>• Repairing problems in the OU structure that OU owners do not have sufficient access rights to fix. |
| Management of external trusts | • Establishing trust relationships with domains outside the forest. |

Other types of service management, such as schema or replication topology management, are the responsibility of the forest owner.

**Domain Owner**

In an organizational domain forest model, *domain owners* are responsible for domain-level service management tasks. Domain owners have authority over the entire domain, as well as access to all other domains in the forest. For this reason, domain owners must be trusted individuals selected by the forest owner.

Delegate domain-level service management to a domain owner if the following conditions are met:

- All groups participating in the forest trust the new domain owner and the service management practices of the new domain.
- The new domain owner trusts the forest owner and all the other domain owners.
- All domain owners in the forest agree that the new domain owner has service administrator management and selection policies and practices that are equal to or more strict than their own.
- All domain owners in the forest agree that domain controllers managed by the new domain owner in the new domain are physically secure.

Keep in mind that if a forest owner delegates domain-level service management to a domain owner, then other groups might choose not to join that forest if they do not trust that domain owner.

All domain owners must be aware that if any of these conditions change in the future, it might become necessary to migrate the organizational domains into a multiple forest deployment.

# Documenting the Forest Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you map all of your design requirements to forest models and select the forest model that meets the needs of your organization, you need to document the proposed forest design. Include in your documentation the name of the group for which the forest is designed, the contact information for the forest owner, the type of forest for each forest that you include, and the requirements that each forest is designed to meet. This documentation will help the design team to ensure that all of the appropriate people are involved in the design process and to clarify the scope of the deployment project.

For a worksheet to assist you in documenting the proposed forest design, see "Proposed Forests" (DSSLOGI_3.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Proposed Forests" on the Web at http://www.microsoft.com/reskit).

At this point, you also need to establish and document the design and deployment teams for each forest. For a worksheet to assist you in documenting the design and deployment teams for each forest, see "Design and Deployment Team Information" (DSSLOGI_1.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Design and Deployment Team Information" on the Web at http://www.microsoft.com/reskit).

# Example: Documenting the Forest Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Contoso Corporation decided to use a single organizational forest for most of the organization. In addition, the Pharmaceuticals group needs to keep their data confidential so they want complete administrative control over their own organizational forest. The manufacturing group wants their own resource forest so that the service accounts used to operate the factory applications can continue to authenticate even if the main corporate forest goes offline. As a result, Contoso is deploying three forests for their forest design.

The design team documented the forests as shown in Figure 2.12.

**Figure 2.12 Example of a Completed Forest Design Worksheet**

Forest Design

| Prepared By | Maria Hammond | Date | 2/19/03 |
|---|---|---|---|

Instructions: Record the group names of any new proposed forest owners, the contact information for the representatives of those groups, the forest type, and the requirements that the forest is designed to meet.

| Group Name | Contact | Forest Type | Requirements |
|---|---|---|---|
| Central IT | Mark Lee<br>mark@contoso.com<br>X874 | Organizational | This is the initial forest created for the corporation. Many groups within the company use this forest. |
| Pharmaceuticals Division | Mary Baker<br>mary@contoso.com<br>x989 | Restricted Access | This group needs data isolation and they need to control who can access the project data for the group. |
| Manufacturing Division | Paul West<br>paul@contoso.com<br>X804 | Resource | The organization needs to maintain control of the manufacturing forest even if the corporate forest is unavailable. |

# Creating a Domain Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The forest owner is responsible for creating a domain design for the forest. Creating a domain design involves examining the replication requirements and the existing capacity of your network infrastructure, and then building a domain structure that enables Active Directory to function in the most efficient way. Figure 2.13 shows the process for creating a domain design.

**Figure 2.13 Creating a Domain Design**

Domains are used to partition the directory so that the information in the directory can be distributed and managed efficiently throughout the enterprise. The goal for your domain design is to maximize the efficiency of the Active Directory replication topology while ensuring that replication does not use too much available network bandwidth and does not interfere with the daily operation of your network.

# Reviewing the Domain Models

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The following factors impact the domain design model that you select:

- The amount of available capacity on your network that you are willing to allocate to Active Directory. The goal is to select a model that provides efficient replication of information with minimal impact on available network bandwidth.

- The number of users in your organization. If your organization includes a large number of users, deploying more than one domain enables you to partition your data and gives you more control over the amount of replication traffic that will pass through a given network connection. This makes it possible for you to control where data is replicated and reduce the load created by replication traffic on slow links in your network.

The simplest domain design is a single domain. In a single domain design, all information is replicated to all of the domain controllers. If necessary, however, you can deploy additional regional domains. This might come about if portions of the network infrastructure are connected by slow links and the forest owner wants to be sure that replication traffic does not exceed the capacity that has been allocated to Active Directory.

It is best to minimize the number of domains that you deploy in your forest. This reduces the overall complexity of the deployment and, as a result, reduces total cost of ownership. Table 2.3 lists the administrative costs associated with adding regional domains.

**Table 2.3 Administrative Costs Associated With Adding Regional Domains to a Forest**

| Cost | Implications |
|---|---|
| Management of multiple Service Administrator groups | Each domain has its own service administrator groups that need to be managed independently. The membership of these service administrator groups must be carefully controlled. |
| Maintaining consistency among Group Policies that are common to multiple domains | Group Policy settings that need to be applied forest-wide must be applied separately to each individual domain in the forest. |
| Maintaining consistency among access control and auditing settings that are common to multiple domains | Access control and auditing settings that need to be applied forest-wide must be applied separately to each individual domain in the forest. |
| Increased likelihood of objects moving between domains | The greater the number of domains, the greater the likelihood that users will need to move from one domain to another. This migration can potentially impact end users. |

# Single Domain Model

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A single domain model is the easiest to administer and the least expensive to maintain. It consists of a forest that contains a single domain. This domain is the forest root domain and it contains all of the user and group accounts in the forest.

A single domain forest model reduces administrative complexity by providing the following advantages:

- Any domain controller can authenticate any user in the forest.
- All domain controllers can be global catalogs; therefore, you do not need to plan for global catalog server placement.

In a single domain forest, all directory data is replicated to all geographic locations that host domain controllers. While this model is the easiest to manage, it also creates the most replication traffic of the two domain models. Partitioning the directory into multiple domains limits the replication of objects to specific geographic regions but results in more administrative overhead.

# Regional Domain Model

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

All object data within a domain is replicated to all domain controllers in that domain. For this reason, if your forest includes a large number of users that are distributed across different geographic locations connected by a wide area network (WAN), you might need to deploy regional domains to reduce replication traffic over the WAN links. Geographically based regional domains can be organized according to network WAN connectivity.

The regional domain model enables you to maintain a stable environment over time. Base the regions used to define domains in your model on stable elements such as continental boundaries. Domains based on other factors, such as groups within the organization, can change frequently and might require you to restructure your environment.

The regional domain model consists of a forest root domain and one or more regional domains, as shown in Figure 2.14.

**Figure 2.14 Regional Domain Model**

Creating a regional domain model design involves identifying which domain is the forest root domain and determining the number of additional domains that are required in order to meet your replication requirements.

**Note**

- If your organization includes groups that require data or service isolation from other groups in the organization, create a separate forest for those groups. Domains do not provide data or service isolation.

# Determining the Number of Domains Required

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Every forest starts with a single domain. The maximum number of users that a single domain forest can contain is based on the slowest link that must accommodate replication between domain controllers and the available bandwidth that you want to allocate to Active Directory. Table 2.4 lists the maximum recommended number of users that a domain can contain based on a single domain forest, the speed of the slowest link and the percentage of bandwidth you want to reserve for replication. This information applies to forests that contain a maximum of 100,000 users and that have a connectivity of 28.8 Kilobits per second (Kbps) or higher.

**Note**

- For recommendations that apply to forests that contain more than 100,000 users or connectivity of less than 28.8 Kbps, consult an experienced Active Directory designer.

**Table 2.4 Maximum Number of Users in a Single Domain**

| Slowest Link Connecting a Domain Controller (Kbps) | Maximum Number of Users if 1% Bandwidth Available | Maximum Number of Users if 5% Bandwidth Available | Maximum Number of Users if 10% Bandwidth Available |
|---|---|---|---|
| 28.8 | 10,000 | 25,000 | 40,000 |
| 32 | 10,000 | 25,000 | 50,000 |
| 56 | 10,000 | 50,000 | 100,000 |
| 64 | 10,000 | 50,000 | 100,000 |
| 128 | 25,000 | 100,000 | 100,000 |
| 256 | 50,000 | 100,000 | 100,000 |
| 512 | 80,000 | 100,000 | 100,000 |
| 1500 | 100,000 | 100,000 | 100,000 |

To use this table:

1. In the Slowest Link Connecting a Domain Controller column, locate the value that matches the speed of the slowest link across which Active Directory will replicate in your domain.

2. In the row that corresponds to your slowest link speed, locate the column that represents the percentage bandwidth you want to allocate to Active Directory. The value at that location is the maximum number of users that the domain in a single domain forest can contain.

The values in Table 2.4 are based on the replication traffic generated in an environment that has the following characteristics:

- New users join the forest at a rate of 20 percent per year.

- Users leave the forest at a rate of 15 percent per year.

- Each user is a member of five global groups and five universal groups.

- The ratio of users to computers is 1:1.

- Active Directory–integrated DNS is used.
- DNS scavenging is used.

**Note**

- The figures listed in Table 2.4 are approximations. The quantity of replication traffic depends largely on the number of changes made to the directory in a given amount of time. Confirm that your network can accommodate your replication traffic by testing the estimated quantity and rate of changes on your design in a lab before deploying your domains.

If you determine that the total number of users in your forest is less than the maximum number of users that your domain can contain, then you can use a single domain. Be sure to accommodate for planned future growth when you make this determination. If you determine that the total number of users in your forest is greater than the maximum number of users that your domain can contain, then you need to reserve a higher percentage of bandwidth for replication, increase your link speed, or divide your organization into regional domains.

# Dividing the Organization into Regional Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you cannot accommodate all of your users in a single domain, then you must select the regional domain model. Divide your organization into regions in a way that makes sense for your organization and your existing network. For example, you might create regions based on continental boundaries.

Keep in mind that because you need to create an Active Directory domain for each region that you establish, it is best to minimize the number of regions that you define for Active Directory. Although it is possible to include an unlimited number of domains in a forest, for manageability reasons it is recommended that a forest include no more than ten domains. You must establish the appropriate balance between optimizing your replication bandwidth and minimizing your administrative complexity when dividing your organization into regional domains.

First, determine the maximum number of users that your forest can host based on the slowest link in the forest across which domain controllers will replicate and the average amount of bandwidth you want to allocate to Active Directory replication. Table 2.5 lists the maximum recommended number of users that a forest can contain based on the speed of the slowest link, and the percentage of bandwidth you want to reserve for replication. This information applies to forests that contain a maximum of 100,000 users and that have a connectivity of 28.8 KBps or higher.

**Table 2.5 Maximum Number of Users in a Forest**

| Slowest Link Connecting a Domain Controller (KBps) | Maximum Number of Users if 1% Bandwidth Available | Maximum Number of Users if 5% Bandwidth Available | Maximum Number of Users if 10% Bandwidth Available |
|---|---|---|---|
| 28.8 | 10,000 | 50,000 | 75,000 |
| 32 | 10,000 | 50,000 | 75,000 |
| 56 | 10,000 | 75,000 | 100,000 |
| 64 | 25,000 | 75,000 | 100,000 |
| 128 | 50,000 | 100,000 | 100,000 |
| 256 | 75,000 | 100,000 | 100,000 |
| 512 | 100,000 | 100,000 | 100,000 |
| 1500 | 100,000 | 100,000 | 100,000 |

To use this table:

1. In the Slowest Link Connecting a Domain Controller column, locate the value that matches the speed of the slowest link across which Active Directory will replicate in your forest.

2. In the row that corresponds to your slowest link speed, locate the column that represents the percentage bandwidth that you want to allocate to Active Directory. The value at that location is the maximum number of users that your forest can host.

**Note**

- The figures listed in Table 2.5 are approximations. The quantity of replication traffic depends largely on the number of changes made to the directory in a given amount of time. Confirm that your network can accommodate your replication traffic by testing the estimated quantity and rate of changes on your design in a lab before deploying your domains.

The values in Table 2.5 are based on the following assumptions:

- All domain controllers are global catalog servers.
- New users join the forest at a rate of 20 percent per year.
- Users leave the forest at a rate of 15 percent per year.
- Users are members of five global groups and five universal groups.
- The ratio of users to computers is 1:1.
- Active Directory–integrated DNS is used.
- DNS scavenging is used.

If the maximum number of users that your forest can host is greater than the number of users that you need to host, then a single forest will work for your design. If you need to host more users than the maximum number that you identified, then you need to increase the minimum link speed, allocate a greater percentage of bandwidth for Active Directory, or deploy additional forests.

If you determine that a single forest will accommodate the number of users that you need to host, the next step is to determine the maximum number of users that each region can support based on the slowest link located in that region. Divide your forest into regions that make sense to you. Make sure that you base your decision on something that is not likely to change. For example, use continents instead of sales regions. These regions will be the basis of your domain structure when you have identified the maximum number of users.

Determine the number of users that need to be hosted in each region and then verify that they do not exceed the maximum allowed based on the slowest link speed and the bandwidth allocated to Active directory in that region. Table 2.6 lists the maximum recommended number of users that a regional domain can contain based on the speed of the slowest link and the percentage of bandwidth you want to reserve for replication. This information applies to forests that contain a maximum of 100,000 users and that have a connectivity of 28.8 KBps or higher.

**Table 2.6 Maximum Number of Users in a Region**

| Slowest Link Connecting a Domain Controller (KBps) | Maximum Number of Users if 1% Bandwidth Available | Maximum Number of Users if 5% Bandwidth Available | Maximum Number of Users if 10% Bandwidth Available |
|---|---|---|---|
| 28.8 | 10,000 | 18,000 | 40,000 |
| 32 | 10,000 | 20,000 | 50,000 |
| 56 | 10,000 | 40,000 | 100,000 |
| 64 | 10,000 | 50,000 | 100,000 |
| 128 | 15,000 | 100,000 | 100,000 |
| 256 | 30,000 | 100,000 | 100,000 |
| 512 | 80,000 | 100,000 | 100,000 |
| 1500 | 100,000 | 100,000 | 100,000 |

To use this table:

1. In the Slowest Link Connecting a Domain Controller column, locate the value that matches the speed of the slowest link across which Active Directory will replicate in your region.

2. In the row that corresponds to your slowest link speed, locate the column that represents the percentage bandwidth that you want to allocate to Active Directory. That value represents the maximum number of users that the region can host.

**Note**

- The figures listed in Table 2.6 are approximations. The quantity of replication traffic depends largely on the number of changes made to the directory in a given amount of time. Confirm that your network can accommodate your replication traffic by testing the estimated quantity and rate of changes on your design in a lab before deploying your domains.

The values in Table 2.6 are based on the following assumptions:

- All domain controllers are global catalog servers.
- New users join the forest at a rate of 20 percent per year.
- Users leave the forest at a rate of 15 percent per year.
- Users are members of five global groups and five universal groups.
- The ratio of users to computers is 1:1.
- Active Directory–integrated DNS is used.
- DNS scavenging is used.

Evaluate each proposed region and determine whether the maximum number of users in each region is less than the recommended maximum number of users that a domain can contain. If you determine that the region can host the number of users that you require, then you can create a domain for that region. If you determine that you cannot host that many users, consider dividing your design into smaller regions and recalculating the maximum number of users that can be hosted in each region. The other alternatives are to allocate more bandwidth or increase your link speed.

Although the total number of users that you can put in a domain in a multidomain forest is smaller than the number of users in the domain in a single domain forest, the overall number of users in the multidomain forest can be higher. The smaller number of users per domain in a multidomain forest accommodates the additional replication overhead created by maintaining the global catalog in that environment.

**Note**

- For recommendations that apply to forests that contain more than 100,000 users or connectivity of less than 28.8 KBps, consult an experienced Active Directory designer.

Figure 2.15 shows the regions that Contoso Corporation chose to use and the slowest link and number of users located in each region.

# Documenting the Regions Identified

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you divide your organization into regional domains, document the regions that you want represented and the number of users that will exist in each region. In addition, note the speed of the slowest links in each region that you will use for Active Directory replication. This information is used to determine whether additional domains or forests are required.

For a worksheet to assist you in documenting the regions you identified, see "Identifying Regions" (DSSLOGI_4.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Identifying Regions" on the Web at http://www.microsoft.com/reskit).

**Example: Documenting the Regions Identified**

Contoso Corporation has facilities all over the world. They want to create a single domain for their entire organization. However, they have 60,000 users and they do not want to allocate any more than 10 percent of the total bandwidth to Active Directory. Based on the slowest link in that Active Directory would use, they can only host up to 50,000 users. With 32 KBps links they can host up to 75,000 users in a single forest as long as they are willing to allocate up to ten percent of the bandwidth to Active Directory. This means that they can still use a single forest but they need to use multiple domains.

Based on the slowest links in each region, Contoso decided to represent their network by using three regions: North America, South America, and Europe. The slowest link in the North America region is 128 KBps. In South America and Europe, the slowest links are 32 KBps. North America has 40,000 users, Europe has 15,000 users, and South America has 5,000 users. Based on these link speeds and an allocation of up to ten percent of the bandwidth, the number of users in each domain is within the maximum limits.

Figure 2.16 shows the documentation that Contoso created for the regions that they identified.

**Figure 2.16 Example of a Completed Identifying Regions Worksheet**

Identifying Regions

# Determining Whether to Upgrade Existing or Deploy New Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Each domain in your design will either be a new domain or an existing domain that has been upgraded in place. Users from existing domains that you do not upgrade in place must be migrated into new domains.

Moving accounts between domains can impact end users. Before deciding whether to migrate users into a new domain or upgrade existing domains in place, evaluate the long-term administrative benefits of a new Active Directory domain against the cost of migrating users into the domain.

If you are upgrading from Windows NT 4.0 to Windows Server 2003, evaluate each Master User Domain (MUD) in your organization to determine whether they are candidates for upgrade to an Active Directory domain. If you are migrating from an operating system other than Windows NT 4.0, plan to create new Active Directory domains. If no Windows NT 4.0 MUD upgrade candidates exist in your current environment, plan to create new Active Directory domains and migrate your existing accounts and resources into them.

For more information about consolidating and upgrading Windows NT 4.0 domains, see "Restructuring Windows NT 4.0 Domains to an Active Directory Forest" in this book.

# Evaluating Current Master User Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Create a list of existing Windows NT 4.0 master user domains (MUDs) and compare it to the regional domains in your domain design. For each regional domain in your design, decide whether you will deploy a new domain or upgrade of one of your existing MUDs in place.

When upgrading from a Windows NT 4.0 environment to Active Directory, upgrading MUDs in place is the least expensive and most efficient method. Upgrading domains in place has no impact on end users. Migrating users to new domains is a more complicated process that creates additional administrative costs.

**Important**

- A domain must be in Windows 2000 native mode or operating at the Windows Server 2003 functional level before it can be the target for user migrations from Windows NT 4.0. If you have a large number of backup domain controllers (BDCs) in remote locations or that require hardware upgrades, you might not be able to achieve this in a timely manner. If time is a consideration for your upgrade process, consider performing an in-place upgrade of a different domain, or creating a new domain to be the target of the migration.

If you identified more than one MUD upgrade candidate, you can do one of the following:

- Upgrade the largest MUD and migrate accounts in the remaining MUDs into that MUD.
- Define additional regions for each MUD upgrade candidate and perform an in-place upgrade of each MUD into a corresponding new region. This option involves additional long-term management overhead costs but saves the short-term administrative costs associated with migrating users between domains.

Figure 2.17 shows how Contoso Corporation chose to create their new domain design based on the geographic regions where they do business.

**Figure 2.17 Contoso Corporation Proposed Domains**

# Documenting Plans for New and Upgraded Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

List your proposed regions and then indicate whether the domain that you create for that region will be a new domain or a MUD that you upgrade. If the new domain is to be the result of an upgrade, record the name of the MUD that will be upgraded and the contact information for the current MUD owner.

For a worksheet to assist you in documenting your plans for new and upgraded domains, see "Domain Planning" (DSSLOGI_5.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Domain Planning" on the Web at http://www.microsoft.com/reskit). You can use the same worksheet to document your domain name choices and forest root domain information later in the design process.

**Example: Documenting Plans for New and Upgraded Domains**
Contoso Corporation has 60,000 users located throughout facilities all over the world. Based on how the offices are connected to the network, they divided their organization into three regions: North America, South America, and Europe. Their current deployment has four MUDs, one in North America, one in South America, and two in Europe. The design team decided to upgrade the North and South American MUDs to Windows Server 2003 Active Directory domains, and to create a new Active Directory domain in Europe and migrate the users from the two European MUDs into the new domain.

Figure 2.18 shows the documentation that the Contoso Corporation design team created to document their plans for new and upgraded domains.

**Figure 2.18 Example of a Domain Planning Worksheet That Includes Upgrade and Migration Plans**

# Assigning Domain Names

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You must assign a name to every domain in your plan. Active Directory domains have two types of names: DNS names and NetBIOS names. In general, both names are visible to end users. The DNS names of Active Directory domains include two parts, a prefix and a suffix. When creating domain names, first determine the DNS prefix. This is the first label in the DNS name of the domain. The suffix is determined when you select the name of the forest root domain. To select the DNS prefix for the domain name:

1. For each Windows NT 4.0 MUD that you choose to upgrade in place, decide whether the current NetBIOS name of the domain will become its DNS prefix. Review prefix naming rules. If the name is appropriate to represent the region and satisfies the prefix naming rules, it is recommended that you retain the current NetBIOS name. In this case, the NetBIOS name of the domain is the same as the DNS prefix of the domain. Table 2.7 lists the prefix naming rules for DNS names.

   **Table 2.7 Rules for Selecting a Prefix for a Registered DNS Name**

   | Rule | Explanation |
   | --- | --- |
   | Select a prefix that is not likely to become outdated. | Avoid names such as a business line or operating system that might change in the future. Geographical names are recommended. |
   | Select a prefix that includes Internet standard characters only. | A-Z, a-z, 0-9, and (-), but not entirely numeric. |
   | Include 15 characters or less in the prefix. | If you choose a prefix length of 15 characters or less, then the NetBIOS name is the same as the prefix. |

   If the current NetBIOS name of the domain is inappropriate to represent the region or fails to satisfy the prefix naming rules, select a new prefix. In this case, the NetBIOS name of the domain is different from the DNS prefix of the domain.

2. For each new domain that you deploy, select a prefix that is appropriate for the region and that satisfies prefix naming rules. It is recommended that the NetBIOS name of the domain be the same as the DNS prefix.

# Documenting Domain Names

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Document the DNS prefix and NetBIOS names that you select for each domain in your forest. You can add the DNS and NetBIOS name information to the worksheet that you created to document your plan for new and upgraded domains.

For a worksheet to assist you in documenting the proposed domain names see "Domain Planning" (DSSLOGI_5.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Domain Planning" on the Web at http://www.microsoft.com/reskit).

**Example: Documenting Domain Names**

Contoso Corporation decided that the DNS prefixes for the North America, South America and European Active Directory domains will be noam, soam, and eur respectively. They also decided to use the prefix as the NetBIOS name.

Figure 2.19 shows the worksheet in which the design team documented the domain names.

**Figure 2.19 Example of a Domain Planning Worksheet That Includes Domain DNS Prefixes and NetBIOS Name**

# Selecting the Forest Root Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The first domain that you deploy in an Active Directory forest is called the forest root domain. This domain remains the forest root domain for the life cycle of the Active Directory deployment.

The forest root domain contains the Enterprise Admins and Schema Admins groups. These service administrator groups are used to manage forest-level operations, such as the addition and removal of domains and the implementation of changes to the schema.

Selecting the forest root domain involves determining whether one of the Active Directory domains in your domain design can function as the forest root domain, or whether you need to deploy a dedicated forest root domain.

# Choosing a Regional or Dedicated Forest Root Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you are applying a single domain model, then the single domain functions as the forest root domain. If you are applying a multiple domain model, then you can choose to deploy a dedicated forest root domain, or select a regional domain to function as the forest root domain.

**Dedicated Forest Root Domain**

A *dedicated forest root* domain is a domain that is created specifically to function as the forest root. It does not contain any user accounts other than the service administrator accounts for the forest root domain, and it does not represent any region in your domain structure. All other domains in the forest are children of the dedicated forest root domain.

Using a dedicated forest root provides the following advantages:

- **Operational separation of forest service administrators from domain service administrators.** In a single domain environment, members of the Domain Admins or built-in Administrators groups can use standard tools and procedures to make themselves members of the Enterprise Admins and Schema Admins groups. In a forest that uses a dedicated forest root domain, members of the Domain Admins or built-in Administrators groups in the regional domains cannot make themselves members of the forest-level service administrator groups by using standard tools and procedures.

  **Warning**

  - Because a domain is not a security boundary, it is possible for a malicious service administrator, such as a member of the Domain Admins group, to use nonstandard tools and procedures to gain full access to any domain in the forest or to any computer in the forest. For example, service administrators in a nonroot domain can make themselves members of the Enterprise Admins or Schema Admins group.

- **Protection from operational changes in other domains.** A dedicated forest root domain does not represent a particular region in your domain structure. For this reason, it is not affected by reorganizations or other changes that result in the renaming or restructuring of domains.

- **Serves as a neutral root so that no region appears to be subordinate to another region.** Some organizations might prefer to avoid the appearance that one country/region is subordinate to another country/region in the namespace. When you use a dedicated forest root domain, all regional domains can be peers in the domain hierarchy.

In a multiple regional domain environment in which a dedicated forest root is used, the replication of the forest root domain has minimal impact on the network infrastructure. This is because the forest root only hosts the service administrator accounts. The majority of the user accounts in the forest and other domain-specific data is stored in the regional domains.

One disadvantage to using a dedicated forest root domain is that it creates additional management overhead to support the additional domain.

**Regional Domain as a Forest Root Domain**

If you choose not to deploy a dedicated forest root domain, then you must select a regional domain to function as the forest root domain. This domain is the parent domain of all the other regional domains and will be the first domain that you deploy. The forest root domain contains user accounts and is managed in the same way that the other regional domains are managed. The primary difference is that it also includes the Enterprise Admins and Schema Admins groups.

The advantage to selecting a regional domain to function as the forest root domain is that it does not create the additional management overhead that maintaining an additional domain creates.

Select an appropriate regional domain to be the forest root, such as the domain that represents your headquarters or the region that has the fastest network connections. If it is difficult for your organization to select a regional domain to be the forest root domain, you can choose to use a dedicated forest root model instead.

In a Windows Server 2003 environment, global availability of the forest root is not as important as it is in Windows 2000 because forest-wide application partitions automatically replicate the forest-wide locator record zone to all domain controllers that are running DNS. Any domain controller can be used to write updates to the forest-wide locator records zone. In a

Windows 2000 environment, DNS does not use a forest-wide application partition; therefore, it is recommended that a dedicated forest root be used to make the zone containing the writable copy of the forest-wide locator records highly available. For more information about DNS and the forest-wide application partition, see "Designing a DNS Infrastructure to Support Active Directory" later in this chapter.

**Forest Root Alternatives With Single Global Domain Model**

This model consists of a forest that contains a dedicated forest root domain and one additional global domain. The global domain contains all the user, computer, and group accounts for the entire organization. Figure 2.20 shows an example of a forest with a single global domain with and without a dedicated forest root.

**Figure 2.20 Single Global Domain Model With and Without Dedicated Root**

**Forest Root Alternatives With Multiple Regional Domains**

This model consists of a dedicated forest root domain or a regional domain that is designated to be the forest root, and multiple regional domains that are children of the forest root, as shown in Figure 2.21.

**Figure 2.21 Multiple Regional Domains With and Without a Dedicated Forest Root**

In the case of multiple regional domains, a third alternative is to make each regional domain a separate tree in a single forest.

While this design is fully supported, it is not recommended because of the complexity of the DNS deployment.

**Figure 2.22 Forest with Multiple Trees**

# Assigning the Forest Root Domain Name

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The forest root domain name is also the name of the forest. The forest root name is a DNS name that consists of a prefix and a suffix in the form of *prefix.suffix*. For example, an organization might have the forest root name corp.contoso.com. In this example, corp is the prefix and contoso.com is the suffix.

Select the suffix from a list of existing names on your network. For the prefix, select a new name that has not been used on your network previously. By attaching a new prefix to an existing suffix, you create a unique namespace. Creating a new namespace for Active Directory ensures that any existing DNS infrastructure does not need to be modified to accommodate Active Directory.

**Selecting a Suffix**
To select a suffix for the forest root domain:

1. Contact the DNS owner for the organization for a list of registered DNS suffixes that are in use on the network that will host Active Directory. Note that the suffixes used on the internal network might be different than the suffixes used externally. For example, an organization might use contosopharma.com on the Internet and contoso.com on the internal corporate network.

2. Consult the DNS owner to select a suffix for use with Active Directory. If no suitable suffixes exist, register a new name with an Internet naming authority.

It is best to use DNS names that are registered with an Internet authority in the Active Directory namespace. Only registered names are guaranteed to be globally unique. If another organization later registers the same DNS domain name, or if your organization merges with, acquires, or is acquired by other company that uses the same DNS names, then the two infrastructures cannot interact with one another.

**Note**

- Using single label names or unregistered suffixes, such as .local, is not recommended.

**Selecting a Prefix**
If you chose a registered suffix that is already in use on the network, select a prefix for the forest root domain name by using the prefix rules in Table 2.8. Add a prefix that is not currently in use to create a new subordinate name. For example, if your DNS root name is contoso.com, then you can create the Active Directory forest root domain name concorp.contoso.com, if the namespace concorp.contoso.com is not already in use on the network. This new branch of the namespace will be dedicated to Active Directory and can be integrated easily with the existing DNS implementation. When selecting a prefix, consider the following:

- If you are performing an in-place upgrade of a Windows NT 4.0 MUD to create the forest root domain, then you might be able to use the NetBIOS name of the domain as the prefix. Determine whether the NetBIOS name is an appropriate name for a root domain and meets the prefix rules listed in Table 2.8.

- If you selected a regional domain to function as a forest root domain, you might need to select a new prefix for the domain. Because the forest root domain name affects all of the other domain names in the forest, a regionally-based name might not be appropriate. For example, if Contoso Corporation decided to use their North American domain, called noam.contoso.com, as their forest root, then the European domain name would be europe.noam.contoso.com. In this case, a better choice would be to select a new prefix, such as corp, for the forest root; in this way, the name of the European domain would be europe.corp.contoso.com.

If you are using a new suffix that is not currently in use on the network, you can use it as the forest root domain name without choosing an additional prefix.

Table 2.8 lists the rules for selecting a prefix for a registered DNS name.

**Table 2.8 Rules for Selecting a Prefix for a Registered DNS Name**

| Rule | Explanation |
| --- | --- |
| Select a prefix that is not likely to become outdated. | Avoid names such as a business line or operating system that might change in the future. Generic names such as corp or ds are recommended. |
| Select a prefix that includes Internet standard characters only. | A-Z, a-z, 0-9, and (-), but not entirely numeric. |
| Include 15 characters or less in the prefix. | If you choose a prefix length of 15 characters or less, then the NetBIOS name is the same as the prefix. |

It is important for the Active Directory DNS owner to work with the DNS owner for the organization to obtain ownership of the name that will be used for the Active Directory namespace. For more information about designing a DNS infrastructure to support Active Directory, see "Designing a DNS Infrastructure to Support Active Directory" later in this chapter.

# Documenting the Forest Root Domain Name

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Document the DNS prefix and suffix that you select for the forest root domain. At this point identify which domain will be the forest root. You can add the forest root domain name information to the worksheet that you created to document your plan for new and upgraded domains and your domain names.

For a worksheet to assist you in documenting the forest root domain name, see "Domain Planning" (DSSLOGI_5.doc) on the *Windows Server 2003 Deployment Kit* companion CD ( or see "Domain Planning" on the Web at https://www.microsoft.com/reskit).

**Example: Documenting the Forest Root Domain Name**
Contoso Corporation decided to use a dedicated forest root domain for their Active Directory deployment. They selected the name corp.contoso.com for their forest. They will use their registered corporate name contoso.com as the suffix for this domain and add the prefix corp to represent this domain specifically. The forest root domain name will therefore be corp.contoso.com. They recorded this information in their Domain Planning worksheet so that the service administrators can reference it as needed when they deploy the forest root domain.

Figure 2.23 shows the worksheet in which the design team documented the forest root domain.

**Figure 2.23 Example of a Domain Planning Worksheet That Includes Forest Root Domain Name Information**

# Domain Planning

# Creating a Consolidation Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you are currently operating in a Windows NT 4.0 environment, you must decide how to restructure the remaining MUDs that you are not upgrading in place and your existing resource domains into the Active Directory domains that you have designed. Because you can use OUs in an Active Directory environment to delegate control, MUDs and resource domains are no longer needed for the delegation of control to administrators. As part of your domain design, decide how you will restructure your MUDs and resource domains into the new Windows Server 2003 environment.

# Restructuring Windows NT 4.0 MUDs into Windows Server 2003 Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If your organization is currently operating in a Windows NT 4.0 environment, you must plan to restructure all MUDs that you did not select for in-place upgrade into your new Active Directory domains. Keep the following points in mind when you consolidate a MUD into an Active Directory domain:

- You can configure OUs to preserve the organization and administrative structure of the Windows NT 4.0 source domain. For more information about configuring OUs, see "Designing Organizational Units for Delegation of Administration" later in this chapter.
- The migration process potentially impacts users involved in the migration.
- If you have a MUD that spans geographic locations, migrate all the users within that MUD to a single Active Directory domain. If you need to relocate some of those users to a different domain, you can do so by means of an intraforest migration after the initial migration process is complete.

For more information about restructuring Windows NT 4.0 account and resource domains to Windows Server 2003 Active Directory, see "Restructuring Windows NT 4.0 Domains to an Active Directory Forest" in this book.

Figure 2.24 shows how the Contoso Corporation chose to restructure Windows NT 4.0 resource domains into OU structures within the new Active Directory regional domains in the same geographical location.

**Figure 2.24 Contoso Corporation Restructuring of Windows NT 4.0 MUDs into Active Directory Regional Domains**

# Documenting the Migration Plan for Windows NT 4.0 Master User Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you identify all remaining Windows NT 4.0 Master User Domains and determine the OUs in the Active Directory domains to which the accounts in these domains will be migrated, you need to document your migration plan.

For a worksheet to assist you in documenting your migration plan for Windows NT 4.0 MUDs, see "Migration Plan for Windows NT 4.0 Master User Domains" (DSSLOGI_6.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migration Plan for Windows NT 4.0 Master User Domains" on the Web at http://www.microsoft.com/reskit).

**Example: Documenting the Migration Plan for Windows NT 4.0 Master User Domains**
Contoso Corporation decided to upgrade the noam and soam domains to Active Directory domains. They chose to migrate the remaining MUDs in Europe into the new European domain eur.corp.contoso.com. They documented their migration plan in a worksheet.

Figure 2.25 shows the Windows NT 4.0 MUD migration plan documentation that the Contoso Corporation design team created.

**Figure 2.25 Example of a Migration Plan for Windows NT 4.0 Master User Domains Worksheet**

# Restructuring Windows NT 4.0 Resource Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can restructure your Windows NT 4.0 resource domains into the Active Directory regional domain that is in the same geographic location, so that resources and the users who need them are in the same location. Keep in mind that when you restructure Windows NT 4.0 resource domains to Windows Server 2003 Active Directory regional domains, you can configure OUs to preserve the organization and administrative structure of the resource domain.

Alternatively, you can maintain the Windows NT 4.0 resource domain until you restructure the domain at a later point or eliminate it by attrition. You might choose to preserve a Windows NT 4.0 resource domain if you are running applications on domain controllers that are not compatible with Windows Server 2003.

**Note**

- If your resource domain is dedicated to hosting Exchange 5.5, do not restructure it into a Windows Server 2003 Active Directory regional domain. For information about upgrading your Microsoft Exchange environment, see the Exchange Server link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

Figure 2.26 shows how Contoso Corporation chose to restructure Windows NT 4.0 resource domains into OU structures within the new Active Directory regional domains in the same geographical location.

**Figure 2.26 Contoso Corporation Restructuring of Windows NT 4.0 Resource Domains into OUs in Active Directory Regional Domains**

# Documenting the Migration Plan for Windows NT 4.0 Resource Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you identify all existing Windows NT 4.0 resource domains and determine how you will migrate the domains to OUs in Active Directory regional domains in the forest, it is important to document this information.

For a worksheet to assist you documenting your plan for restructuring Windows NT 4.0 resource domains, see "Migration Plan for Windows NT 4.0 Resource Domains" (DSSLOGI_7.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migration Plan for Windows NT 4.0 Resource Domains" on the Web at http://www.microsoft.com/reskit).

**Example: Documenting the Migration Plan for Windows NT 4.0 Resource Domains**
Contoso Corporation needs to migrate their Windows NT 4.0 resource domains to OUs in their Active Directory regional domains. After they identified the source and target locations, they documented the target OU for each resource domain that is to be restructured. Figure 2.27 shows the Windows NT 4.0 resource domain migration plan documentation that the Contoso Corporation design team created.

# Designing a DNS Infrastructure to Support Active Directory

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012

After you create your Active Directory forest and domain designs, you must design a DNS infrastructure to support your Active Directory logical structure. DNS enables users to use friendly names that are easy to remember to connect to computers and other resources on IP networks.

Windows Server 2003 uses DNS for name resolution instead of the Windows Internet Name Service (WINS) NetBIOS name resolution method used in Windows NT 4.0–based networks. It is still possible to use WINS for applications that require it; however, Active Directory requires DNS.

The process for designing DNS to support Active Directory varies according to whether your organization already has an existing DNS service or whether you are deploying a new DNS service. Figure 2.28 shows the process for creating a DNS design for Active Directory.

**Figure 2.28 Designing a DNS Infrastructure to Support Active Directory**

Before you design your DNS infrastructure to support Active Directory, it can be helpful to read about the DNS hierarchy, the DNS name resolution process, and how DNS supports Active Directory. For information about the DNS hierarchy and name resolution process, see the DNS Technical Reference (http://go.microsoft.com/fwlink/?LinkID=48145). For information about how DNS supports Active Directory, see the DNS Support for Active Directory Technical Reference (http://go.microsoft.com/fwlink/?LinkID=48147).

# Basic DNS Concepts

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

DNS is a distributed database that represents a *namespace*. The namespace contains all of the information needed for any client to look up any name. Any DNS server can answer queries about any name within its namespace. A DNS server answers queries in one of the following ways:

- If the answer is in its cache, it answers the query from the cache.
- If the answer is in a zone hosted by the DNS server, it answers the query from its zone. A *zone* is a portion of the DNS tree stored on a DNS server. When a DNS server hosts a zone, it is *authoritative* for the names in that zone, which means that the DNS server can answer queries for any name in the zone. For example, a server hosting the zone contoso.com can answer queries for any name in contoso.com.
- If the server cannot answer the query from its cache or zones, it queries other servers for the answer.

It is important to understand the core features of DNS, such as delegation, recursive name resolution, and Active Directory–integrated zones, because they have a direct impact on your Active Directory logical structure design.

For more information about DNS and Active Directory, see "DNS and Active Directory" later in this chapter.

# Delegation

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For a DNS server to be able to answer queries about any name, it must have a direct or indirect path to every zone in the namespace. These paths are created by means of *delegations*. A delegation is a record in a parent zone that lists a name server that is authoritative for the zone in the next level of the hierarchy. Delegations enable servers in one zone to refer clients to servers in other zones. Figure 2.29 shows an example of delegation.

**Figure 2.29 Delegation**

The DNS root server hosts the root zone, represented as a dot ( . ). The root zone contains a delegation to a zone in the next level of the hierarchy, the com zone. The delegation in the root zone tells the DNS root server that, to find the com zone, it must contact the Com server. Likewise, the delegation in the com zone tells the Com server that to find the contoso.com zone, it must contact the Contoso server.

**Note**

- A delegation uses two types of records. The name server (NS) resource record provides the name of an authoritative server. The host (A) resource provides the IP address of an authoritative server.

This system of zones and delegations creates a hierarchical tree that represents the DNS namespace. Each zone represents a layer in the hierarchy and each delegation represents a branch of the tree.

By using the hierarchy of zones and delegations, a DNS root server can find any name in the DNS namespace. The root zone includes delegations that lead directly or indirectly to all other zones in the hierarchy. Any server that can query the DNS root server can use the information in the delegations to find any name in the namespace.

# Recursive Name Resolution

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Recursive name resolution is the process by which a DNS server uses the hierarchy of zones and delegations to respond to queries for which it is not authoritative.

In some configurations, DNS servers include *root hints,* a list of names and IP addresses, which enable them to query the DNS root servers. In other configurations, servers forward all queries that they cannot answer to another server. Forwarding and root hints are both methods that DNS servers can use to resolve queries for which they are not authoritative.

**Resolving Names by Using Root Hints**

Root hints enable any DNS server to locate the DNS root servers. After a DNS server locates the DNS root server, it can resolve any query for that namespace. Figure 2.30 shows how DNS resolves a name by using root hints.

**Figure 2.30 Using Root Hints for Recursive Name Resolution**

In this example, the following events take place:

1. A client sends a recursive query to a DNS server to request the IP address that corresponds to the name ftp.contoso.com. A *recursive query* indicates that the client wants a definitive answer to its query. The response to the recursive query must be a valid address or a message indicating that the address cannot be found.

2. Because the DNS server is not authoritative for the name and does not have the answer in its cache, the DNS server uses root hints to find the IP address of the DNS root server.

3. The DNS server uses an iterative query to ask the DNS root server to resolve the name ftp.contoso.com. An *iterative query* indicates that the server will accept a referral to another server in place of a definitive answer to the query. Because the name ftp.contoso.com ends with the label com, the DNS root server returns a referral to the com server that hosts the com zone.

4. The DNS server uses an iterative query to ask the com server to resolve the name ftp.contoso.com. Because the name ftp.contoso.com ends with the name contoso.com, the com server returns a referral to the Contoso server that hosts the contoso.com zone.

5. The DNS server uses an iterative query to ask the Contoso server to resolve the name ftp.contoso.com. The Contoso server finds the answer in its zone data and returns the answer to the server.

6. The server then returns the result to the client.

**Resolving Names by Using Forwarding**

Forwarding enables you to route name resolution through specific servers instead of using root hints. Figure 2.31 shows how DNS resolves a name by using forwarding.

**Figure 2.31 Using Forwarding for Recursive Name Resolution**

In this example, the following events take place:

1. A client queries a DNS server for the name ftp.contoso.com.

2. The DNS server forwards the query to another DNS server, known as a *forwarder*.

3. Because the forwarder is not authoritative for the name and does not have the answer in its cache, it uses root hints to find the IP address of the DNS root server.

4. The forwarder uses an iterative query to ask the DNS root server to resolve the name ftp.contoso.com. Because the name ftp.contoso.com ends with the name com, the DNS root server returns a referral to the com server that hosts the com zone.

5. The forwarder uses an iterative query to ask the com server to resolve the name ftp.contoso.com. Because the name ftp.contoso.com ends with the name contoso.com, the com server returns a referral to the Contoso server that hosts the contoso.com zone.

6. The forwarder uses an iterative query to ask the Contoso server to resolve the name ftp.contoso.com. The Contoso server finds the answer in its zone files and returns the answer to the server.

7. The forwarder then returns the result to the original DNS server.

8. The original DNS server then returns the result to the client.

For more information about DNS, see the *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit).

# DNS and Active Directory

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Active Directory uses Domain Name System (DNS) name resolution services to make it possible for clients to locate domain controllers and to make it possible for the domain controllers that host the directory service to communicate with each other.

Active Directory enables easy integration of the Active Directory namespace into an existing DNS namespace. Features such as Active Directory–integrated zones make it easier for you to deploy DNS by eliminating the need to set up secondary zones and configure zone transfers.

For information about how DNS supports Active Directory, see the DNS Support for Active Directory Technical Reference (http://go.microsoft.com/fwlink/?LinkID=48147) as well as "Deploying DNS" in Deploying Network Services in this kit.

| **Note** |
| --- |
| If you implement a disjoint namespace in which the Active Directory domain name differs from the primary DNS suffix that clients use, Active Directory integration with DNS is more complex. For more information, see Disjoint Namespace. |

# Domain Controller Location

Updated: October 19, 2007

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Clients use DNS to locate domain controllers to complete operations such as processing logon requests or searching the directory for published resources. Domain controllers register a variety of records in DNS to help clients and other computers locate them. These records are collectively referred to as the *locator records*.

Domain controllers also use DNS to locate other domain controllers and perform tasks such as replication. The process by which domain controllers locate other domain controllers is the same as the process by which clients locate domain controllers.

# Active Directory-Integrated Zones

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

DNS servers running on domain controllers can store their zones in Active Directory. In this way, it is not necessary to configure a separate DNS replication topology that uses ordinary DNS zone transfers, because all zone data is replicated automatically by means of Active Directory replication. This simplifies the process of deploying DNS and provides the following advantages:

- Multiple masters are created for DNS replication. Therefore:
    - Any domain controller in the domain running the DNS server service can write updates to the Active Directory–integrated zones for the domain name for which they are authoritative. A separate DNS zone transfer topology is not needed.
- Secure dynamic updates are supported. Secure dynamic updates allow an administrator to control which computers update which names, and prevent unauthorized computers from overwriting existing names in DNS.

Windows Server 2003 DNS Active Directory stores zone data in application directory partitions. The domain partition was the only Active Directory storage option in Windows 2000 Server, and it is available in Windows Server 2003 DNS for backward compatibility. The following DNS-specific application directory partitions are created during Active Directory installation:

- A forest-wide application directory partition, called ForestDnsZones.
- Domain-wide application directory partitions for each domain in the forest, named DomainDnsZones.

For more information about how Active Directory stores DNS information in application partitions, see the DNS Technical Reference (http://go.microsoft.com/fwlink/?LinkID=48145) and Windows Server 2003 Help and Support.

# Computer Naming

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When a computer running Windows 2000, Microsoft® Windows® XP, or Windows Server 2003 joins a domain, by default the computer assigns itself a name comprising the host name of the computer (Computer Name in the System Properties) and the DNS name of the Active Directory domain that the computer joined (Primary DNS Suffix in System Properties). The concatenation of the host name and DNS name of the domain is known as the fully qualified domain name (FQDN). For example, if a computer with host name Server1 joins the domain corp.contoso.com, the FQDN of the computer is server1.corp.contoso.com.

If a computer already has a different DNS domain name that was statically entered into a DNS zone or registered by an integrated DNS/DHCP service, the FQDN of the computer is distinct from the name that was registered previously. The computer can be referred to by either name.

# Disjoint Namespace

Updated: August 17, 2011

Applies To: Windows Server 2003, Windows Server 2008, Windows Server 2008 R2

A disjoint namespace occurs when one or more domain member computers have a primary Domain Name Service (DNS) suffix that does not match the DNS name of the Active Directory domain of which the computers are members. For example, a member computer that uses a primary DNS suffix of corp.fabrikam.com in an Active Directory domain named na.corp.fabrikam.com is using a disjoint namespace.

A disjoint namespace is more complex to administer, maintain, and troubleshoot than a contiguous namespace. In a contiguous namespace, the primary DNS suffix matches the Active Directory domain name. Network applications that are written to assume that the Active Directory namespace is identical to the primary DNS suffix for all domain member computers do not function properly in a disjoint namespace.

**Support for disjoint namespaces**

Domain member computers, including domain controllers, can function in a disjoint namespace. Domain member computers can register their host (A) resource record and IP version 6 (IPv6) host (AAAA) resource record in a disjoint DNS namespace. When domain member computers register their resource records in this way, domain controllers continue to register global and site-specific service (SRV) resource records in the DNS zone that is identical to the Active Directory domain name.

For example, assume that a domain controller for the Active Directory domain named na.corp.fabrikam.com that uses a primary DNS suffix of corp.fabrikam.com registers host (A) and IPv6 host (AAAA) resource records in the corp.fabrikam.com DNS zone. The domain controller continues to register global and site-specific service (SRV) resource records in the _msdcs.na.corp.fabrikam.com and na.corp.fabrikam.com DNS zones, which makes service location possible.

| **Important** |
| --- |
| Although Windows operating systems may support a disjoint namespace, applications that are written to assume that the primary DNS suffix is the same as the Active Directory domain suffix may not function in such an environment. For this reason, you should test all applications and their respective operating systems carefully before you deploy a disjoint namespace. |

A disjoint namespace should work (and is supported) in the following situations:

- When a forest with multiple Active Directory domains uses a single DNS namespace, which is also known as a DNS zone

  An example of this is a company that uses regional domains with names such as na.corp.fabrikam.com, sa.corp.fabrikam.com, and asia.corp.fabrikam.com and uses a single DNS namespace, such as corp.fabrikam.com.

- When a single Active Directory domain is split into separate DNS namespaces

  An example of this is a company with an Active Directory domain of corp.contoso.com that uses DNS zones such as hr.corp.contoso.com, production.corp.contoso.com, and it.corp.contoso.com.

A disjoint namespace does not work properly (and is not supported) in the following situations:

- A disjoint suffix used by domain members matches an Active Directory domain name in this or another forest. This breaks Kerberos name-suffix routing.

- The same disjoint suffix is used in another forest. This prevents routing these suffixes uniquely between forests.

- When a domain member certification authority (CA) server changes its fully qualified domain name (FQDN) so that it no longer use the same primary DNS suffix that is used by the domain controllers of the domain to which the CA server is a member. In this case, you may have problems validating certificates the CA server issued, depending on what DNS names are used in the CRL Distribution Points. But if you place a CA server in a stable disjoint namespace, it works properly and is supported.

**Considerations for disjoint namespaces**

The following considerations may help you decide if you should use a disjoint namespace.

**Application compatibility**
As previously mentioned, a disjoint namespace can cause problems for any applications and services that are written to assume that a computer primary DNS suffix is identical to the name of the domain name of which it is a member. Before you deploy a disjoint namespace, you must check applications for compatibility issues. Also, be sure to check the compatibility of all applications that you use when you perform your analysis. This includes applications from Microsoft and from other software developers.

**Advantages of disjoint namespaces**
Using a disjoint namespace can have the following advantages:

- Because the primary DNS suffix of a computer can indicate different information, you can manage the DNS namespace separately from the Active Directory domain name.

- You can separate the DNS namespace based on business structure or geographical location. For example, you can separate the namespace based on business unit names or physical location such as continent, country/region, or building.

**Disadvantages of disjoint namespaces**
Using a disjoint namespace can have the following disadvantages:

- You must create and manage separate DNS zones for each Active Directory domain in the forest that has member computers that use a disjoint namespace. (That is, it requires an additional and more complex configuration.)

- You must perform manual steps to modify and manage the Active Directory attribute that allows domain members to use specified, primary DNS suffixes.

- To optimize name resolution, you must perform manual steps to modify and maintain Group Policy to configure member computers with alternate primary DNS suffixes.

  | **Note** |
  | --- |
  | The Windows Internet Name Service (WINS) could be used to offset this disadvantage by resolving single-label names. For more information about WINS, see the WINS Technical Reference (http://go.microsoft.com/fwlink/?LinkId=102303). |

- When your environment requires multiple primary DNS suffixes, you must configure the DNS suffix search order for all of the Active Directory domains in the forest appropriately.

  To set the DNS suffix search order, you can use Group Policy objects or Dynamic Host Configuration Protocol (DHCP) Server service parameters. You can also modify the registry.

- You must carefully test all applications for compatibility issues.

For more information about steps that you can take to address these disadvantages, see Create a Disjoint Namespace (http://go.microsoft.com/fwlink/?LinkId=106638).

**Planning a namespace transition**
Before you modify a namespace, review the following considerations, which apply to transitions from contiguous namespaces to disjoint namespaces (or the reverse):

- Manually configured Service Principal Names (SPNs) may no longer match DNS names after a namespace change. This can cause authentication failures.

  For more information, see Service Logons Fail Due to Incorrectly Set SPNs (http://go.microsoft.com/fwlink/?LinkId=102304).

  - If you use Windows Server 2003–based computers with constrained delegation, those computers may require additional configuration to change SPNs. For more information, see article 936628 in the Microsoft Knowledge

Base (http://go.microsoft.com/fwlink/?LinkId=102306).

- If you want to delegate permissions to modify SPNs to subordinate administrators, see Delegating Authority to Modify SPNs (http://go.microsoft.com/fwlink/?LinkId=106639).

- If you use Lightweight Directory Access Protocol (LDAP) over Secure Sockets Layer (SSL) (known as LDAPS) with a CA in a deployment that has domain controllers that are configured in a disjoint namespace, you must use the appropriate Active Directory domain name and primary DNS suffix when you configure the LDAPS certificates.

  For more information about domain controller certificate requirements, see article 321051 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkId=102307).

| **Note** |
| --- |
| Domain controllers that use certificates for LDAPS may require you to redeploy their certificates. When you do so, domain controllers may not select an appropriate certificate until they are restarted. For more information about LDAPS authentication and a related update for Windows Server 2003, see article 932834 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkId=102308). |

**Planning for disjoint namespace deployments**

Take the following precautions if you deploy computers in an environment that has a disjoint namespace:

1. Notify all software vendors with whom you do business that they must test and support a disjoint namespace. Ask them to verify that they support their applications in environments that use disjoint namespaces.

2. Test all versions of operating systems and applications in disjoint namespace lab environments. When you do, follow these recommendations:

   a. Resolve all software issues before you deploy the software into your environment.

   b. When possible, participate in beta tests of operating systems and applications that you plan to deploy in disjoint namespaces.

3. Ensure that administrators and helpdesk staff are aware of the disjoint namespace and its impact.

4. Create a plan that makes it possible for you to transition from a disjoint namespace to a contiguous namespace, if necessary.

5. Evangelize the importance of disjoint namespace support with operating system and application providers.

# Assigning the Active Directory DNS Owner Role

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The forest owner assigns an Active Directory DNS owner for the forest. The Active Directory DNS owner for the forest is a person or group of people responsible for overseeing the deployment of the Active Directory DNS infrastructure and making sure that, if necessary, domain names are registered with the proper Internet authorities.

The Active Directory DNS owner is responsible for the Active Directory DNS design for the forest. If your organization is currently operating a DNS service, then the DNS designer for the existing DNS service works with the Active Directory DNS owner to delegate the forest root DNS name to DNS servers running on domain controllers.

The Active Directory DNS owner for the forest also maintains contact with the DHCP and DNS teams of the organization and coordinates the plans of the individual DNS owners of each domain in the forest (if any) with these groups. The DNS owner for the forest ensures that the DHCP and DNS teams are involved in the Active Directory DNS design process so that each group is aware of the DNS design plan and can provide input early on.

# Identifying the DNS Infrastructure Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you deploy Active Directory in your environment, you must have a DNS infrastructure available to support the directory service. If you already have an existing DNS infrastructure, you need to integrate the Active Directory namespace into that environment. If you do not have a DNS infrastructure in place, you need to design and deploy a new DNS infrastructure to support Active Directory.

For the purpose of this design process, an organization does not have an existing DNS infrastructure if the following are true:

- The organization does not have any existing DNS servers in the network infrastructure.
- The organization does not have any clients that access DNS servers. This means that the organization does not rely on an external source, such as a network service provider, for DNS services.

For more information about designing a new DNS infrastructure, see the Domain Name System (DNS) Center link on the Web Resources page.

# Integrating Active Directory into an Existing DNS Infrastructure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If your organization already has an existing DNS service, the Active Directory DNS owner must work with the DNS owner for your organization to integrate Active Directory into the existing infrastructure. This involves creating a DNS server and DNS client configuration.

# Creating a DNS Server Configuration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When integrating Active Directory with an existing DNS namespace, it is recommended that you do the following:

- Install the DNS Server service on every domain controller in the forest. This provides fault tolerance in the event that one of the DNS servers is unavailable. In this way, domain controllers do not need to rely on other DNS servers for name resolution. This also simplifies the management environment because all domain controllers have a uniform configuration.
- Configure the Active Directory forest root domain controller to host the DNS zone for the Active Directory forest.
- Configure the domain controllers for each regional domain to host the DNS zones that correspond to their Active Directory domains.
- Configure the zone containing the Active Directory forest-wide locator records (_msdcs.*forestname* zone) to replicate to every DNS server in the forest by using the forest-wide DNS application directory partition.

**Note**

- Active Directory uses forest-wide locator records to enable replication partners find each other and to enable clients to find global catalog servers. Active Directory stores the forest-wide locator records in the _msdcs.*forest_name* zone. Because the information in the zone must be widely available, this zone is replicated to all DNS servers in the forest by means of the forest-wide DNS application directory partition.

The existing DNS structure remains intact. You do not need to migrate any servers or zones. You simply need to create a delegation to your Active Directory zones from your existing DNS hierarchy.

**Configuration When Using Root Hints**

Figure 2.32 illustrates the server configuration model for a network that uses root hints. The DNS root zone is hosted on a DNS server at the root of the existing internal DNS infrastructure.

**Figure 2.32 Existing DNS Service Configured to Use Root Hints**

In this configuration, the DNS servers are configured with root hints that indicate the location of the DNS root servers. When a DNS server needs to resolve a query and cannot resolve it from its cache or zone data, the DNS server queries the DNS servers

listed in the root hints.

**Configuration When Using Forwarding**

Figure 2.33 illustrates the server configuration model for a network that uses forwarding.

**Figure 2.33 Existing DNS Service Configured to Use Forwarding**

In this configuration, the regional DNS servers that are used to support Active Directory forward queries to the nearest DNS server for the Active Directory forest root, which in turn forwards queries to the standard DNS forwarder that is used by the existing DNS infrastructure.

# Creating the DNS Client Configuration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To configure DNS on client computers, the Active Directory DNS owner must specify the computer naming scheme and how the clients will locate DNS servers. Table 2.9 lists the recommended configurations for these design elements.

**Table 2.9 DNS Configuration for Client Computers**

| Design element | Configuration |
|---|---|
| Computer naming | Use default naming. When a Windows 2000, Windows XP, or Windows Server 2003 computer joins a domain, the computer assigns itself a fully qualified domain name (FQDN) comprising the host name of the computer and the name of the Active Directory domain. |
| Client Resolver Configuration | Configure client computers to point to any DNS server on the network. |

**Note**

- Active Directory clients and domain controllers can dynamically register their DNS names even if they are not pointing to the DNS server that is authoritative for their name.

A computer might have a different existing DNS name if the organization previously statically registered the computer in DNS or the organization previously deployed an integrated DHCP solution. If your client computers already have a registered DNS name, when the domain to which they are joined is upgraded to Windows Server 2003 Active Directory, they will have two different names:

- The existing DNS name
- The new FQDN

Clients can still be located by either name. Any existing DNS, DHCP, or integrated DNS/DHCP solution is left intact. The new primary names are created automatically and updated by means of dynamic update. They are cleaned up automatically by means of scavenging.

If you want to take advantage of Kerberos authentication when connecting to a server running Windows 2000, Windows XP, or Windows Server 2003, you must make sure that the client connects to the server by using the primary name.

# Documenting Your DNS Infrastructure Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If your organization has an existing DNS infrastructure, you need to make sure that you understand how your DNS infrastructure will interact with the Active Directory namespace.

For a worksheet to assist you in documenting your existing DNS infrastructure design, see "DNS Inventory" (DSSLOGI_8.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "DNS Inventory" on the Web at http://www.microsoft.com/reskit).

Figure 2.34 shows the DNS infrastructure design documentation that Contoso Corporation created.

**Figure 2.34 Example of a DNS Inventory Worksheet**

| DNS Inventory | | | |
|---|---|---|---|
| Prepared By | Mike Danseglio | Date | 2/20/03 |
| Forest Name | corp.contoso.com | | |
| Forest Owner | Olinda Turner | | |
| Active Directory DNS Owner | Mike Danseglio | | |
| Instructions: Complete this worksheet if you have existing DNS service on your network. | | | |

| DNS Information | | | |
|---|---|---|---|
| Item | Name of Owner | Name of Team | Contact Info |
| DNS Owner | Lori Oviatt | IT Network Infrastructure | lori@contoso.com x633 |
| DHCP Owner | Mandy Vance | IT Network Infrastructure | mandy@contoso.com x992 |

| Recursive Name Resolution Method | |

# Designing Organizational Units for Delegation of Administration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Forest owners are responsible for creating organizational unit designs for their domains. Creating an OU design involves designing the OU structure, assigning the OU owner role, and creating account and resource OUs. Initially, design your OU structure to enable delegation of administration. When the OU design is complete, you can create additional OU structures for the application of Group Policy to the users and computers and to limit the visibility of objects. Figure 2.35 shows the process for creating an organizational unit design.

**Figure 2.35 Process for Creating an Organizational Unit Design**

# Reviewing Organizational Unit Design Concepts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The OU structure for a domain includes the following:

- A diagram of the OU hierarchy.
- A list of OUs.
- For each OU:
  - The purpose for the OU.
  - A list of users or groups that have control over the OU or the objects in the OU.
  - The type of control that users and groups have over the objects in the OU.

The OU hierarchy does not need to reflect the departmental hierarchy of the organization or group. OUs are created for a specific purpose, such as the delegation of administration, the application of Group Policy, or to limit the visibility of objects.

You can design your OU structure to delegate administration to individuals or groups within your organization that require the autonomy to manage their own resources and data. OUs represent administrative boundaries and enable you to control the scope of authority of data administrators.

For example, you can create an OU called ResourceOU and use it to store all the computer accounts that belong to the file and print servers managed by a group. Then you can configure security on the OU such that only data administrators in the group have access to the OU. This prevents data administrators in other groups from tampering with the file and print server accounts. Figure 2.36 shows an organizational unit that is created to enable delegation of administration.

**Figure 2.36 Creating an Organizational Unit to Delegate Administration**

You can further refine your OU structure by creating subtrees of OUs for specific purposes, such as the application of Group Policy, or to limit the visibility of protected objects so that only certain users can see them. For example, if you need to apply Group Policy to a select group of users or resources, you can add those users or resources to an OU and then apply the Group Policy to that OU. You can also use the OU hierarchy to enable further delegation of administrative control.

Figure 2.37 shows a subtree that was created inside the ResourceOU. The subtree includes two additional OUs: The Print Servers OU includes all the computer accounts of the print servers; the File Servers OU includes the computer accounts for all of the file servers. This subtree enables the application of separate Group Policies to each type of server managed in the ResourceOU.

**Figure 2.37 Creating an Organizational Unit Subtree for Application of Group Policy**

**Note**

- While there is no technical limit to the number of levels in your OU structure, for the purpose of manageability, it is recommended that you limit your OU structure to a depth of no more than 10 levels. There is no technical limit to the number of OUs on each level. Note that Active Directory–enabled applications might have restrictions on the number of characters used in the distinguished name (the full LDAP path to the object in the directory), or on the OU depth within the hierarchy.

The Active Directory organizational unit structure is not intended to be visible to end users. The organizational unit structure is an administrative tool for service and data administrators and is easy to change. Continue to review and update your OU structure design to reflect changes in your administrative structure and to support policy-based administration.

# Organizational Unit Owner Role

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The forest owner designates an OU owner for each OU that you design for the domain. OU owners are data managers who control a subtree of objects in Active Directory. OU owners can control how administration is delegated, and how policy is applied to objects within their OU. They can also create new subtrees and delegate administration of OUs within that subtree.

Because OU owners do not own or control the operation of the directory service, you can separate ownership and administration of the directory service from ownership and administration of objects, thereby reducing the number of service administrators who have high levels of access.

OUs provide administrative autonomy and the means to control visibility of objects in the directory. OUs provide isolation from other data administrators but they do not provide isolation from service administrators. Although OU owners have control over a subtree of objects, the forest owner retains full control over all subtrees. This enables the forest owner to correct mistakes, such as an error in an access control list (ACL), or to reclaim delegated subtrees when data administrators are terminated

# Delegating Administration by Using OU Objects

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use organizational units to delegate the administration of objects, such as users or computers, within the OU to a designated individual or group. To delegate administration by using an OU, place the individual or group to which you are delegating administrative rights into a group, place the set of objects to be controlled into an OU, and then delegate administrative tasks for the OU to that group.

Active Directory enables you to control the administrative tasks that can be delegated at a very detailed level; for example, you can assign one group full control of all objects in an OU; assign another group the rights only to create, delete, and manage user accounts in the OU; and assign a third group the right only to reset user account passwords. You can make these permissions inheritable so that they apply to not only a single OU, but also any OUs that are placed in subtrees of the OU.

Default OUs and containers are created during the installation of Active Directory and are controlled by service administrators. It is best if service administrators continue to control these containers. If you need to delegate control over objects in the directory, create additional OUs and place the objects in these OUs. Delegate control over these OUs to the appropriate data administrators. This makes it possible to delegate control over objects in the directory without changing the default control given to the service administrators.

The forest owner determines the level of authority that is delegated to an OU owner. This can range from the ability to create and manipulate objects within the OU to only being allowed to control a single attribute of a single type of object in the OU. Granting a user the ability to create an object in the OU implicitly grants that user the ability to manipulate any attribute of any object that the user creates. In addition, if the object that is created is a container, then the user implicitly has the ability to create and manipulate any objects that are placed in the container.

# Administration of Default Containers and OUs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Every Active Directory domain contains a standard set of OUs and containers that are created during the installation of Active Directory. These include the following:

- Domain container, which serves as the root container to the hierarchy.
- Builtin container, which holds the default service administrator accounts.
- Users container, which is the default location for new user accounts and groups created in the domain.
- Computers container, which is the default location for new computer accounts created in the domain.
- Domain Controllers OU, which is the default location for the computer accounts for domain controllers computer accounts.

The forest owner controls these default OUs and containers.

Figure 2.38 shows the default containers and OUs in a standard Active Directory domain. For more information about resource OUs, see "Creating Resource OUs" later in this chapter.

**Figure 2.38 Default Containers and OUs in an Active Directory Domain**

**Domain Container**

The domain container is the root container of the hierarchy of a domain. Changes to the policies or the ACL on this container can potentially have domain-wide impact. Do not delegate control of this container; it must be controlled by the service administrators.

**Users and Computers Containers**

When you perform an in-place domain upgrade from Windows NT 4.0, existing users and computers are automatically placed into the Users and Computers containers. If you are creating a new Active Directory domain, the Users and Computers containers are the default locations for all new user accounts and non-domain controller computer accounts in the domain.

If you need to delegate control over users or computers, do not modify the default settings on the Users and Computers containers. Instead, create new OUs as needed and move the user and computer objects from their default containers and into the new OUs. Delegate control over the new OUs as needed. It is not recommended that you modify who controls the default containers.

Also, you cannot apply Group Policy settings to the default Users and Computers containers. To apply Group Policy to users and computers, create new OUs and move the user and computer objects into those OUs. Apply the Group Policy setting to the new OUs.

Optionally, you can redirect the creation of objects that are placed in the default containers to be placed in containers of your choice. For more information about redirecting the default location of new objects, see "Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory" in this book.

**Well-known Users and Groups and Built-in Accounts**

By default, several well-known users and groups and built-in accounts are created in a new domain. It is recommended that management of these accounts remains under the control of the service administrators. Do not delegate management of these accounts to an individual who is not a service administrator. Table 2.10 lists the well-known users and groups and built-in accounts that need to remain under the control of the service administrators.

**Table 2.10 Accounts That Need to Remain Under the Control of the Service Administrators**

| Well-known Users and Groups | Built-in Accounts |
|---|---|
| Cert Publishers | Administrator |
| Domain Controllers | Guest |
| Group Policy Creator Owners | Guests |
| KRBTGT | Account Operators |
| Domain Guests | Administrators |
| Administrator | Backup Operators |
| Domain Admins | Incoming Forest Trust Builders |
| Schema Admins (forest root domain only) | Print Operators |
| Enterprise Admins (forest root domain only) | Pre-Windows 2000 Compatible Access |
| Domain Users | Server Operators |
| | Users |

**Domain Controller OU**

When domain controllers are added to the domain, their computer objects are automatically added to the Domain Controller OU. This OU has a default set of policies applied to it. To ensure that these policies are applied uniformly to all domain controllers, it is recommended that you do not move the computer objects of the domain controllers out of this OU. Failure to apply the default policies can cause a domain controller to fail to function properly.

By default, the service administrators control this OU. Do not delegate control of this OU to individuals other than the service administrators.

# Delegating Administration of Account and Resource OUs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Account OUs contain user, group, and computer objects. Forest owners must create an OU structure to manage these objects and then delegate control of the structure to the OU owner. Resource OUs contain resources and the accounts that are responsible for managing those resources. The forest owner is also responsible for creating an OU structure to manage these resources and delegating control of that structure to the OU owner.

**Delegating Administration of Account OUs**

Delegate an account OU structure to data administrators if they need to be able to create and modify user, group, and computer objects. The administrative capabilities of an account OU structure are similar to those of a Windows NT 4.0 Master User Domain. The account OU structure is a subtree of OUs for each account type that must be independently controlled. For example, the OU owner can delegate specific control to various data administrators over child OUs in an account OU for users, computers, groups, and service accounts, as shown in Figure 2.39.

**Figure 2.39 Account OU Structure**

Table 2.11 lists and describes the child OUs that you can create in an account OU structure.

**Table 2.11 Child OUs in the Account OU Structure**

| OU | Purpose |
|---|---|
| Users | Contains user accounts for non-administrative personnel. |
| Service Accounts | Some services that require access to network resources run as user accounts. This OU is created to separate service user accounts from the user accounts contained in the Users OU. Also, placing the different types of user accounts in separate OUs enables you to manage them according to their specific administrative requirements. |
| Computers | Contains accounts for computers other than domain controllers. |
| Groups | Contains groups of all types, except for administrative groups, which are managed separately. |
| Admins | Contains user and group accounts for data administrators in the account OU structure, to allow them to be managed separately from regular users. Enable auditing for this OU so that you can track changes to administrative users and groups. |

Figure 2.40 shows the administrative group design for an Account OU.

**Figure 2.40 Delegation Model for Account OUs**

The owner of the Account OU is the *acct_ou*_OU_admins group, which is comprised of data administrators. This group has full control of the *acct_ou*_OU subtree, and is responsible for creating the standard set of child OUs and the groups to manage them.

Groups that manage the child OUs are granted full control only over the specific class of objects that they are responsible for managing. For example, *acct_ou*_group_admins has control only over group objects.

Note that no separate administrative group manages the Admins OU; rather, it inherits ownership from its parent OU, so it is managed by *acct_ou*_OU_admins. The OU owner might choose to create additional administrative groups, however. For example, the OU owner might create the optional group *acct_ou*_helpdesk_admins in the Admins OU to control password resets.

**Administrative Group Types**

The types of groups that you use to delegate control within an OU structure are based on where the accounts are located relative to the OU structure that is to be managed. If the admin user accounts and the OU structure all exist within a single domain, then the groups that you create to use for delegation must be global groups. Figure 2.41 shows the delegation of administration within a single domain.

**Figure 2.41 Group Type for Delegation Within a Single Domain**

If your organization has a department that manages its own user accounts and exists in more than one region, you might have a group of data administrators who are responsible for managing account OUs in more than one domain. If the accounts of the data administrators all exist in a single domain and you have OU structures in multiple domains to which you need to delegate control, make those administrative accounts members of global groups and delegate control of the OU structures in each domain to those global groups, as shown in Figure 2.42

**Figure 2.42 Using Global Groups to Manage OUs in Multiple Domains**

If the data administrators accounts to which you delegate control of an OU structure come from multiple domains, you must use a universal group. Universal groups can contain users from different domains and can therefore be used to delegate control in multiple domains.

Figure 2.43 shows a configuration in which universal groups are used to manage OUs in multiple domains.

**Figure 2.43 Using Universal Groups to Manage OUs in Multiple Domains**

**Delegating Administration of Resource OUs**

Resource OUs are used to manage access to resources. The resource OU owner creates computer accounts for servers that are joined to the domain that include resources such as file shares, databases, and printers. The resource OU owner also creates groups to control access to those resources.

Figure 2.44 shows the two possible locations for the resource OU.

**Figure 2.44 Resource OU Placement in a Domain**

The resource OU can be located under the domain root or as a child OU of the corresponding account OU in the OU administrative hierarchy. If the domain spans across different countries or regions, or the domain owner is responsible for a large number of OUs, Windows NT 4.0 resource domain owners might prefer to control resource OUs that are subordinate to account OUs, to ensure that they have direct access to support from the account OU owner. Resource OUs do not have any standard child OUs. Computers and groups are placed directly in the resource OU.

The resource OU owner owns the objects within the OU, but does not own the OU container itself. Resource OU owners manage only computer and group objects; they cannot create other classes of objects within the OU, and they cannot create child OUs.

**Note**

- The creator or owner of an object has the ability to set the ACL on the object, regardless of the permissions that are inherited from the parent container. If a resource OU owner can reset the ACL on an OU, he or she can create any class of object in the OU, including users. For this reason, resource OU owners are not permitted to create OUs.

For each resource OU in the domain, create a global group to represent the data administrators who are responsible for managing the contents of the OU. This group has full control over the group and computer objects in the OU, but not over the OU container itself.

Figure 2.45 shows the administrative group design for a resource OU. The *res_ou*_OU_admin group manages its own membership and is located in the resource OU.

**Figure 2.45 Resource OU Administrative Group Design**

Placing the computer accounts into a resource OU gives the OU owner control over the account objects but does not make the OU owner an administrator of the computers. In an Active Directory domain, the Domain Admins group is, by default, placed in the local Administrators group on all computers. This means that service administrators have control over those computers. If resource OU owners require administrative control over the computers in their OU, the forest owner can apply a Restricted Groups Group Policy to make the resource OU owner a member of the Administrators group on the computers in that OU.

# Creating Account OUs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The process that you use to create account OUs varies according to whether you are upgrading a Windows NT 4.0 domain in place or creating a new Windows Server 2003 Active Directory domain. Use one of the following approaches to create account OUs for your domain:

1. If you are upgrading a Windows NT 4.0 MUD in place to an Active Directory domain, create an account OU in the domain for the accounts that are to be upgraded. Leave the service administrator groups and user accounts in the default structure and move the remaining user and group accounts to the newly created account OU.

2. If you are restructuring Windows NT 4.0 MUDs into an Active Directory domain, create an account OU for each independently managed source MUD that is to be migrated into this domain. If the same IT group manages multiple source MUDs, you can migrate accounts from those domains into a single account OU.

3. If you are deploying a new Active Directory domain, create an account OU for the domain so that you can delegate control of the accounts in the domain.

# Creating Resource OUs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Use one of the following approaches to create resource OUs for your domain:

If the domain is the target domain in a Windows NT 4.0 resource domain restructure:

1. Create an OU for each source resource domain that is managed independently and that is to be migrated into this domain.

    - If you are restructuring multiple resource domains that are managed by the same IT group, create a single resource OU and migrate the objects from all domains into that OU.

    - If the source resource domains are managed by former Master User Domain owners, you can migrate objects into the Computers and Groups child OUs of the corresponding account OU subtree, instead of creating a separate resource OU under the account OU.

2. Place the resource OU under the domain root or under an account OU, depending on whether the resource OU owner reports to the account OU owner or directly to the forest owner. The source resource domain owner becomes the resource OU owner.

If the domain is not the target of a resource domain restructure, create resource OUs as needed based on the requirements of each group for autonomy in the management of data and equipment.

# Documenting the OU Design for Each Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Assemble a team to design the OU structure that you use to delegate control over resources within the forest. The forest owner might be involved in the design process and must sign off on the OU design. You might also involve at least one service administrator to ensure that the design is valid. Other design team participants might include the data administrators who will work on the OUs and the OU owners who will be responsible for managing them.

It is important to document your OU design by listing the names of the OUs that you plan to create, and for each OU, documenting the type of OU, the OU owner, the parent OU, if applicable, and the origin of that OU.

For a worksheet to assist you in documenting your OU design, see "Identifying OUs for Each Domain" (DSSLOGI_9.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Identifying OUs for Each Domain" on the Web at http://www.microsoft.com/reskit).

**Example: Documenting the OU Design for Each Domain**
The HR department of Contoso Corporation needs to delegate control over print server administration and user accounts for HR employees and management of the HR database servers to three separate data administrators in their group. They designed an OU structure based on these needs. To assist the deployment team in implementing the OU design, they documented their OU design plans.

Figure 2.46 shows the documentation that the HR department created for their OU design.

**Figure 2.46 Example of an Identifying OUs for Each Domain Worksheet**

# Identifying OUs for Each Domain

| Prepared By | Mark Lee | Date | 2/19/03 |
|---|---|---|---|

| | |
|---|---|
| Forest Name | humrsc.contoso.com |
| Forest Owner | Mark Lee |
| Domain Name | humrsc.contoso.com |
| Domain Owner (Optional) | N/A |

Instructions: Complete this worksheet for each domain in the forest.

| OU Name | Type | Owner | Parent OU | Origin |
|---|---|---|---|---|

# Designing the Site Topology

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An Active Directory® directory service site topology is a logical representation of your physical network. Designing an Active Directory site topology involves planning for domain controller placement and designing sites, subnets, site links, and site link bridges to ensure efficient routing of query and replication traffic.

**In This Chapter**

Overview of Designing a Site Topology

Collecting Network Information

Planning Domain Controller Placement

Creating a Site Design

Creating a Site Link Design

Creating a Site Link Bridge Design

Additional Resources for Designing the Site Topology

**Related Information**

- For more information about designing the Active Directory logical structure and the DNS infrastructure needed to support Active Directory, see "Designing the Active Directory Logical Structure" in this book.
- For more information about determining domain controller hardware requirements, see "Planning Domain Controller Capacity" in this book.
- For more information about deploying a DNS infrastructure for name resolution on your network, see "Deploying DNS" in *Deploying Network Services* of this kit.

# Overview of Designing a Site Topology

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Designing a site topology helps you efficiently route client queries and Active Directory replication traffic. A well-designed site topology helps your organization achieve the following benefits:

- Minimize the cost of replicating Active Directory data.
- Minimize administrative efforts that are required to maintain the site topology.
- Schedule replication that enables locations with slow or dial-up network links to replicate Active Directory data during off-peak hours.
- Optimize the ability of client computers to locate the nearest resources, such as domain controllers and Distributed File System (DFS) servers, reducing network traffic over slow, wide area network (WAN) links, improving logon and logoff processes, and speeding up file download operations.

Before you begin to design your site topology, you must understand your physical network structure. In addition, you must first design your Active Directory logical structure, including the administrative hierarchy, forest plan, and domain plan for each forest. You must also complete your DNS infrastructure design for Active Directory. For more information about designing your Active Directory logical structure and DNS infrastructure, see "Designing the Active Directory Logical Structure" in this book.

After you complete your site topology design, you must verify that your domain controllers meet the hardware requirements for the Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; and Windows® Server 2003, Datacenter Edition, operating systems. You must also determine the appropriate number of domain controllers for each domain that is represented in each site. For more information about determining the appropriate number of domain controllers and their hardware requirements, see "Planning Domain Controller Capacity" in this book.

**Note**

- For a list of job aids that are available to assist you in designing the site topology, see "Additional Resources for Designing the Site Topology" later in this chapter.

# Process for Designing a Site Topology

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Designing a site topology includes determining what locations require domain controllers and determining where you need to create sites, site links, and site link bridges. Figure 3.1 illustrates the site topology design process.

**Figure 3.1 Designing a Site Topology**

# Site Topology Design Background Information

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Your site topology significantly affects the performance of your network and the ability of your users to access network resources. Before you begin to design your site topology, become familiar with the functions for sites in Microsoft® Windows Server 2003, the different network topologies that organizations commonly use, the role of the site topology owner, and some Active Directory replication concepts.

# Functions for Sites in Windows Server 2003

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 uses site information for many purposes, including routing replication, client affinity, system volume replication, DFS, and service location.

**Routing replication**
Active Directory uses a multimaster, store-and-forward method of replication. A domain controller communicates directory changes to a second domain controller, which then communicates to a third, and so on, until all domain controllers have received the change. To achieve the best balance between reducing replication latency and reducing traffic, site topology controls Active Directory replication by distinguishing between replication that occurs within a site and replication that occurs between sites.

Within sites, replication is optimized for speed — data updates trigger replication and the data is sent without the overhead required by data compression. Conversely, replication between sites is compressed to minimize the cost of transmission over WAN links. When replication occurs between sites, a single domain controller per domain at each site collects and stores the directory changes and communicates them at a scheduled time to a domain controller in another site.

**Client affinity**
Domain controllers use site information to inform Active Directory clients about domain controllers present within the closest site as the client. For example, consider a client in the Seattle site that does not know its site affiliation and contacts a domain controller from the Atlanta site. Based on the IP address of the client, the domain controller in Atlanta determines which site the client is actually from and sends the site information back to the client. The domain controller also informs the client whether the chosen domain controller is the closest one to it. The client caches the site information provided by the domain controller in Atlanta and queries for the site-specific service (SRV) resource record (a DNS resource record used to locate domain controllers for Active Directory) and thereby finds a domain controller within the same site.

By finding a domain controller in the same site, the client avoids communications over WAN links. If no domain controllers are located at the client site, a domain controller that has the lowest cost connections relative to other connected sites advertises itself (registers a site-specific SRV resource record in DNS) in the site that does not have a domain controller. The domain controllers that are published in DNS are those from the closest site as defined by the site topology. This process ensures that every site has a preferred domain controller for authentication.

For more information about the process of locating a domain controller, see the *Active Directory Collection* of the *Windows Server 2003 Technical Reference* (or see the Active Directory Collection on the Web at http://www.microsoft.com/reskit).

**SYSVOL replication**
The system volume (SYSVOL) is a collection of folders in the file system that exists on each domain controller in a domain. The SYSVOL folders provide a default Active Directory location for files that must be replicated throughout a domain, including Group Policy objects (GPO), startup and shutdown scripts, and logon and logoff scripts. Windows Server 2003 uses the File Replication service (FRS) to replicate changes made to the SYSVOL folders from one domain controller to other domain controllers. FRS replicates these changes according to the schedule that you create during your site topology design.

**DFS**
DFS uses site information to direct a client to the server that is hosting the requested data within the site. If DFS does not find a copy of the data within the same site as the client, DFS uses the site information in Active Directory to determine which file server that has DFS shared data is closest to the client.

**Service location**
By publishing services such as file and print services in Active Directory, you allow Active Directory clients to locate the requested service within the same or nearest site. Print services use the location attribute stored in Active Directory to let users browse for printers by location without knowing their precise location. For information about enabling printer location tracking, see "Enable printer location tracking" in Help and Support Center for Windows Server 2003. For more information about designing and deploying print servers, see "Designing and Deploying Print Servers" in *Planning Server Deployments* of this kit.

# Site Topology Owner Role

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The administrator who manages the site topology is known as the site topology owner. The site topology owner understands the conditions of the network between sites and has the authority to change settings in Active Directory to implement changes to the site topology. Changes to the site topology affect changes in the replication topology. The site topology owner's responsibilities include:

- Controlling changes to the site topology if network connectivity changes.
- Obtaining and maintaining information about network connections and routers from the network group. The site topology owner must maintain a list of subnet addresses, subnet masks, and the location to which each belongs. The site topology owner must also understand any issues about network speed and capacity that affect site topology in order to effectively set costs for site links.
- Moving Active Directory server objects representing domain controllers between sites if a domain controller's IP address changes to a different subnet in a different site, or if the subnet itself is assigned to a different site. In either case, the site topology owner must manually move the Active Directory server object of the domain controller to the new site.

# Network Topologies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An organization's network topology reflects its business needs. In some organizations, business needs result in users working in a few large locations that are well connected to one another. Alternatively, other organizations have users in many small, satellite locations connected to one of a few, well-connected hub sites. Such network topologies usually are one of three general types: ring, hub and spoke, and complex. These network topologies are illustrated in Figure 3.2.

**Figure 3.2 Network Topologies**

# Active Directory Replication Concepts

Updated: October 27, 2011

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before designing site topology, become familiar with some Active Directory replication concepts.

**Connection object**
A connection object is an Active Directory object that represents a replication connection from one domain controller to another. A domain controller is a member of a single site and is represented in the site by a server object in Active Directory. Each server object has a child NTDS Settings object that represents the replicating domain controller in the site.

The connection object is a child of the NTDS Settings object on the destination server. For replication to occur between two domain controllers, the server object of one must have a connection object that represents inbound replication from the other. All replication connections for a domain controller are stored as connection objects under the NTDS Settings object. The connection object identifies the replication source server, contains a replication schedule, and specifies a replication transport.

The Knowledge Consistency Checker (KCC) creates connection objects automatically, but they can also be created manually. Connection objects created by the KCC appear in the Active Directory Sites and Services snap-in as **<automatically generated>** and are considered adequate under normal operating conditions. Connection objects created by an administrator are manually created connection objects. A manually created connection object is identified by the name assigned by the administrator when it was created. When you modify an **<automatically generated>** connection object, you convert it into an administratively modified connection object and the object appears in the form of a GUID. The KCC does not make changes to manual or modified connection objects.

**KCC**
The KCC is a built-in process that runs on all domain controllers and generates replication topology for the Active Directory forest. The KCC creates separate replication topologies depending on whether replication is occurring within a site (intrasite) or between sites (intersite). The KCC also dynamically adjusts the topology to accommodate new domain controllers, domain controllers moved to and from sites, changing costs and schedules, and domain controllers that are temporarily unavailable.

Within a site, the connections between domain controllers are always arranged in a bidirectional ring, with additional shortcut connections to reduce latency in large sites. On the other hand, the intersite topology is a layering of spanning trees, which means one intersite connection exists between any two sites for each directory partition and generally does not contain shortcut connections. For more information about spanning trees and Active Directory replication topology, see Active Directory Replication Topology Technical Reference in the Windows Server 2003 Technical Reference on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=44137).

On each domain controller, the KCC creates replication routes by creating one-way inbound connection objects that define connections from other domain controllers. For domain controllers in the same site, the KCC creates connection objects automatically without administrative intervention. When you have more than one site, you configure site links between sites and a single KCC in each site automatically creates connections between sites as well.

Figure 3.3 shows two sites (Seattle and Los Angeles) with domain controllers that are all in the same domain. The arrows represent possible inbound connections that the KCC creates. Because all Active Directory updates are transferred in a ring within a site and redundant connections exist, all domain controllers can receive updates from all other domain controllers in the Seattle site, although domain controllers within a site do not necessarily replicate in both directions. For replication to occur between Seattle and Los Angeles, one domain controller in each site has a replication agreement with a domain controller in the other site. Between sites, these replication partners replicate in both directions according to configuration settings for a site link object that represents the physical WAN connecting the two sites. In Figure 3.3, domain controllers DC-3 and DC-4 are replication partners between the Seattle and Los Angeles sites.

**Figure 3.3 Intersite and Intrasite Replication Connections**

**Failover functionality**
Sites ensure that replication is routed around network failures and offline domain controllers. The KCC runs at specified intervals to adjust the replication topology for changes that occur in Active Directory, such as when new domain controllers are added and new sites are created. The KCC reviews the replication status of existing connections to determine if any connections are not working. If a connection is not working due to a failed domain controller, the KCC automatically builds temporary connections to other replication partners (if available) to ensure that replication occurs. If all the domain controllers in a site are unavailable, the KCC automatically creates replication connections between domain controllers from another site.

**Subnet**
A subnet is a segment of a TCP/IP network to which a set of logical IP addresses are assigned. Subnets group computers in a way that identifies their physical proximity on the network. Subnet objects in Active Directory identify the network addresses that are used to map computers to sites.

**Site**
Sites are Active Directory objects that represent one or more TCP/IP subnets with highly reliable and fast network connections. Site information allows administrators to configure Active Directory access and replication to optimize usage of the physical network. Site objects are associated with a set of subnets, and each domain controller in a forest is associated with an Active Directory site according to its IP address. Sites can host domain controllers from more than one domain, and a domain can be represented in more than one site.

**Site link**
Site links are Active Directory objects that represent logical paths that the KCC uses to establish a connection for Active Directory replication. A site link object represents a set of sites that can communicate at uniform cost through a specified intersite transport.

All sites contained within the site link are considered to be connected by means of the same network type. Sites must be manually linked to other sites by using site links so that domain controllers in one site can replicate directory changes from domain controllers in another site. Because site links do not correspond to the actual path taken by network packets on the physical network during replication, you do not need to create redundant site links to improve Active Directory replication efficiency.

When two sites are connected by a site link, the replication system automatically creates connections between specific domain controllers in each site that are called *bridgehead servers*. In Microsoft® Windows® 2000, intersite replication of the directory partitions (domain, configuration, and schema) between domain controllers in different sites is performed by the bridgehead servers (one per directory partition) in those sites. In Windows Server 2003, all domain controllers in a site that host the same directory partition are candidates for being selected as bridgehead servers. The replication connections created by the KCC are randomly distributed among all candidate bridgehead servers in a site to share the replication workload. By default, the randomized selection process takes place only once, when connection objects are first added to the site.

However, you can run the Active Directory Load Balancing tool (Adlb.exe) to rebalance the load each time a change occurs in the site topology or in the number of domain controllers the site. In addition, Adlb can stagger schedules so that the outbound replication load for each domain controller is spread out evenly across time. Consider using Adlb to balance replication traffic between the Windows Server 2003–based domain controllers when they are replicating to more than 20 other sites hosting the same domain. For more information about using Adlb.exe and managing environments that have 100 or more branch sites, see the Windows Server 2003 Active Directory Branch Office Guide on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=28523).

**Site link bridge**
A site link bridge is an Active Directory object that represents a set of site links, all of whose sites can communicate by using a common transport. Site link bridges enable domain controllers that are not directly connected by means of a communication link to replicate with each other. Typically, a site link bridge corresponds to a router (or a set of routers) on an IP network.

By default, the KCC can form a transitive route through any and all site links that have some sites in common. If this behavior is disabled, each site link represents its own distinct and isolated network. Sets of site links that can be treated as a single route are expressed through a site link bridge. Each bridge represents an isolated communication environment for network traffic.

Site link bridges are a mechanism to logically represent transitive physical connectivity between sites. A site link bridge allows the KCC to use any combination of the included site links to determine the least expensive route to interconnect directory partitions held in those sites. The site link bridge does not provide actual connectivity to the domain controllers. If the site link bridge is removed, replication over the combined site links will continue until the KCC removes the links.

Site link bridges are only necessary if a site contains a domain controller hosting a directory partition that is not also hosted on a domain controller in an adjacent site, but a domain controller hosting that directory partition is located in one or more other sites in the forest. Adjacent sites are defined as any two or more sites included in a single site link.

A site link bridge creates a logical connection between two site links, providing a transitive path between two disconnected sites by using an interim site. For the purposes of the intersite topology generator (ISTG), the bridge implies physical connectivity by using the interim site. The bridge does not imply that a domain controller in the interim site will provide the replication path. However, this would be the case if the interim site contained a domain controller that hosted the directory partition to be replicated, in which case a site link bridge is not required.

The cost of each site link is added, creating a summed cost for the resulting path. The site link bridge would be used if the interim site did not contain a domain controller hosting the directory partition and a lower cost link does not exist. If the interim site contained a domain controller that hosts the directory partition, two disconnected sites would set up replication connections to the interim domain controller and not use the bridge.

**Site link transitivity**

By default all site links are transitive, or "bridged." When site links are bridged and the schedules overlap, the KCC creates replication connections that determine domain controller replication partners between sites, where the sites are not directly connected by site links but are connected transitively through a set of common sites. This means that you can connect any site to any other site through a combination of site links.

In general, for a fully routed network, you do not need to create any site link bridges unless you want to control the flow of replication changes. All site links for a specific transport implicitly belong to a single site link bridge for that transport. The default bridging for site links occurs automatically, and no Active Directory object represents that bridge. The **Bridge all site links** setting found in the properties of both the IP and Simple Mail Transfer Protocol (SMTP) intersite transport containers implements automatic site link bridging.

**Global catalog server**

A global catalog server is a domain controller that stores information about all objects in the forest so that applications can search Active Directory without referring to specific domain controllers that store the requested data. Like all domain controllers, a global catalog server stores full, writable replicas of the schema and configuration directory partitions and a full, writable replica of the domain directory partition for the domain that it is hosting. In addition, a global catalog server stores a partial, read-only replica of every other domain in the forest. Partial, read-only domain replicas contain every object in the domain but only a subset of the attributes (those attributes that are most commonly used for searching the object).

**Universal group membership caching**

Universal group membership caching allows the domain controller to cache universal group membership information for users. You can enable domain controllers that are running Windows Server 2003 to cache universal group memberships by using the Active Directory Sites and Services snap-in.

Enabling universal group membership caching eliminates the need for a global catalog server at every site in a domain, which minimizes network bandwidth usage because a domain controller does not need to replicate all of the objects located in the forest. It also reduces logon times because the authenticating domain controllers do not always need to access a global catalog to obtain universal group membership information. For more information about when to use universal group membership caching, see "Planning Global Catalog Server Placement" later in this chapter.

# Collecting Network Information

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The first step in designing an effective Active Directory site topology is to consult your organization's networking group to collect information and communicate with them regularly about your physical network topology. Figure 3.4 shows the process for collecting information about your physical network.

**Figure 3.4 Collecting Network Information**

# Creating a Location Map

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Create a location map that represents the physical network infrastructure of your organization. On the location map, identify the geographic locations that contain groups of computers with internal connectivity of 10 megabits per second (Mbps) or higher (local area network [LAN]-speed or better).

Figure 3.5 shows an example of a location map for Trey Research.

**Figure 3.5 Trey Research Locations**

# Listing Communication Links and Available Bandwidth

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After creating a location map, document the type of communication link, its link speed, and the available bandwidth between each location. Obtain a WAN topology from your networking group. For a list of common WAN circuit types and their bandwidth, see "Determining the Cost" later in this chapter. You need this information to create site links later in the site topology design process.

*Bandwidth* refers to the amount of data that you can transmit across a communication channel in a given amount of time. *Available bandwidth* refers to the amount of bandwidth actually available for use by Active Directory. You can obtain available bandwidth information from your network group or you can analyze traffic on each link by using a protocol analyzer such as Network Monitor, which is a component that ships with Windows Server 2003. For information about installing Network Monitor, see "Monitoring network traffic" on the Microsoft Web site.

Document each location and the other locations that are linked to it. In addition, record the type of communication link and its available bandwidth. For a worksheet to assist you in listing communication links and available bandwidth, see "Geographic Locations and Communication Links" (DSSTOPO_1.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Geographic Locations and Communication Links" on the Web at http://www.microsoft.com/reskit).

Figure 3.6 shows an example of a worksheet listing the locations for Trey Research, the communication links between each location, and the available bandwidth for each communication link.

**Figure 3.6 Example of a Geographic Locations and Communication Links Worksheet**

| Geographic Locations and Communication Links | | | |
|---|---|---|---|
| Prepared By | Site Topology Owner | Date | 1/1/03 |
| Forest Name | Trccorp.treyresearch.net | | |

| Hub Location | Satellite Location | Connection Type | Available Bandwidth |
|---|---|---|---|
| Seattle | Los Angeles | ISDN (128.8 Kbps) | No more than 56 Kbps |
| | Phoenix | ISDN (128.8 Kbps) | No more than 28.8 Kbps |
| | New York | T1 (1.544 Mbps) | No more than 150 Kbps, but with 450-millisecond latency |
| New York | Washington DC | ISDN (128.8 Kbps) | No more than 56 Kbps |
| | Boston | T1 (1.544 Mbps) | No more than 200 Kbps, but with 450-millisecond latency |

# Listing IP Subnets Within Each Location

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you document the communication links and the available bandwidth between each location, record the IP subnets within each location. If you do not already know the subnet mask and IP address within each location, consult your networking group.

Active Directory associates a workstation with a site by comparing the workstation's IP address with the subnets that are associated with each site. As you add domain controllers to a domain, Active Directory also examines their IP addresses and places them in the most appropriate site.

For a worksheet to assist you in listing the IP subnets within each location, see "Locations and Subnets" (DSSTOPO_2.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Locations and Subnets" on the Web at http://www.microsoft.com/reskit).

Figure 3.7 shows an example of a completed worksheet listing the IP subnets within each Trey Research location.

**Figure 3.7 Example of a Locations and Subnets Worksheet**

Locations and Subnets

| | | | |
|---|---|---|---|
| Prepared By | Site Topology Owner | Date | 1/1/03 |
| Forest Name | Trccorp.treyresearch.net | | |

| Location | IP Addresses | Subnet Mask |
|---|---|---|
| Seattle | 172.16.16.0<br>172.16.24.0 | 255.255.252.0<br>255.255.252.0 |
| Boston | 172.16.36.0<br>172.16.40.0 | 255.255.252.0<br>255.255.252.0 |
| New York | 172.16.28.0<br>172.16.32.0 | 255.255.252.0<br>255.255.252.0 |
| Los Angeles | 172.16.136.0<br>172.16.92.0 | 255.255.252.0<br>255.255.252.0 |

# Listing Domains and Number of Users for Each Location

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The number of users for each regional domain that is represented in a location is one of the factors that determine the placement of regional domain controllers and global catalog servers, which is the next step in the site topology design process. For example, plan to place a regional domain controller in a location that contains more than one hundred regional domain users so they can still log on to the domain if the WAN link fails.

Record the locations, the domains that are represented in each location, and the number of users for each domain that is represented in each location. For a worksheet to assist you in listing the domains and the number of users that are represented in each location, see "Domains and Users in Each Location" (DSSTOPO_3.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Domains and Users in Each Location" on the Web at http://www.microsoft.com/reskit).

Figure 3.8 shows a completed worksheet listing the domains that are represented in each Trey Research location, and the number of users for each domain.

**Figure 3.8 Example of a Domains and Users in Each Location Worksheet**

Domains and Users in Each Location

| | | | |
|---|---|---|---|
| Prepared By | Site Topology Owner | Date | 1/1/03 |
| Forest Name | Trccorp.treyresearch.net | | |

| Location | Domains in Location | Users per Domain per Location |
|---|---|---|
| Seattle | trccorp.treyresearch.net | 20 |
| | west.trccorp.treyresearch.net | 15,000 |
| | east.trccorp.treyresearch.net | 200 |
| Los Angeles | west.trccorp.treyresearch.net | 5,000 |
| Washington DC | east.trccorp.treyresearch.net | 50 |
| New York | east.trccorp.treyresearch.net | 7,000 |
| | west.trccorp.treyresearch.net | 200 |
| Boston | east.trccorp.treyresearch.net | 80 |
| Phoenix | west.trccorp.treyresearch.net | 20 |

# Planning Domain Controller Placement

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you have gathered all of the network information that will be used to design your site topology, plan where you want to place domain controllers, including regional domain controllers, forest root domain controllers, operations master role holders, and global catalog servers. Figure 3.9 shows the process for determining domain controller placement.

**Figure 3.9 Planning Domain Controller Placement**

Although this process helps you plan where you intend to place domain controllers, it does not address how you determine the proper number of domain controllers and the domain controller hardware requirements for each domain that is represented in each site. For more information about determining the proper number of domain controllers for each domain that is represented in each site, see "Planning Domain Controller Capacity" in this book.

# Planning Forest Root Domain Controller Placement

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Forest root domain controllers are needed to create trust paths for clients that need to access resources in domains other than their own. Place forest root domain controllers at locations that host datacenters and in hub locations. If users in a given location need to access resources from other domains in the same location, and the network availability between the datacenter and the user location is unreliable, then you can either add a forest root domain controller in the location or create a shortcut trust between the two domains. It is more cost efficient to create a shortcut trust between the domains unless you have other reasons to place a forest root domain controller in that location.

Shortcut trusts help to optimize authentication requests made from users located in either domain. For more information about how to create shortcut trusts between domains, see "Create a shortcut trust" in Help and Support Center for Windows Server 2003.

For a worksheet to assist you in documenting your forest root domain controller placement, see "Domain Controller Placement" (DSSTOPO_4.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Domain Controller Placement" on the Web at http://www.microsoft.com/reskit). For an example of a completed Domain Controller Placement worksheet, see "Example: Determining Domain Controller Placement" later in this chapter.

You need to refer to this information when you create the forest root domain. For more information about deploying the forest root domain, see "Deploying the Windows Server 2003 Forest Root Domain" in this book.

# Planning Regional Domain Controller Placement

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning Regional Domain Controller Placement**

For cost efficiency, plan to place as few regional domain controllers as possible. First review the Geographic Locations and Communication Links worksheet to determine whether a location is a hub. Plan to place regional domain controllers for each domain that is represented in each hub location.

In addition, ensure the physical security of domain controllers in hub locations so that unauthorized personnel cannot access them. Do not place domain controllers in a location in which you cannot guarantee the physical security of the domain controller.

After you place regional domain controllers in all hub locations, evaluate the need for placing regional domain controllers at satellite locations. Eliminating unnecessary regional domain controllers from satellite locations reduces the support costs required to maintain a remote server infrastructure.

To authenticate client logons and access to local file servers, most organizations place regional domain controllers for all regional domains that are represented in a given location. However, you must consider many variables when evaluating whether a business location requires its clients to have local authentication or the clients can rely on authentication and query over a WAN link. Figure 3.10 shows how to determine whether to place domain controllers at satellite locations.

**Figure 3.10 Determining Whether to Place Domain Controllers at Satellite Locations**

**Domain Controller Physical Security**

Do not place a regional domain controller in a satellite location if you cannot ensure the physical security of the domain controller. A person who has physical access to a domain controller can attack the system by:

- Accessing physical disks by starting an alternate operating system on a domain controller.
- Removing (and possibly replacing) physical disks on a domain controller.
- Obtaining and manipulating a copy of a domain controller system state backup.

Add regional domain controllers only to locations in which you can guarantee their physical security. For more information about securing domain controllers, see Best Practice Guide for Securing Windows Server Active Directory Installations on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=28521).

**On-site Technical Expertise Availability**

Domain controllers need to be managed continuously for various reasons. Place a regional domain controller only in locations that include personnel who can administer the domain controller, or be sure that the domain controller can be managed

remotely.

**WAN Link Availability**
WAN links that experience frequent outages can cause significant productivity loss to users if the location does not include a domain controller that can authenticate the users. If your WAN link availability is not 100 percent, place a regional domain controller in locations where the users require the ability to log on when the WAN link is down.

**Authentication Availability**
Certain organizations, such as banks, require that users be authenticated at all times. Place a regional domain controller in a location where the WAN link availability is not 100 percent but users require authentication at all times.

**Logon Performance over WAN Link**
If your WAN link availability is 100 percent, then whether you place a domain controller at the location depends on the logon performance requirements over the WAN link. Factors that influence logon performance over the WAN include link speed and available bandwidth, number of users and usage profiles, and the amount of logon network traffic versus replication traffic.

**WAN link speed and bandwidth utilization**
The activities of a single user can congest a slow WAN link. Place a domain controller at a location if logon performance over the WAN link is unacceptable.

The average percentage of bandwidth utilization indicates how congested a network link is. If a network link has an average bandwidth utilization that is greater than an acceptable value, place a domain controller at that location.

**Number of users and usage profile**
The number of users and their usage profile at a given location can help determine whether you need to place regional domain controllers at that location. To avoid productivity loss in the event of a WAN link failure, place a regional domain controller at a location that has a staff of one hundred or more users.

The usage profile indicates how the users use the network resources. You need not place a domain controller in a location that contains only a few users who do not frequently access network resources.

**Logon network traffic vs. replication traffic**
If a domain controller is not available within the same location as the Active Directory client, then the client creates logon traffic on the network. The amount of logon network traffic that is created on the physical network is influenced by several factors, including group memberships, number and size of GPOs, logon scripts, and IntelliMirror® features such as offline folders, folder redirection, and roaming profiles.

On the other hand, a domain controller that is placed at a given location generates replication traffic on the network. The frequency and amount of updates made on the partitions hosted on the domain controllers influence the amount of replication traffic that is created on the network. The different types of updates that can be made on the partitions hosted on the domain controllers include adding or changing users and user attributes, changing passwords, and adding or changing global groups, printers, or volumes.

To determine if you need to place a regional domain controller at a location, compare the cost of logon traffic created by a location without a domain controller versus the cost of replication traffic created by placing a domain controller at the location.

For example, consider a network that has branch offices that are connected through slow links to the headquarters and in which domain controllers can easily be added. If the daily logon and directory lookup traffic of a few remote site users causes more network traffic than replicating all company data to the branch, consider adding a domain controller to the branch.

If reducing the cost of maintaining domain controllers is more important than network traffic, centralize the domain controllers for that domain and do not place any regional domain controllers at the location.

For a worksheet to assist you in documenting the placement of regional domain controllers and the number of users for each domain that is represented in each location, see "Domain Controller Placement" (DSSTOPO_4.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Domain Controller Placement" on the Web at http://www.microsoft.com/reskit). For an example of a completed Domain Controller Placement worksheet, see "Example: Determining Domain Controller Placement" later in this chapter.

You need to refer to the information about locations in which you need to place regional domain controllers when you deploy regional domains. For more information about deploying regional domains, see "Deploying Windows Server 2003 Regional Domains" in this book.

# Planning Global Catalog Server Placement

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Global catalog placement requires planning except if you have a single-domain forest. In a single-domain forest, configure all domain controllers as global catalog servers. Because every domain controller stores the only domain directory partition in the forest, configuring each domain controller as a global catalog server does not require any additional disk space usage, CPU usage, or replication traffic. In a single-domain forest, all domain controllers act as "virtual global catalog servers" in that they can all respond to any authentication or service request. This special condition for single-domain forests is by design (authentication requests do not require contacting a global catalog server, as they do when there are multiple domains and a user can be a member of a universal group that exists in a different domain). However, only domain controllers that are designated as global catalog servers can respond to global catalog queries on the global catalog port 3268. To simplify administration in this scenario and to ensure consistent responses, designating all domain controllers as global catalog servers eliminates the concern about which domain controllers can respond to global catalog queries. Specifically, any time a user uses Start\Search\For People or Find Printers, these requests go only to the global catalog.

In multiple-domain forests, global catalog servers facilitate user logon requests and forest-wide searches. Figure 3.11 illustrates how to determine which locations require global catalog servers.

**Figure 3.11 Determining the Placement of Global Catalog Servers**

**Adding Global Catalog Servers Based on Application Requirements**

Certain applications, such as Microsoft® Exchange® 2000, Message Queuing (also known as MSMQ), and applications using Distributed COM (DCOM), do not deliver adequate response over latent WAN links and therefore need a highly available global catalog infrastructure to provide low query latency. Determine whether any applications that perform poorly over a slow WAN link are running in locations or whether the locations include Exchange servers. If your locations include applications that do not deliver optimum response over a WAN link, you must place a global catalog server at the location to reduce query latency.

**Adding Global Catalog Servers for a Large Number of Users**

Place global catalog servers at all locations that contain more than 100 users to reduce congestion of network WAN links and to prevent productivity loss in case of WAN link failure.

**Using Highly Available Bandwidth**

You do not need to place a global catalog at a location that does not include applications that require a global catalog server, includes less than 100 users, and is also connected to another location that includes a global catalog server by a WAN link that is 100 percent available for Active Directory. In this case, the users can access the global catalog server over the WAN link.

**Adding Global Catalog Servers for a Large Number of Roaming Users**
Roaming users need to contact the global catalog servers whenever they log on for the first time at any location. Place a global catalog at a location that is visited by a large number of roaming users if the logon time over the WAN link is unacceptable.

**Enabling Universal Group Membership Caching**
For locations that include less than 100 users and do not include a large number of roaming users or applications that require a global catalog server, you can deploy domain controllers that are running Windows Server 2003 and enable universal group membership caching. Ensure that the global catalog servers are not more than one replication hop from the domain controller on which universal group membership caching is enabled, so that universal group information in the cache can be refreshed.

For more information about how to enable universal group membership caching, see "Cache universal group memberships" in Help and Support Center for Windows Server 2003. For information about how universal group caching works, see "How the Global Catalog Works" in the Windows Server 2003 Technical Reference.

For a worksheet to assist you in documenting where you plan to place global catalog servers and domain controllers with universal group caching enabled, see "Domain Controller Placement" (DSSTOPO_4.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Domain Controller Placement" on the Microsoft Web site http://go.microsoft.com/fwlink/?linkid=9568). For an example of a completed Domain Controller Placement worksheet, see "Example: Determining Domain Controller Placement" later in this chapter. You need to refer to the information about locations in which you need to place global catalog servers when you deploy the forest root domain and regional domains.

# Planning Operations Master Role Placement

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Planning Operations Master Role Placement**

Active Directory supports multimaster replication of directory data, which means any domain controller can accept directory changes and replicate the changes to all other domain controllers. However, certain changes, such as schema modifications, are impractical to perform in a multimaster fashion. For this reason certain domain controllers, known as *operations masters*, hold roles responsible for accepting requests for certain specific changes.

Three operations master roles exist in each domain:

- The primary domain controller (PDC) emulator processes all replication requests from Microsoft® Windows NT® 4.0 backup domain controllers (BDCs) and processes all password updates for clients that are not running Active Directory client software.
- The relative identifier (RID) master allocates RIDs to all domain controllers to ensure that all security principals have a unique identifier.
- The infrastructure master for a given domain maintains a list of the security principals from other domains that are members of groups within its domain.

In addition to the three domain-level operations master roles, two operations master roles exist in each forest:

- The schema master governs changes to the schema.
- The domain naming master adds and removes domains to and from the forest.

Place the domain controllers hosting these operations master roles in areas where network reliability is high, and ensure that the PDC emulator and the RID master are consistently available.

Operations master role holders are assigned automatically when the first domain controller in a given domain is created. The two forest-level roles (schema master and domain naming master) are assigned to the first domain controller created in a forest. Additionally, the three domain-level roles (RID master, infrastructure master, and PDC emulator) are assigned to the first domain controller created in a domain.

Place the first domain controller for a domain in a location that has the largest number of users for that domain. Designate a standby operations master for a domain controller that hosts the operations master roles. The standby operations master is a domain controller that you identify as the computer that assumes the operations master role if the original role holder fails. Ensure that the standby operations master is a direct replication partner of the actual operations master.

Place the domain controllers that host these operations master roles in areas where the network is reliable and where the operations masters can be accessed by all other domain controllers in the forest. For more information about how certain operations might be affected if an operations master role holder is not reachable, see "Operations Master Placement for Networks with Limited Connectivity" later in this section.

**Operations Master Placement for Single Domain Forest**

In addition to hosting the operations master roles, the first domain controller created in a forest also hosts the global catalog. In a single domain forest, the database of a global catalog server is identical to that of a domain controller. Therefore, configure all domain controllers as global catalog servers because it does not cause any additional workload for the domain controllers. In a single domain forest where all domain controllers are configured as global catalog servers, leave all operation master roles on the first domain controller that is created in the forest and use the second domain controller as a standby operations master.

**Operations Master Placement for Forest Root Domain**

In a forest hosting multiple domains, if all domain controllers in the forest root domain are also global catalog servers, leave all the operations master roles on the first domain controller. Use the second domain controller deployed in the forest as the standby operations master.

However, if all domain controllers in the forest root domain are not also global catalog servers, move all the operations master roles to the second domain controller deployed in the forest root domain and ensure that this domain controller is never configured as a global catalog server. This is because the first domain controller is always a global catalog server and the infrastructure master should not be placed on a domain controller that is also a global catalog server unless all domain controllers are global catalog servers. To simplify the environment, keep all the operations master roles on the second domain controller. Configure the third domain controller deployed in the forest root domain as the standby operations master and ensure that this domain controller will also never be configured as global catalog server.

**Operations Master Placement for Regional Child Domain**

The three domain-level roles are assigned to the first domain controller in the domain by default. If any domain controllers in the regional domain will not host the global catalog, leave the three-domain-level operations master roles on the first domain controller and ensure that the first domain controller is never configured as a global catalog server. Configure the second domain controller deployed in this domain to be the standby operations master.

**Planning the PDC emulator placement**

The PDC emulator acts as a Windows NT 4.0 PDC if the domain contains pre–Active Directory clients or if it contains Windows NT 4.0 BDCs. It processes password changes from clients and replicates updates to the BDCs. Only one domain controller acts as the PDC emulator in each domain in the forest.

Even if all the domain controllers are upgraded to Windows 2000 or Windows Server 2003 and the domain is operating at the Windows 2000 native functional level, the PDC emulator receives preferential replication of password changes performed by other domain controllers in the domain. If a password was recently changed, that change takes time to replicate to every domain controller in the domain. If logon authentication fails at another domain controller due to a bad password, that domain controller forwards the authentication request to the PDC emulator before rejecting the logon attempt.

Place the PDC emulator in a location that contains a large number of users from that domain for password forwarding operations if needed. In addition, ensure that the location is well connected to other locations to minimize replication latency.

Use the Domain Controller Placement worksheet to document the information about where you plan to place PDC emulators and the number of users for each domain that is represented in each location. For an example of a completed Domain Controller Placement worksheet, see "Example: Determining Domain Controller Placement" later in this chapter.

You need to refer to the information about locations in which you need to place PDC emulators when you deploy regional domains. For information about deploying regional domains, see "Deploying Windows Server 2003 Regional Domains" in this book.

**Requirements for infrastructure master placement**

The infrastructure master updates the names of security principals from other domains that are added to groups in its own domain. For example, if a user from one domain is a member of a group in a second domain and the user's name is changed in the first domain, then the second domain is not notified that the user's name must be updated in the group's membership list. Because domain controllers in one domain do not replicate security principals to domain controllers in another domain, the second domain never becomes aware of the change in the absence of the infrastructure master.

The infrastructure master constantly monitors group memberships, looking for security principals from other domains. If it finds one, it checks with the security principal's domain to verify that the information is updated. If the information is out of date, the infrastructure master performs the update and then replicates the change to the other domain controllers in its domain.

Two exceptions apply to this rule. First, if all domain controllers are global catalog servers, the domain controller that hosts the infrastructure master role is insignificant because global catalogs replicate the updated information regardless of the domain to which they belong. Second, if the forest has only one domain, the domain controller that hosts the infrastructure master role is insignificant because security principals from other domains do not exist.

Do not place the infrastructure master on a domain controller that is also a global catalog server. If the infrastructure master and global catalog are on the same domain controller, the infrastructure master will not function. The infrastructure master will never find data that is out of date, so it will never replicate any changes to the other domain controllers in the domain.

**Operations Master Placement for Networks with Limited Connectivity**

Be aware that if your environment does have a central location or hub site in which you can place operations master role holders, certain domain controller operations that depend on the availability of those operations master role holders might be affected.

For example, suppose that an organization creates sites A, B, C, and D. Site links exist between A and B, between B and C, and between C and D. Network connectivity exactly mirrors the network connectivity of the sites links. In this example, all operations master roles are placed in site A and the option to **Bridge all site links** is not selected.

Although this configuration results in successful replication between all of the sites, the operations master role functions have the following limitations:

- Domain controllers in sites C and D cannot access the PDC emulator in site A to update a password or to check it for a password that has been recently updated.
- Domain controllers in sites C and D cannot access the RID master in site A to obtain an initial RID pool after Active Directory installation and to refresh RID pools thereafter as they become depleted.
- Domain controllers in sites C and D cannot add or remove directory, Domain Name System (DNS), or custom application partitions.
- Domain controllers in sites C and D cannot make schema changes.

Document the information about operations master roles placement. You need to refer to this information when you create the forest root domain and regional domains. For more information about deploying the forest root domain, see "Deploying the Windows Server 2003 Forest Root Domain" in this book. For more information about deploying regional domains, see "Deploying Windows Server 2003 Regional Domains" in this book.

Use the Domain Controller Placement worksheet to document information about where you plan to place operations master role holders. For an example of a completed Domain Controller Placement worksheet, see "Example: Determining Domain Controller Placement" later in this chapter.

For a worksheet to assist you in planning operations master role placement, see "Domain Controller Placement" (DSSTOPO_4.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Domain Controller Placement" on the Web at http://www.microsoft.com/reskit).

# Example: Determining Domain Controller Placement

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Figure 3.12 shows an example of a completed Domain Controller Placement worksheet for Trey Research, which has offices located in Seattle, New York, Los Angeles, Boston, Phoenix, and Washington, DC. Users from three domains exist in the organization: the forest root domain, and the EAST and WEST domains. Seattle is the hub location for Western locations and New York is the hub location for Eastern locations. For each location, Trey Research documented the names of the domains, the number of users for each domain, and the type of domain controllers needed.

**Figure 3.12 Example of a Domain Controller Placement Worksheet**

| Domain Controller Placement | | | | |
|---|---|---|---|---|
| Prepared by | Site Topology Owner | | Date | 1/1/03 |
| Forest name | Trccorp.treyresearch.net | | | |

| Location | Domains in Location | Users per Domain per Location | DC Needed? (Yes/No) | Domain Controller Type |
|---|---|---|---|---|
| Seattle | trccorp.treyresearch.net | 20 | Yes | Forest root<br>Global catalog |
| | west.trccorp.treyresearch.net | 15,000 | Yes | PDC emulator (WEST)<br>Global catalog<br>WEST regional |
| | east.trccorp.treyresearch.net | 200 | Yes | EAST regional |
| Los Angeles | west.trccorp.treyresearch.net | 5,000 | Yes | WEST regional<br>Global catalog |
| Washington DC | east.trccorp.treyresearch.net | 50 | Yes | EAST regional<br>Universal group membership caching enabled |
| New York | trccorp.treyresearch.net | 10 | Yes | Forest root |
| | east.trccorp.treyresearch.net | 7,000 | Yes | PDC emulator (EAST)<br>Global catalog<br>EAST regional |
| | west.trccorp.treyresearch.net | 200 | Yes | WEST regional |
| Boston | east.trccorp.treyresearch.net | 80 | Yes | EAST regional<br>Universal group membership caching enabled |
| Phoenix | west.trccorp.treyresearch.net | 20 | No | |

The following decisions were made regarding placement of domain controllers at each location based on WAN link speed between locations, number of users per domain, the need for users to access resources across the forest, and logon performance over WAN links:

- The PDC emulator for the WEST domain is placed in Seattle because it includes the largest number of users from the WEST domain. The PDC emulator for the EAST domain is placed in New York because it includes the largest number of users from the EAST domain.

- Because Trey Research includes a large number of users that are distributed across different geographic locations connected by a wide area network (WAN), two regional domains are created (EAST and WEST) to reduce replication traffic over slow WAN links. Regional domain controllers hosting the WEST domain are placed in Seattle, Los Angeles, and New York. Regional domain controllers hosting the EAST domain are placed in New York, Boston, Seattle, and Washington, DC. At any given time, an average of 200 mobile users from the WEST domain travel from Seattle to the New York location. Therefore, regional domain controllers hosting the WEST domain are placed in New York so that these mobile users belonging to the WEST domain can log on locally at the New York location. Similarly, at any given time, an average of 200 mobile users from New York travel to the Seattle location. Therefore, regional domain controllers hosting the EAST domain are placed in Seattle so that mobile users belonging to the EAST domain can log on locally in Seattle.

  Because domain controllers from both EAST and WEST domains are placed into the Seattle and New York locations

respectively, the resulting network traffic for replication is similar to the replication traffic created if Trey Research had deployed a single domain forest. However, because there are additional locations (Los Angeles, Phoenix, Boston, and Washington, DC) that are connected to the Seattle and New York hub locations through slower network links, and none of the users from these satellite locations will travel to these hub locations, Trey Research will still save network bandwidth caused by replication.

Because Phoenix has only 20 users from the WEST domain and users at the Phoenix location have acceptable logon performance over the WAN link between Phoenix and Seattle, the organization decides not to place any regional domain controllers in Phoenix. Users in Boston require local authentication at all times but do not have 100 percent WAN link availability between New York and Boston. Therefore, a domain controller hosting the EAST domain is placed at the Boston location.

- The TRCCORP forest root domain controllers are placed in Seattle and New York because they are hub locations in the Trey Research forest. Shortcut trusts are created between the WEST domain and the EAST domain because users in Boston need to regularly access resources from the WEST domain.

- Global catalog servers are placed in Seattle, Los Angeles, and New York because each location hosts more than one hundred users. A domain controller with universal group caching enabled is placed in Boston instead of a global catalog server because that location has only 80 users and does not include any applications that require a global catalog server.

- Washington, DC hosts only 50 users from the EAST domain, and does not have 100 percent WAN link availability between New York. Additionally, no applications that require a global catalog server are running at this location. Because Washington, DC has less than 100 users and also no application that requires a global catalog server is running at this location, no global catalog server is placed in Washington, DC. The users in Washington, DC need local authentication at all times, hence a domain controller running Windows Server 2003 is configured for universal group caching and placed there to facilitate user logon requests.

# Creating a Site Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Creating a site design involves deciding which locations will become sites, creating site objects, creating subnet objects, and associating the subnets with sites. Figure 3.13 shows the steps that are required to create a site design.

**Figure 3.13 Creating a Site Design**

**Deciding Which Locations Will Become Sites**

Figure 3.14 illustrates how to decide which locations will become sites.

**Figure 3.14 Deciding Which Locations Will Become Sites**

Decide which locations to create sites for as follows:

- Create sites for all locations in which you plan to place domain controllers. Refer to the information documented in the Domain Controller Placement worksheet to identify locations that include domain controllers. For an example of a completed Domain Controller Placement worksheet, see "Example: Determining Domain Controller Placement" earlier in this chapter.

- Create sites for those locations that include servers that are running applications that require a site to be created. Certain applications, such as DFS, use site objects to locate the closest servers to clients.

- If a site is not required for a location, add the subnet of the location to a site for which the location has the maximum WAN speed and available bandwidth.

Document those locations that will become sites and the network addresses and subnet masks within each location. For a worksheet to assist you in documenting sites, see "Associating Subnets with Sites" (DSSTOPO_6.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Associating Subnets with Sites" on the Web at http://www.microsoft.com/reskit).

**Creating a Site Object Design**
For every location where you have decided to create sites, plan to create site objects in Active Directory. Document those locations that will become sites in the "Associating Subnets with Sites" worksheet.

For more information about how to create site objects, see "Create a site" in Help and Support Center for Windows Server 2003.

**Creating a Subnet Object Design**
For every IP subnet and subnet mask associated with each location, plan to create subnet objects in Active Directory representing all the IP addresses within the site. To obtain information about IP subnets within each location, refer to the Locations and Subnets worksheet. For an example of a completed Locations and Subnets worksheet, see "Listing IP Subnets Within Each Location" earlier in this chapter.

When creating an Active Directory subnet object, the information about network IP subnet and subnet mask is automatically translated into the network prefix length notation format *<IP address>/<# of bits>*. For example, the network IP address 172.16.4.0 with a subnet mask 255.255.252.0 appears as 172.16.4.0/22.

For more information about how to create subnet objects, see "Create a subnet" in Help and Support Center for Windows Server 2003.

Document the Active Directory subnet object associated with each location in the "Associating Subnets with Sites" worksheet.

**Associating Subnets with Sites**
Associate each subnet object with a site object by referring to the "Associating Subnets with Sites" worksheet to determine which subnet is to be associated with which site.

For more information about associating subnets with sites, see "Associate a subnet with a site" in Help and Support Center for Windows Server 2003.

**Example: Associating Subnets with Sites**
Figure 3.15 shows an example of a completed Associating Subnets with Sites worksheet for Trey Research, which has offices located in Seattle, Los Angeles, Boston, New York, Phoenix, and Washington, DC. Trey Research listed potential site candidates, the locations to be included in those sites, and the corresponding Active Directory subnets. Because the Phoenix location includes fewer than one hundred users, a domain controller is not placed at that location. The Phoenix subnets are associated with the Seattle site because Seattle is the nearest location that has a direct communication link to Phoenix.

**Figure 3.15 Example of Associating Subnets with Sites Worksheet**

| Associating Subnets with Sites | | | |

# Creating a Site Link Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Create a site link design in order to connect your sites with site links. Site links reflect the intersite connectivity and method used to transfer replication traffic. You must connect sites with site links so that domain controllers at each site can replicate Active Directory changes. Figure 3.16 shows the process for creating a site link design.

**Figure 3.16 Creating a Site Link Design**

# Connecting Sites with Site Links

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To connect sites with site links, identify the member sites that you want to connect with the site link, create a site link object in the respective **Inter-Site Transports** container, and then name the site link. After you create the site link, you can proceed to set the site link properties.

When creating site links, ensure that every site is included in a site link. In addition, ensure that all sites are connected to each other through other site links so that the changes can be replicated from domain controllers in any site to all other sites. If you fail to do this, then the KCC generates an error message in the Directory Service log in Event Viewer stating that the site topology is not connected.

Whenever you add sites to a newly created site link, determine if the site being added is a member of other site links and change the site link membership of the site if needed. For example, if you make a site a member of the default-first-site-link when you initially create the site, be sure to remove the site from the default-first-site-link after you add the site to a new site link. If you do not remove the site from the default-first-site-link, the KCC will make routing decisions based on the membership of both site links, which may result in incorrect routing.

To identify the member sites that you want to connect with a site link, use the list of locations and linked locations that you recorded in the "Geographic Locations and Communication Links" worksheet. If multiple sites have the same connectivity and availability to each other, you can connect them with the same site link. For an example of a completed Geographic Locations and Communication Links worksheet, see "Listing Communication Links and Available Bandwidth" earlier in this chapter.

The Inter-Site Transports container provides the means for mapping site links to the transport that the link uses. When you create a site link object, you create it in either the IP container (which associates the site link with the remote call procedure [RPC] over IP transport) or the Simple Mail Transfer Protocol (SMTP) container (which associates the site link with the SMTP transport). When you create a site link object in the respective **Inter-Site Transports** container, Active Directory uses RPC over IP to transfer both intersite and intrasite replication between domain controllers. To keep data secure while in transit, RPC over IP replication uses both the Kerberos authentication protocol and data encryption.

When a direct IP connection is not available, you can configure replication between sites to use SMTP. However, SMTP replication functionality is limited and requires an enterprise certification authority (CA). SMTP can only replicate the configuration, schema, and application directory partitions, and does not support the replication of domain directory partitions.

To name site links, use a consistent naming scheme, such as *name_of_site1-name_of_site2*. Record the list of sites, linked sites, and the names of the site links connecting these sites in a worksheet.

For a worksheet to assist you in recording site names and associated site link names, see "Sites and Associated Site Links" (DSSTOPO_5.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Sites and Associated Site Links" on the Web at http://www.microsoft.com/reskit).

Figure 3.17 shows an example of a completed "Sites and Associated Site Links" worksheet.

**Figure 3.17 Example of a Sites and Associated Site Links Worksheet**

| Sites and Associated Site Links | | | |

| Site Names | Linked Sites | Name of the Site Link | Link Type |
|---|---|---|---|
| Seattle | LosAngeles | LAX-SEA | ISDN (128.8 Kbps) |
| Seattle | NewYork | SEA-NYC | T1 (1.544 Mbps) |
| NewYork | WashingtonDC | NYC-WDC | T1 (1.544 Mbps) |
| NewYork | Boston | NYC-BOS | ISDN (128.8 Kbps) |

# Setting Site Link Properties

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Intersite replication occurs according to the properties of the connection objects. When the KCC creates connection objects, it derives the replication schedule from properties of the site link objects. Each site link object represents the WAN connection between two or more sites.

Setting site link object properties includes the following steps:

- Determining the cost that is associated with that replication path. The KCC uses cost to determine the least expensive route for replication between two sites that replicate the same directory partition.
- Determining the schedule that defines the times during which intersite replication can occur.
- Determining the replication interval that defines how frequently replication should occur during the times when replication is allowed as defined in the schedule.

# Determining the Cost

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You assign cost values to site links to favor inexpensive connections over expensive connections. Certain applications and services, such as Domain Controller Locator and DFS, also use cost information to locate nearest resources. Site link cost can be used to determine which domain controller is contacted by clients located in one site if the domain controller for the specified domain does not exist at that site. The client contacts the domain controller by using the site link that has the lowest cost assigned to it.

It is recommended that the cost value be defined on a site-wide basis. Cost is usually based not only on the total bandwidth of the link but also on the availability, latency, and monetary cost of the link.

To determine the costs to place on site links, perform these tasks:

- Document the connection speed for each site link. Refer to the Geographic Locations and Communication Links worksheet for information about the connection speed that you identified. For an example of a completed Geographic Locations and Communication Links worksheet, see "Listing Communication Links and Available Bandwidth" earlier in this chapter.

  Table 3.1 lists the speeds for different types of networks.

  **Table 3.1 Speeds for Different Network Types**

| Network Type | Speed |
|---|---|
| Very slow | 56 kilobits per second (Kbps) |
| Slow | 64 Kbps |
| ISDN | 64 Kbps or 128 Kbps |
| Frame relay | Variable rate, commonly between 56 Kbps and 1.5 megabits per second (Mbps) |
| T1 | 1.5 Mbps |
| T3 | 45 Mbps |
| 10BaseT | 10 Mbps |
| Asynchronous transfer mode (ATM) | Variable rate, commonly between 155 Mbps and 622 Mbps |
| 100BaseT | 100 Mbps |
| Gigabit Ethernet | 1 gigabit per second (Gbps) |

- Use Table 3.2 to calculate the cost of each site link based on WAN link speed. For WAN link speed that is not listed in the table, you can calculate a relative cost factor by dividing 1024 by the log of the available bandwith as measured in Kbps.

  **Table 3.2 Calculating Costs Based on WAN Link Speed**

| Available Bandwidth (Kbps) | Cost |
|---|---|
| 9.6 | 1042 |

| | |
|---|---|
| 19.2 | 798 |
| 38.4 | 644 |
| 56 | 586 |
| 64 | 567 |
| 128 | 486 |
| 256 | 425 |
| 512 | 378 |
| 1024 | 340 |
| 2048 | 309 |
| 4096 | 283 |

These costs do not reflect differences in reliability between network links. Set higher costs on any failure-prone network links so that you do not need to rely on those links for replication. By setting higher site links costs, you can control replication failover when a site link fails.

# Determining the Schedule

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can control site link availability by setting a schedule on site links. When replication between two sites traverses multiple site links, the intersection of the replication schedules on all relevant links determines the connection schedule between the two sites.

To plan for setting the site link schedule, create two overlapping schedules between site links that contain domain controllers that need to directly replicate with each other. Use the default (100-percent available) schedule on those links unless you want to block replication traffic during peak hours. By blocking replication, you give priority to other traffic, but you also increase replication latency.

Domain controllers store time in Coordinated Universal Time (UTC). Time settings in site link object schedules conform to the local time of the site and computer on which the schedule is set. When a domain controller contacts a computer that is in a different site and time zone, the schedule on the domain controller displays the time setting according to the local time for the site of the computer.

# Determining the Interval

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You must set the site link replication interval property to indicate how frequently you want replication to occur during the times when the schedule allows replication. For example, if the schedule allows replication between 02:00 hours and 04:00 hours, and the replication interval is set for 30 minutes, replication can occur up to four times during the scheduled time. The default replication interval is 180 minutes, or 3 hours.

Consider the following criteria to determine how often replication occurs within the schedule window:

- A small interval decreases latency but increases the amount of WAN traffic.
- To keep domain directory partitions up to date, low latency is preferred.

With a store-and-forward replication strategy, determining just how long a directory update might take to be replicated to every domain controller is difficult. To provide a conservative estimate of maximum latency, perform these tasks:

- Create a table of all the sites on your network, as shown in Table 3.3.

  **Table 3.3 Maximum Latency (in Hours) of Replication Between Sites**

| | Seattle | Boston | Los Angeles | New York | Washington DC |
|---|---|---|---|---|---|
| **Seattle** | 0.25 | | | | |
| **Boston** | | 0.25 | | | |
| **Los Angeles** | | | 0.25 | | |
| **New York** | | | | 0.25 | |
| **Washington DC** | | | | | 0.25 |

  An average, worst-case latency within a site is estimated to be 15 minutes.

- From the replication schedule, determine the maximum replication latency possible on any site link connecting two hub sites.

  For example, if replication occurs between Seattle and New York every three hours, then the maximum delay for replication between these sites is 3 hours. If the replication delay between New York and Seattle is the longest scheduled delay among all hub sites, then the maximum latency between all hubs is 3 hours.

- For each hub site, create a table of the maximum latencies between the hub site and any of its satellite sites.

  For example, if replication occurs between New York and Washington, DC, every four hours and this is the longest replication delay between New York and any of its satellite sites, then the maximum latency between New York and its satellites is four hours.

- Combine these maximum latencies to determine the maximum latency for the entire network.

  For example, if the maximum latency between Seattle and its satellite site in Los Angeles is one day, the maximum replication latency for this set of links (Washington, DC-New York-Seattle-Los Angeles) is 31 hours (4 (Washington, DC-New York)+ 3 (New York-Seattle) + 24 (Seattle-Los Angeles)) as shown in Table 3.4.

  **Table 3.4 Maximum Latency (in Hours) of Replication Between Sites**

| | Seattle | Boston | Los Angeles | New York | Washington DC |
|---|---|---|---|---|---|
| **Seattle** | 0.25 | 4+3 | 24.00 | 3.00 | 4+3 |
| **Boston** | | 0.25 | 4+3+24 | 4.00 | 4.00 |
| **Los Angeles** | | | 0.25 | 24 + 3 | 24+3+4 |
| **New York** | | | | 0.25 | 4.00 |
| **Washington, DC** | | | | | 0.25 |

Review your maximum replication latency, and revise your replication schedule and interval if necessary.

# Example: Creating a Site Link Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As an example of a site link design, Figure 3.18 shows three domain controllers from the same domain at three different Trey Research sites: Los Angeles, New York, and Seattle. The LAX-SEA and SEA-NYC site link objects are created to permit replication between domain controllers at the three sites. The site link object LAX-SEA is assigned a cost of 586, whereas the site link object SEA-NYC is assigned a lower cost of 471 because the T1 communication link that connects the Seattle and New York sites has a more available bandwidth (150 Kbps) than the 56 Kbps available bandwidth between the Seattle and Los Angeles sites.

Active Directory replication topology for the example in Figure 3.18 is computed by the KCC according to a spanning tree algorithm. For intersite replication, a spanning tree algorithm determines how to connect all the sites that need to be connected with the minimum number of connections and the least cost. For the example shown in Figure 3.18, the cost of replication between domain controller DC-2 and domain controller DC-1 is 586, the cost of replication between domain controller DC-1 and domain controller DC-3 is 471. Because no direct communication link exists between the New York and Los Angeles sites, the cost of replication between these two sites is equal to the sum of the replication costs between the Los Angeles and Seattle sites and the Seattle and New York sites (471 + 586 = 1,057).

Based on these calculated costs, the domain controllers in these three sites can replicate the domain information by creating three replication connections: DC-2 replicates with DC-1 (cost =586), DC-3 replicates with DC-1 (cost = 471), and DC-2 replicates with DC-3 (cost = 1,057). Two replication connections between DC-1 and DC-2 and DC-1 and DC-3 are sufficient for replicating the domain information between the three sites. Hence, based on the spanning tree algorithm, connection objects are created between DC-1 and DC-2, and between DC-1 and DC-3.

No site link is created between the Los Angeles and New York sites by the site topology owner because no direct communication link exists between these two locations. Even if a third site link with a cost of 1,057 is created between the Los Angeles and New York sites, no additional connection objects will be created between domain controllers DC-2 and DC-3.

With transitivity enabled in this example, DC-2 at Los Angeles always replicates with DC-1 (cost = 586) in Seattle and not DC-3 (cost = 586 + 471) in New York because the LAX-SEA site link cost is more favorable. Replication connections between DC-2 and DC-3 will only be created if DC-1 at the Seattle site is unavailable.

**Figure 3.18 Example of Site Links**

However, with transitivity disabled in this example, because no direct communication link exists between the Los Angeles and New York sites, DC-2 will only replicate with DC-1 and never replicate with DC-3 even if DC-1 in Seattle fails.

With site link transitivity enabled, if DC-2 in the Los Angeles site and DC-3 in the New York site are from a different domain (domain A) than DC-1 in the Seattle site (domain B), and if the LAX-SEA site link has a schedule of 18:00 hours to 24:00 hours and the SEA-NYC site link has a schedule of 17:00 hours to 20:00 hours, data can be replicated directly from DC-2 to DC-3 between 18:00 hours and 20:00 hours, which is the intersection of the LAX-SEA site link replication schedule and the SEA-NYC site link replication schedule. If the LAX-SEA site link schedule does not overlap with the SEA-NYC site link schedule, then replication between DC-2 and DC-3 can never occur.

# Creating a Site Link Bridge Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A site link bridge connects two or more site links. Figure 3.19 shows the steps for creating a site link bridge design.

**Figure 3.19 Creating a Site Link Bridge Design**

A site link bridge enables transitivity between site links. Each site link in a bridge must have a site in common with another site link in the bridge. The Knowledge Consistency Checker (KCC) uses the information on each site link to compute the cost of replication between sites in one site link and sites in the other site links of the bridge. Without the presence of a common site between site links, the KCC also cannot establish direct connections between domain controllers in the sites that are connected by the same site link bridge.

By default, all site links are transitive and it is recommended to keep transitivity enabled by not changing the default value of **Bridge all site links** (enabled by default). However, you will need to disable **Bridge all site links** and complete a site link bridge design if:

- Your IP network is not fully routed. When you disable **Bridge all site links**, all site links are considered nontransitive, and you can create and configure site link bridge objects to model the actual routing behavior of your network.

  –Or–

  You need to control the replication flow of the changes made in Active Directory. By disabling **Bridge all site links** for the site link IP transport and configuring a site link bridge, the site link bridge becomes the equivalent of a disjointed network. All site links within the site link bridge can route transitively, but they do not route outside of the site link bridge.

For more information about how to use Active Directory Sites and Services to disable the **Bridge all site links** setting, see "Enable or disable site link bridges" in Help and Support Center for Windows Server 2003.

# Creating a Site Link Bridge Design for Disjointed Networks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If your IP network is not fully routed, you must disable **Bridge all site links** for the IP transport and configure site link bridge objects. If your IP network is fully routed but you have too many routes that you categorically do not want the KCC to consider, you also need to disable **Bridge all site links** and manually create site link bridges.

For more information about how to use the Active Directory Sites and Services snap-in to disable the **Bridge all site links** setting, see "Enable or disable site link bridges" in Help and Support Center for Windows Server 2003.

# Creating a Site Link Bridge Design to Control Active Directory Replication Flow

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Two scenarios where you might want to control replication flow include controlling replication failover and controlling replication through a firewall.

**Controlling Replication Failover**

If your organization has a hub-and-spoke network topology, you generally do not want the satellite sites to create replication connections to other satellite sites if all domain controllers in the hub site fail. In such scenarios, you must disable **Bridge all site links** and create site link bridges such that replication connections are created between the satellite site and another hub site that is just one or two hops away from the satellite site.

**Example: Creating a site link bridge design to control replication failover**

Figure 3.20 illustrates an organization's hub-and-spoke network topology, consisting of two hub sites (A and B) and six satellite sites (C through H). The site links between all sites are named A-B, A-C, A-D, A-E, B-F, B-G, and B-H.

**Figure 3.20 Creating a Site Link Bridge to Control Replication Failover**

With **Bridge All Site Links** enabled, if DC-1 in hub site A fails, DC-3 can create replication connections between DC-2, DC-4, DC-5, DC-6, DC-7 or DC-8. The only intended connection for DC-3 in this case is with DC-2 in hub site B, as this connection will not congest network traffic. To ensure that DC-3 only replicates with DC-2 when DC-1 fails, you can disable site link transitivity and create the AC-AB site link bridge between the A-C and A-B site links. Similarly, you can create the AB-BH site link bridge between the A-B and B-H site links. With the AC-AB site link bridge, if DC-1 is unavailable, the replication connections from DC-3 are created only with DC-2 in hub site B. With the AB-BH site link bridge, if DC-2 is unavailable, the replication connections from DC-8 are created only with DC-1 in hub site A. Create similar site link bridges between all satellite sites so that the KCC failover occurs only to the domain controllers at the hub sites.

**Controlling Replication Through a Firewall**

If two domain controllers representing the same domain in two different sites are specifically allowed to communicate with each other only through a firewall, you can disable **Bridge all Site Links** and create site link bridges for sites on the same side of the firewall.

**Example: Creating a site link bridge design to control replication through a firewall**

Figure 3.21 illustrates a similar scenario as shown in Figure 3.20, but in this case a firewall separates hub site A and hub site B. IPSec is used to replicate through the firewall. The IPSec policy allows only DC-1 and DC-2 to communicate through the firewall by using IPSec. With transitivity enabled, if DC-1 fails, then DC-3 in satellite site C can create replication connections not only with DC-4 and DC-5 as intended, but it can try to create replication connections across the firewall with DC-2, DC-6, DC-7, or DC-8.

To ensure that DC-3 directly replicates only on one side of the firewall, you can disable transitivity and create the WEST site link bridge, which includes site links A-C, A-D, and A-E. Creating the WEST site link bridge ensures that if domain controller DC-1

fails, DC-3, DC-4, and DC-5 directly replicate only with each other and not with DC-2, DC-6, DC-7, or DC-8. Similarly, you can create the EAST site link bridge, which includes site links B-F, B-G, and B-H, to ensure that if DC-2 fails, then DC-6, DC-7, or DC-8 directly replicate only with each other.

**Figure 3.21 Creating Site Link Bridges to Control Replication Through a Firewall**

Therefore, if your network is separated by firewalls, it is recommended that you disable transitivity of site links and create site link bridges for the network on one side of the firewall. For information about managing replication through firewalls, see "Active Directory in Networks Segmented by Firewalls" on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=37928).

# Additional Resources for Designing the Site Topology

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information and tools related to this chapter.

# Planning for Active Directory Forest Recovery

Updated: April 25, 2013

Applies To: Windows Server 2000, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012

This guide contains best-practice recommendations for recovering an Active Directory® forest if forest-wide failure renders all domain controllers (DCs) in the forest incapable of functioning normally. The steps it contains serve as a template for your forest recovery plan, which you can customize for your particular environment. These steps apply to DCs that run Microsoft® Windows Server 2012, Windows Server 2008 R2, Windows Server 2008, and Windows Server 2003 operating systems.

| **Note** |
| --- |
| Procedures that are unique for DCs that run Windows Server 2003 are consolidated in Appendix D. |

**In this guide**

- New Features, Assumptions, and Prerequisites for Using This Guide for Planning Active Directory Forest Recovery
- Devising a Custom Forest Recovery Plan
- Recovering Your Active Directory Forest
- Appendix A: Forest Recovery Procedures
- Appendix B: Frequently Asked Questions
- Appendix C: Recovering a Single Domain within a Multidomain Forest
- Appendix D: Forest Recovery with Windows Server 2003 Domain Controllers
- Additional Resources

**Publication and revision history**

The following table summarizes the revision history for this guide, including its original publication on Microsoft TechNet.

| Date | Revision |
| --- | --- |
| April 2013 | Updated to reflect new features in Windows Server 2012. |
| May 2009 | Updated to reflect new features in Windows Server 2008. |
| October 2006 | Updated for Windows Server 2003 and published on TechNet |
| June 2002 | Original publication on Microsoft Download Center |

# New Features, Assumptions, and Prerequisites for Using This Guide for Planning Active Directory Forest Recovery

Updated: April 25, 2013

Applies To: Windows Server 2008, Windows Server 2008 R2, Windows Server 2012

This topic describes how the new virtualized domain controller cloning feature in Windows Server 2012 improves the forest recovery process and other issues to review before you use the guidelines.

- Using virtualized domain controller cloning in Windows Server 2012 to expedite forest recovery
- Assumptions for Using This Guide for Planning Active Directory Forest Recovery
- Prerequisites for Using This Guide for Planning Active Directory Forest Recovery

**Using virtualized domain controller cloning in Windows Server 2012 to expedite forest recovery**
Virtualized domain controller (DC) cloning simplifies and expedites the process for installing additional virtualized DCs in a domain, especially in centralized locations such as datacenters where several DCs run on hypervisors. After you restore one virtual DC in each domain from backup, additional DCs in each domain can be rapidly brought online by using the virtualized DC cloning process. You can prepare the first virtualized DC that you recover, shut it down, and then copy that virtual hard disk as many times as is necessary in order to create cloned virtualized DCs to build out the domain.

The requirements for virtualized DC cloning are:

- The hypervisor must support VM-GenerationID. Hyper-V in Windows Server 2012 and Windows 8 is an example of a hypervisor that supports VM-GenerationID. Check with your hypervisor vendor if VM-GenerationID is supported.
- The virtualized DC that is used as a source for cloning must run Windows Server 2012 and be a member of the Cloneable Domain Controllers group.
- The PDC emulator must run Windows Server 2012. You can clone PDC emulator if it is virtualized.

For step-by-step instructions about how to perform virtualized DC cloning, see Introduction to Active Directory Domain Services (AD DS) Virtualization (Level 100). For details about how virtualized DC cloning works, see Virtualized Domain Controller Technical Reference (Level 300).

**Assumptions for Using This Guide for Planning Active Directory Forest Recovery**
First, this guide assumes that you have:

- Worked with Microsoft Support to determine the cause of the forest-wide failure. This guide does not suggest a cause of the failure or recommend any procedures to prevent the failure.
- Evaluated any possible remedies.
- Concluded, in consultation with Microsoft Support, that restoring the whole forest to its state before the failure occurred is the best way to recover from the failure. In many cases, forest recovery should be the last option.

Second, this guide assumes that you have followed the Microsoft best-practice recommendations for using Active Directory–integrated Domain Name System (DNS). Specifically, there should be an Active Directory–integrated DNS zone for each Active Directory domain. If this is not the case, you can still use the basic principles of this guide to perform forest recovery. However, you will need to take specific measures for DNS recovery based on your own environment. For more information about using Active Directory–integrated DNS, see Designing a DNS Infrastructure to Support Active Directory.

Although the objectives of this guide are to recover the forest and maintain or restore full DNS functionality, recovery can result in a DNS configuration that is changed from the configuration before the failure. After the forest is recovered, you can revert to the original DNS configuration. The recommendations in this guide do not describe how to configure DNS servers to perform name resolution of other portions of the corporate namespace where there are DNS zones that are not stored in

AD DS.

Finally, although this guide is intended as a generic guide for forest recovery, not all possible scenarios are covered. For instance, beginning with Windows Server 2008, there is a Server Core version, which is a full version of Windows Server but without a full GUI. Although it is certainly possible to recover a forest consisting of just DCs that run Server Core, this guide has no detailed instructions. However, based on the guidance discussed here you will be able to design the required command-line actions yourself.

**Prerequisites for Using This Guide for Planning Active Directory Forest Recovery**
Before you begin planning for recovery of an Active Directory forest, you should be familiar with the following:

- Fundamental Active Directory concepts
- The importance of operations master roles (also known as flexible single master operations or FSMO). These roles include the following:
    - Schema master
    - Domain naming master
    - Relative ID (RID) master
    - Primary domain controller (PDC) emulator master
    - Infrastructure master

In addition, you should have backed up and restored AD DS and SYSVOL in a lab environment on a regular basis. For more information, see Backing up the System State data and Performing a nonauthoritative restore of Active Directory Domain Services.

# Devising a Custom Forest Recovery Plan

Updated: April 25, 2013

Applies To: Windows Server 2008, Windows Server 2008 R2, Windows Server 2012

Depending on your environment and business requirements, you might or might not need to perform all the steps described in this guide to perform a successful forest recovery. Given that this guide serves only as a template for forest recovery, it is vital that you devise a custom forest recovery plan that suits your environment and meets your business needs.

For example, in your forest recovery plan, you should have a detailed topology map of your forests. The map should list all the information about the DCs, such as their names, their roles and backup status, and the trust relationships between them. For a tool that you can use to create a topology map, see Microsoft Active Directory Topology Diagrammer.

You should practice your forest recovery plan at least once a year. Also, it is a good idea to perform a forest recovery drill when there are membership changes to the Enterprise Admins or Domain Admins group. This helps ensure that your information technology (IT) staff fully understands the forest recovery plan.

# Recovering Your Active Directory Forest

Updated: April 25, 2013

Applies To: Windows Server 2000, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012

This section provides an overview of the recommended path for recovering a forest. The forest recovery steps are described in detail later.

The following list summarizes the recovery steps at a high level:

1. Identify the problem

   Work with IT and Microsoft Support to determine the scope of the problem and potential causes, and evaluate possible remedies with all business stakeholders. In many cases total forest recovery should be the last option.

2. Decide how to recover the forest

   After you determine that forest recovery is necessary, complete preliminary steps to prepare for it: determine the current forest structure, identify the functions that each DC performs, decide which DC to restore for each domain, and ensure that all writeable DCs are taken offline.

3. Perform initial recovery

   In isolation, recover one DC for each domain, clean them, and reconnect the domains. Reset privileged accounts, and rectify problems caused by security breaches in this phase.

4. Redeploy remaining DCs

   Redeploy the forest to return it to its state before the failure. This step will need to be adapted to your specific design and requirements. Virtualized domain controller cloning can help expedite this process.

5. Cleanup

   After functionality has been restored, reconfigure name resolution as needed, and get LOB applications working.

The following flowchart shows the recovery process.

The steps in this guide are designed to minimize the possibility of reintroducing dangerous data into the recovered forest. You might have to modify these steps to account for such factors as:

- Scalability
- Remote manageability

- Speed of recovery

However, modifications to these forest recovery steps can increase the risk of reintroducing dangerous data. For more information about possible modifications to these forest recovery steps, see What can I do to speed up recovery?

**Identify the problem**

When symptoms of a forest-wide failure appear, such as in event logs or other monitoring solutions, work with Microsoft Support to determine the cause of the failure, and evaluate any possible remedies.

Examples of forest-wide failures include the following:

- All DCs have been logically corrupted or physically damaged to a point that business continuity is impossible; for example, all business applications that depend on AD DS are nonfunctional.
- A rogue administrator has compromised the Active Directory environment.
- An attacker intentionally—or an administrator accidentally—runs a script that spreads data corruption across the forest.
- An attacker intentionally—or an administrator accidentally—extends the Active Directory schema with malicious or conflicting changes.
- An attacker has managed to install malicious software on DCs, and you have been advised by Microsoft Support to recover the forest from backup.

  **Important**

  This paper does not cover security recommendations about how to recover a forest that has been hacked or compromised. In general, it is recommended to follow Pass-the-Hash mitigation techniques to harden the environment. For more information, see Mitigating Pass-the-Hash (PtH) Attacks and Other Credential Theft Techniques.

- None of the DCs can replicate with their replication partners.
- Changes cannot be made to AD DS at any domain controller.
- New DCs cannot be installed in any domain.

**Decide how to recover the forest**

Recovering an entire Active Directory forest involves either restoring it from backup or reinstalling Active Directory Domain Services (AD DS) on every domain controller (DC) in the forest. Recovering the forest restores each domain in the forest to its state at the time of the last trusted backup. Consequently, the restore operation will result in the loss of at least the following Active Directory data:

- All objects (such as users and computers) that were added after the last trusted backup
- All updates that were made to existing objects since the last trusted backup
- All changes that were made to either the configuration partition or the schema partition in AD DS (such as schema changes) since the last trusted backup

For each domain in the forest, the password of a Domain Admin account must be known. Preferably, this is the password of the built-in Administrator account, which must not be disabled. You must also know the DSRM password to perform a system state restore of a DC. In general, it is a good practice to archive the Administrator account and DSRM password history in a safe place for as long as the backups are valid, that is, within the tombstone lifetime period or within the deleted object lifetime period if Active Directory Recycle Bin is enabled. You can also synchronize the DSRM password with a domain user account in order to make it easier to remember. For more information, see KB article 961320. Synchronizing the DSRM account must be done in advance of the forest recovery, as part of preparation.

**Note**

The Administrator account is a member of the built-in Administrators group by default, as are the Domain Admins and Enterprise Admins groups. This group has full control of all DCs in the domain.

**Determining which backups to use**

Back up at least two writeable DCs for each domain regularly so you have several backups to choose from. Note that you cannot use the backup of a read-only domain controller (RODC) to restore a writeable DC. We recommend that you restore the DCs by using backups that were taken a few days before the occurrence of the failure. In general, you must determine a tradeoff between the recentness and the safeness of the restored data. Choosing a more recent backup recovers more useful data, but it might increase the risk of reintroducing dangerous data into the restored forest.

Restoring system state backups depends on the original operating system and server of the backup. For example, you should not restore a system state backup to a different server. In this case, you may see the following warning:

"The specified backup is of a different server than the current one. We do not recommend performing a system state recovery with the backup to an alternate server because the server might become unusable. Are you sure you want to use this backup for recovering the current server?"

If you need to restore Active Directory to different hardware, create full server backups and plan to perform a full server recovery.

**Important**

Beginning with Windows Server 2008, it is not supported to restore system state backup to a new installation of Windows Server on new hardware or the same hardware. If Windows Server is reinstalled on the same hardware, as recommended later in this guide, then you can restore the domain controller in this order:

1. Perform a full server restore in order to restore the operating system and all files and applications.

2. Perform a system state restore using wbadmin.exe in order to mark SYSVOL as authoritative.

For more information, see Microsoft KB article 249694.

If the time of the occurrence of the failure is unknown, investigate further to identify backups that hold the last safe state of the forest. This approach is less desirable. Therefore, we strongly recommend that you keep detailed logs about the health state of AD DS on a daily basis so that, if there is a forest-wide failure, the approximate time of failure can be identified. You should also keep a local copy of backups to enable faster recovery.

If Active Directory Recycle Bin is enabled, the backup lifetime is equal to the **deletedObjectLifetime** value or the **tombstoneLifetime** value, whichever is less. For more information, see Active Directory Recycle Bin Step-by-Step Guide (http://go.microsoft.com/fwlink/?LinkId=178657).

As an alternative, you can also use the Active Directory database mounting tool (Dsamain.exe) and a Lightweight Directory Access Protocol (LDAP) tool, such as Ldp.exe or Active Directory Users and Computers, to identify which backup has the last safe state of the forest. The Active Directory database mounting tool, which is included in Windows Server 2008 and later Windows Server operating systems, exposes Active Directory data that is stored in backups or snapshots as an LDAP server. Then, you can use an LDAP tool to browse the data. This approach has the advantage of not requiring you to restart any DC in Directory Services Restore Mode (DSRM) to examine the contents of the backup of AD DS.

For more information about using the Active Directory database mounting tool, see the Active Directory Database Mounting Tool Step-by-Step Guide.

You can also use the **ntdsutil snapshot** command to create snapshots of the Active Directory database. By scheduling a task to periodically create snapshots, you can obtain additional copies of the Active Directory database over time. You can use these copies to better identify when the forest-wide failure occurred and then choose the best backup to restore. To create snapshots, use the version of **ntdsutil** that ships with Windows Server 2008 or the Remote Server Administration Tools (RSAT) for Windows Vista or later. The target DC can run any version of Windows Server. For more information about using the **ntdsutil snapshot** command, see Snapshot.

**Determining which domain controllers to restore**

Ease of the restore process is an important factor when deciding which domain controller to restore. It is recommended to have a dedicated DC for each domain that is the preferred DC for a restore. A dedicated restore DC makes it easier to reliably plan and execute the forest recovery because you use the same source configuration that was used to perform restore tests.

You can script the recovery, and not contend with different configurations, such as whether the DC holds operations master roles or not, or whether it is a GC or DNS server or not.

| **Note** |
| --- |
| While it is not recommended to restore an operations master role holder in the interest of simplicity, some organizations may choose to restore one for other advantages. For example restoring the RID master may help prevent problems with managing RIDs during the recovery. |

Choose a DC that best meets the following criteria:

- A DC that is writeable. This is mandatory.
- A DC running Windows Server 2012 as a virtual machine on a hypervisor that supports VM-GenerationID. This DC can be used as a source for cloning.
- A DC that is accessible, either physically or on a virtual network, and preferably located in a datacenter. This way, you can easily isolate it from the network during forest recovery.
- A DC that has a good full server backup. A good backup is a backup that can be restored successfully, was taken a few days before the failure, and contains as much useful data as possible.
- A DC that was a Domain Name System (DNS) server before the failure. This saves the time required to reinstall DNS.
- If you also use Windows Deployment Services, choose a DC that is not configured to use BitLocker Network Unlock. In this case, BitLocker Network Unlock is not supported to be used for the first DC that you restore from backup during a forest recovery.

  BitLocker Network Unlock as the *only* key protector *cannot* be used on DCs where you have deployed Windows Deployment Services (WDS) because doing so results in a scenario where the first DC requires Active Directory and WDS to be working in order to unlock. But before you restore the first DC, Active Directory is not yet available for WDS, so it cannot unlock.

  To determine if a DC is configured to use BitLocker Network Unlock, check that a Network Unlock certificate is identified in the following registry key:

  HKEY_LOCAL_MACHINE\Software\Policies\Microsoft\SystemCertificates\FVE_NKP

Maintain security procedures when handling or restoring backup files that include Active Directory. The urgency that accompanies forest recovery can unintentionally lead to overlooking security best practices. For more information, see the section titled "Establishing Domain Controller Backup and Restore Strategies" in Best Practice Guide for Securing Active Directory Installations and Day-to-Day Operations: Part II.

**Identify the current forest structure and DC functions**

Determine the current forest structure by identifying all the domains in the forest. Make a list of all of the DCs in each domain, particularly the DCs that have backups, and virtualized DCs which can be a source for cloning. A list of DCs for the forest root domain will be the most important because you will recover this domain first. After you restore the forest root domain, you can obtain a list of the other domains, DCs, and the sites in the forest by using Active Directory snap-ins.

Prepare a table that shows the functions of each DC in the domain, as shown in the following example. This will help you revert back to the pre-failure configuration of the forest after recovery.

| DC name | Operating system | FSMO | GC | RODC | Backup | DNS | Server Core | VM | VM-GenID |
| --- | --- | --- | --- | --- | --- | --- | --- | --- | --- |
| DC_1 | Windows Server 2012 | Schema master, Domain naming master | Yes | No | Yes | No | No | Yes | Yes |

For each domain in the forest, identify a single writeable DC that has a trusted backup of the Active Directory database for that domain. Use caution when you choose a backup to restore a DC. If the day and cause of the failure are approximately known, the general recommendation is to use a backup that was made a few days before that date.

In this example, there are four backup candidates: DC_1, DC_2, DC_4, and DC_5. Of these backup candidates, you restore only one. The recommended DC is DC_5 for the following reasons:

- It satisfies requirements for using it as a source for virtualized DC cloning, that is, it runs Windows Server 2012 as a virtual DC on a hypervisor that supports VM-GenerationID, runs software that is allowed to be cloned (or that can be removed if it is not able to be cloned). After the restore, the PDC emulator role will be seized to that server and it can be added to the Cloneable Domain Controllers group for the domain.

- It runs a full installation of Windows Server 2012. A DC that runs a Server Core installation can be less convenient as a target for recovery.

- It is a DNS server. Therefore, DNS does not have to be reinstalled.

**Note**

Because DC_5 is not a global catalog server, it also has an advantage in that the global catalog does not need to be removed after the restore. But whether or not the DC is also a global catalog server is not a decisive factor because beginning with Windows Server 2012, all DCs are global catalog servers by default, and removing and adding the global catalog after the restore is recommended as part of the forest recovery process in any case.

**Recover the forest in isolation**

The preferred scenario is to shut down all writeable DCs before the first restored DC is brought back into production. This ensures that any dangerous data does not replicate back into the recovered forest. It is particularly important to shut down all operations master role holders.

**Note**

There may be cases where you move the first DC that you plan to recover for each domain to an isolated network while allowing other DCs to remain online in order to minimize system downtime. For example, if you are recovering from a failed schema upgrade, you may choose to keep domain controllers running on the production network while you perform recovery steps in isolation.

If you are running virtualized DCs, you can move them to a virtual network that is isolated from the production network where you will perform recovery. Moving virtualized DCs to a separate network provides two benefits:

- Recovered DCs are prevented from reoccurrence of the problem that caused the forest recovery because they are isolated.

- Virtualized DC cloning can be performed on the separate network so that a critical number of DCs can be running and tested before they are brought back to the production network.

If you are running DCs on physical hardware, disconnect the network cable of the first DC that you plan to restore in the forest root domain. If possible, also disconnect the network cables of all other DCs. This prevents DCs from replicating, if they are accidentally started during the forest recovery process.

In a large forest that is spread across multiple locations, it can be difficult to guarantee that all writeable DCs are shut down. For this reason, the recovery steps—such as resetting the computer account and krbtgt account, in addition to metadata cleanup—are designed to ensure that the recovered writeable DCs do not replicate with dangerous writeable DCs (in case some are still online in the forest).

However, only by taking writeable DCs offline can you guarantee that replication does not occur. Therefore, whenever possible, you should deploy remote management technology that can help you to shut down and physically isolate the writeable DCs during forest recovery.

RODCs can continue to operate while writeable DCs are offline. No other DC will directly replicate any changes from any RODC—especially, no Schema or Configuration container changes—so they do not pose the same risk as writeable DCs during recovery. After all the writeable DCs are recovered and online, you should rebuild all the RODCs.

RODCs will continue to allow access to local resources that are cached in their respective sites while the recovery operations are going on in parallel. Local resources that are not cached on the RODC will have authentication requests forwarded to a writeable DC. These requests will fail because writeable DCs are offline. Some operations such as password changes will also not work until you recover writeable DCs.

If you are using a hub-and-spoke network architecture, you can concentrate first on recovering the writeable DCs in the hub sites. Later, you can rebuild the RODCs in remote sites.

**Perform initial recovery**
This section includes the following steps:

- Restore the first writeable domain controller in each domain
- Reconnect each restored writeable domain controller to a common network
- Add the global catalog to a domain controller in the forest root domain

**Restore the first writeable domain controller in each domain**
Beginning with a writeable DC in the forest root domain, complete the steps in this section in order to restore the first DC. The forest root domain is important because it stores the Schema Admins and Enterprise Admins groups. It also helps maintain the trust hierarchy in the forest. In addition, the forest root domain usually holds the DNS root server for the forest's DNS namespace. Consequently, the Active Directory–integrated DNS zone for that domain contains the alias (CNAME) resource records for all other DCs in the forest (which are required for replication) and the global catalog DNS resource records.

After you recover the forest root domain, repeat the same steps to recover the remaining domains in the forest. You can recover more than one domain simultaneously; however, always recover a parent domain before recovering a child to prevent any break in the trust hierarchy or DNS name resolution.

For each domain that you recover, restore only one writeable DC from backup. This is the most important part of the recovery because the DC must have a database that has not been influenced by whatever caused the forest to fail. It is important to have a trusted backup that is thoroughly tested before it is introduced into the production environment.

Then perform the following steps. Procedures for performing certain steps are in Appendix A: Forest Recovery Procedures.

1. If you plan to restore a physical server, ensure that the network cable of the target DC is not attached and therefore is not connected to the production network. For a virtual machine, you can remove the network adapter or use a network adapter that is attached to another network where you can test the recovery process while isolated from the production network.

2. Because this is the first writeable DC in the domain, you must perform a nonauthoritative restore of AD DS and an authoritative restore of SYSVOL. The restore operation must be completed by using an Active Directory-aware backup and restore application, such as Windows Server Backup (that is, you should not restore the DC by using unsupported methods such as restoring a VM snapshot).

   An authoritative restore of SYSVOL is required because replication of the SYSVOL replicated folder must be started after you recover from a disaster. All subsequent DCs that are added in the domain must resynchronize their SYSVOL folder with a copy of the folder that has been selected to be authoritative before the folder can be advertised.

   **Caution**

| |
|---|
| Perform an authoritative (or primary) restore operation of SYSVOL only for the first DC to be restored in the forest root domain. Incorrectly performing primary restore operations of the SYSVOL on other DCs leads to replication conflicts of SYSVOL data. |

There are two options perform a nonauthoritative restore of AD DS and an authoritative restore of SYSVOL:

- Perform a full server recovery and then then force an authoritative synchronization of SYSVOL. For detailed procedures, see Performing a full server recovery and Perform an authoritative synchronization of DFSR-replicated SYSVOL.

- Perform a full server recovery followed by a system state restore. This option requires that you create both types of backups in advance: a full server backup and a system state backup. For detailed procedures, see Performing a full server recovery and Performing a nonauthoritative restore of Active Directory Domain Services.

3. After you restore and restart the writeable DC, verify that the failure did not affect the data on the DC. If the DC data is damaged, then repeat step 2 with a different backup.

   If the restored domain controller hosts an operations master role, you may need to add the following registry entry to avoid AD DS being unavailable until it has completed replication of a writeable directory partition:

   **HKLM\System\CurrentControlSet\Services\NTDS\Parameters\Repl Perform Initial Synchronizations**

   Create the entry with the data type **REG_DWORD** and a value of **0**. After the forest is recovered completely, you can reset the value of this entry to **1**, which requires a domain controller that restarts and holds operations master roles to have successful AD DS inbound and outbound replication with its known replica partners before it advertises itself as domain controller and starts providing services to clients. For more information about initial synchronization requirements, see KB article 305476.

   Continue to the next steps only after you restore and verify the data and before you join this computer to the production network.

4. If you suspect that the forest-wide failure was related to network intrusion or malicious attack, reset the account passwords for all administrative accounts, including members of the Enterprise Admins, Domain Admins, Schema Admins, Server Operators, Account Operators groups, and so on. The reset of administrative account passwords should be completed before additional domain controllers are installed during the next phase of the forest recovery.

5. On the first restored DC in the forest root domain, seize all domain-wide and forest-wide operations master roles. Enterprise Admins and Schema Admins credentials are needed to seize forest-wide operations master roles.

   In each child domain, seize domain-wide operations master roles. Although you might retain the operations master roles on the restored DC only temporarily, seizing these roles assures you regarding which DC hosts them at this point in the forest recovery process. As part of your post-recovery process, you can redistribute the operations master roles as needed. For more information about seizing operations master roles, see Seizing an operations master role. For recommendations about where to place operations master roles, see What Are Operations Masters?.

6. Clean up metadata of all other writeable DCs in the forest root domain that you are not restoring from backup (all writeable DCs in the domain except for this first DC). If you use the version of Active Directory Users and Computers or Active Directory Sites and Services that is included with Windows Server 2008 or later or RSAT for Windows Vista or later, metadata cleanup is performed automatically when you delete a DC object. In addition, the server object and computer object for the deleted DC are also deleted automatically. For more information, see Cleaning metadata of removed writable DCs.

   Cleaning up metadata prevents possible duplication of NTDS-settings objects if AD DS is installed on a DC in a different site. Potentially, this could also save the Knowledge Consistency Checker (KCC) the process of creating replication links when the DCs themselves might not be present. Moreover, as part of metadata cleanup, DC Locator DNS resource

records for all other DCs in the domain will be deleted from DNS.

Until the metadata of all other DCs in the domain is removed, this DC, if it were a RID master before recovery, will not assume the RID master role and therefore will not be able to issue new RIDs. You might see event ID 16650 in the System log in Event Viewer indicating this failure, but you should see event ID 16648 indicating success a little while after you have cleaned the metadata.

7. If you have DNS zones that are stored in AD DS, ensure that the local DNS Server service is installed and running on the DC that you have restored. If this DC was not a DNS server before the forest failure, you must install and configure the DNS server.

| **Note** |
| --- |
| If the restored DC runs Windows Server 2008, you need to install the hotfix in KB article 975654 or connect the server to an isolated network temporarily in order to install DNS server. The hotfix is not required for any other versions of Windows Server. |

In the forest root domain, configure the restored DC with its own IP address (or a loopback address, such as 127.0.0.1) as its preferred DNS server. You can configure this setting in the TCP/IP properties of the local area network (LAN) adapter. This is the first DNS server in the forest. For more information, see Configure TCP/IP to use DNS.

In each child domain, configure the restored DC with the IP address of the first DNS server in the forest root domain as its preferred DNS server. You can configure this setting in the TCP/IP properties of the LAN adapter. For more information, see Configure TCP/IP to use DNS.

In the _msdcs and domain DNS zones, delete NS records of DCs that no longer exist after metadata cleanup. Check if the SRV records of the cleaned up DCs have been removed. To help speed up DNS SRV record removal, run:

```
nltest.exe /dsderegdns:server.domain.tld
```

8. Raise the value of the available RID pool by 100,000. For more information, see Raising the value of available RID pools. If you have reason to believe that raising the RID Pool by 100,000 is insufficient for your particular situation, you should determine the lowest increase that is still safe to use. RIDs are a finite resource that should not be used up needlessly.

If new security principals were created in the domain after the time of the backup that you use for the restore, these security principals might have access rights on certain objects. These security principals no longer exist after recovery because the recovery has reverted to the backup; however, their access rights might still exist. If the available RID pool is not raised after a restore, new user objects that are created after the forest recovery might obtain identical security IDs (SIDs) and could have access to those objects, which was not originally intended.

To illustrate, consider the example of the new employee named Amy that was mentioned in the introduction. The user object for Amy no longer exists after the restore operation because it was created after the backup that was used to restore the domain. However, any access rights that were assigned to that user object might persist after the restore operation. If the SID for that user object is reassigned to a new object after the restore operation, the new object would obtain those access rights.

9. Invalidate the current RID pool. The current RID pool is invalidated after a system state restore. But if a system state restore was not performed, the current RID pool needs to be invalidated to prevent the restored DC from re-issuing RIDs from the RID pool that was assigned at the time the backup was created. For more information, see Invalidating the current RID pool.

| **Note** |
| --- |
| The first time that you attempt to create an object with a SID after you invalidate the RID pool you will receive an error. The attempt to create an object triggers a request for a new RID pool. Retry of the operation succeeds because the new RID pool will be allocated. |

10. Reset the computer account password of this DC twice. For more information, see Resetting the computer account

password of the domain controller.

11. Reset the krbtgt password twice. For more information, see Resetting the krbtgt password.

    Because the krbtgt password history is two passwords, reset passwords twice to remove the original (prefailure) password from password history.

    | **Note** |
    | --- |
    | If the forest recovery is in response to a security breach, you may also reset the trust passwords. For more information, see Resetting a trust password on one side of the trust. |

12. If the forest has multiple domains and the restored DC was a global catalog server before the failure, clear the **Global catalog** check box in the NTDS Settings properties to remove the global catalog from the DC. The exception to this rule is the common case of a forest with just one domain. In this case, it is not required to remove the global catalog. For more information, see Removing the global catalog.

    By restoring a global catalog from a backup that is more recent than other backups that are used to restore DCs in other domains, you might introduce lingering objects. Consider the following example. In domain A, DC1 is restored from a backup that was taken at time T1. In domain B, DC2 is restored from a global catalog backup that was taken at time T2. Suppose T2 is more recent than T1, and some objects were created between T1 and T2. After these DCs are restored, DC2, which is a global catalog, holds newer data for domain A's partial replica than domain A holds itself. DC2, in this case, holds lingering objects because these objects are not present on DC1.

    The presence of lingering objects can lead to problems. For instance, e-mail messages might not be delivered to a user whose user object was moved between domains. After you bring the outdated DC or global catalog server back online, both instances of the user object appear in the global catalog. Both objects have the same e-mail address; therefore, e-mail messages cannot be delivered.

    A second problem is that a user account that no longer exists might still appear in the global address list. A third problem is that a universal group that no longer exists might still appear in a user's access token.

    If you did restore a DC that was a global catalog—either inadvertently or because that was the solitary backup that you trusted—we recommend that you prevent the occurrence of lingering objects by disabling the global catalog soon after the restore operation is complete. Disabling the global catalog flag will result in the computer losing all its partial replicas (partitions) and relegating itself to regular DC status.

13. Configure Windows Time Service. In the forest root domain, configure the PDC emulator to synchronize time from an external time source. For more information, see Configure the Windows Time service on the PDC emulator in the Forest Root Domain.

**Reconnect each restored writeable domain controller to a common network**

At this stage you should have one DC restored (and recovery steps performed) in the forest root domain and in each of the remaining domains. Join these DCs to a common network that is isolated from the rest of the environment and complete the following steps in order to validate forest health and replication.

| **Note** |
| --- |
| When you join the physical DCs to an isolated network, you may need to change their IP addresses. As a result, the IP addresses of DNS records will be wrong. Because a global catalog server is not available, secure dynamic updates for DNS will fail. Virtual DCs are more advantageous in this case because they can be joined to a new virtual network without changing their IP addresses. This is one reason why virtual DCs are recommended as the first domain controllers to be restored during forest recovery. |

After validation, Join the DCs to the production network and complete the steps to verify forest replication health.

- To fix name resolution, create DNS delegation records and configure DNS forwarding and root hints as needed. Run **repadmin /replsum** to check replication between DCs.

- If the restored DC's are not direct replication partners, replication recovery will be much faster by creating temporary connection objects between them.

- To validate metadata cleanup, run **Repadmin /viewlist *** for a list of all DCs in the forest. Run **Nltest /DCList:**<*domain*> for a list of all DCs in the domain.

- To check DC and DNS health, run DCDiag /v to report errors on all DCs in the forest.

**Add the global catalog to a domain controller in the forest root domain**
A global catalog is required for these and other reasons:

- To enable logons for users.

- To enable the Net Logon service running on the DCs in each child domain to register and remove records on the DNS server in the root domain.

Although it is preferred that the forest root DC become a global catalog, it is possible to elect any of the restored DCs to become a global catalog.

| **Note** |
| --- |
| A DC will not be advertised as a global catalog server until it has completed a full synchronization of all directory partitions in the forest. Therefore, the DC should be forced to replicate with each of the restored DCs in the forest.<br><br>Monitor the Directory Service event log in Event Viewer for event ID 1119, which indicates that this DC is a global catalog server, or verify the following registry key has a value of 1:<br><br>**HKLM\System\CurrentControlSet\Services\NTDS\Parameters\Global Catalog Promotion Complete** |

For more information, see Adding the global catalog.

At this stage you should have a stable forest, with one DC for each domain and one global catalog in the forest. You should make a new backup of each of the DCs that you have just restored. You can now begin to redeploy other DCs in the forest by installing AD DS.

**Redeploy remaining DCs**
The steps up to this point apply to all forests: find a valid backup for each domain, recover the domains in isolation, reconnect them, reset the global catalog, and clean up. In this next step you will redeploy the forest. The way to do this will greatly depend on your forest design, your service level agreements, site structure, available bandwidth, and numerous other factors. You will need to design your own redeployment plan based on the principles and suggestions in this section, in a way that is best suited to your business requirements.

The next step is to install AD DS on all DCs that were present before the forest recovery took place. If the DCs still exist, the AD DS service will need to be removed forcibly, or the DCs can be reinstalled. Any existing backups for these DCs cannot be reused, because the corresponding metadata has been removed during forest recovery. In an uncomplicated environment this redeployment process can be as simple as reconnecting the recovered DCs to the production network, and promoting new DCs as needed.

In a large enterprise faced with a worldwide infrastructure, a more sophisticated plan is needed. The first phase is usually to restore the AD as a service; this means to install strategically placed DCs such that all critical business divisions and applications can start working again. It may be acceptable for branch offices to temporarily have reduced performance as a result of this. As a second phase, all remaining and less critical DCs are redeployed.

There are two methods to install additional DCs, both of which can be automated:

- Cloning

  For virtualized environments that run Windows Server 2012, cloning is the fastest and simplest way to recover a large number of DCs. You can automate the recovery of all virtualized DCs in a domain after you restore a single virtualized DC from backup.

For more information about cloning and prerequisites, see Introduction to Active Directory Domain Services (AD DS) Virtualization (Level 100).

- Re-install AD DS by using Windows PowerShell on servers that run Windows Server 2012 (or Dcpromo.exe on servers that run earlier versions of Windows Server) or by using the user interface

  To expedite re-installing AD DS, you can use Install from Media (IFM) option to reduce replication traffic during the installation. For more information about using the **ntdsutil ifm** command to create installation media, see Installing AD DS from Media.

Consider the following additional points for each replica DC that is recovered in the forest by virtualized DC cloning or by installing AD DS (as opposed to restoring from backup):

- All software on a DC that is used as the source for cloning must be able to be cloned. Applications and services that cannot be cloned should be removed before cloning is initiated. If that is not possible, an alternative virtualized DC should be chosen as the source.

- If you clone additional virtualized DCs from the first virtualized DC to be restored, the source DC will need to be shut down while its VHDX file is copied. Then it will need to be running and available online when the clone virtual DCs are first started. If the downtime required by the shutdown is not acceptable for the first recovered DC, deploy an additional virtualized DC by installing AD DS to act as the source for cloning.

- There is no restriction on the host name of the cloned virtualized DC or the server on which you want to install AD DS. You can use a new host name or the host name that was in use previously. For more information about DNS host name syntax, see Creating DNS Computer Names (http://go.microsoft.com/fwlink/?LinkId=74564).

- Configure each server with the first DNS server in the forest (the first DC that was restored in the root domain) as the preferred DNS server in the TCP/IP properties of its network adapter. For more information, see Configure TCP/IP to use DNS.

- Redeploy all RODCs in the domain, either by virtualized DC cloning if several RODCs are deployed in a central location, or by the traditional method of rebuilding them by removing and reinstalling AD DS if they are deployed individually in isolated located locations such as branch offices.

  Rebuilding RODCs ensures that they do not contain any lingering objects and can help prevent replication conflicts from occurring later. When you remove AD DS from an RODC, *choose the option to retain DC metadata*. Using this option retains the krbtgt account for the RODC and retains the permissions for the delegated RODC administrator account and the Password Replication Policy (PRP), and prevents you from having to use Domain Admin credentials to remove and reinstall AD DS on an RODC. It also retains the DNS server and global catalog roles if they are installed on the RODC originally.

  When you rebuild DCs (RODCs or writeable DCs), there may be increased replication traffic during their reinstallation. To help reduce that impact, you can stagger the schedule of the RODC installations, and you can use the Install From Media (IFM) option. If you use the IFM option, run the **ntdsutil ifm** command on a writeable DC that you trust to be free of damaged data. This helps prevent possible corruption from appearing on the RODC after the AD DS reinstallation is complete. For more information about IFM, see Installing AD DS from Media.

  For more information about rebuilding RODCs, see RODC Removal and Reinstallation.

- If a DC was running the DNS Server service before the forest malfunction, install and configure the DNS Server service during the installation of AD DS. Otherwise, configure its former DNS clients with other DNS servers.

- If you require additional global catalogs to share authentication or query load for users or applications, you can either add the global catalog to the source virtualized DC before cloning or you can make a DC a global catalog server during the installation of AD DS.

**Cleanup**

Perform the following post recovery steps as needed:

- After the entire forest is recovered, you can revert to the original DNS configuration, including configuration of the preferred and alternate DNS servers on each of the DCs. After the DNS servers are configured as they were before the malfunction, their previous name resolution capabilities will be restored. Delete any DNS records for DCs that have not been recovered.

- Delete Windows Internet Name Service (WINS) records for all DCs that have not been recovered.

- You can transfer the operations master roles to other DCs in the domain or forest and add more global catalog servers based on the configuration before the failure.

- Because the entire forest is restored to a previous state, any objects (such as users and computers) that were added and all updates (such as password changes) that were made to existing objects after this point are lost. Therefore, you should re-create these missing objects and reapply the missing updates as appropriate.

- You might also need to restore outgoing trusts with external domains and forests, because these external trust relationships are not restored automatically from backups.

# Appendix A: Forest Recovery Procedures

Updated: April 25, 2013

Applies To: Windows Server 2000, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012

This appendix contains procedures related to the forest recovery process described earlier in this guide. The procedures are applicable for Windows Server 2012, and are also applicable to Windows Server 2008 R2 and Windows Server 2008 with some minor exceptions. Procedures that include steps that vary for Windows Server 2003 are found in Appendix D: Forest Recovery with Windows Server 2003 Domain Controllers.

- Backing up a full server
- Backing up the System State data
- Performing a full server recovery
- Performing an authoritative synchronization of DFSR-replicated SYSVOL
- Performing a nonauthoritative restore of Active Directory Domain Services

  These steps explain how to perform an authoritative restore of SYSVOL at the same time.
- Configuring the DNS Server service
- Removing the global catalog
- Raising the value of available RID pools
- Invalidating the current RID pool
- Seizing an operations master role
- Cleaning metadata of removed writable domain controllers
- Resetting the computer account password of the domain controller
- Resetting the krbtgt password
- Resetting a trust password on one side of the trust
- Adding the global catalog
- Resources to verify replication is working

**Backing up a full server**

A full server backup is recommended to prepare for a forest recovery because it can be restored to different hardware or a different operating system instance. To perform a full server backup, perform the following procedure using Windows Server Backup. Windows Server Backup is not installed by default. In Windows Server 2012, install it by selecting **Windows Server Backup** on the **Select Features** page in the **Add Roles and Features Wizard** in **Server Manager**. For steps to install it in Windows Server 2008 and Windows Server 2008 R2, see Installing Windows Server Backup.

**To perform a full server backup using Windows Server Backup**

1. In Windows Server 2012, open **Server Manager**, click **Tools**, and then click **Windows Server Backup**.

   In Windows Server 2008 R2 and Windows Server 2008, click **Start**, point to **Administrative Tools**, and then click

**Windows Server Backup**.

2. If you are prompted, in the **User Account Control** dialog box, provide Backup Operator credentials, and then click **OK**.
3. In Windows Server 2012 only, first click **Local Backup**.
4. On the **Action** menu, click **Backup once**.
5. In the Backup Once Wizard, on the **Backup options** page, click **Different options**, and then click **Next**.
6. On the **Select backup configuration** page, click **Full server (recommended)**, and then click **Next**.
7. On the **Specify destination type** page, click **Local drives** or **Remote shared folder**, and then click **Next**.
8. On the **Specify destination type** page, choose the backup location as follows:
   - If you are backing up to a local volume, in **Backup destination**, select a drive, and then click **Next**.

     When you are prompted to exclude the destination volume from the list of items to be backed up, click **OK**.

   - If you are backing up to a remote shared folder, do the following:

     a. Type the path to the shared folder.

     b. Under **Access Control**, select **Do not inherit** or **Inherit** to determine access to the backup, and then click **Next**.

     c. In the **Provide user credentials for Backup** dialog box, provide the user name and password for a user who has write access to the shared folder, and then click **OK**.

9. On the **Confirmation** page, review your selections, and then click **Backup**.
10. After the Backup Once Wizard begins the backup, click **Close** at any time. The backup runs in the background and you can view backup progress at any time during the backup. The wizard closes automatically when the backup is complete.

**To perform a full server backup using Wbadmin.exe**

1. Open an elevated command prompt, type the following command and press ENTER:

```
wbadmin start backup -backuptarget:<Drive_letter_to store_backup>: -include:
<Drive_letter_to_include>: -quiet
```

**Backing up the System State data**

A System State backup must be restored to the same operating system instance and hardware. Therefore it is not as flexible during a forest recovery as a full server backup. But a system state backup can be used to perform a non-authoritative restore of AD DS and an authoritative restore of SYSVOL at the same time (using wbadmin.exe), which may be more convenient than the full server restore option.

To back up System State data, complete the following procedures:

**Backing up the System State data**

Use the following procedure to perform a system state backup on a DC by using Windows Server Backup or wbadmin.exe.

**To perform a system state backup using Windows Server Backup**

1. In Windows Server 2012, open **Server Manager**, click **Tools**, and then click **Windows Server Backup**.

   In Windows Server 2008 R2 and Windows Server 2008, click **Start**, point to **Administrative Tools**, and then click **Windows Server Backup**.

2. If you are prompted, in the **User Account Control** dialog box, provide Backup Operator credentials, and then click **OK**.
3. In Windows Server 2012 only, first click **Local Backup**.

4. On the **Action** menu, click **Backup once**.
5. In the Backup Once Wizard, on the **Backup options** page, click **Different options**, and then click **Next**.
6. On the **Select backup configuration** page, click **Custom**, and then click **Next**.
7. On the **Select backup items** page:

   In Windows Server 2012, click **Add Items**, click **System state**, then click **Next**.

   In Windows Server 2008 R2 and Windows Server 2008, select the volumes to include in the backup. If you select the **Enable system recovery** check box, all critical volumes are selected.

   As an alternative, you can clear that check box, select the individual volumes that you want to include, and then click **Next**.

   Your selection must include the volumes that store the operating system, Ntds.dit, and SYSVOL.

   | **Note** |
   | --- |
   | If you select a volume that hosts an operating system, all volumes that store system components are also selected. |

8. On the **Specify destination type** page, choose the backup location as follows:
   - If you are backing up to a local volume, in **Backup destination**, select a drive, and then click **Next**.

     When you are prompted to exclude the destination volume from the list of items to be backed up, click **OK**.

   - If you are backing up to a remote shared folder, do the following:

     a. Type the path to the shared folder.

     b. Under **Access Control**, select **Do not inherit** or **Inherit** to determine access to the backup, and then click **Next**.

     c. In the **Provide user credentials for Backup** dialog box, provide the user name and password for a user who has write access to the shared folder, and then click **OK**.

9. For Windows Server 2008 R2 and Windows Server 2008, on the **Specify advanced option** page, select **VSS copy backup** and then click **Next**,
10. On the **Confirmation** page, review your selections, and then click **Backup**.
11. After the Backup Once Wizard begins the backup, click **Close** at any time. The backup runs in the background and you can view backup progress at any time during the backup. The wizard closes automatically when the backup is complete.

**To perform a system state backup using Wbadmin.exe**

1. Open an elevated command prompt, type the following command and press ENTER:

```
wbadmin start systemstatebackup -backuptarget:<targetDrive>: -allCritical -quiet
```

**Performing a full server recovery**

Use the following procedure to perform a full server recovery for Windows Server 2012. A full server recovery is necessary if you are restoring to different hardware or a different operating system instance. The number drives on the target server needs to be equal to the number in the backup and they need to be the same size or greater.

The target server needs to be started from the operating system DVD in order to access the **Repair your computer** option. If the target DC is running in a VM on Hyper-V and the backup is stored on a network location, you must install a legacy network adapter.

After you perform a full server recovery, you need to separately perform an authoritative restore of SYSVOL, as described in the next section.

**To perform a full server recovery**

1. Start Windows Setup, specify the Language, Time and currency format, and keyboard options and click **Next**.
2. Click **Repair your computer**. If the backup is stored locally, skip to step 6. If the backup is stored on a network location, continue with step 3.
3. Click **Troubleshoot**, click **Command Prompt**.
4. Type the following command and press ENTER:

   ```
   wpeinit
   ```

5. To confirm the name of the network adapter, type:

   ```
   show interfaces
   ```

   Type the following commands and press ENTER after each command:

   ```
   netsh

   interface

   tcp

   ipv4

   set address "Name of Network Adapter" static IPv4 AddressSubnetMaskIPv4 Gateway
   Address 1
   ```

   For example:

   ```
   set address "Local Area Connection" static 192.168.1.2 255.0.0.0 192.168.1.1 1
   ```

   Type `quit` to return to a command prompt. Type `ipconfig /all` to verify the network adapter has an IP address and try to ping the IP address of the server that hosts the backup share to confirm connectivity. Close the command prompt when you are done.

6. Click **Troubleshoot**, click **System Image Recovery**, and click **Windows Server 2012**.
7. If you are restoring the most recent local backup, click **Use the latest available system image (recommended)** and click **Next** twice, click **Finish**, and click **Yes** to confirm the restore operation.

   If you are restoring a different backup, click **Select a system image** and click **Next**.

8. Click the name of a local backup file or click **Advanced** and click **Search for a system image over the network** to search for a backup over the network.
9. Type the UNC path to the backup share location (for example, \\server1\backups) and click **OK**. You can also type the IP address of the target server, such as \\192.168.1.3\backups.
10. Type credentials necessary to access the share and click OK.
11. Select the name of the backup file and click **Next**.
12. Select the drives in the backup file and click **Next**.
13. Click **Format and repartition disks** and click **Next**.
14. Click **Finish**, and click **Yes** to confirm that all disks will be restored.

**Performing an authoritative synchronization of DFSR-replicated SYSVOL**

There are different ways to perform an authoritative restore of SYSVOL. You can either edit the **msDFSR-Options** attribute or perform a system state restore using wbadmin –authsysvol. If you have the option to restore a system state backup (that is, you are restoring AD DS to the same hardware and operating system instance) then using wbadmin –authsysvol is simpler. But if you need to perform a bare metal restore, then you need to edit the **msDFSR-Options** attribute.

Use the following steps to perform an authoritative synchronization of SYSVOL (if it is replicated using DFSR) by editing the

**msDFSR-Options** attribute. If SYSVOL is replicated using FRS, see article 290762.

**To perform an authoritative synchronization of DFSR-replicated SYSVOL**

1. Open Active Directory Users and Computers.
2. Click **View**, and then select **Users, Contacts, Groups, and Computers as containers** and **Advanced Features**.
3. In the tree-view, click **Domain Controllers**, the name of the DC you restored, **DFSR-LocalSettings**, and then **Domain System Volume**.
4. In the Details pane, right-click **SYSVOL Subscription**, click **Properties**, and click **Attribute Editor**.
5. Click **msDFSR-Options**, click **Edit**, type **1**, and click **OK**
6. Click **OK** to close the Attribute Editor.

**Performing a nonauthoritative restore of Active Directory Domain Services**
To perform a nonauthoritative restore, complete the following procedure.

The following procedures use the Wbadmin.exe to perform a nonauthoritative restore of Active Directory or Active Directory Domain Services (AD DS). If you are using a different backup solution or if you intend to complete the authoritative restore of SYSVOL later in the forest recovery process, you can perform an authoritative restore of SYSVOL by using these alternative methods:

- If you are using File Replication Service (FRS) to replicate SYSVOL, follow the steps in article 290762 in the Microsoft Knowledge Base, using the **BurFlags** registry key to reinitialize FRS replica sets, or if necessary, article 315457 315457to rebuild the SYSVOL tree. To determine if SYSVOL is replicated by FRS, see Determining Whether a Domain Controller's SYSVOL Folder is Replicated by DFSR or FRS.

- If you are using Distributed File System (DFS) Replication to replicate SYSVOL, see Performing an authoritative synchronization of DFSR-replicated SYSVOL.

**Performing a nonauthoritative restore**
Use the following procedure to perform a nonauthoritative restore of AD DS and an authoritative restore of SYSVOL at the same time by using wbadmin.exe on a DC that runs Windows Server 2012, Windows Server 2008 R2, or Windows Server 2008. The backup must explicitly include system state data; a full server backup that is used for full server recovery will not work. For more information about creating a system state backup, see Backing up the System State data.

**To perform a nonauthoritative restore of AD DS and authoritative restore of SYSVOL using wbadmin.exe**

- Include the **-authsysvol** switch in your recovery command, as shown in the following example:

  ```
  wbadmin start systemstaterecovery <otheroptions> -authsysvol
  ```

  For example:

  ```
  wbadmin start systemstaterecovery -version:11/20/2012-13:00 -authsysvol
  ```

**Configuring the DNS Server service**
If the DNS server role is not installed on the DC that you restore from backup, you must install and configure the DNS server.

**Install and configure the DNS Server service**
Complete this step for each restored DC that is not running as a DNS server after the restore is complete.

| **Note** |
| --- |
| If the DC that you restored from backup is running Windows Server 2008, you must connect the DC to an isolated network in order to install DNS server. Then connect each of the restored DNS servers to a mutually shared, isolated network. Run repadmin /replsum to verify that replication is functioning between the restored DNS servers. After you verify replication, you can connect the restored DCs to the production network If the DNS server role is already installed, you can apply a hotfix that makes it possible for a DNS server to start while the server is not connected to any network. You should slipstream the hotfix into the operating system installation image during your automated build processes. For more information about the hotfix, see Article 975654 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkId=184691). |

**To install and configure the DNS Server service using Server Manager**

1. Open Server Manager and start the **Add Roles Wizard**.
2. In the Add Roles Wizard, if the **Before You Begin** page appears, click **Next**.
3. In the **Roles** list, click **DNS Server**, and then click **Next**.
4. Read the information on the **DNS Server** page, and then click **Next**.
5. On the **Confirm Installation Options** page, verify that the DNS Server role will be installed, and then click **Install**.

   After the installation, complete the following steps to configure the DNS server.
6. Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **DNS**.
7. Create DNS zones for the same DNS domain names that were hosted on the DNS servers before the critical malfunction. For more information, see Add a Forward Lookup Zone (http://go.microsoft.com/fwlink/?LinkId=74574).
8. Configure the DNS data as it existed before the critical malfunction. For example:
   - Configure DNS zones to be stored in AD DS. For more information, see Change the Zone Type (http://go.microsoft.com/fwlink/?LinkId=74579).
   - Configure the DNS zone that is authoritative for domain controller locator (DC Locator) resource records to allow secure dynamic update. For more information, see Allow Only Secure Dynamic Updates (http://go.microsoft.com/fwlink/?LinkId=74580).
9. Ensure that the parent DNS zone contains delegation resource records (name server (NS) and glue host (A) resource records) for the child zone that is hosted on this DNS server. For more information, see Create a Zone Delegation (http://go.microsoft.com/fwlink/?LinkId=74562).
10. After you configure DNS, you can speed up registration of the NETLOGON Records.

    | **Note** |
    | --- |
    | Secure dynamic updates only work when a global catalog server is available. |

    At the command prompt, type the following command, and then press ENTER:

    **net stop netlogon**
11. Type the following command, and then press ENTER:

    **net start netlogon**

**Removing the global catalog**

Use the following procedure to remove the global catalog from a DC.

Restoring a global catalog server from backup could result in the global catalog holding newer data for one of its partial replicas than the corresponding domain that is authoritative for that partial replica. In such a case, the newer data will not be removed from the global catalog and might even replicate to other global catalog servers. As a result, even if you did restore a DC that was a global catalog server, either inadvertently or because that was the solitary backup you trusted, you should remove the global catalog soon after the restore operation is complete. When the global catalog is removed, the computer removes all its partial replicas.

**To remove the global catalog using Active Directory Sites and Services**

1. Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Sites and Services**.
2. In the console tree, expand the **Sites** container, and then select the appropriate site that contains the target server.
3. Expand the **Servers** container, and then expand the *server* object for the DC from which you want to remove the global catalog.
4. Right-click **NTDS Settings**, and then click **Properties**.

5. Clear the **Global Catalog** check box.

**To remove the global catalog using Repadmin**

1. Open an elevated command prompt, type the following command, and press ENTER:

   ```
   repadmin.exe /options DC_NAME -IS_GC
   ```

**Raising the value of available RID pools**

Use the following procedure to raise the value of the relative ID (RID) pools that the RID operations master will allocate after that DC is restored. By raising the value of the available RID pools, you can ensure that no DC allocates a RID for a security principal that was created after the backup that was used to restore the domain.

Each domain has an object **CN=RID Manager$,CN=System,DC=**<*domain_name*>. This object has an attribute named **rIDAvailablePool**. This attribute value maintains the global RID space for an entire domain. The value is a large integer with upper and lower parts. The upper part defines the number of security principals that can be allocated for each domain (0x3FFFFFFF or just over 1 billion). The lower part is the number of RIDs that have been allocated in the domain.

| **Note** |
| --- |
| In Windows Server 2012, the number of security principals that can be allocated is increased to just over 2 billion. For more information, see Managing RID issuance. |

- Sample Value: 4611686014132422708
- Low Part: 2100 (beginning of the next RID pool to be allocated)
- Upper Part: 1073741823 (total number of RIDs that can be created in a domain)

When you increase the value of the large integer, you increase the value of the low part. For example, if you add 100,000 to the sample value of 4611686014132422708 for a sum of 4611686014132522708, the new low part is 102100. This indicates that the next RID pool that will be allocated by the RID master will begin with 102100 instead of 2100.

**To raise the value of available RID pools using adsiedit and the calculator**

1. At an elevated command prompt, type:

   ```
   adsiedit.msc
   ```

2. Connect do the Default Naming Context, and browse to the following distinguished name path: **CN=RID Manager$,CN=System,DC=**<*domain name*>.
3. Open the properties of CN=RID Manager$.
4. Select the attribute **rIDAvailablePool**, click **Edit**, and then copy the large integer value to the clipboard.
5. Start calculator, and from the **View** menu, select **Scientific Mode**.
6. Add 100,000 to the current value.
7. Using ctrl-c, or the **Copy** command from the **Edit** menu, copy the value to the clipboard.
8. In the edit dialog of adsiedit, paste this new value.
9. Click **OK** in the dialog, and **Apply** in the property sheet to update the **rIDAvailablePool** attribute.

**To raise the value of available RID pools using LDP**

1. At the command prompt, type the following command, and then press ENTER:

   **ldp**

2. Click **Connection**, click **Connect**, type the name of RID manager, and then click **OK**.

3. Click **Connection**, click **Bind**, type your administrative credentials, and then click **OK**.
4. Click **View**, click **Tree**, and then type the following distinguished name path:

   CN=RID Manager$,CN=System,DC=*domain name*

5. Click **Browse**, and then click **Modify**.
6. Add 100,000 to the current **rIDAvailablePool** value, and then type the sum into **Values**.
7. In **Dn**, type **cn=RID Manager$,cn=System,dc=**<*domain name*>.
8. In **Edit Entry Attribute**, type **rIDAvailablePool**.
9. Select **Replace** as the operation, and then click **Enter**.
10. Click **Run** to run the operation.
11. To validate the change, select the cn=RID Manager$,cn=System,dc=<domain name> object and verify then value of the **rIDAvailablePool** attribute.

**Invalidating the current RID pool**

Use the following procedure to us Windows PowerShell to invalidate the current RID pool on a domain controller. Windows PowerShell is enabled by default on Windows Server 2012 and Windows Server 2008 R2, but not Windows Server 2008 where it must be installed by using **Add Features**. It can be downloaded to run on Windows Server 2003.

To verify the command completed successfully, check for event ID 16654 (source is Directory-Services-SAM) in the System log in Event Viewer in Windows Server 2012. Earlier versions of Windows do not log this event.

| **Note** |
| --- |
| After you invalidate the RID pool, you will receive an error when you first attempt to create security principal (user, computer, or group). The attempt to create an object triggers a request for a new RID pool. Retry of the operation succeeds because the new RID pool will be allocated. |

**To invalidate the current RID pool**

1. Open an elevated Windows PowerShell session, run the following command and press ENTER:

```
$Domain = New-Object System.DirectoryServices.DirectoryEntry
$DomainSid = $Domain.objectSid
$RootDSE = New-Object System.DirectoryServices.DirectoryEntry("LDAP://RootDSE")
$RootDSE.UsePropertyCache = $false
$RootDSE.Put("invalidateRidPool", $DomainSid.Value)
$RootDSE.SetInfo()
```

**Seizing an operations master role**

Use the following procedure to seize an operations master role (also known as a flexible single master operations (FSMO) role). You can use Ntdsutil.exe, a command-line tool that is installed automatically on all DCs.

**To seize an operations master role**

1. At the command prompt, type the following command, and then press ENTER:

```
ntdsutil
```

2. At the **ntdsutil:** prompt, type the following command, and then press ENTER:

```
roles
```

3. At the **FSMO maintenance:** prompt, type the following command, and then press ENTER:

```
connections
```

4. At the **server connections:** prompt, type the following command, and then press ENTER:

```
Connect to server ServerFQDN
```

Where *ServerFQDN* is the fully qualified domain name (FQDN) of this DC, for example: **connect to server nycdc01.example.com**.

If *ServerFQDN* does not succeed, use the NetBIOS name of the DC.

5. At the **server connections:** prompt, type the following command, and then press ENTER:

```
quit
```

6. Depending on the role that you want to seize, at the **FSMO maintenance:** prompt, type the appropriate command as described in the following table, and then press ENTER.

| Role | Credentials | Command |
|---|---|---|
| Domain naming master | Enterprise Admins | **Seize naming master** |
| Schema master | Schema Admins | **Seize schema master** |
| Infrastructure master<br>**Note**<br>After you seize the infrastructure master role, you may receive an error later if you need to run Adprep /Rodcprep. For more information, see KB article 949257. | Domain Admins | **Seize infrastructure master** |
| PDC emulator master | Domain Admins | **Seize pdc** |
| RID master | Domain Admins | **Seize rid master** |

After you confirm the request, Active Directory or AD DS attempts to transfer the role. When the transfer fails, some error information appears, and Active Directory or AD DS proceeds with the seizure. After the seizure is complete, a list of the roles and the Lightweight Directory Access Protocol (LDAP) name of the server that currently holds each role appears. You can also run **Netdom Query FSMO** at an elevated command prompt to verify current role holders.

**Note**

If this computer was not a RID master before the failure and you attempt to seize the RID master role, the computer tries to synchronize with a replication partner before accepting this role. However, because this step is performed when the computer is isolated, it will not succeed in synchronizing with a partner. Therefore, a dialog box appears asking you whether you want to continue with the operation despite this computer not being able to synchronize with a partner. Click **Yes**.

**Cleaning metadata of removed writable domain controllers**

Metadata cleanup removes Active Directory data that identifies a DC to the replication system.

Use the following procedure to delete the DC objects for DCs that you plan to add back to the network by reinstalling AD DS.

If you are using the version of Active Directory Users and Computers or Active Directory Sites and Services that is included Remote Server Administration Tools (RSAT), metadata cleanup is performed automatically when you delete a DC object.

**Deleting a domain controller using Active Directory Users and Computers**

When you use the version of Active Directory Users and Computers or Active Directory Administrative Center in Remote Server Administration Tools (RSAT), metadata cleanup is performed automatically when you delete the DC object. The server object and the computer object are also deleted automatically.

As an alternative, you can also use Active Directory Sites and Services in RSAT to delete a DC object. If you use Active Directory Sites and Services, you must delete the associated server object and NTDS Settings object before you can delete the DC object.

To download RSAT:

- Remote Server Administration Tools for Windows 8
- Remote Server Administration Tools for Windows 7 with Service Pack 1 (SP1)
- Microsoft Remote Server Administration Tools for Windows Vista

The following procedure is the same for DCs that run either Windows Server 2012, Windows Server 2008 R2, or Windows Server 2008. The target DC of the metadata cleanup operation can run any version of Windows Server.

**To delete a domain controller object using Active Directory Users and Computers in RSAT**

1. Click **Start**, click **Administrative Tools**, and then click **Active Directory Users and Computers**.
2. In the console tree, double-click the domain container, and then double-click the **Domain Controllers** organizational unit (OU).
3. In the details pane, right-click the DC that you want to delete, and then click **Delete**.
4. Click **Yes** to confirm the deletion. Select the **This Domain Controller is permanently offline and can no longer be demoted using the Active Directory Domain Services Installation Wizard (DCPROMO)** check box and click **Delete**.
5. If the DC was a global catalog server, click **Yes** confirm that the deletion.

**Resetting the computer account password of the domain controller**
Use the following procedure to reset the computer account password of the DC.

**To reset the computer account password of the domain controller**

1. At a command prompt, type the following command, and then press ENTER:

   ```
   netdom help resetpwd
   ```

2. Use the syntax that this command provides for using the Netdom command-line tool to reset the computer account password, for example:

   ```
   netdom resetpwd /server:domain controller name /userD:administrator /passwordd:*
   ```

   Where *domain controller name* is the local DC that you are recovering.

   | **Note** |
   | --- |
   | You should run this command twice. |

**Resetting the krbtgt password**
Use the following procedure to reset the krbtgt password for the domain. The following procedure applies writeable DCs, but not read-only domain controllers (RODCs).

| **Important** |
| --- |
| If you plan to recover RODCs online during the forest recovery, do not delete the krbtgt accounts for the RODCs. The krbtgt account for an RODC is listed in the format krbtgt_*number*.<br><br>If you use a customized password filter (such as passfilt.dll) on a DC, then you might receive an error when you try to reset the krbtgt password. For more information, including a workaround, see Microsoft Knowledge Base article 2549833 (http://support.microsoft.com/kb/2549833). |

**To reset the krbtgt password**

1. Click **Start**, point to **Control Panel**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
2. Click **View**, and then click **Advanced Features**.

3. In the console tree, double-click the domain container, and then click **Users**.
4. In the details pane, right-click the **krbtgt** user account, and then click **Reset Password**.
5. In **New password**, type a new password, retype the password in **Confirm password**, and then click **OK**. The password that you specify is not significant because the system will generate a strong password automatically independent of the password that you specify.

| **Note** |
| --- |
| You should perform this operation twice. The password history of the krbtgt account is two, meaning it includes the two most recent passwords. By resetting the password twice you effectively clear any old passwords from the history, so there is no way another DC will replicate with this DC by using an old password. |

**Resetting a trust password on one side of the trust**

If the forest recovery is related to a security breach, use the following procedure to reset a trust password on one side of the trust. This includes implicit trusts between child and parent domains as well as explicit trusts between this domain (the trusting domain) and another domain (the trusted domain).

Reset the password on only the trusting domain side of the trust, also known as the incoming trust (the side where this domain belongs). Then, use the same password on the trusted domain side of the trust, also known as the outgoing trust. Reset the password of the outgoing trust when you restore the first DC in each of the other (trusted) domains.

Resetting the trust password ensures that the DC does not replicate with potentially bad DCs outside its domain. By setting the same trust password while restoring the first DC in each of the domains, you ensure that this DC replicates with each of the recovered DCs. Subsequent DCs in the domain that are recovered by installing AD DS will automatically replicate these new passwords during the installation process.

**To reset a trust password on one side of the trust**

1. At a command prompt, type the following command, and then press ENTER:

   ```
   netdom experthelp trust
   ```

2. Use the syntax that this command provides for using the NetDom tool to reset the trust password.

   For example, if there are two domains in the forest—parent and child—and you are running this command on the restored DC in the parent domain, use the following command syntax:

   ```
   netdom trust parent domain name /domain:child domain name /resetOneSide
   /passwordT:password /userO:administrator /passwordO:*
   ```

   When you run this command in the child domain, use the following command syntax:

   ```
   netdom trust child domain name /domain:parent domain name /resetOneSide
   /password:password /userO:administrator /passwordO:*
   ```

| **Note** |
| --- |
| **passwordT** should be the same value on both sides of the trust. Run this command only once (unlike the **netdom resetpwd** command) because it automatically resets the password twice. |

**Adding the global catalog**

Use the following procedure to add the global catalog to a DC.

**To add the global catalog**

1. Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Sites and Services**.
2. In the console tree, expand the **Sites** container, and then select the appropriate site that contains the target server.
3. Expand the **Servers** container, and then expand the server object for the DC to which you want to add the global catalog.
4. Right-click **NTDS Settings**, and then click **Properties**.

5. Select the **Global Catalog** check box.

**To add the global catalog using Repadmin**

1. Open an elevated command prompt, type the following command, and press ENTER:

```
repadmin.exe /options DC_NAME +IS_GC
```

The following are ways to speed up the process of adding the global catalog to the DC in the root domain:

- Ideally, the DC in the root domain should be a replication partner of the restored DCs in the non-root domains. If so, confirm that the Knowledge Consistency Checker (KCC) has created the corresponding **repsFrom** object for the source DC and partition in the root DC. You can confirm this by running the **repadmin /showreps /v** command.

- If there is no **repsFrom** object created, create this object for the configuration partition. This way, the DC in the root domain can determine which DCs in the non-root domain have been deleted. You can do this with the following commands:

  ```
  repadmin /add ConfigurationNamingContext DestinationDomainController
  SourceDomainControllerCNAME
  ```

  ```
  repadmin /options DSA -Disable_NTDSCONN_XLATE
  ```

  The format for the *SourceDomainControllerCNAME* is:

  ```
  sourceDCGuid._msdcs.root domain
  ```

  For example, the repadmin /add command for the configuration partition of the contoso.com domain could be:

  ```
  repadmin /add cn=configuration,DC=contoso,DC=com DC01 937ef930-7356-43c8-88dc-
  8baaaa781cf6._msdcs.dDSP17A22.contoso.com
  ```

- If the **repsFrom** object is present, try to sync the DC in the root domain with the DC in the non-root domain as follows:

  ```
  Repadmin /sync DomainNamingContext DestinationDomainController
  SourceDomainControllerGUID
  ```

  Where *DestinationDomainController* is the DC in the root domain and *SourceDomainController* is the restored DC in the non-root domain.

- The root domain DNS server should have the alias (CNAME) resource records for the source DC. Ensure that the parent DNS zone contains delegation resource records (name server (NS) and host (A) resource records) for the correct DCs (the DCs that have been restored from backup) in the child zone.

- Make sure that the DC in the root domain is contacting the correct Key Distribution Center (KDC) in the non-root domain. To test this, at the command prompt, type the following command, and then press ENTER:

  ```
  nltest /dsgetdc:nonroot domain name /KDC /Force
  ```

**Resources to verify replication is working**

After you have restored or re-installed all DCs, you can verify that AD DS and SYSVOL are recovered and replicating correctly by using **repadmin /replsum**, which runs on any version of Windows Server.

**Tip**

You can also download and run the Active Directory Replication Status Tool (ADReplStatus), a free tool that monitors replication status of DCs and reports errors. ADReplStatus requires .NET Framework 4, which will be installed if it is not already present.

Check the DFS Replication log in Event Viewer for Event ID 4602 (or File Replication Service event ID 13516), which indicates SYSVOL has been initialized.

If the first recovered DC logs Event ID 4614 ("the domain controller is waiting to perform initial replication. The replicated folder will remain in the initial synchronization state until it has replicated with its partner") in the DFS Replication log, then Event ID 4602 does not appear and you need to perform the following manual steps to recover SYSVOL if it is replicated by DFSR:

1. When DFSR Event 4612 appears on the first restored DC perform a manual authoritative restore as described in 2218556: How to force an authoritative and non-authoritative synchronization for DFSR-replicated SYSVOL (like "D4/D2" for FRS) (http://support.microsoft.com/kb/2218556).

2. Set **SysvolReady Flag** to 1 manually, as described in 947022 The NETLOGON share is not present after you install Active Directory Domain Services on a new full or read-only Windows Server 2008-based domain controller.

You can also create a diagnostic report DFS Replication. For more information, see Create a Diagnostic Report for DFS Replication and DFS Step-by-Step Guide for Windows Server 2008. If the server is running Windows Server 2008 R2, you can use dfsrdiag.exe ReplicationState command line switch.

You can also run the Replications test using dcdiag.exe to check for replication errors. For more information, see Knowledge Base article 249256.

# Appendix B: Frequently Asked Questions

Updated: April 25, 2013

Applies To: Windows Server 2000, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012

This appendix contains frequently asked questions (FAQs) regarding forest recovery:

- What can I do to speed up recovery?
- Can I automate the forest recovery process?

**What can I do to speed up recovery?**

Although speed of recovery is not the primary goal of this guide, you can achieve shorter recovery times by:

- Creating a detailed forest recovery plan, updating it on a regular basis, and practicing it in a simulated test environment of reasonable size at least once a year
- Using virtualized domain controller (DC) cloning

  Virtualized DC cloning expedites the process to get additional DCs running after one DC is restored from backup in each domain. The additional virtualized DCs can be cloned rather than waiting for potentially lengthy AD DS installations to be completed and for the completion of non-critical replication after installation.

  Forests where virtual DCs are hosted in a relatively small number of well-connected data centers potentially benefit most from cloning during recovery. However, any environment where multiple virtualized DCs for the same domain are co-located on the same hypervisor host should benefit.
- Deploying read-only domain controllers (RODCs)

  RODCs can provide business continuity during the recovery process because they do not have to be disconnected from the network as writable DCs do. RODCs do not perform outbound replication. Therefore, they do not present the same risk that writable DCs pose for replicating damaging data back into the recovered environment.

Other factors that affect the duration of the forest recovery process include the following:

- When you restore DCs from backups, it takes time to:
  - Locate the physical backup media, such as tapes.
  - Reinstall the operating system.
  - Restore data from backup media.

  You can reduce the time required to reinstall the operating system and restore data from backup by performing full server recovery instead of system state restore. Because full server recovery is binary-based, it completes much faster than system state restore.

  However, if the server contains data that is excluded from system state data that you do not want to restore, full server recovery might not be a viable alternative to system state restore. Consider the advantages of performing a full server recovery instead of a system state restore for your servers specifically, and prepare accordingly by performing the appropriate type of backup that you plan to restore later.
- When you rebuild DCs, it takes time to replicate data for network-based promotions.

You can decrease the time required for restoring DCs by performing the following steps:

- Reduce the time for retrieving backup media by:

    - Using the Active Directory Database Mounting Tool (Dsamain.exe) to identify the best backup to use for restore operations. For more information about using the Active Directory Database Mounting Tool, see the Active Directory Database Mounting Tool Step-by-Step Guide (http://go.microsoft.com/fwlink/?LinkId=132577).

    - Labeling the backup media clearly and storing the media in an organized fashion at a convenient, yet secure, location that allows fast retrieval.

    - Using the Volume Shadow Copy Service with a storage area network (SAN) to maintain backups from different points in time. For more information, see Windows Server 2003 Active Directory Fast Recovery with Volume Shadow Copy Service and Virtual Disk Service (http://go.microsoft.com/fwlink/?LinkId=70781).

- Force the removal of AD DS from the DCs instead of reinstalling the operating system. If the cause of the forest-wide failure has been identified to be purely within the scope of AD DS, you do not have to reinstall the operating system on the DCs.

  For more information about forcing the removal of AD DS from a DC that runs Windows Server 2008 or later, see Forcing the Removal of a Windows Server 2008 Domain Controller (http://go.microsoft.com/fwlink/?LinkId=132627). For more information about forcing the removal of AD DS from a DC that runs Windows Server 2003, see article 332199 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkId=70780).

- Use faster tape devices or disk backups to reduce the time that is required for restore operations.

You can also help accelerate AD DS installations by using the Install from Media (IFM) feature to rebuild DCs in each domain. IFM reduces the replication latency that is incurred when you rebuild DCs in each domain.

Businesses that have a more aggressive service-level agreement (SLA) might consider altering the forest recovery procedures to speed recovery.

**Can I automate the forest recovery process?**
Because of the complex and critical nature of the forest recovery process, there is currently no end-to-end automation of it. The forest recovery process is more a logistical and organizational challenge of restoring business continuity than a technical problem of process automation. Therefore, the individual who administers the environment should create a forest recovery plan that is specific to that environment and then automate sections of it that can be automated successfully.

You can perform most of the forest recovery steps by using command-line tools. Therefore, most of the steps are scriptable. For example, Ntdsutil.exe is one of the most frequently used tools in the forest recovery process.

Although scripts can speed recovery, you must thoroughly test these scripts before you apply them in a real environment. Also, you must update them according to changes in the Active Directory environment, such as the addition of a new domain or DC, or a new version of Active Directory.

# Appendix C: Recovering a Single Domain within a Multidomain Forest

Published: April 25, 2013

Updated: April 25, 2013

Applies To: Windows Server 2008, Windows Server 2008 R2, Windows Server 2012

There can be times when it is necessary to recover only a single domain within a forest that has multiple domains, rather than a full forest recovery. This topic covers considerations for recovering a single domain and possible strategies for recovery.

A single domain recovery presents a unique challenge for rebuilding global catalog (GC) servers. For example, if the first domain controller (DC) for the domain is restored from a backup that was created one week earlier, then all other GCs in the forest will have more up-to-date data for that domain than the restored DC. To re-establish GC data consistency, there are a couple options:

- Unhost and then rehost all GCs in the forest, except those in the recovered domain, at the same time.
- Follow the forest recovery process to recover the domain, and then remove lingering objects from GCs in other domains.

The following sections provide general considerations for each option. The complete set of steps that need to be done for the recovery will vary for different Active Directory environments.

**Rehost all GCs**
Rehosting all GCs can be done using repadmin /unhost and repadmin /rehost commands (part of repadmin /experthelp). You would run the repadmin commands on every GC in each domain that is not recovered.

| ⚠**Warning** |
| --- |
| The password of the built-in Administrator account for all domains must be ready for use in case a problem prevents access to a GC for logon. |

This option can be advantageous for a small organization that has only a few domain controllers for each domain. All of the GCs could be rebuilt on a Friday night and, if necessary, complete replication for all read-only domain partitions before Monday morning. But if you need to recover a large domain that covers sites across the globe, rehosting the read-only domain partition on all GCs for other domains can significantly impact operations and potentially require down time.

**Remove lingering objects**
Similar to the forest recovery process, you restore one DC from backup in the domain that you need to recover, perform metadata cleanup of remaining DCs, and then re-install AD DS to build out the domain. On the GCs of all other domains in the forest, you remove the lingering objects for the read-only partition of the recovered domain.

The source for the lingering object cleanup must be a DC in the recovered domain. To be certain that the source DC does not have any lingering objects for any domain partitions, you can remove the global catalog if it was a GC.

Removing lingering objects is advantageous for larger organizations that cannot risk the down time associated with the other options.

For more information, see Use Repadmin to remove lingering objects.

# Appendix D: Forest Recovery with Windows Server 2003 Domain Controllers

Published: April 25, 2013

Updated: April 25, 2013

Applies To: Windows Server 2008, Windows Server 2008 R2, Windows Server 2012

This topic includes forest recovery procedures for domain controllers (DCs) that run Windows Server 2003. The general process for forest recovery is no different with Windows Server 2003 DCs, but specific procedures can differ because of different tools. For example, Ntdsutil.exe can be used to backup and restore DCs that run Windows Server 2003 DCs, whereas Windows Server Backup or Wbadmin.exe is used for DCs that run Windows Server 2008 or later.

- Backing up the System State data
- Performing a nonauthoritative restore
- Install and configure the DNS Server service

**Backing up the System State data**

Use the following procedure to back up the System State data, along with any other data you have selected for the current backup operation, of a DC that runs Windows Server 2003. Windows Server 2003 includes the Ntbackup tool, which you can use to back up System State data.

Membership in **Administrators** or **Backup Operators**, or equivalent, is the minimum required to back up files and folders. Review details about using the appropriate accounts and group memberships at Local and Domain Default Groups (http://go.microsoft.com/fwlink/?LinkId=83477).

If you are backing up the System State data to a tape, and the Backup program indicates that there is no unused media available, you might have to use Removable Storage. This adds your tape to the free media pool so that Backup can use it.

You can only back up the System State data on a local computer. You cannot back it up on a remote computer.

**To back up the System State data on a domain controller that runs Windows Server 2003**

1. Click **Start**, point to **All Programs**, point to **Accessories**, point to **System Tools**, and then click **Backup**.
2. On the **Welcome** page, click **Advanced Mode**.
3. On the **Backup** tab, select the check box for any drive, folder, or file that you want to back up.
4. Select the **System State** check box.
5. Click **Start Backup**.

**Performing a nonauthoritative restore**

Use the following procedure to perform a nonauthoritative restore of a DC that runs Windows Server 2003. By performing a nonauthoritative restore on Active Directory in Windows Server 2003, you automatically perform a nonauthoritative restore of SYSVOL. No additional steps are required.

| **Note** |
| --- |
| If you are also reinstalling the Windows Server 2003 operating system, you might or might not join the computer to the domain and you can give any name to the computer during setup of the operating system. Do not install Active Directory. After reinstalling the operating system, go directly to step 4. |

On Windows Server 2003 domain controllers where you have restored only system state data, you need to also reinstall any software applications that were running on DCs before recovery. Restoring AD DS on the first DC in the domain also restores the registry because they both are part of System State data. Keep this in mind if you had any applications running on these DCs and if they had any information stored in the registry.

To save time required to re-install software, determine if applications that need to be installed on the DCs are compatible with virtual DC cloning. Such applications can be installed on the source DC prior to cloning in order to save the time and effort required to install them on the cloned virtual DCs.

**To perform a nonauthoritative restore**

1. After you start the DC, press F8 to restart the computer in Directory Services Restore Mode (DSRM).
2. Select **Directory Services Restore Mode (Windows domain controllers only)**.
3. Select the operating system that you want to start in restore mode.
4. Log on as an administrator (you can only use a local computer account, no domain logon option is available).
5. At a command prompt, type **ntbackup**, and then press ENTER.
6. On the **Welcome** page, click **Advanced Mode**, and then select the **Restore and Manage Media** tab. (Do not select **Restore Wizard**.)
7. Select the appropriate backup file to restore from and ensure that the **System disk** and **System State** check boxes are selected.
8. Click **Start Restore**.
9. When the restore operation is complete, restart the computer.

Use the following procedure to perform an authoritative (also known as primary) restore of SYSVOL on a DC that runs Windows Server 2003. Perform this procedure only on the first Windows Server 2003 DC that is restored in the domain.

**To perform an authoritative restore of SYSVOL**

1. Perform steps 1 through 8 in the previous procedure.
2. In the **Confirm Restore** dialog box, click **Advanced**.
3. To perform an authoritative restore of SYSVOL, select the check box **When restoring replicated data sets, mark the restored data as the primary data for all replicas**.

   | **Note** |
   | --- |
   | Marking the restored data as the primary data in the Backup is equivalent to setting the **BurFlags** entry to D4 under the following registry subkey:<br><br>**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NtFrs\Parameters\Cumulative Replica Sets***GUID* |

4. When the restore operation is complete, restart the computer.

**Install and configure the DNS Server service**

If the DC that you restored from backup is running Windows Server 2003, you can install DNS server without connecting the DC to any network.

**To install and configure the DNS Server service**

1. Open Windows Components Wizard. To open the wizard:
   - Click **Start**, click **Control Panel**, and then click **Add or Remove Programs**.
   - Click **Add/Remove Windows Components**.
2. In **Components**, select the **Networking Services** check box, and then click **Details**.
3. In **Subcomponents of Networking Services**, select the **Domain Name System (DNS)** check box, click **OK**, and then click **Next**.
4. If you are prompted, in **Copy files from**, type the full path of the distribution files, and then click **OK**.

After the installation, complete the following steps to configure the DNS server.

5. Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **DNS**.

6. Create DNS zones for the same DNS domain names that were hosted on the DNS servers before the critical malfunction. For more information, see Add a Forward Lookup Zone (http://go.microsoft.com/fwlink/?LinkId=74574).

7. Configure the DNS data as it existed before the critical malfunction. For example:

   - Configure DNS zones to be stored in AD DS. For more information, see Change the Zone Type (http://go.microsoft.com/fwlink/?LinkId=74579).

   - Configure the DNS zone that is authoritative for domain controller locator (DC Locator) resource records to allow secure dynamic update. For more information, see Allow Only Secure Dynamic Updates (http://go.microsoft.com/fwlink/?LinkId=74580).

8. Ensure that the parent DNS zone contains delegation resource records (name server (NS) and glue host (A) resource records) for the child zone that is hosted on this DNS server. For more information, see Create a Zone Delegation (http://go.microsoft.com/fwlink/?LinkId=74562).

9. After you configure DNS, at the command prompt, type the following command, and then press ENTER:

   **net stop netlogon**

10. Type the following command, and then press ENTER:

    **net start netlogon**

| **Note** |
| --- |
| Net Logon will register the DC Locator resource records in DNS for this DC. If you are installing the DNS Server service on a server in the child domain, this DC will not be able to register its records immediately. This is because it is currently isolated as part of the recovery process, and its primary DNS server is the forest root DNS server. Configure this computer with the same IP address as it had before the disaster to avoid DC service lookup failures. |

# Additional Resources

Updated: April 25, 2013

Applies To: Windows Server 2000, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012

This section contains additional resources related to forest recovery.

The following resources are useful for recovering domain controllers that run Windows Server 2012:

- Introduction to Active Directory Domain Services (AD DS) Virtualization (Level 100)
- Maintaining Business Continuity of Virtualized Environments with Hyper-V Replica: scenario overview. For more information about setting up Hyper-V Replica, see
- Deploy Hyper-V Replica
- Remote Server Administration Tools for Windows 8

The following resources are useful for recovering domain controllers that run Windows Server 2008 R2 or Windows Server 2008:

- Remote Server Administration Tools for Windows 7 with Service Pack 1 (SP1)
- Microsoft Remote Server Administration Tools for Windows Vista (http://go.microsoft.com/fwlink/?LinkID=115118)
- Active Directory Database Mounting Tool Step-by-Step Guide (http://go.microsoft.com/fwlink/?LinkId=132577)
- Ntdsutil (http://go.microsoft.com/fwlink/?LinkId=132629)
- Forcing the Removal of a Windows Server 2008 Domain Controller (http://go.microsoft.com/fwlink/?LinkID=132627)
- Installing Active Directory Domain Services from Media (http://go.microsoft.com/fwlink/?LinkId=132630)
- Performing an Unscheduled Backup of a Domain Controller (http://go.microsoft.com/fwlink/?LinkId=132632)
- Performing a Nonauthoritative Restore of AD DS (http://go.microsoft.com/fwlink/?LinkId=132637)

# Enabling Advanced Windows Server 2003 Active Directory Features

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Microsoft® Windows® Server 2003 Active Directory® directory service enables you to introduce advanced features into your environment by raising the domain or forest functional level. You can raise the functional level when all domain controllers in the domain or forest are running an appropriate version of Windows. Raising the functional level allows you to introduce new features but also limits the versions of Windows that can run on domain controllers in your environment.

**In This Chapter**

Overview of Enabling Advanced Active Directory Features

Preparing to Enable Functional Levels

Enabling Windows Server 2003 Active Directory Functional Levels

Additional Resources for Enabling Advanced Windows Server 2003 Active Directory Features

**Related Information**

- For more information about domain and forest functional levels, see the *Active Directory Collection* of the *Windows Server 2003 Technical Reference* (or see the Active Directory Collection on the Web at http://www.microsoft.com/reskit).
- For more information about enabling functional levels in a new Microsoft® Windows® Server 2003 environment, see "Deploying the Windows Server 2003 Forest Root Domain" in this book.
- For more information about enabling functional levels after upgrading from Microsoft® Windows NT® 4.0, see "Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory" in this book.
- For more information about enabling functional levels after upgrading from Microsoft® Windows® 2000, see "Upgrading from Windows 2000 Domains to Windows Server 2003 Domains" in this book.

# Overview of Enabling Advanced Active Directory Features

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Functional levels in Windows Server 2003 Active Directory enable you to implement advanced features — such as efficient group membership replication, deactivation and redefinition of attributes and classes in the schema, and domain rename — that require that domain controllers within a domain or forest be running the Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; or Windows® Server 2003, Datacenter Edition operating systems. If you want to enable these advanced Windows Server 2003 Active Directory features in your organization, you must raise the domain and/or forest to the appropriate functional level.

Before you can identify and enable the functional level that best meets the needs of your organization, you must identify the Windows operating systems that you are currently running and that you plan to maintain in your environment after you deploy Windows Server 2003.

If you are currently running Windows NT 4.0 and you do not plan to deploy Windows 2000 in your environment, after you deploy the first Windows Server 2003–based domain controller, raise the forest functional level to Windows Server 2003 interim to take advantage of the advanced features available at that forest functional level.

If you are currently running both Windows 2000 and Windows NT 4.0 in your environment, after you deploy a Windows Server 2003–based domain controller, keep the forest functional level set to Windows 2000. This enables you to take advantage of all advanced features available at that forest functional level.

If you are currently running only Windows 2000 in your environment or you are planning to install any number of Windows 2000–based domain controllers in the future, after you deploy a Windows Server 2003–based domain controller, keep the forest functional level set to Windows 2000. This enables you to take advantage of all advanced features available at that forest functional level.

If you are deploying a new Windows Server 2003 environment and plan to run only Windows Server 2003–based domain controllers, after you deploy the first Windows Server 2003–based domain controller you can raise the forest functional level to Windows Server 2003 to take advantage of all available Windows Server 2003 Active Directory features.

**Note**

- For a list of the job aids that are available to assist you in enabling functional levels, see "Additional Resources for Enabling Advanced Windows Server 2003 Active Directory Features" later in this chapter.

# Process for Enabling Advanced Active Directory Features

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Enabling advanced Active Directory features involves identifying the operating systems that are running on the domain controllers in your environment and the functional level that best meets the needs of your organization based on your existing infrastructure, and raising the domain or forest functional level as appropriate. Figure 5.1 shows the process for enabling advanced Active Directory features.

**Figure 5.1 Enabling Advanced Active Directory Features**

# Functional Levels Background Information

Updated: July 9, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 Active Directory functional levels expand on the mixed and native modes introduced in the Windows 2000 operating system. In Windows 2000, a mixed mode domain supports domain controllers running either Windows 2000 or the Windows NT 4.0 operating system. Domains in native mode only support Windows 2000–based domain controllers. If all domain controllers in a mixed mode domain are upgraded to Windows 2000, the domain administrator can change the mode to native, making additional Windows 2000 features available.

In Windows Server 2003, the functional level of a domain or forest defines the set of advanced Windows Server 2003 Active Directory features that are available in that domain or forest. The functional level of a domain or forest also defines the set of Windows operating systems that can run on the domain controllers in that domain or forest.

**Note**

- The functional level of a domain or forest defines only the set of Windows operating systems that can run on domain controllers. It does not define the client operating systems that are supported in the forest.

When the first Windows Server 2003–based domain controller is deployed in a domain or forest, a set of default Active Directory features becomes available. Table 5.1 summarizes the Active Directory features that are available by default on any domain controller running Windows Server 2003.

**Table 5.1 Default Windows Server 2003 Active Directory Features**

| Feature | Functionality |
|---|---|
| Multiple selection of user objects | Allows you to modify common attributes of multiple user objects at one time. |
| Drag and drop functionality | Allows you to move Active Directory objects from container to container by dragging one or more objects to a location in the domain hierarchy. You can also add objects to group membership lists by dragging one or more objects (including other group objects) to the target group. |
| Efficient search capabilities | Search functionality is object-oriented and provides an efficient search that minimizes network traffic associated with browsing objects. |
| Saved queries | Allows you to save commonly used search parameters for reuse in Active Directory Users and Computers |
| Active Directory command-line tools | Allows you to run new directory service commands for administration scenarios. |
| InetOrgPerson class | The inetOrgPerson class has been added to the base schema as a security principal and can be used in the same manner as the user class. |
| Application directory partitions | Allows you to configure the replication scope for application-specific data among domain controllers. For example, you can control the replication scope of Domain Name System (DNS) zone data stored in Active Directory so that only specific domain controllers in the forest participate in DNS zone replication. |
| Ability to add additional domain controllers by using backup media | Reduces the time it takes to add an additional domain controller in an existing domain by using backup media. |

| | |
|---|---|
| Universal group membership caching | Prevents the need to locate a global catalog across a wide area network (WAN) when logging on by storing universal group membership information on an authenticating domain controller. |
| Secure Lightweight Directory Access Protocol (LDAP) traffic | Active Directory administrative tools sign and encrypt all LDAP traffic by default. Signing LDAP traffic guarantees that the packaged data comes from a known source and that it has not been tampered with. |
| Partial synchronization of the global catalog | Provides improved replication of the global catalog when schema changes add attributes to the global catalog partial attribute set. Only the new attributes are replicated, not the entire global catalog. |
| Active Directory quotas | Quotas can be specified in Active Directory to control the number of objects a user, group, or computer can own in a given directory partition. Members of the Domain Administrators and Enterprise Administrators groups are exempt from quotas. |

For more information about the default Active Directory features that are available on any Windows Server 2003 domain controller, see "New features for Active Directory" in Help and Support Center for Windows Server 2003.

When the first Windows Server 2003–based domain controller is deployed in a domain or forest, the domain or forest operates by default at the lowest functional level that is possible in that environment. This allows you to take advantage of the default Active Directory features while running versions of Windows earlier than Windows Server 2003.

When you raise the functional level of a domain or forest, a set of advanced features becomes available. For example, the Windows Server 2003 interim forest functional level supports more features than the Windows 2000 forest functional level, but fewer features than the Windows Server 2003 forest functional level supports. Windows Server 2003 is the highest functional level that is available for a domain or forest. The Windows Server 2003 functional level supports the most advanced Active Directory features; however, only Windows Server 2003 domain controllers can operate in that domain or forest.

If you raise the domain functional level to Windows Server 2003, you cannot introduce any domain controllers that are running versions of Windows earlier than Windows Server 2003 into that domain. This applies to the forest functional level as well.

Table 5.2 lists the Windows Server 2003 domain functional levels, the operating systems that they support, and the Windows Server 2003 features that are available at each domain functional level.

**Table 5.2 Windows Server 2003 Domain Functional Levels**

| **Windows Server 2003 Domain Functional Level** | **Supported Domain Controller Operating Systems** | **Advanced Features Available at Each Domain Functional Level** |
|---|---|---|
| Windows 2000 mixed | Windows NT 4.0<br>Windows 2000<br>Windows Server 2003 | All default Active Directory features, and:<br>• Universal Groups are enabled for distribution groups, but are disabled for security groups. |

| | | |
|---|---|---|
| Windows 2000 native | Windows 2000<br>Windows Server 2003 | All default Active Directory features, all features from the Windows 2000 mixed domain functional level, and:<br>• Universal Groups are enabled for both distribution and security groups.<br>• Group conversion is enabled, allowing conversion between security and distribution groups.<br>• Group nesting is available, allowing nesting of groups within other groups.<br>• Security identifier (SID) history is available, allowing the migration of security principals from one domain to another. |
| Windows Server 2003 interim | Windows NT 4.0<br>Windows Server 2003 | Same as Windows 2000 mixed. |
| Windows Server 2003 | Windows Server 2003 | All default Active Directory features, all features from the Windows 2000 native domain functional level, and:<br>• Supports new functionality of the netdom.exe tool to prepare domain controllers for rename. It is recommended that you rename a domain controller by using netdom.exe to ensure that all appropriate steps are taken.<br>• Enables updates to the logon timestamp attribute. The *lastLogonTimestamp* attribute is updated with the last logon time of the user or computer. This attribute is replicated within the domain.<br>• Provides the ability to set the *userPassword* attribute as the effective password on inetOrgPerson and user objects.<br>• Provides the ability to redirect the Users and Computers containers in order to define a new well-known location for user and computer accounts.<br>• Allows for authorization manager to store its authorization policies in Active Directory.<br>• Includes constrained delegation, which allows applications to take advantage of the secure delegation of user credentials by means of Kerberos authentication protocol. Delegation can be configured to be allowed only to specific destination services.<br>• Supports selective authentication, by which it is possible to specify the users and groups from a trusted forest who are allowed to authenticate to resource servers in a trusting forest. |

Table 5.3 lists the Windows Server 2003 forest functional levels, the operating systems that they support, and the Windows Server 2003 features that are available at each forest functional level.

**Table 5.3 Windows Server 2003 Forest Functional Levels**

| Windows Server 2003 Forest Functional Level | Supported Domain Controller Operating Systems | Advanced Features Available at Each Forest Functional Level |
|---|---|---|

| | | |
|---|---|---|
| Windows 2000 | Windows NT 4.0<br>Windows 2000<br>Windows Server 2003 | All default Active Directory features. |
| Windows Server 2003 interim | Windows NT 4.0<br>Windows Server 2003 | All default Active Directory features, and:<br>• Linked value replication.<br>• Improved KCC algorithms and scalability.<br>• The following attributes included in the global catalog:<br>  • Ms-DS-Trust-Forest-Trust-Info<br>  • Trust-Direction<br>  • Trust-Attributes<br>  • Trust-Type<br>  • Trust-Partner<br>  • Security-Identifier<br>  • Ms-DS-Entry-Time-To-Die<br>  • MSMQ-Secured-Source<br>  • MSMQ-Multicast-Address<br>  • Print-Memory<br>  • Print-Rate<br>  • Print-Rate-Unit<br>  • MS-DRM-Identity-Certificate |

| | | |
|---|---|---|
| Windows Server 2003 | Windows Server 2003 | All Active Directory features available at the Windows Server 2003 interim level, and:<br>• The ability to create instances of the dynamic auxiliary class called *dynamicObject* in a domain naming context.<br>• The ability to convert an *inetOrgPerson* object instance into a *User* object instance and vice versa.<br>• The ability to create instances of the new group types *basic* and *query based*, used by the role–based Authorization Manager.<br>• Deactivation and redefinition of attributes and classes in the schema. The following attributes can be reused: ldapDisplayName, schemaIdGuid, OID, and mapiID.<br>• Forest trust.<br>• Domain rename. |

**Guidelines for Raising Domain Functional Levels**
The following guidelines apply to raising the domain functional level:

- You must be a member of the Domain Admins group to raise the domain functional level.
- You can raise the domain functional level on the primary domain controller (PDC) emulator operations master only. The Active Directory administrative tools used to raise the domain functional level (Active Directory Domains and Trusts and Active Directory Users and Computers) automatically target the PDC emulator when you raise the domain functional level.
- You can raise the functional level of a domain only if all domain controllers in the domain are running the version or versions of Windows that the new functional level supports.
- You cannot lower the functional level of a domain after it has been raised.

**Guidelines for Raising Forest Functional Levels**
The following guidelines apply to raising the forest functional level:

- You must be a member of the Enterprise Admins group to raise the forest functional level.
- You can raise the forest functional level on the schema operations master only. The Active Directory Domains and Trusts console automatically targets the schema operations master when you raise the forest functional level.
- You can raise the functional level of a forest only if all domain controllers in the forest are running the version or versions of Windows that the new functional level supports.
- You can raise the forest to the Windows Server 2003 functional level only if all domains are at either the Windows 2000 native or Windows Server 2003 functional level.
- You cannot lower the functional level of a forest after it has been raised.

**Important**

- Raising the domain and forest functional levels are one-way operations that cannot be reversed. In the event that you need to revert to a lower functional level, you need to rebuild the domain or forest or restore it from a backup. For more

information about domain and forest recovery, see the Best Practices: Active Directory Forest Recovery link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

When you raise the forest functional level to Windows Server 2003, Active Directory automatically raises all domains that are operating at the Windows 2000 native domain functional level to the Windows Server 2003 domain functional level. However, if any domains in your environment are operating at the Windows 2000 mixed domain functional level, you cannot raise the forest functional level to Windows Server 2003.

For more information about raising functional levels, see "Raising domain and forest functional levels" in Help and Support Center for Windows Server 2003.

# Preparing to Enable Functional Levels

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you can enable domain and forest functional levels, you need to evaluate your current environment and identify the functional level scenario that best meets the needs of your organization. For a worksheet to assist you in preparing to enable functional levels, see "Assess Your Current Environment" later in this chapter.

Figure 5.2 shows the process for preparing to enable functional levels.

**Figure 5.2 Preparing to Enable Functional Levels**

# Assess Your Current Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Assess your current environment by identifying the domains in your forest, the domain controllers that are located in each domain, the operating system that each domain controller is running, and the date that you plan to upgrade the domain controller. If you plan to retire a domain controller, document the reasons for this decision.

Circumstances that might prevent you from upgrading an earlier version of the Windows operating system and enabling the Windows Server 2003 functional level include:

- Insufficient hardware
- A domain controller running an antivirus program that is incompatible with Windows Server 2003
- Use of a version-specific program that does not run on Windows Server 2003
- The need to perform a Service Pack upgrade

Documenting this information will help you identify the steps that are required for you to achieve a fully functional Windows Server 2003 environment.

For a worksheet to assist you in assessing your current environment, see "Domain Controller Assessment" (DSSPFL_1.doc) on the *Microsoft® Windows® Server 2003 Deployment Kit* companion CD (or see "Domain Controller Assessment" on the Web at http://www.microsoft.com/reskit). Complete a separate worksheet for each domain, regardless of your forest structure.

Figure 5.3 shows an example of a completed worksheet for a domain assessment.

**Figure 5.3 Example of a Domain Controller Assessment Worksheet**

| Domain Controller Assessment | | | | |
|---|---|---|---|---|
| Prepared By | Forest Owner | | Date | 1/2/03 |
| Forest Name | Concorp.contoso.com | | | |
| Domain Name | Noam.concorp.contoso.com<br>☑ Mixed Mode ☐ Native Mode | | | |
| DC Name | Operating System/Service Pack | Deployment Blocker | Upgrade Date | Retire Date |
| SEA-NOAM-DC01 | Windows NT 4.0 SP6 | Insufficient hardware | | 3/10/03 |
| SEA-NOAM-DC02 | Windows 2000 Advanced Server | None | 3/3/03 | |
| SEA-NOAM-DC03 | Windows 2000 Advanced Server | None | 3/3/03 | |
| SEA-NOAM-DC04 | Windows NT 4.0 SP4 | Need Service Pack Upgrade to SP6 | 3/10/03 | |

# Identify Your Functional Level Scenario

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you assess your current environment, identify the functional level scenario — Windows NT 4.0 environment, Windows 2000 mixed-mode environment, Windows 2000 native-mode environment, or new Windows Server 2003 forest — that applies to your organization.

**Windows NT 4.0 environment** You have a pure Windows NT 4.0 environment consisting of one or more Windows NT 4.0 PDCs and backup domain controllers (BDCs). You want to upgrade directly to Windows Server 2003 and take advantage of all Windows Server 2003 forest- and domain-level features without deploying any Windows 2000 domain controllers in the environment.

**Windows 2000 mixed mode environment** You have a mixed mode Windows 2000 domain that includes both Windows 2000 and Windows NT 4.0–based domain controllers. You want to upgrade to Windows Server 2003 to take advantage of all Windows Server 2003 forest- and domain-level features.

**Windows 2000 native mode environment** You have a native mode Windows 2000 domain consisting of only Windows 2000–based domain controllers. You want to upgrade to Windows Server 2003 to take advantage of all Windows Server 2003 forest- and domain-level features.

**New Windows Server 2003 forest** You are creating a new Windows Server 2003 forest by installing Active Directory on a Windows Server 2003–based member server. You want to take advantage of all Windows Server 2003 forest- and domain-level features.

# Enabling Windows Server 2003 Active Directory Functional Levels

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Enabling advanced Windows Server 2003 Active Directory features in your environment involves installing Windows Server 2003 Active Directory, determining the functional level that is appropriate for your environment, and then raising domain and forest functional levels to meet your requirements. If you choose to raise your existing infrastructure to the Windows Server 2003 functional level, you can take advantage of all the Windows Server 2003 Active Directory features that are available.

You can determine the current domain functional level by viewing the properties of the domain object in either Active Directory Users and Computers or Active Directory Domains and Trusts. You can determine the current forest functional level by using Active Directory Domains and Trusts to view the properties of the **Active Directory Domains and Trusts** node.

To raise the forest functional level to Windows Server 2003, use Active Directory Domains and Trusts. To raise the domain functional level to Windows Server 2003 or Windows 2000 native, use Active Directory Domains and Trusts or Active Directory Users and Computers. For more information about how to view and raise domain and forest functional levels, see "Raise the domain functional level" and "Raise the forest functional level" in Help and Support Center for Windows Server 2003.

**Figure 5.4 Enabling Windows Server 2003 Active Directory Functional Levels**

# Enabling Windows Server 2003 Functional Levels in a Windows NT 4.0 Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If all of the domain controllers in your environment are running Windows NT 4.0, and you plan to upgrade them to Windows Server 2003 *without* ever upgrading to Windows 2000 or installing a new Windows 2000–based domain controller, maintain the Windows Server 2003 interim functional level in your domains and forest until you upgrade all Windows NT 4.0 domain controllers to Windows Server 2003.

**Important**

- If you choose to raise the forest and domain functional level to Windows Server 2003 interim, you cannot return to the Windows 2000 mixed domain functional level or the Windows 2000 forest functional level, and therefore you cannot add Windows 2000–based domain controllers to the forest.

For more information about deploying Windows Server 2003 in a Windows NT 4.0 environment, see "Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory" in this book.

If you intend to add one or more Windows 2000–based domain controllers instead of having only domain controllers running Windows Server 2003 in your environment, see "Enabling Windows Server 2003 Functional Levels in a Mixed Windows 2000 Environment" later in this chapter.

**Important**

- If you are running Windows NT 4.0 or Windows 2000 domain controllers in your environment, do not raise the functional level of your domain or forest to Windows Server 2003. You cannot operate at the Windows Server 2003 functional level until all of your domain controllers are running Windows Server 2003.

Windows 2000 Active Directory group replication limits the size of groups in a Windows 2000 forest. You must divide groups that include more than 5,000 members into smaller groups when you upgrade to Windows 2000. The Windows Server 2003 interim forest functional level is ideal if the groups in any domains in your existing Windows NT 4.0 environment include more than 5,000 members. When you are operating at the Windows Server 2003 interim functional level, you can take advantage of group membership replication improvements, which support large groups of more than 5,000 members.

When upgrading your Windows NT 4.0 environment to Windows Server 2003, you can choose to do one of the following:

- Upgrade to a regional domain in an existing Windows Server 2003 forest.
- Upgrade to a single domain forest.

Whether you decide to upgrade to a regional domain in an existing Windows Server 2003 forest or upgrade to a single domain forest, if you choose to raise the forest functional level to Windows Server 2003 interim, you must remain at the Windows Server 2003 interim functional level until you upgrade all other Windows NT 4.0–based domain controllers to Windows Server 2003 or retire them from service. The Windows Server 2003 interim functional level supports both Windows NT 4.0–based domain controllers and Windows Server 2003–based domain controllers.

**Upgrading to a Regional Domain in an Existing Windows Server 2003 Forest**

When you upgrade a Windows NT 4.0 domain to a regional domain in an existing Windows Server 2003 forest, it is recommended that you raise the forest functional level of the existing forest to Windows Server 2003 interim before upgrading the Windows NT 4.0 PDC to take advantage of the added features of the Windows Server 2003 interim functional level. After you raise the forest functional level of the existing forest to Windows Server 2003 interim, the domain functional level of the forest root domain and all subsequent regional domains is set by default to Windows Server 2003 interim.

When you upgrade a Windows NT 4.0 domain to a regional domain in an existing Windows Server 2003 forest, where the forest functional level is set to Windows 2000, functional levels are set in the new regional domain to the following by default, and they remain in effect until you raise them manually:

- Windows 2000 mixed domain functional level
- Windows 2000 forest functional level

You cannot use Active Directory administrative consoles to raise the forest functional level of the existing Windows Server 2003 forest root domain to Windows Server 2003 interim. Instead, use a Lightweight Directory Access Protocol (LDAP) application such as ADSI Edit or LDP in Windows Support Tools to edit the value of the *msDS-Behavior-Version* attribute.

**To raise the forest functional level of the existing forest to Windows Server 2003 interim by using ADSI Edit**

1. In ADSI Edit, expand the Configuration partition, and expand **CN=Configuration,DC=forestname,DC=domainname,DC=com**.
2. Right-click **CN=Partitions**, and then click **Properties**.
3. Select the **msDS-Behavior-Version** attribute.
4. Click **Edit**.
5. In the **Value** field, type **1** to raise the forest functional level to Windows Server 2003 interim.
6. Click OK.

After you raise the forest functional level to Windows Server 2003 interim forest, you cannot add Windows 2000–based domain controllers to the forest.

If you are deploying a new Windows Server 2003 forest root domain and are planning to upgrade a Windows NT 4.0 domain to a regional domain in this new environment, after you raise the forest functional level to Windows Server 2003 interim, upgrade the Windows NT 4.0 domain to Windows Server 2003. Select **Child domain in an existing domain tree** when prompted by the Active Directory Installation Wizard.

For more information about deploying a Windows Server 2003 forest root domain, see "Deploying the Windows Server 2003 Forest Root Domain" in this book.

**Upgrading to a Single Domain Forest**

When upgrading to a new Windows Server 2003 single domain forest by upgrading an existing Windows NT 4.0 PDC to Windows Server 2003, you are prompted to use the Active Directory Installation Wizard to install Active Directory. The wizard gives you the option of setting the forest functional level to Windows Server 2003 interim during the Active Directory installation process.

If you set the functional level during the Active Directory installation, both the domain and forest will be set at Windows Server 2003 interim after the installation process is complete and the computer is restarted.

**Important**

- If you do not set the functional level to Windows Server 2003 interim during the Active Directory installation process, functional levels are set by default to the following:
    - Windows 2000 forest functional level
    - Windows 2000 mixed domain functional level
- Use the preceding procedure to use ADSI Edit to manually raise the forest functional level to Windows Server 2003 interim after the Active Directory installation process is complete and the computer is restarted.

# Raise the Domain Functional Level to Windows Server 2003

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you upgrade all Windows NT 4.0–based domain controllers in a domain to Windows Server 2003, you can raise the functional level of each domain in the forest to Windows Server 2003. Before you raise the domain functional level, however, you must ensure that no Windows NT 4.0–based domain controllers remain in the domain.

**Warning**

- If Windows NT 4.0–based domain controllers are running in a domain when you raise the domain functional level to Windows Server 2003, they will no longer be able to communicate with the new Windows Server 2003 domain controllers and will not receive necessary updates.

Use the following LDAP query to identify any Windows NT 4.0 domain controllers remaining in the domain. Run the LDAP query against the Domain container in Active Directory Users and Computers. If you have not manually changed the value of the *operatingSystemVersion* attribute of the computer object, this query is conclusive for domain controllers running Windows NT 4.0. You must be a member of the Domain Admins group to run the following query.

**To identify Windows NT 4.0–based domain controllers in a domain**

1. From any Windows Server 2003–based domain controller, open Active Directory Users and Computers.
2. If the domain controller is not already connected to the appropriate domain, connect it to the domain as follows:
   a. Right-click the current domain object, and then click **Connect to domain**.
   b. In the **Domain** dialog box, type the DNS name of the domain that you want to connect to, or click **Browse** to select the domain from the domain tree, and then click **OK**.
3. Right-click the domain object, and then click **Find**.
4. In the **Find** dialog box, click **Custom Search**.
5. Click the domain for which you want to change the functional level.
6. Click the **Advanced** tab.
7. In the **Enter LDAP query** box, type the following, leaving no spaces between any characters (the query is not case-sensitive):

   ```
   (&(objectCategory=computer)(operatingSystemVersion=4*)
   (userAccountControl:1.2.840.113556.1.4.803:=8192))
   ```

8. Click **Find Now**. This produces a list of the computers in the domain that are running Windows NT 4.0 and functioning as domain controllers.

   A domain controller might appear in the list for any of the following reasons:

   - The domain controller is running Windows NT 4.0 and must be upgraded.
   - The domain controller has been upgraded to Windows Server 2003, but the change has not replicated to the target domain controller.
   - The domain controller is no longer in service, but its computer object has not been removed from the domain.

Before you can change the domain functional level to Windows Server 2003, you must physically locate any domain controller in the list, determine its current status, and either upgrade or remove the domain controller as appropriate.

For more information about LDAP queries, see the *Active Directory Collection* of the *Windows Server 2003 Technical Reference* (or see the Active Directory Collection on the Web at http://www.microsoft.com/reskit).

# Raise the Forest Functional Level to Windows Server 2003

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After all domains are operating at the Windows Server 2003 functional level, raise the forest functional level to Windows Server 2003. This enables you to take advantage of all Windows Server 2003 forest-level features.

If any domains in the forest are still operating at the Windows Server 2003 interim functional level, you will be unable to raise the forest functional level to Windows Server 2003. Ensure that all domains are operating at the Windows Server 2003 functional level before you raise the forest functional level.

# Enabling Windows Server 2003 Functional Levels in a Mixed Windows 2000 Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If your Windows 2000 forest includes one or more domains that contain Windows NT 4.0–based domain controllers, those domains are in Windows 2000 mixed mode. Domains that include only Windows 2000–based domain controllers might be in Windows 2000 mixed mode or native mode. Functional levels in a mixed Windows 2000 forest are set by default when you deploy the first Windows Server 2003–based domain controller.

For more information about deploying Windows Server 2003 in a mixed Windows 2000 environment, see "Upgrading from Windows 2000 Domains to Windows Server 2003 Domains" in this book.

You can introduce a Windows Server 2003–based domain controller in a mixed environment in one of two ways:

- By installing a new Windows Server 2003–based domain controller.
- By upgrading an existing Windows 2000 domain controller in the forest to Windows Server 2003.

Functional levels are set at the following levels by default, and remain at these levels until they are raised manually:

- Windows 2000 mixed or Windows 2000 native domain functional level, depending on whether the domain was in mixed mode or native mode prior to the upgrade.
- Windows 2000 forest functional level.

If the domain functional level is set to Windows 2000 mixed after the initial upgrade, the domain must remain at that level for as long as Windows NT 4.0–based domain controllers are in the domain. If you upgrade all Windows NT 4.0–based domain controllers to either Windows 2000 or Windows Server 2003 and decommission the Windows NT 4.0–based domain controllers that you do not intend to upgrade, you can raise the domain functional level to Windows 2000 native.

If the domain functional level is set to Windows 2000 native after the initial upgrade, the domain must remain at that level for as long as Windows 2000–based domain controllers are operating in the domain.

**Note**

- This also applies to Windows NT 4.0 environments in which you intend to deploy one or more Windows 2000 domain controllers in the future. After the initial upgrade, the domain must remain at a functional level of Windows 2000 mixed.

After you upgrade all Windows 2000–based domain controllers to Windows Server 2003, you can raise the functional levels of the domains in the forest to Windows Server 2003. Before you raise the domain functional level, you must verify that no Windows NT 4.0–based domain controllers remain in the domain. For more information about identifying Windows NT 4.0–based domain controllers in a domain, see "Enabling Windows Server 2003 Functional Levels in a Windows NT 4.0 Environment" earlier in this chapter.

If all domain controllers in the domain are running Windows Server 2003, you can raise the domain functional level from Windows 2000 mixed to Windows Server 2003 directly. Alternatively, you can raise the functional level step by step — from Windows 2000 mixed to Windows 2000 native and then to Windows Server 2003.

After you upgrade all domain controllers in the forest to Windows Server 2003 and raise all domains to the Windows 2000 native or Windows Server 2003 functional level, you can raise the forest functional level to Windows Server 2003. This automatically raises the functional level of any remaining domains that are operating at the Windows 2000 native functional level to Windows Server 2003.

# Enabling Windows Server 2003 Functional Levels in a Native Windows 2000 Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If the domains in your Windows 2000 forest include only Windows 2000 domain controllers and are in Windows 2000 native mode, deploy a Windows Server 2003–based domain controller to enable functional levels.

For more information about deploying Windows Server 2003 in a Windows 2000 environment, see "Upgrading from Windows 2000 Domains to Windows Server 2003 Domains" in this book.

In an environment that contains only domain controllers running Windows 2000, you can introduce a Windows Server 2003–based domain controller in one of two ways:

- By installing a new Windows Server 2003–based domain controller.
- By upgrading an existing Windows 2000 domain controller in the forest to Windows Server 2003.

Functional levels are set by default to the following levels, and they remain at these levels until they are raised manually:

- Windows 2000 native domain functional level
- Windows 2000 forest functional level

**Note**

- If your Windows 2000 forest consists solely of Windows 2000–based domain controllers, but one or more of your domains are operating in mixed mode, see "Enabling Windows Server 2003 Functional Levels in a Mixed Windows 2000 Environment" earlier in this chapter.

To take advantage of the Windows Server 2003 domain-level features without waiting to complete the upgrade of your Windows 2000 forest to Windows Server 2003, raise only the domain functional level to Windows Server 2003. Before you raise the domain functional level, you must upgrade all Windows 2000–based domain controllers in the domain to Windows Server 2003.

After you upgrade all Windows 2000–based domain controllers in the forest to Windows Server 2003, make sure that the domain functional level of each domain is set to Windows 2000 native or higher. Then raise the forest functional level to Windows Server 2003. Raising the forest functional level to Windows Server 2003 automatically raises the functional level of all domains in the forest that are set to Windows 2000 native or higher to Windows Server 2003.

# Enabling Windows Server 2003 Functional Levels in a New Windows Server 2003 Forest

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you have installed the first domain controller in a new Windows Server 2003 forest, functional levels are set by default to the following levels, and remain at these levels until they are raised manually:

- Windows 2000 mixed domain functional level
- Windows 2000 forest functional level

Functional levels are set at these levels to allow you the option of adding Windows 2000 or Windows NT 4.0–based domain controllers to your new Windows Server 2003 forest.

After you create a forest root domain, the domain functional level for each additional domain that you add to the Windows Server 2003 forest is set to Windows 2000 mixed.

**Important**

- If the forest is operating at the Windows Server 2003 functional level, and you attempt to install Active Directory on a Windows 2000–based member server, the installation will fail. If you install Active Directory on a Windows Server 2003–based member server in order to create a new regional domain, the domain functional level is set to Windows Server 2003.

After you deploy the new Windows Server 2003 forest and the domain functional level is set in all domains, raise the domain functional level and then the forest functional level to Windows Server 2003. This enables you to take advantage of all Windows Server 2003 forest- and domain-level features. Thereafter, all new domains that you create are set at the Windows Server 2003 domain functional level.

# Additional Resources for Enabling Advanced Windows Server 2003 Active Directory Features

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information and tools related to this chapter.

**Related Information**

# Overview of Deploying the Forest Root Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The first domain that you create in your Active Directoryforest is automatically designated as the forest root domain. The forest root domain provides the foundation for your Active Directory forest infrastructure. You must create the forest root domain before you create regional domains or upgrade other Microsoft® Windows NT® 4.0 domains in order to join them to an existing forest. In addition, services that are running on forest root domain controllers, such as the Kerberos version 5 authentication protocol, must be highly available to ensure that users maintain access to resources throughout the forest.

Before you deploy your forest root domain, your design team must design your Active Directory logical structure and site topology and plan your hardware requirements for domain controllers that are running the Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; and Windows® Server 2003, Datacenter Edition operating systems. During the forest root domain deployment, you begin to implement the Active Directory design that your design team has provided, including the DNS infrastructure that Active Directory requires.

The forest owner is responsible for deploying the forest root domain. After the forest root domain deployment is complete, deploy the remainder of your Active Directory forest as specified by your Active Directory design. The tasks that you must perform to deploy the remainder of your Active Directory forest depend on whether your design specifies a single domain forest or a multiple domain forest.

- **Single domain forest.** If your Active Directory forest design requires only a single domain, then the forest root domain will also contain all your users, groups, and resources. To deploy this model, you can create an organizational unit (OU) structure after the forest root domain deployment is complete. Then you can restructure Windows NT account and resource domains into the forest root domain.

- **Multiple domain forest.** In a multiple domain design, the forest root domain can be a dedicated root used only for administration of the forest, or it can contain users, groups, and resources in addition to the forest administration accounts. Once the forest root domain is deployed, the forest owner will create one or more regional child domains to complete the Active Directory forest hierarchy. The regional domains can be created either by upgrading existing Windows NT 4.0 or Microsoft® Windows® 2000 domains or by deploying additional new domains.

For more information about upgrading Windows NT domains, see "Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory" in this book. For more information about deploying additional regional domains, see "Deploying Windows Server 2003 Regional Domains" in this book. For more information about restructuring Windows NT domains, see "Restructuring Windows NT 4.0 Domains to an Active Directory Forest" in this book.

# Process for Deploying the Forest Root Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Deploying the forest root domain involves completing the tasks that are shown in Figure 6.1. Only organizations with an existing DNS infrastructure or organizations whose DNS services are provided by an Internet service provider will configure DNS for the forest root domain. Other organizations will skip the task, allowing the Active Directory Installation Wizard to automatically create an internal root zone, which acts as the authoritative root for the organization.

**Figure 6.1 Deploying the Forest Root Domain**

# Background Information for Deploying the Forest Root Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you deploy the forest root domain, understand the importance of maintaining the availability of forest root domain controllers. Also become familiar with how you can save time during the deployment process by automating installations and by using the Active Directory Installation Wizard.

**Forest Root Domain Controller Availability**
The forest root domain has different characteristics than other domains in the forest. It is the center of Kerberos authentication referrals and the domain controllers in the forest root domain host the forest-level operations master roles, in addition to domain-level operations master roles.

Because it has a unique role in the forest, special considerations must be made to ensure forest root domain controller availability.

- Because forest root domain controllers are used for Kerberos authentication referrals, ensure that at least one forest root domain controller is always online.
- Changes to the schema require the schema master to be online.
- Changes to the domain infrastructure, including adding, removing, or renaming domains or application directory partitions, require the domain naming master to be online.

Maintain current backups of forest root domain controllers. Although corrupted data does not replicate out to other domains, maintaining current backups allows you to quickly restore a domain controller to its original state if data on the domain controller ever becomes corrupted.

For information about planning forest root domain controller placement to ensure availability, see "Designing the Site Topology" in this book.

**Automated Installations**
You can perform an unattended installation of Active Directory by supplying an answer file when you run the Active Directory Installation Wizard. The answer file options for installing Active Directory are in the DCInstall section of the Unattend.txt file. You can find instructions for creating an answer file for an Active Directory installation in the Deploy.cab file in the Support\Tools folder on the Windows Server 2003 product CD. Inside the Deploy.cab file, open Ref.chm to access the Unattend.txt file. In the left pane, expand **Unattend.txt**, and click **DCInstall**. Use Windows Explorer to extract this document. You can rename the Unattend.txt file and save it in any location. The Unattend.txt file also contains sample answer files.

You can also automate the installation of Windows Server 2003 by using Sysprep.exe or an unattended installation. For more information about automating installations of Windows Server 2003, see *Automating and Customizing Installations* in this kit.

**The Active Directory Installation Wizard**
Windows Server 2003 includes improvements to the Active Directory Installation Wizard. When you install the first domain controller in a domain, you can allow the wizard to automatically install and configure Active Directory–integrated DNS. Even if you need to manually configure some settings later, the wizard saves time and prevents errors during the initial configuration.

# Reviewing the Active Directory Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Begin your forest root domain deployment by reviewing Active Directory design information, as shown in Figure 6.2.

**Figure 6.2 Reviewing the Active Directory Design**

# Review the Active Directory Logical Structure Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Review the Active Directory logical structure design that your design team completed, including the DNS infrastructure that is planned for supporting Active Directory. If your organization has an existing DNS infrastructure, review current network diagrams and DNS domain hierarchy diagrams. Also review the existing DNS zone configuration, replication, and resource records that are used for delegation and forwarding.

Document the information that you will need to install Windows Server 2003 and to configure DNS on each domain controller in the forest root domain. For a worksheet to assist you in documenting this information, see "Domain Controller Configuration" (DSSDFR_1.doc) on the *Microsoft® Windows® Server 2003 Deployment Kit* companion CD (or see "Domain Controller DNS Configuration" on the Web at http://www.microsoft.com/reskit).

**Example: Reviewing the Active Directory Logical Structure Design for Trey Research**
The Active Directory logical structure design for Trey Research requires the deployment team to create a new dedicated forest root domain, trccorp.treyresearch.net. They will then create two regional domains:

- A new regional domain, west.trccorp.treyresearch.net.
- A regional domain, east.trccorp.treyresearch.net**,** created by upgrading an existing Windows NT 4.0 domain, and then restructuring several other existing Windows NT 4.0 domains into it.

The deployment team reviews the existing DNS infrastructure for the Trey Research business unit. Their existing DNS infrastructure provides name resolution for all internal resources, including:

- Any servers, such as Web or mail servers, residing in the perimeter network (also known as the DMZ) and are accessed by Internet users.
- Any computers, or other network devices, that reside in the private network and run a non-Windows operating system, such as UNIX or Macintosh operating systems.

**Note**

- Windows NT 4.0–based computers in the private network use Windows Internet Name Service (WINS) to provide name resolution.

Trey Research's registered DNS domain name is treyresearch.net. This DNS domain name:

- Provides DNS naming for computers that are accessed by Internet users.
- Represents the *external* DNS namespace for the business unit.
- Runs on the Berkeley Internet Name Domain (BIND) DNS servers (SEA-TREY-DNS-01 and SEA-TREY-DNS-02) that are placed in the perimeter network.

Figure 6.3 shows an example of a completed domain controller configuration worksheet, showing the TCP/IP client settings for the domain controllers planned for the Trey Research forest root domain. For each domain controller, the preferred DNS server is the local domain controller, and the alternate is the closest DNS server. Initially, however, Trey Research configures the first domain controller in the domain to use a DNS server in its parent DNS domain as its preferred DNS server. During installation of Active Directory on the first domain controller, the preferred DNS server is changed to the local domain controller. Then, after the second domain controller is online, Trey Research reconfigures the first domain controller to use the second domain controller as its alternate DNS server.

**Figure 6.3 Example of a Domain Controller Configuration Worksheet**

| Domain Controller Configuration | | | |
|---|---|---|---|
| Prepared By | Active Directory Deployment Team | Date | 01/01/03 |

| | |
|---|---|
| Forest Name | trccorp.treyresearch.net |
| Forest Owner | forest owner |
| Domain Name | trccorp.treyresearch.net |

| Domain Controller | IP Address | Mask | Preferred DNS Server | Alternate DNS Server |
|---|---|---|---|---|
| SEA-TRC-DC01 | 172.16.16.2 | 255.255.252.0 | IP - SEA-TREY-DNS-01 (temp)<br>172.16.16.3 (final) | (none)(temp)<br>172.16.16.3 (final) |
| SEA-TRC-DC02 | 172.16.16.3 | 255.255.252.0 | 172.16.16.3 | 172.16.16.2 |
| SEA-TRC-DC03 | 172.16.16.4 | 255.255.252.0 | 172.16.16.4 | 172.16.16.3 |
| NYC-TRC-DC01 | 172.16.28.8 | 255.255.252.0 | 172.16.28.8 | 172.16.16.2 |

# Review Site Topology Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Review your site topology design information, including:

- Site and subnet design.
- Site link design.

The site topology design team can provide worksheets that document the site topology information that you will need to configure the site topology for the forest.

Figure 6.4 shows an example of a completed Associating Subnets with Sites worksheet for Trey Research. The worksheet lists the sites that will be created for Trey Research and the corresponding locations and subnets to be included in each site. The Trey Research site topology design specifies that the Phoenix subnets are associated with the Seattle site.

**Figure 6.4 Example of an Associating Subnets with Sites Worksheet**

| Associating Subnets with Sites | | | |
|---|---|---|---|
| Prepared By | Site Topology Owner | Date | 1/1/03 |
| Forest Name | Trccorp.treyresearch.net | | |

| Site Candidate | Location | Active Directory Subnets |
|---|---|---|
| Seattle | Seattle<br><br>Phoenix | 172.16.16.0/22<br>172.16.24.0/22<br><br>172.16.64.0/22 |
| Boston | Boston | 172.16.36.0/22<br>172.16.40.0/22 |
| New York | New York | 172.16.28.0/22<br>172.16.32.0/22 |
| Los Angeles | Los Angeles | 172.16.136.0/22<br>172.16.92.0/22 |
| Washington DC | Washington DC | 172.16.116.0/22<br>172.16.140.0/22 |

Figure 6.5 shows an example of a completed Sites and Associated Site Links worksheet for Trey Research, including the communication links between locations.

**Figure 6.5 Example of a Sites and Associated Site Links Worksheet**

| Sites and Associated Site Links | | | |
|---|---|---|---|
| Prepared By | Site Topology Owner | Date | 1/1/03 |
| Forest Name | Trccorp.treyresearch.net | | |

| Site Names | Linked Sites | Name of the Site Link | Link Type |
|---|---|---|---|
| Seattle | LosAngeles | LAX-SEA | ISDN (128.8 Kbps) |
| Seattle | NewYork | SEA-NYC | T1 (1.544 Mbps) |
| NewYork | WashingtonDC | NYC-WDC | T1 (1.544 Mbps) |
| NewYork | Boston | NYC-BOS | ISDN (128.8 Kbps) |

# Review Hardware Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Ensure that each computer that you plan to use as a domain controller meets the hardware requirements for running Windows Server 2003. For more information about assessing the hardware requirements of domain controllers in a Windows Server 2003 domain, see "Planning Domain Controller Capacity" in this book.

# Configuring DNS for the Forest Root Domain

Updated: October 19, 2007

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To configure Domain Name System (DNS) for the forest root domain, the DNS administrator of your organization delegates the zone that matches the name of the forest root domain to the DNS servers (domain controllers) that you plan to install in the forest root domain.

**Important**

When no DNS infrastructure exists, you do not have to configure the forest root domain. To complete the next step in the deployment process, see Creating the Forest Root Domain. The remainder of this document describes the process of configuring and delegating a zone in the existing DNS internal namespace.

If you plan to implement an Active Directory domain namespace that does not match the DNS namespace, first read Disjoint Namespace, and then follow the steps in Create a Disjoint Namespace. If a disjoint namespace already exists, and you want to use a contiguous namespace, see Transition from a Disjoint Namespace to a Contiguous Namespace.

The following illustration shows when you configure DNS for the forest root domain in the forest root domain deployment process.

In preparation for the forest root domain deployment, you create a delegation for the DNS servers that will run on the domain controllers in the forest root domain. To create the delegation, you add DNS name server (NS) and host (A) resource records to the parent DNS zone.

**Note**

The delegation that occurs references the first forest root domain controller, which does not currently exist. You install and configure the DNS service on the first forest root domain controller in a subsequent step.

**To delegate the DNS zone for the forest root domain**

1. Create a name server (NS) resource record in the parent zone.

   Use the left-most portion of the forest root domain name, and the full DNS name of the domain controller, as shown in the following syntax:

   forest_root_domain IN NS domain_controller_name

2. Create a host (A) resource record in the parent zone.

   Use the full DNS name of the domain controller, as shown in the following syntax:

   domain_controller_name IN A domain_controller_ip_address

   For example, the DNS administrator for Trey Research created the following DNS resource records in the parent zone, treyresearch.net:

- trccorp in the name server (NS) SEA-TRC-DC01.trccorp.treyresearch.net
- SEA-TRC-DC01.trccorp.treyresearch.net in the 172.16.16.2 domain

# Creating the Forest Root Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The first step in creating the forest root domain is deploying the first forest root domain controller. The forest owner is responsible for deploying the forest root domain.

Figure 6.7 illustrates the process for creating the forest root domain.

**Figure 6.7 Creating the Forest Root Domain**

# Deploy the First Forest Root Domain Controller

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To deploy the first domain controller in the forest root domain, complete the following tasks:

- Install Windows Server 2003
- Install Active Directory
- Verify the Active Directory installation
- Configure the Windows Time Service
- Verify DNS server recursive name resolution

# Install Windows Server 2003 on the First Forest Root Domain Controller

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The first step in deploying the first forest root domain controller is to install Windows Server 2003 on the computer that you want to make the domain controller.

**Note**

- Before installing Windows Server 2003, ensure that DNS was never previously installed on the computer. If DNS was previously installed, configuration of the DNS resolver and forwarders might fail.

  - Insert the Windows Server 2003 operating system CD in the CD-ROM drive of the domain controller and select the option to install the operating system, or use an automated installation method. If the Windows Server 2003 media is shared on the network, run the Winnt32.exe command. Use the NTFS file system to format the partitions. Enter the computer name, static IP address, and subnet mask as specified by your design.

  - In TCP/IP Properties, configure the DNS client settings by using the information documented in the "Domain Controller Configuration" worksheet. The DNS settings are temporary and will be changed after you install Active Directory.

  - Enable Remote Desktop for Administration (formerly known as Terminal Services in Remote Administration mode) to enable administrators to log on remotely if necessary. To enable Remote Desktop for Administration, in Control Panel, double-click **System**, select the **Remote** tab, and then select **Allow users to connect remotely to this computer**.

  - Install Windows Support Tools, which are available in the \Support\Tools folder on the Windows Server 2003 operating system CD.

# Install Active Directory on the First Forest Root Domain Controller

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Install Active Directory by running the Active Directory Installation Wizard on the computer that you want to make the first forest root domain controller. The Active Directory Installation Wizard creates the Active Directory database and initializes the directory data in the database.

In addition, on the first domain controller in a domain, the wizard also:

- Prompts the administrator to verify the installation and configuration of the DNS Server service.
- Configures DNS recursive name resolution by forwarding, by adding the IP addresses of the existing entries for **Preferred DNS server** and **Alternate DNS server** to the list of DNS servers on the **Forwarders** tab of the **Properties** sheet in the DNS snap-in for the domain controller.

  **Notes**

  - If you want to set different forwarders, or do not want to enable forwarding, you can change this setting manually by using the DNS snap-in.
  - If your domain controller is multihomed, forwarding is not configured automatically.
  - For manual configuration instructions, see "Verify DNS Server Recursive Name Resolution on the First Forest Root Domain Controller" later in this chapter.
- Configures DNS recursive name resolution by root hints, by adding the root hints that are configured on the **Preferred DNS server**
- Configures the **Preferred DNS server** to point to the DNS server that is running locally on the domain controller, and configures the **Alternate DNS server** to point to the DNS server that is connected through the minimum number of network segments.
- Creates two application directory partitions that are used by DNS. The DomainDnsZones application directory partition holds domain-wide DNS data, and the ForestDnsZones application directory partition holds forest-wide DNS data.

**To install Active Directory on the first forest root domain controller**

1. Log on to the Windows Server 2003–based member server.
2. At the command line, type:

   **dcpromo**

   – Or –

   Open **Administrative Tools** and click **Configure Your Server Wizard**. Select **Domain Controller (Active Directory)** to configure your domain controller. After the Configure Your Server Wizard finishes, the Active Directory Installation Wizard begins.

   Use Table 6.1 to complete the Active Directory Installation Wizard. Table 6.1 includes the specific actions taken by Trey Research as they deploy their first forest root domain controller, SEA-TRC-DC01.

   **Table 6.1 Information to Install Active Directory on the First Forest Root Domain Controller**

| Wizard Page or Dialog Box | Action | Example |
|---|---|---|
| Domain Controller Type | Select **Domain controller for a new domain** | |
| Create New Domain | Select **Domain in a new forest** | |
| New Domain Name | Type the full DNS name of the domain. | trccorp.treyresearch.net |
| NetBIOS Domain Name | Confirm or type the NetBIOS name. | TRCCORP |
| Database and Log Folders | Type the folder locations specified by your design. | Database folder: C:\WINNT\NTDS<br><br>Log folder: D:\Logs |
| Shared System Volume | Confirm or type the location specified by your design. | C:\WINNT\SYSVOL |
| DNS Registration Diagnostics | For organizations with an existing DNS infrastructure, a message will indicate that the wizard cannot contact the DNS server with which this DC will be registered. This is because the pre-created delegation record points to the local computer and DNS has not been installed on the domain controller at this point.<br><br>Select **Install and configure the DNS server on this computer and set this computer to use this DNS server as its preferred DNS server**. | Before running the Active Directory Installation Wizard, the Trey Research deployment team set the Preferred DNS server to 172.16.24.4, which is the IP address of a DNS server in the parent zone, treyresearch.net. This address will be automatically moved to the list of forwarders, and Preferred DNS server will be set to the local host. |
| Permissions | Select the security level specified by your design:<br>• Permissions compatible with pre-Windows 2000 server operating systems<br>• Permissions compatible only with Windows 2000 or Windows Server 2003 operating systems | Because Trey Research currently has server programs running on Windows NT 4.0 servers, they selected **Permissions compatible with pre-Windows 2000 server operating systems**. |
| Directory Service Restore Mode Administration Password | In the **Password** and **Confirm password** boxes, type any strong password. | |

For more information about installing and removing Active Directory, see the *Active Directory Collection* of the *Windows Server 2003 Technical Reference* (or see the Active Directory Collection on the Web at http://www.microsoft.com/reskit).

# Verify the Active Directory Installation on the First Forest Root Domain Controller

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To verify the Active Directory installation on the first forest root domain controller:

1. Review the Windows Server 2003 event log and resolve any errors.

2. At the command line, run Dcdiag.exe and Netdiag.exe and resolve any errors that are reported.

   For more information about tests you can perform by using Dcdiag and Netdiag, see the Active Directory link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources. Search under "Administration and Configuration Guides" and download the *Active Directory Operations Guide*.

3. Run Task Manager and verify that the processor and memory system resources are within acceptable limits.

4. Open the DNS snap-in, navigate to **Forward Lookup Zones**, and verify that the zones _msdcs.*forest_root_domain_name* and *forest_root_domain_name* were created. Expand the *forest_root_domain_name* node and verify that **DomainDnsZones** and **ForestDnsZones** were created.

# Configure the Windows Time Service

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When deploying the forest root domain, it is important to correctly configure the Windows Time Service to meet your organization's needs. The Windows Time Service provides time synchronization to peers and clients, ensuring consistent time throughout an enterprise.

By default, the first domain controller deployed holds the primary domain controller (PDC) emulator operations master role. Set the PDC emulator to synchronize from a valid Network Time Protocol (NTP) source. If no source is configured, the service will log a message to the event log, and use the local clock when providing time to clients.

Follow these best practices for configuring the time source on the forest-root PDC emulator, in this order of preference:

- Install a hardware clock, such as a radio or GPS device, as the source for the PDC. There are many consumer and enterprise devices that use the Network Time Protocol (NTP), allowing you to install the device on an internal network for usage with the PDC.

- Configure the Windows Time service to synchronize with an external time server. External time servers allow users to synchronize computer clocks by means of dial-up, network, and radio links.

  The Microsoft time server (time.windows.com) uses NIST, the National Institute of Standards and Technology, located in Boulder, Colorado, as its external time provider. NIST provides the Automated Computer Time Service (ACTS), which can set a computer clock with an uncertainty of less than 10 milliseconds. The U.S. Naval Observatory (USNO) Time Service Department in Washington D.C. is another source for accurate time synchronization in the United States. Many other sites exist throughout the world that can be used for time synchronization. To find them, search for "time synchronization" on the Internet.

| **Note** |
| --- |
| Because synchronization with an external time source is not authenticated, it is less secure. |

Repeat this operation if you transfer or seize the PDC emulator operations master role to another domain controller in the forest root domain.

**To configure the Windows Time Service on first forest root domain controller**

1. Log on to the domain controller.

2. Type the following command to display the time difference between the local computer and a target computer, and then press ENTER:

   **w32tm /stripchart /computer:***target***/samples:***1***/dataonly**

   Where *target* specifies the DNS name or IP address of the NTP server that you are comparing the local computer's time against, such as time.windows.com and *1* specifies the number of time samples that will be returned from the target computer. In this example, only one sample will be returned to test basic NTP communication.

3. Open UDP port 123 for outgoing traffic if needed.

4. Open UDP port 123 (or a different port you have selected) for incoming NTP traffic.

5. Type the following command to configure the PDC emulator and then press ENTER:

   **w32tm /config /manualpeerlist:***peers* **/syncfromflags:manual /reliable:yes /update**

   *Peers* specifies the list of DNS names and/or IP addresses of the NTP time source that the PDC emulator synchronizes

from. For example, you can specify time.windows.com. When specifying multiple peers, use a space as the delimiter and enclose them in quotation marks. For example, if you wanted to configure time synchronization with a server named Ntp in the contoso.com domain and a server named Time in the fabrikam.com domain, you would enter the following command: **w32tm /config /update /manualpeerlist:"Ntp.contoso.com Time.fabrikam.com time.windows.com" /syncfromflags:manual /update**.

**Note**

- When specifying a manual peer, do not use the DNS name or IP address of a computer that uses the forest root domain controller as its source for time, such as another domain controller in the forest. The time service will not operate correctly if there are cycles in the time source configuration.

For more information about configuring and deploying the Windows Time Service, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

# Verify DNS Server Recursive Name Resolution on the First Forest Root Domain Controller

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

DNS server recursive name resolution is configured automatically during the Active Directory installation process, as described in "Install Active Directory on the Second Domain Controller" earlier in this chapter. If your design specifies a different configuration, you can use the DNS snap-in or Dnscmd.exe to modify these settings.

**To verify DNS server recursive name resolution on the first forest root domain controller**

- Use the DNS snap-in to verify DNS server recursive name resolution for the method used in your organization based on the information in Table 6.2.

**Table 6.2 Information to Verify DNS Server Recursive Name Resolution**

| Method | Configuration |
|---|---|
| Recursive name resolution by root hints | Root hints are the recommended method to use for recursive name resolution in a Windows Server 2003 environment.<br><br>No additional configuration is necessary. When the DNS server specified as the Preferred DNS server during the installation process is properly configured, the root hints are automatically configured. To verify the root hints by using the DNS snap-in:<br><br>In the console tree, right-click the domain controller name, and then click **Properties**.<br><br>In the **Properties** sheet for the domain controller, view the root hints on the **Root Hints** tab. |
| Recursive name resolution by forwarding | Only use Forwarders if that is what your organization's design specifies. Root hints are the recommended method to use for recursive name resolution in a Windows Server 2003 environment.<br><br>Forward unresolved queries to specified DNS servers. To verify forwarding by using the DNS snap-in:<br><br>In the console tree, right-click the domain controller name, and then click **Properties**.<br><br>On the **Forwarders** tab, in the selected domain's **Forwarders** list, verify that the IP addresses match those specified by your design. |
| No existing DNS infrastructure | No additional configuration is necessary.<br><br>In this environment, if you want to configure internal DNS servers to resolve queries for external names, then configure this DNS server to forward unresolved queries to an external server, such as one in your perimeter network, or one hosted by an Internet service provider. |

# Deploy the Second Domain Controller in the Same Site

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you deploy the first forest root domain controller, deploy the second forest root domain controller in the same site, according to the design provided by your design team. To deploy the second forest root domain controller, complete the following tasks:

- Install Windows Server 2003
- Install Active Directory
- Install DNS Server service
- Verify the Active Directory installation

# Install Windows Server 2003 on the Second Domain Controller

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The first step in deploying the second forest root domain controller is to install Windows Server 2003 on the computer that you want to make the second domain controller.

**Note**

- Before installing Windows Server 2003, ensure that DNS was not previously installed.

  - Insert the Windows Server 2003 operating system CD in the CD-ROM drive of the domain controller and select the option to install the operating system, or use an automated installation method. If the Windows Server 2003 media is shared on the network, run the Winnt32.exe command. Use NTFS to format the partitions. Enter the computer name, static IP address, and subnet mask as specified by your design.

  - Configure the DNS client settings by using the information documented in the "Domain Controller Configuration" worksheet (DSSDFR_1.doc).

  - Enable Remote Desktop for Administration (formerly known as Terminal Services in Remote Administration mode) to enable administrators to log on remotely if necessary. To enable Remote Desktop for Administration, in Control Panel, double-click **System**, select the **Remote** tab, and then select **Allow users to connect remotely to this computer**.

  - Install Windows Support Tools, which are available in the \Support\Tools folder on the Windows Server 2003 operating system CD.

# Install Active Directory on the Second Domain Controller

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Install Active Directory on the computer that you want to make the second forest root domain controller by running the Active Directory Installation Wizard.

The Active Directory Installation Wizard:

- Creates the Active Directory database.
- Initializes the directory data in the database.

On domain controllers other than the first domain controller in a domain, installation of DNS is not automatic.

To deploy an additional domain controller in an existing domain, you can either let replication copy domain information from an existing source domain controller over the network or you can use the install from media feature, new in Windows Server 2003. Install from media allows you to pre-populate Active Directory with System State data backed up from an existing domain controller. This backup can be present on local CD, DVD, or hard disk partition. Installing from media drastically reduces the time required to install directory information by reducing the amount of data that is replicated over the network. Installing from media is most beneficial in environments with very large domains or for installing new domain controllers that are connected by a slow network link. To use the install from media feature, you first create a backup of System State from the existing domain controller, and then restore it to the new domain controller by using the **Restore to: Alternate location** option.

**To install Active Directory on the second domain controller**

1. Log on to the Windows Server 2003–based member server.
2. If you want to copy domain information from restored backup files, at the command line, type:

   **dcpromo /adv**

   – or –

   If you want to copy domain information over the network, either type **dcpromo** (without the /adv switch) or open **Administrative Tools**, click **Configure Your Server Wizard**, andselect **Domain Controller (Active Directory)** to configure your domain controller. After the Configure Your Server Wizard finishes, the Active Directory Installation Wizard begins.
3. Use Table 6.3 to help you complete the Active Directory Installation Wizard. Table 6.3 also includes the specific actions taken by Trey Research as they deployed their second forest root domain controller, SEA-TRC-DC02.

   **Table 6.3 Information to Install Active Directory on the Second Forest Root Domain Controller**

| Wizard Page or Dialog Box | Action | Example |
|---|---|---|
| Domain Controller Type | Select **Additional domain controller for an existing domain** | |

| | | |
|---|---|---|
| Copying Domain Information | (This dialog box appears only when you started the Active Directory Installation Wizard by typing dcpromo with the /adv switch at the command line or used the Configure Your Server Wizard.)<br><br>Select either:<br><br>● Over the network from a domain controller<br><br>● From these restored backup files | Trey Research is copying from the first TRCCORP domain controller, SEA-TRC-DC01,which is in the same location as the new one, so they selected **Over the network** to copy the information in the shortest time. |
| Global Catalog | (This dialog box appears only when **From these restored backup files** was selected, if the domain controller that you backed up was a global catalog server.)<br><br>Specify whether this domain controller should be configured as a global catalog server. | |
| Network Credentials | In the **User name** box, type a user account that has sufficient rights to add a domain controller, typically a member of Domain Admins.<br><br>In the **Password** box, type the password of the user account. | |
| Additional Domain Controller | (This dialog box appears only when **Over the network** was selected.)<br><br>Confirm or type the full DNS name of the forest root domain. | trccorp.treyresearch.net |
| Database and Log Folders | Type the folder locations specified by your design. | Database folder: C:\WINNT\NTDS<br><br>Log folder: D:\Logs |
| Shared System Volume | Confirm or type the location specified by your design. | C:\WINNT\SYSVOL |
| Directory Service Restore Mode Administration Password | In the **Password and Confirm password** boxes, type any strong password. | |

# Install DNS Server on the Second Domain Controller

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After Active Directory installation has finished and the computer has restarted, install DNS on the second Windows Server 2003–based domain controller that is added to the domain.

**To install DNS on additional domain controllers by using the Windows Components Wizard**

1. Click **Start**, point to **Settings**, and click **Control Panel**.
2. Double-click **Add or Remove Programs**, and then click **Add/Remove Windows Components**.
3. In **Components**, select the **Networking Services** check box, and then click **Details**.
4. In **Subcomponents of Networking Services**, select the **Domain Name System (DNS)** checkbox, click **OK**, and then click **Next**.
5. If prompted, in **Copy files from**, type the full path to the distribution files and then click **OK**. The required files will be copied to your hard disk.

# Verify the Active Directory Installation on the Second Domain Controller

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Use the same steps as shown in the procedure for the first domain controller, but instead of verifying that **DomainDnsZones** and **ForestDnsZones** were created, use the repadmin /showreps command to verify that the **ForestDnsZones** and **DomainDnsZones** application directory partitions are replicated successfully. Use the DNS snap-in to verify that DNS server recursive name resolution is configured according to the method used by your organization.

# Reconfigure the DNS Service

Updated: October 19, 2007

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Reconfigure the DNS service to account for the addition of the second domain controller in the forest root domain. You can also use these procedures as you deploy additional domain controllers that are running the DNS service. To reconfigure the DNS service:

- Enable Aging and Scavenging for DNS
- Configure the DNS Client Settings of the First and Subsequent Domain Controllers
- Update the DNS Delegation

# Enable Aging and Scavenging for DNS

Updated: October 19, 2007

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Enable aging and scavenging on two Windows Server 2003–based domain controllers running the DNS Server service per domain, to allow automatic cleanup and removal of stale resource records (RRs), which can accumulate in zone data over time.

With dynamic update, RRs are automatically added to zones when computers start on the network. However, in some cases, they are not automatically removed when computers leave the network. For example, if a computer registers its own host (A) RR at startup and is later improperly disconnected from the network, its host (A) RR might not be deleted. If your network has mobile users and computers, this situation can occur frequently.

If left unmanaged, the presence of stale RRs in zone data might cause problems including:

- If a large number of stale RRs remain in server zones, they can eventually take up server disk space and cause unnecessarily long zone transfers.
- DNS servers loading zones with stale RRs might use outdated information to answer client queries, potentially causing the clients to experience name resolution problems on the network.
- The accumulation of stale RRs at the DNS server can degrade its performance and responsiveness.

**Caution**

- By default, the aging and scavenging mechanism for the DNS Server service is disabled. Enable aging and scavenging only after you understand all parameters. Otherwise, the server could be accidentally configured to delete resource records that should not be deleted. If a resource record is accidentally deleted, not only will users fail to resolve queries for that resource record, but any user can create the resource record and take ownership of it, even on zones configured for secure dynamic update.
- For more information about how to configure aging and scavenging, see "Understanding aging and scavenging" in Help and Support Center for Windows Server 2003.

To enable the aging and scavenging features, perform the following steps to configure the applicable server and its Active Directory–integrated zones:

- Enable aging and scavenging at the server. These settings determine the effect of zone-level properties for any Active Directory–integrated zones loaded at the server.
- Enable aging and scavenging for selected zones at the DNS server. When zone-specific properties are set for a selected zone, these settings apply only to the applicable zone and its resource records. Unless these zone-level properties are otherwise configured, they inherit their default settings from comparable settings maintained in the DNS server aging/scavenging properties.

**To set aging and scavenging properties for the DNS server**

1. Log on to the computer that is running the DNS Server service with an account that is a member of the local Administrators group.
2. In the DNS console tree, right-click the applicable DNS server, and then click **Set Aging/Scavenging for all zones**.
3. Select the **Scavenge stale resource records** check box.
4. Modify other aging and scavenging properties as needed.

**To set aging and scavenging properties for a zone**

1. Log on to the computer that is running the DNS Server service with an account that is a member of the local Administrators group.

2. In the DNS console tree, right-click the applicable zone, then click **Properties**.

3. On the **General** tab, click **Aging**, and then select the **Scavenge stale resource records** check box.

4. Modify other aging and scavenging properties as needed.

# Configure the Domain Name System (DNS) Client Settings of the First and Subsequent Domain Controllers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you have deployed an additional domain controller, modify the DNS client settings on the first forest root domain controller. Because no other domain controllers were running when you deployed the first forest root domain controller, modify the DNS client settings on the first forest root domain controller to include the additional domain controller. As you deploy more domain controllers, you might also need to modify the Alternate DNS server setting specified on existing domain controllers to ensure that this setting points to the DNS server that is connected through the minimum number of network segments.

**To configure the DNS client settings on previously installed domain controllers**

1. Open **Network Connections**, double-click your **Local Area Connection**, click **Properties**, click **Internet Protocol (TCP/IP)** to highlight it, and then click **Properties**.

2. For the **Preferred DNS server**, type the IP address of the DNS server that is running locally on the domain controller (local host).

3. Determine whether a newly installed domain controller is now closer to this domain controller than the domain controller that you originally specified as the **Alternate DNS server**. If it is, for **Alternate DNS server**, type the IP address of the newly installed domain controller.

# Update the DNS Delegation

Updated: October 19, 2007

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you install the DNS Server service on new domain controllers, update the DNS delegation for the forest root domain on a DNS server that is authoritative for the parent zone.

**To update the DNS delegation records for the additional domain controller**

1. Create a name server (NS) resource record in the parent zone. Use the left-most portion of the forest root domain name, and the full DNS name of the additional domain controller.

   **forest_root_domain** IN NS **additional_domain_controller_name**

2. Create a host address (A) resource record in the parent zone. Use the full DNS name of the domain controller.

   **additional_domain_controller_name** IN A **additional_domain_controller_ip_address**

   For example, the DNS administrator for Trey Research created the following DNS resource records in the parent zone, treyresearch.net:

   - **trccorp** IN NS **SEA-TRC-DC02.trccorp.treyresearch.net**
   - **SEA-TRC-DC02.trccorp.treyresearch.net** IN A **172.16.16.3**

# Transition Namespaces

Updated: May 3, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you decide to modify your network name resolution infrastructure after you read Disjoint Namespace, you must perform several steps. Whether you want to create a disjoint namespace or transition from a disjoint namespace to a contiguous namespace, you must configure the following components appropriately:

- Primary Domain Name System (DNS) suffixes
- Service principal names (SPNs)
- Group Policy objects (GPOs)
- Permissions to Active Directory objects

The primary differences between implementing a disjoint namespace and transitioning to a contiguous namespace are as follows:

- When you transition to a contiguous namespace from a disjoint namespace, you must ensure that the Active Directory domain name and the DNS namespace are identical.
- When you create a disjoint namespace, you must create different Active Directory and DNS namespaces.

If you create a disjoint namespace accidentally, you can reverse the erroneous steps. The process for doing so is similar to transitioning a namespace, but not as complex.

For more information about working with disjoint namespaces successfully, see the following documents:

- Create a Disjoint Namespace
- Reverse an Accidentally Created Disjoint Namespace
- Transition from a Disjoint Namespace to a Contiguous Namespace

Disjoint Namespace

# Transition from a Disjoint Namespace to a Contiguous Namespace

Updated: October 19, 2007

Applies To: Windows Server 2003, Windows Server 2003 with SP2

If your network uses a disjoint namespace and you decide to change to a contiguous namespace, there are several tasks to complete:

- Configure member computers to use a primary Domain Name System (DNS) suffix that is the same as the Active Directory domain name.
- Remove any Group Policy objects (GPOs) that specify disjoint namespaces.
- Clear DNS suffixes from the client search lists that no longer apply.
- Remove no longer needed permissions for Active Directory.

The actual number of tasks that are required for the change depends on how much configuration was accomplished to make the disjoint namespace work. For example, if custom DNS suffix search lists were never created, there is obviously no need to remove them.

| **Note** |
| --- |
| If any of your servers have service principal names (SPNs) that were manually configured, you may have to modify them. For instructions on how to manually configure SPNs, see Setspn Overview. |

**Configure domain member computers to use the same DNS suffix as the Active Directory domain**

You can configure the DNS client's primary DNS suffix by using Group Policy, manually through **System Properties** on each computer, or through a registry modification. These options are described in the following sections.

**Configure primary DNS suffixes by using a GPO**

On Windows Server 2003 servers, use a GPO to configure the primary DNS suffix for each member computer. Set the DNS Client policy for **Primary DNS Suffix** to the desired primary DNS suffix to match DNS suffix of the Active Directory domain name. The **Primary DNS Suffix** setting is located in the following GPO path: **Computer Configuration\Administrative Templates\Network\DNS Client**.

| **Note** |
| --- |
| For more information about managing Group Policy, see Group Policy Object Editor Tools and Settings (http://go.microsoft.com/fwlink/?LinkId=102368) and Enterprise Management with the Group Policy Management Console (http://go.microsoft.com/fwlink/?LinkId=29909) |

**Configure the primary DNS suffix by using System Properties**

To change from a disjoint namespace that is created on a local computer running Microsoft Windows 2000, Windows XP, or Windows Vista, complete the following procedure.

Membership in **Administrators**, or equivalent, is the minimum required to complete this procedure. Review details about using the appropriate accounts and group memberships at Local and Domain Default Groups (http://go.microsoft.com/fwlink/?LinkId=83477).

**To configure the primary DNS suffix by using System Properties**

1. Open the **System Properties** dialog box:
    a. To open the **System Properties** dialog box in Windows 2000 or Windows XP, click **Start**, click **Run**, type **sysdm.cpl**, and then press ENTER.

b. To open the **System Properties** dialog box in Windows Vista, click **Start**, in **Start Search** type **sysdm.cpl**, and then press ENTER.

2. On the **Computer Name** tab, click **Change**, and then click **More**.
3. Verify that the value in **Primary DNS suffix of this computer** is the same as the Active Directory domain name.
4. Verify that the **Change primary DNS suffix when domain membership changes** check box is selected, and then click **OK** twice.
5. Click **OK** to confirm that the computer must be restarted, and then click **Close**.
6. When you are prompted to restart your computer, click **Restart Now**.

   If you choose to restart your computer later, any changes that you make will take effect at that time.

**Change the primary DNS Suffix in the Registry**

If you use a script (or directly modify the registry) to configure the Primary DNS suffix, there are two values to modify: **Domain** and **SyncDomainWithMembership**. Both of these values are in the **Parameters** key under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip**. To create a contiguous namespace, enable **SyncDomainWithMembership** by setting its value to **1**, and then enter the primary DNS suffix that is identical to the Active Directory domain for the **Domain** value. If the **SyncDomainWithMembership** value does not exist, you can create it as a **REGDWORD**. For more information about registry scripts, see article 264584 in the Microsoft Knowledge base (http://go.microsoft.com/fwlink/?LinkId=102370). If you configure these values in the registry, be sure to restart the computers to have the settings take effect.

**Remove unnecessary entries in the DNS suffix search list**

When you change from a disjoint namespace to a contiguous namespace, there are likely to be several entries in the DNS suffix search list that clients no longer need. There may also be some different values that should be added to the DNS suffix search list. The following sections describe the three main methods for modifying the DNS suffix search list, which use:

- Group Policy
- Network Connections
- The registry

**Changing the DNS suffix search list with a GPO**

On Windows Server 2003 servers, remove any GPOs or settings that were used to create custom DNS suffix search lists that applied to the disjoint namespace. Remove the **DNS Suffix Search List** or configure it with the correct DNS suffixes for the contiguous namespace. The GPO path for the **DNS Suffix Search List** policy setting is Computer Configuration\Administrative Templates\Network\DNS Client.

**Changing the DNS suffix search list by using Network Connections**

To change the DNS suffix search list by using the graphical user interface (GUI) on Windows 2000, Windows XP, or Windows Vista, complete the following procedure.

Membership in **Administrators**, or equivalent, is the minimum required to complete this procedure. Review details about using the appropriate accounts and group memberships at Local and Domain Default Groups (http://go.microsoft.com/fwlink/?LinkId=83477).

**To change the DNS suffix search list by using Network Connections**

1. Open Network Connections.

   a. To open the **Network Connections** dialog box in Windows 2000 or Windows XP, click **Start**, click **Run**, type **ncpa.cpl**, and then press ENTER.

   b. To open the **Network Connections** dialog box in Windows Vista, click **Start**, type **ncpa.cpl** in **Start Search**, and then press ENTER.

2. Right-click the icon that represents the computer's local network connection (**Local Area Connection**, by default), and then click **Properties**.

3. In **This connection uses the following items**, select **Internet Protocol (TCP/IP)**, and then click **Properties**.

4. Click **Advanced**.

5. On the **DNS** tab, click **Append these DNS suffixes (in order)**,and then click **Add**. Type the first DNS suffix that you want the client to use when it searches for single-label names (names that do not have DNS suffixes), and then click **Add**. Repeat this step for each successive DNS suffix that you want clients to use when they try to resolve a name.

   | **Note** |
   | --- |
   | As an alternative, you can select **Append primary and connection specific DNS suffixes** and, as an option, also select **Append parent suffixes of the primary DNS suffix**, assuming that there is no longer a need for a custom list that includes other domains. |

6. Click **OK** twice to confirm your changes.

7. Close the **Local Area Connection Properties** and the **Network Connections** dialog boxes.

**Changing the DNS suffix search list in the registry**

If you want to use a script (or directly modify the registry) to configure the DNS suffix search list, you can modify the **SearchList** value that is located in the **Parameters** key under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip**. For more information about registry scripts, see article 264584 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkId=102370) .

**Remove no-longer-needed DNS suffixes from Active Directory**

To remove permissions that may have been added to grant client computers permission to modify their primary DNS suffixes in Active Directory, complete the following procedure.

| **Note** |
| --- |
| The ADSI Edit tool is included when you install Windows Server 2003 Support Tools from the product CD or from the Microsoft Download Center (http://go.microsoft.com/fwlink/?LinkId=100114). For more information about how to install Windows Support Tools from the product CD, see Install Windows Support Tools (http://go.microsoft.com/fwlink/?LinkId=62270). |

Membership in **Domain Admins**, or equivalent, is the minimum required to complete this procedure. Review details about using the appropriate accounts and group memberships at Local and Domain Default Groups (http://go.microsoft.com/fwlink/?LinkId=83477).

**To remove no-longer-needed DNS suffixes from Active Directory**

1. On any domain controller in the Active Directory domain, click **Start**, click **Run**, type **adsiedit.msc**, and then press ENTER.

   | **Note** |
   | --- |
   | If you recently installed the Support Tools to the default location, you may have to type **C:\Program Files\Support Tools\ADSIEdit.msc**, and then press ENTER. If you did not install the Support Tools to the default location, use the file path to which the tools were installed. |

2. Expand the **Domain Naming Context (NC)** to expose the directory partition that relates to the Active Directory domain for which you want to allow a disjoint namespace.

3. Right-click the Active Directory domain partition, and then click **Properties**. For example, DC=fabrikam,DC=com is the domain partition for Fabrikam.com.

4. In **Attributes**, locate and click the **msDS-AllowedDNSSuffixes** attribute, and then click **Edit**.

5. If there are any DNS suffixes entered in **Values**, select each one separately, and then click **Remove**.

6. When all the unnecessary DNS suffixes have been removed, click **OK** on the two open dialog boxes to confirm your changes.

7. Close ADSI Edit.

**Remove no-longer-needed permissions for Windows 2000 computers**

If Active Directory was modified to allow member computers or domain controllers running Windows 2000 to update the **dNSHostName** and **servicePrincipleName** attributes of their Active Directory computer accounts, you can revert those changes by completing the following procedure.

Membership in **Domain Admins**, or equivalent, is the minimum required to complete this procedure. Review details about using the appropriate accounts and group memberships at Local and Domain Default Groups (http://go.microsoft.com/fwlink/?LinkId=83477).

**To remove no-longer-needed permissions for Windows 2000 computers**

1. Open Active Directory Users and Computers. To open Active Directory Users and Computers, click **Start**, click **Run**, type **dsa.msc**, and then press ENTER.
2. Click **View**, and then ensure that the **Advanced Features** check box is selected. If it is not selected, click **Advanced Features**. If the domain to which you want to allow a disjoint namespace does not appear in the console, do the following:
    a. In the console tree, right-click **Active Directory Users and Computers**, and then click **Connect to Domain**.
    b. In the **Domain** box, type the name of the Active Directory domain to which you want to allow the disjoint namespace (or use the **Browse** button to locate it), and then click **OK**.
3. In the console tree, right-click the object that represents the domain to which you want to allow a disjoint namespace, and then click **Properties**.
4. Right-click the domain, and then click **Properties**.
5. On the **Security** tab, click **Advanced**.
6. On the **Permissions** tab, click **Add**.
7. In the **Enter the object name to select** box, type **self**, and then click **OK**.
8. Configure the **Apply onto** box for **Computer objects**.
9. At the bottom of the **Permissions** box, ensure that the **Allow** check boxes that correspond to the **Validated write to DNS host name** and **Validated write to service principal name** permissions are cleared, and then click **OK** on the three open dialog boxes to confirm your changes.
10. Close Active Directory Users and Computers.

# Reverse an Accidentally Created Disjoint Namespace

Updated: October 19, 2007

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An administrator can configure a computer to be in a disjoint namespace accidentally in the either of the following ways:

- The local administrator can clear the **Change primary DNS suffix** policy setting when domain membership changes.
- On servers running Windows Server 2003, a domain or enterprise administrator can add a Domain Name System (DNS) domain name to the **Primary DNS Suffix** policy setting on the DNS client. This policy setting overrides the **Change primary DNS suffix when domain membership changes** policy setting on DNS clients.

The following sections describe how to reverse a disjoint namespace that an administrator accidentally created.

**Reverse a locally configured disjoint namespace**
Membership in **Administrators**, or equivalent, is the minimum required to complete this procedure. Review details about using the appropriate accounts and group memberships at Local and Domain Default Groups (http://go.microsoft.com/fwlink/?LinkId=83477).

To reverse a disjoint namespace that an administrator created on a local computer running the Microsoft Windows 2000, Windows XP, or Windows Vista operating systems, perform the following steps:

**Reverse a locally configured disjoint namespace**

1. Open the **System Properties** dialog box.
   a. To open the **System Properties** dialog box in Windows 2000 or Windows XP, click **Start**, click **Run**, type **sysdm.cpl**, and then press ENTER.
   b. To open System Properties using Windows Vista, click **Start**, in **Start Search** type **sysdm.cpl**, and then press ENTER.
2. On the **Computer Name** tab, click **Change**, and then click **More**.
3. Verify that the value in **Primary DNS suffix of this computer** is the same as the Active Directory domain name.
4. Verify that the **Change primary DNS suffix when domain membership changes** check box is selected, and then click **OK** twice.
5. Click **OK** to confirm that the computer must be restarted, and then click **Close**.
6. When you are prompted to restart your computer, click **Restart Now**.

   If you choose to restart your computer later, any changes that you made will take effect at that time.

**Reverse a disjoint namespace that was created using Group Policy**
Domain controllers can use Group Policy to deploy a primary DNS suffix to computers that are members of the domain. The Group Policy object (GPO) path for the **Primary DNS Suffix** policy setting is Computer Configuration\Administrative Templates\System\DNS Client.

To reverse a disjoint namespace that an administrator created using Group Policy, remove or revise the GPO that implements the **Primary DNS Suffix** policy setting. To determine which policy settings are implemented, you can use the Group Policy Results tool (Gpresult.exe) from the DNS client. For more information about Gpresult, see article 321709 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkId=102289). You can use the Group Policy Management Console (GPMC) to determine which GPO implements the policy. For more information, see GPMC How To (http://go.microsoft.com/fwlink/?LinkID=102282).

**Note**

The **Primary DNS Suffix** policy setting does not apply to Windows 2000-based domain controllers. If you are running only Windows 2000-based domain controllers, you must manually modify the namespace of those computers. For more information, see Primary DNS Suffix (http://go.microsoft.com/fwlink/?LinkId=102283).

# Create a Disjoint Namespace

Updated: October 19, 2007

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you decide to create a disjoint namespace on your network, first read about the advantages and disadvantages of doing so that are discussed in Disjoint Namespace. To create the disjoint namespace, you perform the following tasks:

1. Create appropriate DNS forward lookup zones
2. Configure different primary DNS suffixes
3. Enable computers to register disjoint names
4. Update the DNS suffix search ist

Although you do not have to complete these tasks before you deploy Active Directory, you must complete them for the disjoint namespace to function properly or to receive support from Microsoft for problems with the disjoint namespace.

| **Note** |
| --- |
| If there are manually configured service principal names (SPNs) on any of your servers, they may require modification. For instructions on how to manually configure SPNs, see Setspn Overview. |

The following sections describe the tasks that you must complete to create a working disjoint namespace.

**Create appropriate DNS forward lookup zones**
On a DNS server for the domain, you must add the appropriate forward lookup zone for each primary DNS suffix. For information about adding a forward lookup zone to Windows 2000 Server, see article 308201 in the Microsoft Knowledge Base (http://support.microsoft.com/kb/308201). For information about adding a forward lookup zone using a Windows Server 2003–based computer, see article 323445 in the Microsoft Knowledge Base (http://support.microsoft.com/kb/323445).

**Configure different primary DNS suffixes**
You can configure the **Primary DNS Suffix** policy setting on the DNS client by using Group Policy, by manually changing the settings in the **System Properties** dialog box on each computer, or by modifying the registry on each computer. The following sections describe these options.

**Configure primary DNS suffixes by using a GPO**
On Windows Server 2003–based servers, you use a Group Policy object (GPO) to configure the primary DNS suffix for each member computer. You set the **Primary DNS Suffix** policy setting to the primary DNS suffix that you want to use on the member computers that will apply this policy setting. The GPO path for the **Primary DNS Suffix** policy setting is Computer Configuration\Administrative Templates\Network\DNS Client.

| **Note** |
| --- |
| For more information about managing Group Policy, see Group Policy Object Editor Tools and Settings (http://go.microsoft.com/fwlink/?LinkId=102368) and Enterprise Management with the Group Policy Management Console (http://go.microsoft.com/fwlink/?LinkId=29909) |

**Change the primary DNS suffix by using System Properties**
Membership in **Administrators**, or equivalent, is the minimum required to complete this procedure. Review details about using the appropriate accounts and group memberships at Local and Domain Default Groups (http://go.microsoft.com/fwlink/?LinkId=83477).

To manually set the primary DNS suffix on a local computer running Windows 2000, Windows XP, or Windows Vista, complete the following procedure.

**Change the primary DNS suffix by using System Properties**

1. Open the **System Properties** dialog box.

   a. To open the **System Properties** dialog box in Windows 2000 or Windows XP, click **Start**, click **Run**, type **sysdm.cpl**, and then press ENTER.

   b. To open the **System Properties** dialog box in Windows Vista, click **Start**, in **Start Search** type **sysdm.cpl**, and then press ENTER.

2. On the **Computer Name** tab, click **Change**, and then click **More**.
3. In **Primary DNS suffix of this computer**, set the primary DNS suffix to the domain name that you want.
4. Verify that the **Change primary DNS suffix when domain membership changes** check box is cleared, and then click **OK** twice.
5. Click **OK** to confirm that the computer must be restarted, and then click **Close**.
6. When you are prompted to restart your computer, click **Restart Now**.
7. If you choose to restart the computer later, any changes that you made will take effect at that time.

**Change the primary DNS suffix by using the registry**

If you plan to use a script (or to modify the registry manually) when you configure the primary DNS suffix, you must modify the **Domain** and **SyncDomainWithMembership** values. Both of these values are in the **Parameters** key under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip**. To allow a disjoint namespace to be created, disable the **SyncDomainWithMembership** value by setting its value to **0**, and then enter the name of the primary DNS suffix that you want to use for the **Domain** value. If the **SyncDomainWithMembership** value does not exist, you can create it as a REGDWORD data type. For more information about registry scripts, see article 264584 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkId=102370). If you configure these values using a registry script or Registry Editor, you must restart the computer for the settings to take effect.

**Enable computers to register disjoint names**

By default, Active Directory does not allow you to register another domain name as the DNS suffix for a domain. If you want to use a disjoint namespace, you must modify the security settings on the **msDS-AllowedDNSSuffixes** attribute. Otherwise, the default security settings prevent member computers from registering a different namespace.

**Allow additional primary DNS suffixes**

To add the additional primary DNS suffixes to the list of allowed suffixes in Active Directory, perform the following steps.

> **Note**
>
> ADSI Edit (AdsiEdit.msc) is a Windows Server tool that you can use to view and edit raw Active Directory directory service attributes through the Active Directory Service Interfaces (ADSI) protocol. ADSI Edit is included when you install Windows Server 2003 Support Tools from the product CD or from the Microsoft Download Center. To download Windows Server 2003 Service Pack 2 32-bit Support Tools, see (http://go.microsoft.com/fwlink/?LinkId=100114). For information about how to install Windows Support Tools from the product CD, see Install Windows Support Tools (http://go.microsoft.com/fwlink/?LinkId=62270).

Membership in **Domain Admins**, or equivalent, is the minimum required to complete this procedure. Review details about using the appropriate accounts and group memberships at Local and Domain Default Groups (http://go.microsoft.com/fwlink/?LinkId=83477).

**To add the additional primary DNS suffixes to the list of allowed suffixes in Active Directory**

1. On any domain controller in the Active Directory domain, click **Start**, click **Run**, type **adsiedit.msc**, and then press ENTER.

   > **Note**
   >
   > If you recently installed Windows Support Tools to the default location, you may have to type **C:\Program Files\Support Tools\ADSIEdit.msc**, and then press ENTER. If you did not install Windows Support Tools to the default location, use the file path to which the tools were installed.

2. Expand the domain naming context (NC) to expose the directory partition that relates to the Active Directory domain for

which you want to allow a disjoint namespace.

3. Right-click the Active Directory domain partition, and then click **Properties**.

   For example, DC=fabrikam,DC=com is the domain partition for Fabrikam.com.

4. In **Attributes**, click the **msDS-AllowedDNSSuffixes** attribute, and then click **Edit**.

5. In **Value to add**, type the name of a primary DNS suffix that you want to allow.

   For example, type na.corp.fabrikam.com if you have computers that will use that primary DNS suffix, and then click **Add**. To configure multiple DNS suffixes, repeat this step for each one.

6. When you have entered all the additional DNS suffixes that you would like to allow, click **OK** twice to confirm your changes.

7. Close ADSI Edit.

If the domain has no Windows 2000–based computers, you should skip the following section and go directly to Update the DNS Suffix Search List.

**Allow Windows 2000–based computers to update attributes**

If the domain has member computers or domain controllers running Windows 2000, you must allow these computers to update the **dNSHostName** and **servicePrincipleName** attributes of their Active Directory computer accounts.

| **Note** |
| --- |
| These steps do not have to be performed if you have no Windows 2000 computers on your network. |

Membership in **Domain Admins**, or equivalent, is the minimum required to complete this procedure. Review details about using the appropriate accounts and group memberships at Local and Domain Default Groups (http://go.microsoft.com/fwlink/?LinkId=83477).

**To allow Windows 2000–based computers to update attributes**

1. Open Active Directory Users and Computers.

   To open Active Directory Users and Computers, click **Start**, click **Run**, type **dsa.msc**, and then press ENTER.

2. Click **View**, and then select the **Advanced Features** check box, if it is not already selected.

3. If the domain to which you want to allow a disjoint namespace is not in the console tree, perform the following steps:

   a. In the console tree, right-click Active Directory Users and Computers, and then click **Connect to Domain**.

   b. In **Domain**, type the name of the Active Directory domain to which you want to allow the disjoint namespace, and then click **OK**. (You can also use the **Browse** button to locate the name of the domain.)

4. In the console tree, right-click the domain to which you want to allow a disjoint namespace, and then click **Properties**.

5. On the **Security** tab, click **Advanced**.

6. On the **Permissions** tab, click **Add**.

7. In **Enter the object name to select**, type **self**, and then click **OK**.

8. In the **Apply onto** box, select **Computer objects**.

9. At the bottom of the **Permissions** box, select the **Allow** check boxes that correspond to the **Validated write to DNS host name** and **Validated write to service principal name** permissions.

10. Click **OK** three times to confirm your changes and close the dialog boxes.

11. Close Active Directory Users and Computers.

**Update the DNS suffix search list**

When you transition to a disjoint namespace, consider creating customized DNS suffix search lists to ensure that clients can

locate services and other computers when they perform single-label name queries. Single-label name queries occur when a computer or user queries a name, but does not provide a DNS suffix. The DNS suffixes that are you add to the DNS suffix search list are used by the DNS client to create fully qualified domain names (FQDNs) when resolving single-label names. For example, if your computer sends a query for the name computer2, the DNS suffix search list can be used by your computer to make a name resolution query for computer2.contoso.com, computer2.na.corp.contoso.com, computer2.corp.contoso.com, or whatever is in the DNS suffix search list.

You can configure the DNS suffix search list by using Group Policy or by modifying each computer on the network through the user interface (UI) or registry. The following sections discuss the three primary methods for modifying the DNS suffix search list:

- Group Policy
- Network connections
- The registry

**Change the DNS suffix search list by using a GPO**

On Windows Server 2003–based servers, you use a GPO to configure the DNS suffix search list for each member computer. You set the DNS Client policy for **DNS Suffix Search List** to the DNS suffix search list that you want to use on the member computers that will apply this policy setting. The GPO path for the **DNS Suffix Search List** policy setting is Computer Configuration\Administrative Templates\Network\DNS Client.

| **Note** |
| --- |
| By default, the **DNS Suffix Search List** policy setting is not available on a server running Windows 2000 Server. However, you can add it by using the Windows XP administrative templates. For more information, see article 307900 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkId=102373). |

For more information about managing Group Policy, see Group Policy Object Editor Tools and Settings (http://go.microsoft.com/fwlink/?LinkId=102368) and Enterprise Management with the Group Policy Management Console (http://go.microsoft.com/fwlink/?LinkId=22814)

**Change the DNS suffix search list by using network connections**

To change the **DNS Suffix Search List** policy setting by using the UI in Windows 2000, Windows XP, or Windows Vista, complete the following procedure.

Membership in **Administrators**, or equivalent, is the minimum required to complete this procedure. Review details about using the appropriate accounts and group memberships at Local and Domain Default Groups (http://go.microsoft.com/fwlink/?LinkId=83477).

**To change the DNS suffix search list by using network connections**

1. Open the **System Properties** dialog box.
   a. To open the **System Properties** dialog box in Windows 2000 or Windows XP, click **Start**, click **Run**, type **sysdm.cpl**, and then press ENTER.
   b. To open the **System Properties** dialog box in Windows Vista, click **Start**, in **Start Search** type **sysdm.cpl**, and then press ENTER.
2. Right-click the icon that represents the computer's local network connection, and then click **Properties**.

   **Local Area Connection** is the default connection.
3. In **This connection uses the following items**, click **Internet Protocol (TCP/IP)**, and then click **Properties**.
4. Click **Advanced**.
5. On the **DNS** tab, click **Append these DNS suffixes (in order)**
6. Click **Add**, and then type the first DNS suffix that you want the clients to use when they search for single-label names (those that do not have DNS suffixes).

7. Repeat the previous step for each DNS suffix that you want clients to try when resolving a name.

| **Note** |
| --- |
| Be sure to include the Active Directory domain name and all other domain names in your organization that clients might have to resolve in the appropriate order. |

8. Click **OK** twice to confirm your changes.

9. Close the **Local Area Connection Properties** and the **Network Connections** dialog boxes.

**Change the DNS suffix search list in the registry**

If you plan to use a script (or to modify the registry manually) when you configure the DNS suffix search list, you can modify the **SearchList** value that is located in the **Parameters** key under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip**. For more information about registry scripts, see article 264584 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkId=102370).

# Configure Site Topology

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The site topology owner configures the site topology for the forest. Configuring the site topology for the forest involves the following tasks:

- Delegate Active Directory site administration
- Create Active Directory sites
- Create and assign Active Directory subnets
- Create Active Directory site links

# Delegate Active Directory Site Topology Administration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Configuring the site topology for the forest starts when the forest owner delegates administration of the Active Directory sites and site topology to the site topology owner.

**To delegate Active Directory site topology administration in your environment**

1. Create a global group named **SiteAdmins** in the forest root domain.

2. Add administrative users to the **SiteAdmins** global group.

   **Note**

   - The user accounts that you add must reside in the forest root domain. If you want to add users from regional domains to this group, it must be a universal group, and the forest root domain and the regional domain must be operating at the Microsoft® Windows® 2000 native or Windows Server 2003 functional level.

3. In **Active Directory Sites and Services**, right-click the **Sites** node, and then click **Delegate Control**.

4. Complete the Delegation of Control Wizard to delegate Full Control of the **Sites** node to **SiteAdmins**.

# Create Active Directory Sites

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Create Active Directory sites by using Active Directory Sites and Services.

**To create the Active Directory sites**

1. Review the site topology design information in the Associating Subnets with Sites worksheet provided by your design team.

2. Create the sites specified in the site topology design. For more information about how to create site objects, see "Create a site" in Help and Support Center for Windows Server 2003.

# Create and Assign Active Directory Subnets

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Create Active Directory subnets by using Active Directory Sites and Services.

**To create Active Directory subnets and associate them with sites**

1. Review the site topology design information in the "Associating Subnets with Sites" worksheet provided by your design team.

2. Create the Active Directory subnets specified in the worksheet and associate the Active Directory subnet with the appropriate site. For more information about how to create subnet objects and associate subnets to Active Directory sites, see "Create a subnet" and "Associate a subnet with a site" in Help and Support Center for Windows Server 2003.

# Create Active Directory Site Links

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Create Active Directory site links by using Active Directory Sites and Services.

**To create Active Directory site links**

1. Review the site topology design information in the "Sites and Associated Site Links" worksheet provided by your design team.

2. Create the Active Directory site links and configure the site link properties as specified in the site topology design. For more information about how to create site link objects, see "Create a site link" on the Microsoft Web site.

# Deploy Additional Domain Controllers in Other Sites

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If your design specifies deployment of additional forest root domain controllers in other sites, deploy them by using the procedures in "Deploy the Second Domain Controller in the Same Site" earlier in this chapter.

# Configure Operations Master Roles

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Configure the forest-level and domain-level operations master roles for the forest root domain. By default, the first domain controller in the forest root domain is assigned all operations master roles.

- If your design specifies that all domain controllers in the forest root domain are global catalog servers, leave all five operations master roles on the first domain controller, and designate the second domain controller as the standby.

- If any domain controllers in the forest root domain will not be global catalog servers, move all operations master roles from the first domain controller to the second domain controller, and ensure that the second domain controller will never be a global catalog server. Designate the third domain controller as the standby, and never make it a global catalog server.

  **Note**

  - In a single domain forest, the database content of a domain controller and a global catalog server are the same. Therefore, to load balance client lookups across global catalog servers in a single domain forest, ensure that all domain controllers are global catalog servers.

For a procedure to help you transfer operations master roles, see "Transfer operations master roles" in Help and Support Center for Windows Server 2003.

If your Active Directory design specifies that you designate a standby operations master for the current operations master role holder, configure the current role holder and the standby as direct replication partners by manually creating a connection object between them. Designating a standby operations master can save some time if you must reassign any operations master roles to the standby operations master.

Of all the operations master roles, the PDC emulator role has the highest impact on the performance of the domain controller hosting that role. In domains with more than 10,000 users, it might be necessary to reduce the number of authentication requests performed by the PDC emulator to decrease its workload and allow it to perform other tasks. If CPU utilization is higher than 50 percent or disk queues remain higher than 2 for several hours or days, reduce the number of client authentication requests received by the PDC emulator.

**Note**

- Other factors that can increase the workload on the PDC emulator include pre-Active Directory clients or applications that have been written to contact the PDC emulator.

To reduce the number of client authentication requests that are processed by the PDC emulator, adjust its weight or its priority in the DNS environment. If you want to proportionately reduce the number of client authentication requests received by the PDC emulator, adjust its weight. If you want to ensure that the PDC emulator does not receive any client authentication requests, adjust its priority.

Active Directory assigns a default value of 100 for the weight. By creating a new registry entry for the weight and assigning it a decreased value of 50, you can proportionately reduce the number of client authentication requests sent to the PDC emulator. This ensures that the PDC emulator will authenticate half of the number of clients than it would if the weight value remained at 100.

Active Directory assigns a default value of zero for the priority. By creating a new registry entry for the priority and assigning it an increased value of 200, you can ensure that the PDC emulator will never receive client authentication requests unless it is the only accessible domain controller.

Repeat these procedures if the PDC emulator operations master role is transferred or seized to another domain controller in the forest root domain.

**Caution**

- The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to

reinstall Windows. If you must edit the registry, back it up first and see the "Registry Reference" on the *Microsoft Windows Server 2003 Deployment Kit* companion CD or on the Microsoft Web site.

**To change the weight for DNS SRV records by using the registry**

1. In the **Run** dialog box, type **regedit**, and press ENTER.
2. In the registry editor, navigate to HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters.
3. Click **Edit**, click **New**, and then click **DWORD value**.
4. For the new entry name, type **LdapSrvWeight** and press ENTER. (The value name is not case sensitive.)
5. Double-click the entry name you just typed to open the **Edit DWORD Value** dialog box.
6. Choose **Decimal** as the **Base** option.
7. Enter a value from 0 through 65535. The recommended value is 50.
8. Click **OK**.
9. Click **File**, and then click **Exit** to close the registry editor.

Adjusting the priority of the domain controller also reduces the number of client referrals. However, rather than reducing it proportionally to the other domain controllers, changing the priority causes DNS to stop referring all clients to this domain controller unless all domain controllers with a lower priority setting are unavailable.

**Note**

- A lower value entered for **LdapSrvPriority** indicates a higher priority. A domain controller with an **LdapSrvPriority** setting of 100 has a lower priority than a domain controller with a setting of 10. Therefore, clients attempt to use the domain controller with the setting of 10 first.

**To change the priority for DNS SRV records by using the registry**

1. In the **Run** dialog box, type **regedit**, and press ENTER.
2. In the registry editor, navigate to HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters
3. Click **Edit**, click **New**, and then click **DWORD value**.
4. For the new entry name, type **LdapSrvPriority**, and press ENTER.
5. Double-click the entry name that you just typed to open the **Edit DWORD Value** dialog box.
6. Choose **Decimal** as the **Base** option.
7. Enter a value from 0 through 65535. The recommended value is 200.
8. Click **OK**.
9. Click **File**, and then click **Exit** to close the registry editor.

For more information about adjusting the weight or the priority of the PDC emulator, see the Active Directory link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources. Search under "Administration and Configuration Guides" and download the *Active Directory Operations Guide*.

# Raising the Functional Level

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you deploy the first Windows Server 2003–based domain controller in your forest root domain, the forest operates by default at the Windows 2000 forest functional level, and the domain operates by default at the Windows 2000 mixed functional level. If your organization has only Windows NT 4.0 domains and your forest design requires upgrading Windows NT 4.0 domains and joining them to this Active Directory forest, you might want to raise the forest functional level to Windows Server 2003 interim after you deploy the forest root domain and before you begin the process for upgrading your Windows NT 4.0 domain to Windows Server 2003 Active Directory. If you raise the forest functional level to Windows Server 2003 interim, you can take advantage of the advanced features available at that functional level.

Figure 6.8 shows raising the functional level as the last step in the forest root domain deployment process.

**Figure 6.8 Raising the Functional Level**

Although the Windows Server 2003 domain functional level provides a number of features and advantages, only enable this functional level when your environment is ready and all of your Windows NT 4.0–based backup domain controllers (BDCs) have been upgraded.

Although it is possible for a domain to include both Windows NT 4.0–based and Windows Server 2003–based domain controllers, the Windows Server 2003 domain functional level provides more features.

When you have determined that your environment is ready, use Active Directory Domains and Trusts to enable the Windows Server 2003 domain functional level.

After all domains are operating at the Windows Server 2003 functional level, raise the forest functional level to Windows Server 2003 to take advantage of all Windows Server 2003 forest-level features.

To determine when to raise the functional level, and for procedures to perform those tasks, see "Enabling Advanced Windows Server 2003 Active Directory Features" in this book. For more information about upgrading Windows NT domains to Windows Server 2003 Active Directory, see "Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory" in this book.

# Additional Resources for Deploying the Root Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information and tools related to this chapter.

# Deploying Windows Server 2003 Regional Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Deploying Microsoft® Windows® Server 2003 regional domains involves creating new geographically based child domains under the forest root domain. Deploying new Windows Server 2003 regional domains allows you to create a new domain structure or improve your existing domain structure to take advantage of available bandwidth and optimize replication traffic.

**In This Chapter**

Overview of Deploying Regional Domains

Reviewing the Regional Domain Design

Delegating the DNS Domain for the New Regional Domain

Deploying the First Domain Controller in a New Regional Domain

Deploying Additional Domain Controllers in a New Regional Domain

Reconfiguring the DNS Service

Configuring Operations Master Roles

Additional Resources for Deploying Windows Server 2003 Regional Domains

**Related Information**

- For more information about the Active Directory® directory service logical structure, see "Designing the Active Directory Logical Structure" in this book.
- For more information about Active Directory site topology, see "Designing the Site Topology" in this book.
- For more information about hardware requirements for domain controllers, see "Planning Domain Controller Capacity" in this book.
- For more information about deploying the forest root domain, see "Deploying the Windows Server 2003 Forest Root Domain" in this book.

# Overview of Deploying Regional Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you complete the deployment of the forest root domain, you are ready to deploy any new Windows Server 2003 regional domains specified by your design. Windows Server 2003 regional domains include domain controllers that are running the Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; or Windows® Server 2003, Datacenter Edition operating systems.

The design team determines which regional domains to deploy. As an alternative or in addition to creating a new regional domain, your Active Directory design might require upgrading existing domains. For more information about performing an in-place upgrade of a Microsoft® Windows NT® 4.0 account domain to a regional domain, see "Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory" in this book. For information about performing an in-place upgrade of a Microsoft® Windows® 2000 domain to a regional domain, see "Upgrading from Windows 2000 Domains to Windows Server 2003 Domains" in this book.

**Note**

- You can simultaneously create multiple regional domains and perform in-place upgrades of multiple Windows NT 4.0 or Windows 2000 domains. You do not need to complete the deployment of one regional domain before proceeding to the next regional domain.

After you deploy a new regional domain, you can create an organizational unit (OU) structure and either add new users, groups, and resources to the domain, or use the domain as a target for restructuring existing Windows NT 4.0 or Windows 2000 domains.

# Process for Deploying Regional Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Deploying regional domains involves completing the tasks that are shown in Figure 7.1.

**Figure 7.1 Deploying Regional Domains**

# Background Information for Deploying Regional Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you deploy regional domains, become familiar with how you can save time during the deployment process by automating installations and using the Active Directory Installation Wizard.

**Automating Installations**

You can perform an unattended installation of Active Directory by supplying an answer file when you run the Active Directory Installation Wizard. For more information about using an answer file to install Active Directory, in Help and Support Center for Windows Server 2003, click **Tools**, and click Windows Support Tools. Search for Ref.chm in the Deploy.cab file for examples and instructions about creating an answer file.

You can automate the installation of Windows Server 2003 by using Sysprep.exe or an unattended installation. For more information about automating installations, see *Automating and Customizing Installations* in this kit.

**Using the Active Directory Installation Wizard**

Windows Server 2003 includes improvements to the Active Directory Installation Wizard. When you install the first domain controller in a domain, you can allow the wizard to automatically install and configure Active Directory–integrated DNS zones. Even if you choose to manually configure some settings later, the wizard saves time and prevents errors during the initial configuration.

# Reviewing the Regional Domain Design

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In preparation for deployment, gather and review all design information from the design team and ensure that the domain controller hardware you plan to use meets the requirements for Windows Server 2003.

Reviewing the regional domain design involves two tasks, as shown in Figure 7.2.

**Figure 7.2 Reviewing the Regional Domain Design**

# Collect Regional Domain Design Information

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you begin the deployment, collect the design information that documents domain controller assignments. Record the computer name, static IP address, subnet mask, and DNS client settings for each domain controller in the regional domain. For a blank worksheet to assist you in documenting this information, see "Domain Controller Configuration" (DSSDFR_1.doc) on the *Microsoft® Windows® Server 2003 Deployment Kit* companion CD (or see "Domain Controller Configuration" on the Web at http://www.microsoft.com/reskit).

**Example: Reviewing the Regional Domain Design for Trey Research**
The regional domain design for Trey Research specifies deployment of a new regional domain, west.trccorp.treyresearch.net. This regional domain is a child domain of the dedicated Windows Server 2003 forest root domain, trccorp.treyresearch.net.

**Note**

- The other regional domain in the example,east.trccorp.treyresearch.net, is created by upgrading a Windows NT 4.0 account domain, then restructuring other Windows NT 4.0 resource domains. Those portions of the example are covered in "Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory," and "Restructuring Windows NT 4.0 Domains to an Active Directory Forest" in this book.

The West domain will have domain controllers in two locations: Seattle and Los Angeles. Figure 7.3 shows an example of a completed regional domain controller configuration worksheet for the West regional domain for Trey Research. For each domain controller, the preferred DNS server is the local domain controller, and the alternate is the closest DNS server. Initially, however, Trey Research configures the first domain controller in the domain to use a DNS server in its parent domain as its preferred DNS server. During installation of Active Directory on the first domain controller, the preferred DNS server is changed to the local domain controller. Then, after the second domain controller is online, Trey Research reconfigures the first domain controller to use the second domain controller as its alternate DNS server.

**Figure 7.3 Example of a Domain Controller Configuration Worksheet**

| Domain Controller Configuration | | | | |
|---|---|---|---|---|
| Prepared By | Active Directory Deployment Team | | Date | 01/01/03 |
| Regional Domain Name | west.trccorp.treyreserach.net | | | |
| Forest Owner | forest owner | | | |
| Parent Domain Name | trccorp.treyresearch.net | | | |
| Domain Controller | IP Address | Mask | Preferred DNS Server | Alternate DNS Server |
| SEA-WEST-DC01 | 172.16.16.20 | 255.255.252.0 | 172.16.16.2 (temp) 172.16.16.20 (final) | 172.16.16.3 (temp) 172.16.16.21 (final) |
| SEA-WEST-DC02 | 172.16.16.21 | 255.255.252.0 | 172.16.16.21 | 172.16.16.2 |
| LAX-WEST-DC01 | 172.16.136.2 | 255.255.252.0 | 172.16.136.2 | 172.16.136.3 |
| LAX-WEST-DC02 | 172.16.136.3 | 255.255.252.0 | 172.16.136.3 | 172.16.136.2 |

# Review Hardware Requirements for Domain Controllers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Ensure that each computer that you plan to use as a domain controller meets the hardware requirements for running Windows Server 2003. For more information about assessing the hardware requirements of domain controllers running Windows Server 2003, see "Planning Domain Controller Capacity" in this book.

# Delegating the DNS Domain for the New Regional Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Active Directory DNS owner is responsible for delegating the zone matching the name of the regional domain to the DNS servers (domain controllers) that you will be installing in the regional domain.

Figure 7.4 shows when the DNS domain is delegated during the regional domain deployment process.

**Figure 7.4 Delegating the DNS Domain for the New Regional Domain**

Before you create the new regional domain, delegate the DNS domain for the new Windows Server 2003 regional domain:

- In the forest root domain DNS zone.
- On any forest root domain controller.

**To delegate the DNS domain for the new regional domain**

1. Open the DNS snap-in from any domain controller in the forest root domain.
2. In the console tree, right-click the forest root domain zone, and then click **New Delegation**.
3. Complete the New Delegation Wizard by using the information documented in your Domain Controller Configuration worksheet and the instructions in Table 7.1. Accept the default settings when no information is supplied. Table 7.1 includes sample data entered by Trey Research for their first two regional domain controllers, SEA-WEST-DC01 and SEA-WEST-DC02.

   **Table 7.1 Delegating the DNS Domain for the Regional Domain**

| Wizard Page | Action | Example |
|---|---|---|
| Delegated Domain Name | In the **Delegated Domain** box, type the name of the regional domain. | **west** |
| Name Servers | Click **Add**. In the **New Resource Record** dialog box, in the **Server name** box, type the name of the first domain controller you plan to deploy. | **SEA-WEST-DC01. west.trccorp.treyresearch.net** |

| | |
|---|---|
| In the **New Resource Record** dialog box, in the **IP address** box, type the corresponding IP address of the domain controller, click **Add**, and then click **OK**. | **172.16.16.20** |
| Click **Add**, and in the **New Resource Record** dialog box, in the **Server name** box, type the name of another domain controller you plan to deploy in the regional domain. | **SEA-WEST-DC02. west.trccorp.treyresearch.net** |
| In the **New Resource Record** dialog box, in the **IP address** box, type the corresponding IP address of the other domain controller, click **Add**, and then click **OK**. | **172.16.16.21** |

# Deploying the First Domain Controller in a New Regional Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For each regional domain, the forest owner is responsible for deploying the domain controllers. Figure 7.5 shows the process for deploying the first domain controller in a new regional domain.

**Figure 7.5 Deploying the First Domain Controller in a New Regional Domain**

# Install Windows Server 2003

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The first step in deploying a regional domain is to install Windows Server 2003 on the first computer that you want to make the domain controller.

**Note**

- Before installing Windows Server 2003, ensure that DNS was never previously installed on the computer. If DNS was previously installed, configuration of the DNS resolver and forwarders might fail.

  - Insert the Windows Server 2003 operating system CD in the CD-ROM drive of the domain controller and select the option to install the operating system, or use an automated installation method. If the Windows Server 2003 media is shared on the network, run the Winnt32.exe command. Use the NTFS file system to format the partitions. Enter the computer name, static IP address, and subnet mask as specified by your design.

  - Configure the DNS client settings by using the information documented in the Domain Controller Configuration worksheet. The DNS settings are temporary and will be changed after you install Active Directory.

  - Enable Remote Desktop for Administration (formerly known as Terminal Services in Remote Administration mode) to enable administrators to log on remotely if necessary. To enable Remote Desktop for Administration, in Control Panel, double-click **System**, select the **Remote** tab, and then select **Allow users to connect remotely to this computer**.

  - Install Windows Support Tools, which are available in the \Support\Tools folder on the Windows Server 2003 operating system CD.

# Install Active Directory by Running the Active Directory Installation Wizard

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Install Active Directory by running the Active Directory Installation Wizard on the computer that you want to make the first regional domain controller. The Active Directory Installation Wizard creates the Active Directory database and initializes the directory data in the database.

In addition, on the first domain controller in a domain, after you run the wizard and restart the computer, the wizard also:

- Prompts the administrator to verify the installation and configuration of the DNS Server service.
- Configures DNS recursive name resolution by forwarding, by adding the IP addresses of the existing entries for **Preferred DNS server** and **Alternate DNS server** to the list of DNS servers on the **Forwarders** tab of the **Properties** sheet in the DNS snap-in for the domain controller.
- Configures DNS recursive name resolution by root hints, by adding the root hints that are configured on the **Preferred DNS server**.

  **Notes**

  - If you want to set different forwarders, or do not want to enable forwarding, you can change this setting manually by using the DNS snap-in.
  - If your domain controller is multihomed, forwarding is not configured automatically.
  - For manual configuration instructions, see "Verify DNS Server Recursive Name Resolution" later in this chapter.
- Configures the **Preferred DNS server** to point to the DNS server that is running locally on the domain controller, and configures the **Alternate DNS server** to point to the DNS server that is connected through the minimum number of network segments.

**To install Active Directory on the first regional domain controller**

1. Log on to the Windows Server 2003–based member server.
2. Verify that you can contact the parent DNS zone. At the command line, type:

   **nslookup parent_domain**

   (using the fully qualified domain name of the parent DNS zone of the regional domain.)
3. At the command line, type:

   **dcpromo**

   - or -

   Open **Administrative Tools** and click **Configure Your Server Wizard**. Select **Domain Controller (Active Directory)** to configure your domain controller. When the Configure Your Server Wizard finishes, the Active Directory Installation Wizard begins.
4. Use Table 7.2 to complete the Active Directory Installation Wizard for the first domain controller in the regional domain. Table 7.2 also includes information entered by Trey Research as they deploy their first regional domain controller, SEA-

WEST-DC01.

**Table 7.2 Installing Active Directory on the First Domain Controller in a New Regional Domain**

| Wizard Page or Dialog Box | Action | Example |
|---|---|---|
| Domain Controller Type | Select **Domain controller for a new domain**. | |
| Create New Domain | Select **Create a new child domain in an existing domain tree**. | |
| Network Credentials | In the **User name** box, type a user account that has sufficient rights to add a domain, typically a member of Enterprise Admins.<br><br>In the **Password** box, type the password of the user account.<br><br>In the **Domain** box, type the name of the forest root domain. | Forest root domain: **trccorp.treyresearch.net** |
| Child Domain Installation | Click **Browse**.<br><br>In the **Browse for Domain** dialog box, click the Parent domain name, and then click **OK**.<br><br>In the **Child Domain** box, type the NetBIOS name of the regional domain. | Parent domain: **trccorp.treyresearch.net**<br><br>Child Domain: **west** |
| NetBIOS Domain Name | Confirm or type the NetBIOS name. | **WEST** |
| Database and Log Folders | Type the folder locations specified by your design. | Database folder: C:\WINNT\NTDS<br><br>Log folder: D:\Logs |
| Shared System Volume | Confirm or type the location specified by your design. | C:\WINNT\SYSVOL |
| DNS Registration Diagnostics | A message will indicate that the wizard cannot contact the DNS server with which this domain controller will be registered. This is because the pre-created delegation record points to the local computer and DNS has not been installed on the domain controller at this point.<br><br>Select **Install and configure the DNS server on this computer and set this computer to use this DNS server as its preferred DNS server**. | |
| Permissions | Select the security level specified by your design:<br><br>• Permissions compatible with pre-Windows 2000 server operating systems<br><br>• Permissions compatible only with Windows 2000 or Windows Server 2003 operating systems | Because Trey Research currently has server programs running on Windows NT 4.0–based servers, they selected **Permissions compatible with pre-Windows 2000 server operating systems**. |

| | | |
|---|---|---|
| Directory Service Restore Mode Administration Password | In the **Password** and **Confirm password** boxes, type any strong password. | |

For more information about installing and removing Active Directory, see the *Active Directory Collection* of the *Windows Server 2003 Technical Reference* (or see the Active Directory Collection on the Web at http://www.microsoft.com/reskit).

# Verify the Active Directory Installation

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you run the Active Directory Installation Wizard to install Active Directory, verify the Active Directory installation by performing the following tasks:

1. Review the Windows Server 2003 event log and resolve any errors.

2. At the command line, run Dcdiag.exe and review and resolve any errors that are reported.

3. Run Task Manager and verify that the processor and memory system resources are within acceptable limits.

4. Open the DNS snap-in, expand **Forward Lookup Zones**, and verify that the zones _msdcs.*forest_root_domain_name* and *regional_domain_name* are present.

# Verify DNS Server Recursive Name Resolution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

DNS server recursive name resolution is configured automatically during the Active Directory installation process. If your design specifies a different configuration, you can use the DNS snap-in or Dnscmd.exe to modify these settings.

**To verify name resolution on the regional domain controller**

- Use the DNS snap-in to verify DNS server recursive name resolution for the method used in your organization, based on the information in Table 7.3.

**Table 7.3 Information to Verify DNS Server Recursive Name Resolution**

| Method | Configuration |
|---|---|
| Recursive name resolution by root hints | Root hints are the recommended method to use for recursive name resolution in a Windows Server 2003 environment.<br><br>No additional configuration is necessary.<br><br>When the DNS server specified as the Preferred DNS server during the installation process is properly configured, the root hints are automatically configured.<br><br>To verify the root hints by using the DNS snap-in:<br><br>In the console tree, right-click the domain controller name, and then click **Properties**. Click the **Root Hints** tab to view the root hints. |
| Recursive name resolution by forwarding | Only use Forwarders if that is what your organization's design specifies. Root hints are the recommended method to use for recursive name resolution in a Windows Server 2003 environment.<br><br>Forward unresolved queries to specified DNS servers.<br><br>To verify forwarding by using the DNS snap-in:<br><br>In the console tree, right-click the domain controller name, and then click **Properties**.<br><br>On the **Forwarders** tab, in the selected domain's **Forwarders** list, verify that the IP addresses match those specified by your design. |

# Deploying Additional Domain Controllers in a New Regional Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Figure 7.6 shows the process for deploying additional domain controllers in a new regional domain.

**Figure 7.6 Deploying Additional Domain Controllers in a New Regional Domain**

**Install Windows Server 2003**

Install Windows Server 2003 on additional computers by completing the same steps as for installing Windows Server 2003 on the first domain controller. Note that you do not need to configure temporary DNS client settings on additional domain controllers; instead, enter the IP addresses of the DNS servers that are connected through the minimum number of network segments, as documented in the Domain Controller Configuration worksheet. For more information about installing Windows Server 2003, see "Install Windows Server 2003" earlier in this chapter.

**Install Active Directory**

Install Active Directory on the computer that you want to make an additional regional domain controller by running the Active Directory Installation Wizard. You must complete the Active Directory installation and verify that installation is correct on the first domain controller before beginning installation of Active Directory on the second and subsequent domain controllers in the domain. For more information about verifying the Active Directory installation on the first regional domain controller, see "Verify the Active Directory Installation" earlier in this chapter.

The procedure for installing Active Directory on additional domain controllers in a domain differs slightly from the procedure for installing Active Directory on the first domain controller. For additional domain controllers in an existing domain, you have the option of using the install from media feature, which is new in Windows Server 2003. Install from media allows you to pre-populate Active Directory with System State data backed up from an existing domain controller. This backup can be present on local CD, DVD, or hard disk partition. Installing from media drastically reduces the time required to install directory information by reducing the amount of data that is replicated over the network. Installing from media is most beneficial in large domains or for installing new domain controllers that are connected by a slow network link. To use the install from media feature, you first create a backup of System State from the existing domain controller, then restore it to the new domain controller by using the **Restore to: Alternate location** option.

**To install Active Directory on additional regional domain controllers**

1. Log on to the Windows Server 2003–based member server.

2. If you want to copy domain information from restored backup files, at the command line, type:

   **dcpromo /adv**

– or –

If you want to copy domain information over the network, either type **dcpromo** (without the /adv switch) or open **Administrative Tools**, click **Configure Your Server Wizard**, andselect **Domain Controller (Active Directory)**.

3. Use Table 7.4 to complete the Active Directory Installation Wizard for subsequent domain controllers in the regional domain. Table 7.4 includes information entered by Trey Research as they deploy their second regional domain controller, SEA-WEST-DC02.

**Table 7.4 Installing Active Directory on Additional Domain Controllers in a New Regional Domain**

| Wizard Page or Dialog Box | Action | Example |
|---|---|---|
| Domain Controller Type | Select **Additional domain controller in an existing domain** | |
| Copying Domain Information | (This dialog box appears only when you started dcpromo with the /adv switch or used the **Configure Your Server Wizard**.)<br>Select either:<br>• Over the network from a domain controller<br>• From these restored backup files | Trey Research is copying from the first WEST domain controller, SEA-WEST-DC01,which is in the same location, so they selected **Over the network** to copy the information in the shortest time. |
| Global Catalog | (This dialog box appears only when **From these restored backup files** was selected, if the domain controller you backed up was a global catalog server.)<br>Specify whether to configure this domain controller as a global catalog server. | |
| Network Credentials | In the **User name** box, type a user account that has sufficient rights to add a domain controller, typically a member of Domain Admins.<br>In the **Password** box, type the password of the user account. | |
| Additional Domain Controller | (This dialog box appears only when **Over the network** was selected.)<br>Confirm or type the full DNS name of the forest root domain. | **west.trccorp.treyresearch.net** |
| Database and Log Folders | Type the folder locations specified by your design. | Database folder: C:\WINNT\NTDS<br>Log folder: D:\Logs |
| Shared System Volume | Confirm or type the location specified by your design. | C:\WINNT\SYSVOL |

| | | |
|---|---|---|
| Directory Service Restore Mode Administration Password | In the **Password and Confirm password** boxes, type any strong password. | |

For more information about installing and removing Active Directory, see the *Active Directory Collection* of the *Windows Server 2003 Technical Reference* (or see the Active Directory Collection on the Web at http://www.microsoft.com/reskit).

**Install DNS Server Service**

After Active Directory installation has finished and the computer has restarted, install DNS on the additional Windows Server 2003–based domain controller that is added to the domain.

**To install DNS on additional domain controllers using the Windows Components Wizard**

1. Click **Start**, point to **Settings**, and click **Control Panel**.
2. Double-click **Add or Remove Programs**, and then click **Add/Remove Windows Components**.
3. In **Components**, select the **Networking Services** check box, and then click **Details**.
4. In **Subcomponents of Networking Services**, select the **Domain Name System (DNS)** checkbox, click **OK**, and then click **Next**.
5. If prompted, in **Copy files from**, type the full path to the distribution files and then click **OK**. The required files will be copied to your hard disk.

**Verify the Active Directory Installation**

Use the same steps as shown in the procedure for the first domain controller, but instead of verifying that **DomainDnsZones** and **ForestDnsZones** were created, use the repadmin /showreps command to verify that the **ForestDnsZones** and **DomainDnsZones** application partitions are replicated successfully. Use the DNS snap-in to verify that DNS server recursive name resolution is configured according to the method used by your organization.

For more information about verifying the Active Directory installation, see "Verify the Active Directory Installation" earlier in this chapter.

# Reconfiguring the DNS Service

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Reconfigure the DNS service to enable aging and scavenging of stale resource records and to account for the additional domain controllers in the regional domain. Figure 7.7 shows the process for reconfiguring the DNS service.

**Figure 7.7 Reconfiguring the DNS Service**

# Enable Aging and Scavenging for Domain Name System

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Enable aging and scavenging on two Windows Server 2003–based domain controllers running the DNS Server service per domain, to allow automatic cleanup and removal of stale resource records (RRs), which can accumulate in zone data over time.

With dynamic update, RRs are automatically added to zones when computers start on the network. However, in some cases, they are not automatically removed when computers leave the network. For example, if a computer registers its own host (A) RR at startup and is later improperly disconnected from the network, its host (A) RR might not be deleted. If your network has mobile users and computers, this situation can occur frequently.

If left unmanaged, the presence of stale RRs in zone data might cause problems including:

- If a large number of stale RRs remain in server zones, they can eventually take up server disk space and cause unnecessarily long zone transfers.
- DNS servers loading zones with stale RRs might use outdated information to answer client queries, potentially causing the clients to experience name resolution problems on the network.
- The accumulation of stale RRs at the DNS server can degrade its performance and responsiveness.

**Caution**

- By default, the aging and scavenging mechanism for the DNS Server service is disabled. Enable aging and scavenging only after you understand all parameters. Otherwise, the server could be accidentally configured to delete resource records that should not be deleted. If a resource record is accidentally deleted, not only will users fail to resolve queries for that resource record, but any user can create the resource record and take ownership of it, even on zones configured for secure dynamic update.
- For more information about how to configure aging and scavenging, see "Understanding aging and scavenging" in Help and Support Center for Windows Server 2003.

To enable the aging and scavenging features, perform the following steps to configure the applicable server and its Active Directory–integrated zones:

- Enable aging and scavenging at the server. These settings determine the affect of zone-level properties for any Active Directory–integrated zones loaded at the server.
- Enable aging and scavenging for selected zones at the DNS server. When zone-specific properties are set for a selected zone, these settings apply only to the applicable zone and its resource records. Unless these zone-level properties are otherwise configured, they inherit their default settings from comparable settings maintained in the DNS server aging/scavenging properties.

**To set aging and scavenging properties for the DNS server**

1. Log on to the computer that is running the DNS Server service with an account that is a member of the local Administrators group.
2. In the DNS console tree, right-click the applicable DNS server, and then click **Set Aging/Scavenging for all zones**.
3. Select the **Scavenge stale resource records** check box.
4. Modify other aging and scavenging properties as needed.

**To set aging and scavenging properties for a zone**

1. Log on to the computer that is running the DNS Server service with an account that is a member of the local Administrators group.

2. In the DNS console tree, right-click the applicable zone, then click **Properties**.

3. On the **General** tab, click **Aging**, and then **s**elect the **Scavenge stale resource records** check box.

4. Modify other aging and scavenging properties as needed.

# Configure the DNS Client Settings of the First and Subsequent Domain Controllers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you have deployed an additional domain controller, modify the DNS client settings on the first domain controller. Because no other domain controllers were running when you deployed the first domain controller, modify the DNS client settings on the first domain controller to include the additional domain controller. As you deploy more domain controllers, you might also need to modify the **Alternate DNS server** setting specified on existing domain controllers to ensure that this setting points to the DNS server that is connected through the minimum number of network segments.

**To configure the DNS client settings on previously installed domain controllers**

1. Open **Network Connections**, double-click your **Local Area Connection**, click **Properties**, click **Internet Protocol (TCP/IP)** to highlight it, and then click **Properties**.

2. For the **Preferred DNS server**, type the IP address of the DNS server that is running locally on the domain controller (local host).

3. Determine whether a newly installed domain controller is now closer to this domain controller than the domain controller that you originally specified as the **Alternate DNS server**. If it is, for **Alternate DNS server**, type the IP address of the newly installed domain controller.

# Update the DNS Delegation for the Regional Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you deployed the first regional domain controllers, the DNS administrator delegated the DNS domain for the new regional domain. During that process, the DNS administrator added DNS name server (NS) and address (A) resource records to the parent DNS zone for each planned domain controller in your design. If you deploy additional domain controllers that you have not previously created resource records for, update the DNS delegation.

You can update the DNS delegation by using the DNS snap-in on any forest root domain controller, as described in "Delegating the DNS Domain for the New Regional Domain" earlier in this chapter.

# Configuring Operations Master Roles

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Configure operations master roles to ensure the availability and performance of those domain controllers. Figure 7.8 shows when configuring operations master roles occurs in the regional domain deployment process.

**Figure 7.8 Configuring Operations Master Roles**

It is generally recommended that you leave the operations master roles on the first domain controller in the regional domain. Monitor this domain controller closely and ensure that it is not a global catalog server. Deploy an additional domain controller in the same site to act as the standby operations master.

Host the PDC emulator role on a powerful and reliable domain controller to ensure that it is available and capable of handling the workload.

Of all the operations master roles, the PDC emulator role has the highest impact on the performance of the domain controller hosting that role. In domains with more than 10,000 users, it might be necessary to reduce the number of authentication requests performed by the PDC emulator to decrease its workload and allow it to perform other tasks. If CPU utilization is higher than 50 percent or disk queues remain higher than 2 for several hours or days, reduce the number of client authentication requests received by the PDC emulator.

**Note**

- Other factors that can increase the workload on the PDC emulator include pre-Active Directory clients or applications that have been written to contact the PDC emulator.

To reduce the number of client authentication requests that are processed by the PDC emulator, adjust its weight or its priority in the DNS environment. If you want to proportionately reduce the number of client authentication requests received by the PDC emulator, adjust its weight. If you want to ensure that the PDC emulator does not receive any client authentication requests, adjust its priority.

Active Directory assigns a default value of 100 for the weight. By creating a new registry entry for the weight and assigning it a decreased value of 50, you can proportionately reduce the number of client authentication requests sent to the PDC emulator. This ensures that the PDC emulator will authenticate half of the number of clients that it would if the weight value remained at 100.

Active Directory assigns a default value of zero for the priority. By creating a new registry entry for the priority and assigning it an increased value of 200, you can ensure that the PDC emulator will never receive client authentication requests unless it is the only accessible domain controller.

Repeat these procedures if the PDC emulator operations master role is transferred or seized to another domain controller in the forest root domain.

**Caution**

- The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Windows Server 2003 Resource Kit Registry Reference on the *Microsoft Windows Server 2003 Deployment Kit* companion CD or on the Web at http://www.microsoft.com/reskit.

**To change the weight for DNS SRV records by using the registry**

1. In the **Run** dialog box, type **regedit**, and press ENTER.
2. In the registry editor, navigate to HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters.
3. Click **Edit**, click **New**, and then click **DWORD value**.
4. For the new entry name, type **LdapSrvWeight** and press ENTER. (The value name is not case sensitive.)
5. Double-click the entry name you just typed to open the **Edit DWORD Value** dialog box.
6. Choose **Decimal** as the **Base** option.
7. Enter a value from 0 through 65535. The recommended value is 50.
8. Click **OK**.
9. Click **File**, and then click **Exit** to close the registry editor.

Adjusting the priority of the domain controller also reduces the number of client referrals. However, rather than reducing it proportionally to the other domain controllers, changing the priority causes DNS to stop referring all clients to this domain controller unless all domain controllers with a lower priority setting are unavailable.

**Note**

- A lower value entered for **LdapSrvPriority** indicates a higher priority. A domain controller with an **LdapSrvPriority** setting of 100 has a lower priority than a domain controller with a setting of 10. Therefore, clients attempt to use the domain controller with the setting of 10 first.

**To change the priority for DNS SRV records by using the registry**

1. In the **Run** dialog box, type **regedit**, and press ENTER.
2. In the registry editor, navigate to HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters
3. Click **Edit**, click **New**, and then click **DWORD value**.
4. For the new entry name, type **LdapSrvPriority**, and press ENTER.
5. Double-click the entry name that you just typed to open the **Edit DWORD Value** dialog box.
6. Choose **Decimal** as the **Base** option.
7. Enter a value from 0 through 65535. The recommended value is 200.
8. Click **OK**.
9. Click **File**, and then click **Exit** to close the registry editor.

For more information about adjusting the weight or the priority of the PDC emulator, see the Active Directory link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources. Search under "Administration and Configuration Guides" and download the *Active Directory Operations Guide*.

# Additional Resources for Deploying Windows Server 2003 Regional Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information and tools related to this chapter.

# Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Upgrading your domains from Microsoft® Windows NT® 4.0 to Windows® Server 2003 Active Directory® directory service enables your organization to improve the security and scalability of your network infrastructure while reducing administrative overhead. As an alternative to restructuring Windows NT 4.0 domains, the in-place upgrade is an efficient, time-saving process that minimizes the effect on the Windows NT 4.0 production environment.

# Overview of Upgrading Windows NT 4.0 Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Upgrading your Windows NT 4.0 domains to the Microsoft® Windows® Server 2003, Standard Edition and Windows® Server 2003, Enterprise Edition operating systems enables you to simplify and reduce network administration. Windows Server 2003 Active Directory integrates with other applications and services and allows you to delegate administrative responsibility at the appropriate level when you have multiple organizations existing in a single domain structure.

When you upgrade your Windows NT 4.0 domains to Windows Server 2003 Active Directory, you improve scalability because Active Directory domains can scale to meet the needs of your organization. You also gain new capabilities by using Group Policy, and you gain more flexibility for business units.

In addition, performing an in-place upgrade of Windows NT 4.0 domains to Windows Server 2003 Active Directory has no adverse effect on your Windows NT 4.0 production environment. There are fewer administrative complexities than with restructuring your environment, such as maintaining access to shared directories, files, and printers. Groups and group memberships are retained. You do not need to migrate local profiles, and you retain the existing passwords and profiles for domain users.

Before planning and implementing Windows NT 4.0 in-place upgrades, ensure that your organization has already:

- Designed the Active Directory logical structure of the forest and Domain Name System (DNS) for your Active Directory environment.
- Designed a site topology to efficiently locate domain controllers.
- Deployed a Windows Server 2003 forest root domain if that is the upgrade path that your organization has decided on. For more information about the paths for in-place upgrading a Windows NT 4.0 environment, see "Upgrading Domains from Windows NT 4.0 to Windows Server 2003 Active Directory" later in this chapter.

After completing the in-place upgrade process, you can perform an in-place upgrade for any remaining Windows NT domains or restructure them into your new Windows Server 2003 forest. For information about restructuring Windows NT 4.0 domains to a Windows Server 2003 forest, see "Restructuring Windows NT 4.0 Domains to an Active Directory Forest" in this book.

**Note**

- For a list of the job aids that are available to assist you in upgrading your Windows NT 4.0 domains to Windows Server 2003 Active Directory, see "Additional Resources for Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory" later in this chapter.

# Process for Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Upgrading your Windows NT 4.0 domains to Windows Server 2003 Active Directory involves first completing the necessary preparation tasks and then following the steps to complete the upgrade. Figure 8.1 shows the process for upgrading Windows NT 4.0 domains to Windows Server 2003 Active Directory.

**Figure 8.1 Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory**

# Background Information for Upgrading to Windows Server 2003 Active Directory

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you begin the Windows NT 4.0 in-place domain upgrade, become familiar with some important issues that affect the upgrade process.

**PDC Offline Operations**
During the process of upgrading the operating system on the primary domain controller (PDC) from Windows NT 4.0 to Windows Server 2003 and installing Active Directory, client operations such as logon and resource access will continue to function because these services are provided by backup domain controllers. However, because the PDC will be offline during most phases of the upgrade process, typically between one and three hours, operations that require data to be written to the domain will not succeed. For example, users will not be able to change their passwords and administrators will not be able to create, delete, or unlock user accounts. Administrative tools, such as User Manager for Domains or Server Manager, can be used only in read-only mode on backup domain controllers in the domain. In addition, you will not be able to create new objects, such as users and groups, while the PDC is offline.

**Full Synchronization of the Local Security Authority Database**
After upgrading a Windows NT 4.0 PDC, or after transferring the PDC role to another domain controller, the LSA will perform a single full synchronization of all objects in the database. This synchronization causes events to be logged in Event Viewer; specifically, Event Viewer in Windows Server 2003 will log Event ID 5713 and Event Viewer in Windows NT 4.0 will log Event ID 5717. However, the LSA database contains relatively few objects and the full synchronization does not affect network performance.

Do not confuse the full synchronization of the LSA database with a backup domain controller (BDC) full synchronization. A BDC full synchronization typically happens when too many changes occur on a PDC before the PDC can replicate the changes to a BDC. The number of objects that are replicated during a BDC full synchronization and the amount of network traffic that is generated depends on the number of users, groups, and workstations in the domain.

**Domain Users and Client Workstation Operating Systems**
When Microsoft® Windows® 2000, Microsoft® Windows® XP, and Windows Server 2003 clients attempt to authenticate with a domain controller, they first retrieve a list of domain controllers from either DNS or WINS, and will then authenticate with the first domain controller that responds to their authentication request. The first domain controller to respond is usually a domain controller located closest to the client. The client and the domain controller will then negotiate which authentication protocol to use.

When Windows 2000, Windows XP, and Windows Server 2003 clients are members of a Windows NT 4.0 domain, they will only use the NTLM protocol to authenticate because that is the only authentication protocol supported by Windows NT 4.0. Windows 2000 and Windows Server 2003 domain controllers are capable of using either the NTLM or the more secure Kerberos authentication protocol.

When performing an in-place upgrade of a Windows NT 4.0 domain to Windows Server 2003, the first domain controller upgraded is the Windows NT 4.0 PDC. If clients in the domain running Windows 2000, Windows XP, and Windows Server 2003 select the new Active Directory domain controller for authentication, the negotiation of the authentication protocol will reveal that there are now domain controllers in the domain that support the Kerberos protocol. These clients will then upgrade their secure channel to exclusively use the Kerberos protocol for authentication requests and will no longer attempt to authenticate using the NTLM protocol, potentially causing the new Active Directory domain controller to become overloaded with authentication requests.

To prevent Windows Server 2003–based domain controllers from being overloaded with authentication requests, configure each Windows Server 2003–based domain controller to emulate a Windows NT 4.0–based domain controller during the upgrade process. Configuring a newly upgraded Windows Server 2003–based domain controller to emulate a Windows NT 4.0–based domain controller by using the NT4Emulator registry entry shields the new domain controller from getting too many authentication requests from Active Directory clients. Shielding the Active Directory domain controller takes place before the operating system is upgraded to Windows Server 2003 to prevent clients running Windows 2000, Windows XP, and Windows Server 2003 from ever establishing exclusive communications with a Windows Server 2003–based domain controller.

When upgrading additional Windows NT 4.0–based domain controllers after the PDC has been configured to emulate a

Windows NT 4.0–based domain controller, you must remember to configure the computer you are upgrading with the NeutralizeNT4Emulator registry entry. This is so that the additional domain controller will recognize the upgraded PDC that is emulating a Windows NT 4.0–based domain controller as an Active Directory domain controller. If the computer is not configured to neutralize emulation, you will not be able to install Active Directory because the additional domain controller will not be able to authenticate to an Active Directory domain controller.

For each site in which clients are running Windows 2000, Windows XP, and Windows Server 2003, ensure that you have enough Windows Server 2003–based domain controllers deployed in that site before removing Windows NT 4.0 emulation.

For more information about emulating Windows NT 4.0–based domain controllers, see "Configure Protection Against Domain Controller Overload on Additional Domain Controllers" later in this chapter.

For more information about domain controller placement, see "Designing the Site Topology" in this book. For more information about domain controller capacity planning and determining the number of domain controllers needed in each site to service Active Directory clients, see "Planning Domain Controller Capacity" in this book.

**Service Compatibility**

In Windows NT 4.0 and earlier server operating systems, services running in the context of the Local System account communicate with other services over the network by using *null sessions* (a session in which a user name or password is not provided). In Windows 2000 and later operating systems, services running in the context of the Local System account on the local computer use the local computer account to authenticate to other servers. By default, Active Directory does not accept null session queries.

Of all the services that run in the context of the Local System account, Remote Access Services (RAS) is the most prominent. You cannot use null sessions to access network resources by using NTLM authentication unless the remote computer allows access with null credentials.

In an Active Directory environment containing both Windows NT 4.0–based and Windows Server 2003–based domain controllers, a member server that is running Windows NT 4.0 and is configured as a RAS server cannot retrieve information from a Windows Server 2003–based domain controller. For example, if a caller tries to dial into your network and accesses a Windows NT 4.0 member server that is configured as a RAS server, the RAS server must query a domain controller first to verify whether the caller has permission to dial into the network. Therefore, RAS operates correctly only if the domain controller responding to the RAS authentication request is a Windows NT 4.0–based BDC or the Active Directory domain has been configured to allow resources to be accessed by using null credentials. By upgrading the operating system on Windows NT 4.0 member servers that are configured as RAS servers to Windows Server 2003, you ensure that RAS callers are successfully authenticated by a Windows Server 2003 Active Directory–based domain controller.

The recommended solution is to upgrade the RAS servers to Windows Server 2003. However, if this cannot be done, the alternatives are:

- While installing Active Directory on the upgraded Windows NT 4.0 PDC, on the Permissions page of the Active Directory Installation wizard, select **Permissions compatible with pre-Windows 2000 Server operating systems**.

  – Or –

  Add the Everyone group and the Anonymous Logon group to the Pre-Windows 2000 Compatible Access built-in group by using Active Directory Users and Computers or the command line.

**To add the Everyone group to the Pre-Windows 2000 Compatible Access Group by using the command line**

- At the command line, type:

```
net localgroup "Pre-Windows 2000 Compatible Access" Everyone /add
```

**To add the Anonymous Logon group to the Pre-Windows 2000 Compatible Access Group by using the command line**

- At the command line, type:

```
net localgroup "Pre-Windows 2000 Compatible Access" “Anonymous Logon” /add
```

**Note**

- After this update to the Pre-Windows 2000 Compatible Access group replicates, you must restart the Server service on all domain controllers.

Both of these methods combined allow null sessions to read information out of the directory. After you upgrade all RAS servers, and when you no longer need backward compatibility with operating systems earlier than Windows 2000, remove the Everyone group and the Anonymous Logon group from the Pre-Windows 2000 Compatible Access built-in group. For more information about removing the Everyone group and the Anonymous Logon group from the Pre-Windows 2000 Compatible Access group, see "Eliminate Anonymous Connections to Domain Controllers" later in this chapter.

**LAN Manager Replication Service and the File Replication Service**
In Windows NT 4.0, the LAN Manager Replication (LMRepl) service provides single master replication of logon scripts and other database information located in the NETLOGON share on a Windows NT 4.0–based domain controller that is designated as an export server to all other Windows NT 4.0–based domain controllers in the domain. LMRepl can be configured only on Windows NT 4.0–based domain controllers. In Windows 2000 and Windows Server 2003, logon scripts and profile information are stored in the NETLOGON shared folder (which contains policies and scripts for non-Active Directory clients) and the SYSVOL shared folder (which contains Group Policy files and scripts for Active Directory clients). The *File Replication Service (FRS)*, a multimaster replication engine that runs automatically on all Windows Server 2003–based domain controllers, replaces the LMRepl service and replicates the NETLOGON and SYSVOL shared folders between domain controllers in a Windows Server 2003 domain.

During the in-place domain upgrade process, your environment includes Windows NT 4.0–based BDCs operating with Windows Server 2003–based domain controllers. FRS and LMRepl are not backward compatible. Therefore, to provide support for the LMRepl service in the Active Directory environment, you need to create a bridge between LMRepl and FRS to replicated new files created in the NETLOGON folder on Windows Server 2003 domain controllers to the Windows NT 4.0 export server. The bridge is created by using the Lbridge.cmd script and the Robocopy.exe tool so that both services can operate autonomously. Do this by selecting one Windows Server 2003–based domain controller to copy the SYSVOL shared folder to the Windows NT 4.0 export directory of the Windows NT 4.0 export server. You can use a regularly scheduled script to copy the shared folder. For more information about creating this script, see "Synchronize File Replication Services" later in this chapter.

**Security Policy Considerations when Upgrading from Windows NT 4.0 to Windows Server 2003**
Server message block (SMB) packet signing and secure channel signing are security policies that are enabled by default on Windows Server 2003–based domain controllers. To allow clients running earlier versions of Windows to communicate with domain controllers running Windows Server 2003, you might need to temporarily disable these security policies during the upgrade process.

**SMB packet signing**
SMB packet signing is a security mechanism that protects the data integrity of SMB traffic between client computers and servers, and prevents man-in-the-middle attacks by providing a form of mutual authentication. This is done by placing a digital security signature into each SMB packet, which is then verified by the receiving party. Server-side SMB signing is required by default on Windows Server 2003–based domain controllers, which means that all clients are required to have SMB packet signing enabled.

Clients running Windows NT 4.0 with Service Pack 2 or earlier, and clients running Microsoft® Windows® 95 without the Directory Service Client Pack, do not support SMB packet signing. These clients will not be able to authenticate to a Windows Server 2003–based domain controller. To ensure successful authentication, upgrade these clients to a later version of the operating system or Service Pack. However, if you cannot upgrade your clients, you can allow them to be authenticated by configuring SMB packet signing on all Windows Server 2003–based domain controllers so that SMB packet signing is preferred but not required.

For more information about SMB packet signing, see "Microsoft network server: Digitally sign communications (always)" on the Microsoft Web site.

For more information about configuring SMB packet signing on Windows Server 2003–based domain controllers, see "Modify Security Policies" later in this chapter.

For more information about the Directory Services Client Pack, see article 323466, "Availability of the Directory Services Client Update for Windows 95 and Windows 98" in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Secure channel signing and encryption**
When a computer becomes a member of a domain, a computer account is created. Each time the computer starts, it uses the computer account password to create a secure channel with a domain controller for its domain. This secure channel is used to ensure secure communications between a domain member and a domain controller for its domain. Secure channel signing is required by default on Windows Server 2003–based domain controllers, which means that all clients must enable secure

channel signing and encryption.

Clients running Windows NT 4.0 with Service Pack 3 or earlier installed do not support secure channel signing. These clients will not be able to establish communications with a Windows Server 2003–based domain controller. To ensure successful communication, upgrade these clients to a later version of the operating system or Service Pack. However, if you cannot upgrade your clients, you must disable secure channel signing on all Windows Server 2003–based domain controllers so that the traffic passing through the secure channel is not required to be signed or encrypted.

**Note**

- Unlike SMB packet signing, secure channel signing does not affect Windows 95 clients.

For more information about secure channel signing, see "Domain member: Digitally encrypt or sign secure channel data (always)" in Help and Support Center for Windows Server 2003.

For more information about configuring secure channel signing on Windows Server 2003–based domain controllers, see "Modify Security Policies" later in this chapter.

# Collecting Design Information

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In preparation for deployment, the forest owner in your organization is responsible for working with the deployment team to acquire the following information:

- Documentation of your current Windows NT 4.0 environment.
- Names of the Windows NT 4.0 domains that will be upgraded and the order in which to upgrade them.
- Supported operating system upgrade paths for your Windows NT 4.0–based domain controllers.

Information such as domain diagrams, network services, and trust relationships might have been documented as part of the design process, and collecting it will be a matter of querying the design team. However, information such as the existing network and hardware configuration of each domain controller might have to be collected or documented by the forest owner during the deployment phase of the project.

In addition, the forest owner is responsible for developing a test plan and for developing a recovery plan in the event that the deployment does not complete successfully.

Figure 8.2 shows the steps involved in collecting the design information that will be used to upgrade Windows NT 4.0 domains to Windows Server 2003 Active Directory.

**Figure 8.2 Collecting Design Information**

# Document the Existing Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before upgrading a Windows NT 4.0 domain to Windows Server 2003 Active Directory, document the existing Windows NT 4.0 domain structure.

Create a diagram that includes the following information:

- The names of all account and resource domains.
- The inbound and outbound trust relationships that each domain shares.

If documentation already exists for your domain, review the existing documentation for accuracy and clarity.

Figure 8.3 shows an example of the existing Windows NT 4.0 domain structure for a fictitious company, Trey Research.

**Figure 8.3 Example of a Windows NT 4.0 Domain Diagram**

In addition to documenting the existing domain structure, document the following:

- The domain controllers and the services that each provides in the domain.
- The existing hardware configuration on all domain controllers in the domain.
- The existing network configuration, including IP address and network adapter information for each domain controller.
- The current domain controller assignments and the role that you plan to assign to each domain controller after the in-place domain upgrade.

# Document Domain Controllers and Services

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Identify and document the domain controllers in the existing Windows NT 4.0 domain. Include in your documentation the role that each domain controller assumes in the domain and the services that each domain controller provides. Identify domain controllers that provide Remote Access Service and the LAN Manager Replication (LMRepl) service, because upgrading to Windows Server 2003 Active Directory affects these services.

For a worksheet to assist you in documenting domain controllers and services see "Windows NT 4.0 Domain Controllers and Services" (DSSUPNT_1.doc) or "Windows NT 4.0 Domain Controller Documentation" (DSSUPNT_5.xls) on the *Microsoft® Windows® Server 2003 Deployment Kit* companion CD (or see "Windows NT 4.0 Domain Controllers and Services" or "Windows NT 4.0 Domain Controller Documentation" on the Web at http://www.microsoft.com/reskit). "Windows NT 4.0 Domain Controller Documentation" is a master worksheet combining the information from all four individual worksheets in this section.

**Example: Documenting Windows NT 4.0 Domain Controllers and Services**
Trey Research has a Windows NT 4.0 account domain that includes nine domain controllers running Windows NT 4.0. Because the resource domains hold all of the application servers, the account domain does not include member servers. The PDC, SEA-EAST-DC01, is also a Windows Internet Name Service (WINS) server, as are two BDCs, BOS-EAST-DC01 and BOS-EAST-DC02.

Trey Research documented the domain controllers and services in their Windows NT 4.0 domain, as shown in Figure 8.4.

**Figure 8.4 Example of Windows NT 4.0 Domain Controllers and Services Worksheet**

| Windows NT 4.0 Domain Controllers and Services | | | |
|---|---|---|---|
| Prepared By | Forest Owner | Date | 1/2/03 |
| Domain Name | EAST | | |

| Domain Controller Name | Domain Controller Role | Services |
|---|---|---|
| SEA-EAST-DC01 | PDC | WINS, LMRepl export server |
| SEA-EAST-DC02 | BDC | LMRepl import server, RAS server |
| WDC-EAST-DC01 | BDC | LMRepl import server |
| WDC-EAST-DC02 | BDC | LMRepl import server |
| NYC-EAST-DC01 | BDC | LMRepl import server, RAS server |
| NYC-EAST-DC02 | BDC | LMRepl import server, RAS server |
| NYC-EAST-DC03 | BDC | LMRepl import server |
| BOS-EAST-DC01 | BDC | WINS, LMRepl import server |
| BOS-EAST-DC02 | BDC | WINS, LMRepl import server |

For more information about the effect of upgrading to Windows Server 2003 Active Directory on the RAS service and the LMRepl service, see "Background Information for Upgrading to Windows Server 2003 Active Directory" earlier in this chapter.

# Document the Existing Hardware Configuration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Review and document the existing hardware configuration of each domain controller that you plan to upgrade to Windows Server 2003. Use this information to identify the domain controllers in your environment that you can upgrade to Windows Server 2003 and the domain controllers that do not meet the hardware requirements for Windows Server 2003. Retain at least one domain controller that does not meet Windows Server 2003 hardware requirements to serve as a rollback server in the event that you must roll back your deployment.

If the PDC does not meet the hardware requirements, you can transfer the PDC role to a backup domain controller (BDC) that does meet the hardware requirements and upgrade it. If none of your Windows NT 4.0 domain controllers meet Windows Server 2003 hardware requirements, install a Windows NT 4.0 BDC on a computer that does meet the hardware requirements for a domain controller that is running Windows Server 2003 and transfer the PDC role to it.

You can also add a Windows Server 2003–based member server to a Windows NT 4.0 domain at any time before you upgrade to Windows Server 2003 Active Directory because Windows Server 2003–based member servers can operate within a Windows NT 4.0 environment. You can install Active Directory on the member server after you upgrade the PDC.

For more information about the hardware requirements of domain controllers in a Windows Server 2003 domain, see "Planning Domain Controller Capacity" in this book. To determine whether your hardware configuration is compatible with Windows Server 2003, see the Windows Server Catalog link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

For a worksheet to assist you in documenting your existing domain controller hardware configuration, see "Windows NT 4.0 Hardware Configuration" (DSSUPNT_2.doc) or "Windows NT 4.0 Domain Controller Documentation" (DSSUPNT_5.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Windows NT 4.0 Hardware Configuration" or "Windows NT 4.0 Domain Controller Documentation" on the Web at http://www.microsft.com/reskit).

**Example: Documenting the Windows NT 4.0 Hardware Configuration**

Figure 8.5 shows an example of a Hardware Configuration worksheet for the Windows NT 4.0–based domain controllers in the EAST domain for Trey Research.

**Figure 8.5 Example of a Windows NT 4.0 Hardware Configuration Worksheet**

| Windows NT 4.0 Hardware Configuration | | | |
|---|---|---|---|
| Prepared By | Forest Owner | Date | 1/2/03 |
| Domain Name | EAST | | |

| DC Name | Operating System | Hardware Information | | | Upgradeable to Windows Server 2003 DC? |
|---|---|---|---|---|---|
| | | RAM | CPU | Disk Space | |
| SEA-EAST-DC01 | Windows NT 4.0 | 2 GB | 1 x 850 MHz | 20 GB | Yes |
| SEA-EAST-DC02 | Windows NT 4.0 | 2 GB | 1 x 850 MHz | 20 GB | Yes |
| WDC-EAST-DC01 | Windows NT 4.0 | 1 GB | 1 x 850 MHz | 20 GB | Yes |
| WDC-EAST-DC02 | Windows NT 4.0 | 256 MB | 1 x 850 MHz | 10 GB | No |
| NYC-EAST-DC01 | Windows NT 4.0 | 2 GB | 4 x 850 MHz | 40 GB | Yes |
| NYC-EAST-DC02 | Windows NT 4.0 | 2 GB | 4 x 850 MHz | 40 GB | Yes |
| NYC-EAST-DC03 | Windows NT 4.0 | 2 GB | 4 x 850 MHz | 40 GB | Yes |
| BOS-EAST-DC01 | Windows NT 4.0 | 1 GB | 1 x 850 MHz | 20 GB | Yes |
| BOS-EAST-DC02 | Windows NT 4.0 | 256 MB | 1 x 850 MHz | 8 GB | No |

Domain controllers BOS-EAST-DC02 and WDC-EAST-DC02 do not meet the minimum memory requirements for a Windows Server 2003–based domain controller. Therefore, Trey Research has determined that BOS-EAST-DC02 will be used as the Windows NT 4.0 rollback server if a problem occurs during the in-place upgrade process and WDC-EAST-DC02 will be assigned as a member server in the Windows Server 2003 forest. All other Windows NT 4.0–based domain controllers are capable of supporting Windows Server 2003 Active Directory.

# Document the Existing Network Configuration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Document the existing network configuration for your Windows NT 4.0 domain. Some network adapter drivers that are included with earlier versions of the operating system are not distributed with Windows Server 2003. If you attempt to upgrade a Windows NT 4.0–based domain controller to Windows Server 2003 and a network adapter is installed for which a driver is not provided, your network information might be lost or detected incorrectly during the upgrade.

**Note**

- You can install device drivers that are not included on the Windows Server 2003 operating system CD from the vendor's Web site.

Create a network configuration table listing the type of network adapter that each domain controller uses. Also include the TCP/IP configuration information for each domain controller, including IP address, subnet mask, and default gateway. You can run the ipconfig command at the command line to determine IP address, subnet mask, and default gateway. For more information about the ipconfig command, type **ipconfig /?** at the command line.

To determine whether the network card is supported by Windows Server 2003, see the Windows Server Catalog link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

For a worksheet to assist you in documenting your existing Windows NT 4.0 network configuration, see "Windows NT 4.0 Network Configuration" (DSSUPNT_3.doc) or "Windows NT 4.0 Domain Controller Documentation" (DSSUPNT_5.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Windows NT 4.0 Network Configuration" or "Windows NT 4.0 Domain Controller Documentation" on the Web at http://www.microsoft.com/reskit).

Figure 8.6 shows an example of a network configuration worksheet for the EAST domain for Trey Research.

**Figure 8.6 Example of a Windows NT 4.0 Network Configuration Worksheet**

# Windows NT 4.0 Network Configuration

| Prepared By | Forest Owner | Date | 1/2/03 |
|---|---|---|---|

| Domain Name | EAST |
|---|---|

| DC Name | Network Adapter | IP Address | Subnet Mask | Default Gateway |
|---|---|---|---|---|
| SEA-EAST-DC01 | NETGEAR FA310TX Fast Ethernet Adapter | 172.16.16.10 | 255.255.252.0 | 172.16.16.1 |
| SEA-EAST-DC02 | Intel PRO/100 VE Desktop Connection | 172.16.16.11 | 255.255.252.0 | 172.16.16.1 |
| WDC-EAST-DC01 | IBM Netfinity 10/100 Ethernet Adapter | 172.16.116.2 | 255.255.252.0 | 172.16.116.1 |
| WDC-EAST-DC02 | IBM Netfinity 10/100 Ethernet Adapter | 172.16.116.3 | 255.255.252.0 | 172.16.116.1 |
| NYC-EAST-DC01 | 3Com EtherLink III LAN PC Card (3C589) (Ethernet) | 172.16.28.2 | 255.255.252.0 | 172.16.28.1 |
| NYC-EAST-DC02 | IBM Netfinity 10/100 Ethernet Adapter | 172.16.28.3 | 255.255.252.0 | 172.16.28.1 |
| NYC-EAST-DC03 | IBM Netfinity 10/100 Ethernet Adapter | 172.16.28.4 | 255.255.255.0 | 172.16.28.1 |
| BOS-EAST-DC01 | Intel PRO/100 VE Desktop Connection | 172.16.36.2 | 255.255.252.0 | 172.16.36.1 |
| BOS-EAST-DC02 | Kingston EtherRx KNE111TX PCI Fast Ethernet Adapter | 172.16.36.3 | 255.255.252.0 | 172.16.36.1 |

# Document Domain Controller Role Assignments

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As part of your in-place domain upgrade plan, assign the existing Windows NT 4.0–based domain controllers roles that they will assume in the Windows Server 2003 domain after the upgrade is complete. Assign one of the following three roles to Windows NT 4.0–based domain controllers in a Windows Server 2003 domain:

- **Windows Server 2003–based domain controller.** Assign the role of Windows Server 2003–based domain controller to any Windows NT 4.0 PDCs and other Windows NT 4.0–based domain controllers that meet the appropriate hardware and software requirements.

- **Rollback server.** Assign the role of rollback server in the Windows Server 2003 domain to a Windows NT 4.0 BDC that does not meet the Windows Server 2003 domain controller hardware requirements.

- **Windows Server 2003–based member server.** Assign the role of member server in the Windows Server 2003 domain to a Windows NT 4.0–based BDC that does not meet the Windows Server 2003 domain controller hardware requirements.

For more information about the software and hardware requirements for Windows Server 2003–based domain controllers, see "Determine Supported Operating System Upgrades" later in this chapter and "Document the Existing Hardware Configuration" earlier in this chapter.

Create a domain controller assignment table that outlines the roles that you plan to assign to your Windows NT 4.0–based domain controllers in the Windows Server 2003 domain. In this table, list the Windows NT 4.0–based domain controllers in your domain, indicate whether they meet the hardware requirements for Windows Server 2003, and list the role for each domain controller before and after you upgrade the domain, as shown in Figure 8.7.

For a worksheet to assist you in documenting Windows NT 4.0–based domain controller roles, see "Windows NT 4.0 Domain Controller Role Assignment" (DSSUPNT_4.doc) or "Windows NT 4.0 Domain Controller Documentation" (DSSUPNT_5.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Windows NT 4.0 Domain Controller Role Assignment" or "Windows NT 4.0 Domain Controller Documentation" on the Web at http://www.microsoft.com/reskit).

**Figure 8.7 Example of a Windows NT 4.0 Domain Controller Role Assignment Worksheet**

| Windows NT 4.0 Domain Controller Role Assignment | | | |
|---|---|---|---|
| Prepared By | Forest Owner | Date | 1/2/03 |
| Domain Name | EAST | | |

| DC Name | Meets hardware requirements? | Role before upgrade | Role after upgrade |
|---|---|---|---|
| SEA-EAST-DC01 | Yes | Windows NT 4.0 PDC | Windows Server 2003 domain controller |
| SEA-EAST-DC02 | Yes | Windows NT 4.0 BDC | Windows Server 2003 domain controller |
| WDC-EAST-DC01 | Yes | Windows NT 4.0 BDC | Windows Server 2003 domain controller |
| WDC-EAST-DC02 | No | Windows NT 4.0 BDC | Windows Server 2003 member server |
| NYC-EAST-DC01 | Yes | Windows NT 4.0 BDC | Windows Server 2003 domain controller |
| NYC-EAST-DC02 | Yes | Windows NT 4.0 BDC | Windows Server 2003 domain controller |
| NYC-EAST-DC03 | Yes | Windows NT 4.0 BDC | Windows Server 2003 domain controller |
| BOS-EAST-DC01 | Yes | Windows NT 4.0 BDC | Windows Server 2003 domain controller |
| BOS-EAST-DC02 | No | Windows NT 4.0 BDC | Windows NT 4.0 Rollback Server |

# Determine the Domain Upgrade Order

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you begin the in-place domain upgrade process, determine the order in which you plan to upgrade your Windows NT 4.0 domains. Because account domains generally contain more objects than resource domains, upgrade your account domains before upgrading your resource domains. This allows your organization to take advantage of Windows Server 2003 security and administration features early in the upgrade process.

The order in which you upgrade account domains in your organization can affect the efficiency of your in-place domain upgrade process. Use the following guidelines to determine the order in which to upgrade multiple account domains:

- Upgrade domains that will become targets for restructuring first. After upgrading these domains, you can restructure remaining domain objects into the restructuring target. Target domains must be set at the Windows 2000 native domain functional level before restructuring objects into them.

- Upgrade domains over which you have direct control and to which you have easy access. This allows convenient access to these domains in the event that you must roll back your deployment if the upgrade does not go as planned.

For more information about restructuring Windows NT domains, see "Restructuring Windows NT 4.0 Domains to an Active Directory Forest" in this book.

# Determine Supported Operating System Upgrades

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Identify the Windows NT 4.0 platforms that are running in your environment and determine whether an operating system upgrade to Windows Server 2003 is supported, or whether you must perform a clean operating system installation.

Table 8.1 lists the Windows NT 4.0 platforms and indicates which platforms you can upgrade directly to each edition of Windows Server 2003. You do not need to reinstall applications on platforms that you can upgrade directly to Windows Server 2003.

**Table 8.1 Supported Upgrade Paths to Windows Server 2003**

| Platform | Upgrade to Windows Server 2003, Standard Edition | Upgrade to Windows Server 2003, Enterprise Edition | Upgrade to Windows Server 2003, Datacenter Edition |
|---|---|---|---|
| Windows NT 4.0 Server, Standard Edition | ● | ● | |
| Windows NT 4.0 Terminal Server | ● | ● | |
| Windows NT 4.0 Server, Enterprise Edition | | ● | |

**Important**

- All versions of Windows NT 4.0 must have Service Pack 5 or later installed before upgrading to Windows Server 2003.

If you have computers in your environment that are running operating systems that you cannot upgrade directly to a version of Windows Server 2003, such as Windows NT 3.51, you must do one of the following:

- If you need to retain applications that are located on those computers, upgrade the computers to run an operating system that you can upgrade to Windows Server 2003 after verifying that those applications will function on and are supported by Windows Server 2003.

- If you do not need to retain applications that are located on those computers, perform a clean installation of Windows Server 2003 on those computers.

# Develop a Test Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Develop a plan for testing your in-place domain upgrade procedures throughout the in-place domain upgrade process to ensure that they have completed successfully and to determine whether the process of upgrading Windows NT 4.0 domains to Windows Server 2003 Active Directory was successful.

Table 8.2 lists the Active Directory configurations that you must test and the tools that you can use to test each configuration. For more information about the options that are available for these tools, see "Active Directory support tools" in Windows Server 2003 Help on the Microsoft Web site. For more information about specific configuration and functionality tests that you can perform before and after the Active Directory installation, see the Active Directory link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources. Search under "Administration and Configuration Guides" and download the *Active Directory Operations Guide*.

**Table 8.2 Active Directory Configuration Test Components**

| Configuration | Tool | Purpose |
|---|---|---|
| Active Directory service | Dcdiag.exe | Tests for successful Active Directory connectivity and functionality. Confirms that the domain controller has passed the diagnostic tests (such as connectivity and replicated objects). Each test must return a "passed" result. |
| | Netdiag.exe | Diagnoses networking and connectivity problems by performing a series of tests to determine the state of your network client and whether it is functional. |
| Active Directory replication | Repadmin.exe /replsum | Returns all replication events taking place between the forest root domain and other Active Directory domain controllers. This must return a successful replication event with all inbound and outbound replication partners. |
| BDC replication status | Nltest.exe /bdc_query:*domainname* | Shows connection status for all the BDCs. This must show "status = success" for each domain controller within the domain. |

After you confirm that the Active Directory configuration is correct, you need to verify that Active Directory is functioning correctly. Table 8.3 lists the Active Directory functions that you need to test and the methods that you can use to perform the tests.

**Table 8.3 Active Directory Functionality Test Components**

| Function | Test | Method |
|---|---|---|
| Trust relationships | Verify the transitive trusts with the parent domain and the one-way trusts with Windows NT 4.0 domains. | Use the verify feature in Active Directory Domains and Trusts on the upgraded PDC to validate the trust relationships that are in place. |
| New user creation | Create a new user on the Windows Server 2003–based domain controller. | Log on with administrator credentials and use Active Directory Users and Computers to verify that the new user was created successfully. |
| New user object replication | After replication to BDCs takes place, determine whether new user is replicated to BDCs. | 1. Type **Net User** at a command prompt on a Windows NT 4.0–based domain controller, and then verify that the new user account exists.<br>2. Modify a property of an existing user and verify that the modified property replicates with the user. |

| | | |
|---|---|---|
| Successful logon request | Verify that users can log on successfully. | 1. Disconnect the Windows Server 2003–based domain controller to confirm that the Windows NT 4.0–based domain controller is validating the user logon request.<br><br>2. Verify that you can log on successfully by using the new user account credentials from each client computer.<br><br>3. Verify that all client operating systems in the upgraded domain and the domains that it trusts can log on successfully.<br><br>4. Repeat step number two over trust relationships where the trusting domain controller has a secure channel with the Windows NT 4.0–based and Windows Server 2003–based domain controllers in the trusted domain. |
| Successful resource access | Verify that the user can access important resources. | 1. Access e-mail resources.<br><br>2. Access roaming profiles.<br><br>3. Access printers.<br><br>4. Resource permissions belonging to the user and a group. |

# Develop a Recovery Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Create a recovery plan for use if the in-place domain upgrade process does not go as planned. Select a Windows NT 4.0 BDC to be used as a rollback server. Synchronize the BDC with the PDC and take the rollback server offline in the event that it must be promoted to a PDC to restore the domain to its original state. Although you are unlikely to need the offline domain controller, it is recommended that you take one offline as a precautionary step if the Security Accounts Manager (SAM) account database on all domain controllers becomes corrupt.

Include the following in your recovery plan:

- The steps needed for recovery. Be sure to provide clear instructions so that the deployment team can restore normal operations to the organization if necessary.

- The estimated time that can elapse before recovery must take place. When elements of the upgrade process test unsuccessfully, you might spend unanticipated amounts of time identifying and correcting errors. Establish clear guidelines for the time period after which the deployment team must restore operations for end users.

- Team review and sign-off. All members of the deployment team must sign off on the recovery plan. This signifies consensus about the recovery plan and reduces the chances that misunderstandings occur when the upgrade process does not go as planned.

**Restoring the Domain to its Original State**

If your in-place upgrade process fails, you can roll back a Windows Server 2003 Active Directory domain to its original state as a Windows NT 4.0 domain. There are two ways to roll back the deployment to its original state:

**Note**

- The first recovery method is preferred for restoring a domain to its original state. The second recovery method should only be used if the SAM database on all domain controllers becomes corrupt.

1. Remove (either by disconnecting the network cable or turning off) any Windows Server 2003–based domain controllers from the domain.

2. Promote a Windows NT 4.0 BDC to become the PDC.

3. Synchronize all Windows NT 4.0–based domain controllers.

4. Test Windows NT 4.0 server operations and domain validation.

5. Document the reasons for the unsuccessful domain upgrade and communicate them to your design team.

6. Restart the design phase for the in-place domain upgrade. Be sure to include steps to mitigate the factors that caused the first in-place domain upgrade to fail.

   – Or –

   If a failure occurs after performing the steps above, remove all Windows Server 2003–based domain controllers from the network and promote the Windows NT 4.0 BDC that has been designated as the rollback server to become the PDC.

7. Perform a full synchronization of all Windows NT 4.0 BDCs.

8. Test Windows NT 4.0 server operations and domain validation.

9. Document the reasons for the unsuccessful domain upgrade and communicate them to your design team.

10. Restart the design phase for the in-place domain upgrade. Be sure to include steps to mitigate the factors that caused the first in-place domain upgrade to fail.

**Important**

- You must take all Windows Server 2003–based domain controllers offline before you promote the rollback server to become the new PDC. If any Windows Server 2003–based domain controllers remain online in the domain, the promotion of the BDC to a PDC will not work.

# Complete Pre-Upgrade Tasks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you create your plan for upgrading your Windows NT 4.0 domains to Windows Server 2003 Active Directory, you must complete the pre-upgrade tasks shown in Figure 8.8 before beginning the in-place upgrade process for your domain.

**Figure 8.8 Completing Pre-Upgrade Tasks**

# Relocate the LMRepl File Replication Service

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To maintain the replication of files in the NETLOGON shared folder from the Windows NT 4.0 export server to all other Windows NT 4.0 BDCs running the LMRepl replication engine during the in-place domain upgrade process, upgrade all servers that are hosting import directories before you upgrade the server that is hosting the export directory.

If the server hosting the export directory is the PDC, you can do one of the following:

- Promote a BDC that meets the Windows Server 2003 domain controller hardware requirements to become the new PDC and demote the existing PDC to serve as a BDC hosting the export server.

  – Or –

  Reconfigure the LMRepl export server on a BDC and remove it from the PDC.

To test the new configuration to ensure that LMRepl continues to work correctly, place an empty file on the export server and verify that the file is replicated to the import directories during replication. Next, delete the replicated file from the import directory, and then verify that the file is deleted during the next replication.

# Ensure Remote Access Service Compatibility

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To ensure remote access compatibility in a mixed Windows NT 4.0 and Windows Server 2003 environment, upgrade the operating system on all remote access servers in the domain to Windows Server 2003 before you begin the in-place domain upgrade process. If RAS is running on a domain controller, upgrade that domain controller early in the in-place domain upgrade process to minimize security risks.

# Enable the Windows NT 4.0 Environment Change Freeze

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you upgrade the PDC in your Windows NT 4.0 domain to Windows Server 2003 Active Directory, you must freeze the Windows NT 4.0 environment to ensure that no other domain changes occur until after the PDC is upgraded. Freeze the Windows NT 4.0 environment when:

- You have completed all of the updates to the Windows NT 4.0 domain and have replicated them to all domain controllers.
- You have synchronized a BDC and have taken it offline for recovery purposes.

When you freeze the Windows NT 4.0 environment, no additional domain changes can take place until you upgrade the Windows NT 4.0 PDC to Windows Server 2003. Communicate to all appropriate individuals that changes to the environment, such as password updates, will not be accepted after a specific date.

# Upgrading Domains from Windows NT 4.0 to Windows Server 2003 Active Directory

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you begin the Windows NT 4.0 in-place upgrade process, determine the upgrade path that your Active Directory design specifies. The Active Directory design will specify one of two possible in-place upgrade paths:

- Upgrade to a regional domain in an existing forest.

  Before upgrading a Windows NT 4.0 domain and joining an existing forest as a regional domain, you must first deploy a Windows Server 2003 forest root domain. Complete the planning and design phases of your Active Directory deployment and then complete the process for deploying the forest root domain. After the forest root domain is deployed, complete the in-place domain upgrade process by following the steps outlined in "Upgrade to a Regional Domain in an Existing Forest" later in this chapter. For more information about deploying the Windows Server 2003 forest root domain, see "Deploying the Windows Server 2003 Forest Root Domain" in this book.

  **Note**

  - If your organization already has a Windows 2000 or Windows Server 2003 Active Directory infrastructure in place, complete the in-place upgrade process by upgrading to a regional domain in an existing forest.

  To help illustrate the process for upgrading to a regional domain in an existing forest, sample data for Trey Research, is provided within the context of the tasks that must be performed.

- Upgrade to a single domain forest.

  To create a new single domain forest, complete the in-place domain upgrade process by following the steps outlined in "Upgrade to a Single Domain Forest" later in this chapter. To help illustrate the process for upgrading to a single domain forest, sample data for a fictitious company, Fabrikam, Inc, is provided within the context of the tasks that must be performed.

For more information about designing an Active Directory logical structure and determining what forest design model best suits your organization, see "Designing the Active Directory Logical Structure" in this book.

Figure 8.9 shows the two paths available for upgrading domains from Windows NT 4.0 to Windows Server 2003 Active Directory and additional tasks that all organizations must perform regardless of which option is specified by the Active Directory design. The additional tasks, including modifying security policies, synchronizing file replication services, recreating trusts, using DNS registration to decrease the workload on the PDC emulator, and upgrading additional domain controllers, are performed after the PDC is upgraded.

**Figure 8.9 Upgrading Domains from Windows NT 4.0 to Windows Server 2003 Active Directory**

After the in-place domain upgrade is complete, you can upgrade additional Windows NT 4.0 domains in-place or restructure the remaining Windows NT 4.0 domains into your Windows Server 2003 Active Directory environment. For more information about restructuring Windows NT 4 domains, see "Restructuring Windows NT 4.0 Domains to an Active Directory Forest" in this book.

# Upgrade to a Regional Domain in an Existing Forest

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To complete the process for upgrading to a regional domain in an existing forest, perform the following tasks:

1. Back up all domain data.
2. Enable the Windows Server 2003 interim forest functional level in the existing forest.
3. Delegate the DNS zone in the forest root domain.
4. Configure protection against domain controller overload.
5. Upgrade the operating system of the Windows NT 4.0 PDC.
6. Install Active Directory.
7. Perform post-upgrade tests.

# Back Up Your Domain Data

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Back up your Windows NT 4.0 domain data before you begin the upgrade. This task varies according to the operations and procedures that already exist in your environment. At minimum, complete the following steps:

- Back up the PDC.
- Back up the BDC that you designated as the rollback server.
    - Test all backup media to ensure that the data can be restored successfully.

**Important**

- Store backup media in a secure offsite location designated by and accessible to the deployment team before you begin the upgrade process.

# Enable the Windows Server 2003 Interim Forest Functional Level

Updated: August 3, 2009

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If all domain controllers in the existing forest are running Windows Server 2003, the functional level of the forest is set at Windows 2000, and the functional level of the forest root domain is set at Windows 2000 mixed, you can raise the forest functional level to Windows Server 2003 interim. Raising the forest functional level to Windows Server 2003 interim is recommended in order to take advantage of the Windows Server 2003 Active Directory features available at that level. However, if you are considering adding Windows 2000–based domain controllers to your environment at any time, you can maintain the Windows 2000 forest functional level and still upgrade your Windows NT 4.0 domains.

Raise the forest functional level in the existing forest to Windows Server 2003 interim before upgrading the PDC and joining the existing forest during the Active Directory installation. By raising the forest functional level in the existing forest before you upgrade the PDC, any additional domains that you upgrade as regional domains will automatically join the Windows Server 2003 forest at the Windows Server 2003 interim domain functional level.

**Important**

- If you raise the forest and domain functional level to Windows Server 2003 interim, you cannot return to the Windows 2000 mixed domain functional level or to the Windows 2000 forest functional level. After you raise the functional level to Windows Server 2003 interim, the environment only supports Windows NT 4.0– and Windows Server 2003–based domain controllers. You can no longer add Windows 2000–based domain controllers into this environment.

You cannot use Active Directory administrative consoles to raise the forest functional level to Windows Server 2003 interim. Instead, use a Lightweight Directory Access Protocol (LDAP) application such as ADSI Edit or LDP in Windows Support Tools to edit the value of the *msDS-Behavior-Version* attribute. You must be a member of the Enterprise Admins group to raise the forest functional level, and you must do this on the domain controller that holds the schema master role.

**To raise the forest functional level to Windows Server 2003 interim by using ADSI Edit**

1. In ADSI Edit, expand the **Configuration** partition, expand **CN=Configuration,DC=*forestname*,DC=*domainname*,DC=com**

2. Right-click **CN=Partitions,** and then click **Properties**.

3. Select the **msDS-Behavior-Version** attribute, and then click **Edit**.

4. In the **Value** field, type **1** to raise the forest functional level to Windows Server 2003 interim, and then click **OK**.

For more information about raising functional levels, see "Enabling Advanced Windows Server 2003 Active Directory Features" in this book.

# Delegate the DNS Zone for the New Regional Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Active Directory DNS owner in your organization is responsible for delegating the zone that matches the name of the regional domain to the DNS servers that are running on the domain controllers in the regional domain.

Before you create the new regional domain, delegate the DNS zone for the new Windows Server 2003 regional domain on any domain controller in the forest root domain DNS zone.

**To delegate the DNS zone for the new regional domain**

1. Open the DNS snap-in from any domain controller in the forest root domain.

2. In the console tree, right-click the forest root domainzone, and then click **New Delegation**.

3. Table 8.4 lists information to complete the New Delegation Wizard, as well as sample data for delegating the DNS domain for the first two regional domain controllers in the east.trccorp.treyresearch.net domain, SEA-EAST-DC01 and SEA-EAST-DC02. Accept the default settings when no information is supplied.

**Table 8.4 Delegating the DNS Domain for the New Regional Domain**

| Wizard Page | Action | Example |
|---|---|---|
| Delegated Domain Name | In the **Delegated Domain** box, type the name of the regional domain. | **East** |
| Name Servers | a. Click **Add**. In the **New Resource Record** dialog box, in the **Server** name box, type the name of the first domain controller you plan to deploy.<br><br>b. In the **New Resource Record** dialog box, in the **IP address** box, type the corresponding IP address of the domain controller, click **Add**, and then click **OK**.<br><br>c. Click **Add**, and in the **New Resource Record** dialog box, in the **Server name** box, type the name of another domain controller you plan to deploy in the regional domain.<br><br>d. In the **New Resource Record** dialog box, in the **IP address box**, type the corresponding IP address of the other domain controller, click **Add**, and then click **OK**. | **SEA-EAST-DC01.trccorp.treyresearch.net**<br><br>**172.16.16.10**<br><br>**SEA-EAST-DC02.trccorp.treyresearch.net**<br><br>**172.16.16.11** |

# Configure Protection From Domain Controller Overload

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before installing Windows Server 2003 on the Windows NT 4.0 PDC, shield the domain controller by configuring it to emulate a Windows NT 4.0–based domain controller. By shielding the domain controller, clients running Windows 2000, Windows XP, and Windows Server 2003 will not recognize it as an Active Directory domain controller. Clients will authenticate with the new Windows Server 2003–based domain controller as if it were a Windows NT 4.0–based domain controller. This step protects the domain controller from being overloaded with authentication requests from Active Directory clients.

Maintain the emulation setting until enough Windows Server 2003–based domain controllers are in each site to service all Active Directory clients.

**Note**

- After removing the NT4Emulator registry entry, Windows 2000, Windows XP, and Windows Server 2003 clients will not immediately begin to use the Kerberos authentication protocol. This will be delayed until each client resets its secure channel or is restarted.

If no Windows 2000, Windows XP, or Windows Server 2003 clients are running in a particular site, or if a Windows Server 2003–based domain controller has the capacity to support the number of clients that are present in the site, you do not need this configuration.

**Caution**

- The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Windows Server 2003 Resource Kit Registry Reference.

**To configure emulation on a Windows NT 4.0–based domain controller before upgrade**

1. In the **Run** dialog box, type **regedit**, and then press ENTER.
2. In the registry editor, navigate to HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters
3. Click **Edit**, click **New**, and then click **DWORD Value**.
4. For the new entry name, type **NT4Emulator**, and then press ENTER.
5. Double-click the entry name that you typed in the previous step.
6. In the **Edit DWORD Value** dialog box, type **1** in the **Value data:** box, and then click **OK**.
7. Click **Registry**, and then click **Exit** to close the registry editor.

Repeat this procedure as needed on each Windows NT 4.0–based domain controller that you plan to upgrade to Windows Server 2003.

After you protect the PDC from becoming overloaded, you must be sure to neutralize the emulation on any additional domain controllers you upgrade. Additional domain controllers in the same domain must be able to contact an Active Directory domain controller in their domain for the Active Directory installation to succeed.

On Windows NT 4.0 BDCs, setting the NT4Emulator registry entry before the operating system upgrade will protect the domain controller from overload. Setting the NeutralizeNT4Emulator registry entry immediately afterward allows the BDC to contact an Active Directory domain controller that has the NT4Emulator registry entry set and successfully install Active Directory. For more information about neutralizing Windows NT 4.0 emulation, see "Neutralize Windows NT 4.0 Domain Controller Emulation" later in this chapter.

After you upgrade all domain controllers, or you have enough Windows Server 2003–based domain controllers to authenticate the clients in your domain that are running Windows 2000, Windows XP, and Windows Server 2003, you can reverse this configuration by editing the registry again and removing the NT4Emulator registry entry.

# Upgrade the Operating System of the Windows NT 4.0 PDC

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before upgrading the operating system to Windows Server 2003, use the Winnt32.exe command-line tool to detect any upgrade problems you might have to resolve. This tool reports potential upgrade problems, such as inadequate hardware resources or compatibility problems.

**To determine potential upgrade problems**

- At the command line, connect to the I386 directory located at your installation source and type the following command:

```
winnt32 /checkupgradeonly
```

Resolve any reported problems before performing the upgrade.

To install the operating system on the computer, insert the Windows Server 2003 operating system CD in the CD-ROM drive of the domain controller and select the option to install the operating system, or use an automated installation method. If the Windows Server 2003 media is shared on the network, run the Winnt32.exe command from the installation source.

Complete the operating system installation by doing the following:

- Select **Upgrade** for the Installation type.
- Use the NTFS file system to convert the partitions. The installation of Active Directory will not succeed if you do not have at least one NTFS partition available on which to locate the SYSVOL shared folder.
- Verify that you are using a static IP address.
- Configure DNS client settings by using the IP address of the closest DNS server for the **Preferred DNS server** setting and either leave the **Alternate DNS server** setting blank or use the IP address of the closest DNS server. These DNS client settings are temporary and will be changed during the installation of Active Directory.
- Install Windows Support Tools, which are available in the \Support\Tools folder on the Windows Server 2003 operating system CD.

During the operating system upgrade the computer will restart three times. After you upgrade the operating system on a Windows NT 4.0 domain controller to Windows Server 2003, the computer is in an intermediate state, meaning that the computer is no longer a Windows NT 4.0–based domain controller, and it is not a Windows Server 2003–based member server or domain controller until Active Directory is installed. After the computer restarts for the last time, the Welcome to the Active Directory Installation Wizard appears.

# Installing Active Directory

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Active Directory Installation Wizard creates the Active Directory database and moves objects from the Windows NT 4.0 Security Accounts Manager (SAM) to the Active Directory database.

**Note**

- When you are upgrading to a regional domain in an existing Active Directory forest, ensure that the domain naming master in the forest root domain is running Windows Server 2003 before installing Active Directory on the newly upgraded PDC. This ensures that application directory partitions are created on the first domain controller in the new regional domain.

In addition, on the first domain controller in a new regional domain in an existing forest, the wizard does the following:

- Prompts the administrator to verify the installation and configuration of the DNS Server service.
- Configures DNS recursive name resolution forwarding by adding the IP addresses of the existing entries for **Preferred DNS server** and **Alternate DNS server** to the list of DNS servers on the **Forwarders** tab of the **Properties** sheet for the domain controller.
- Configures DNS recursive name resolution by root hints, by adding the root hints that are configured on the **Preferred DNS server** to the list of DNS servers on the **Root Hints** tab of the **Properties** sheet for the domain controller.
- Configures the **Preferred DNS server** to point to the DNS server that is running locally on the domain controller, and configures the **Alternate DNS server** to point to the closest DNS server.
- Creates the DomainDnsZones application directory partition that is used by DNS to hold domain-wide DNS data.

Table 8.5 lists information to install Active Directory on an upgraded Windows NT 4.0 PDC and sample data for installing Active Directory on the first domain controller in a new regional domain in the trccorp.treyresearch.net forest, SEA-EAST-DC01.

**Table 8.5 Information to Install Active Directory on a Windows NT 4.0 PDC**

| Wizard Page or Dialog Box | Action | Example |
|---|---|---|
| Create New Domain | Select **ChildDomain in an existing domain tree** | |
| Network Credentials | Type the user name and password of an account with sufficient privileges to install Active Directory on this computer, and the fully qualified domain name of the parent domain. | |
| Child Domain Installation | Enter the full DNS name of the parent domain and the single label name of the new regional domain. | **trccorp.treyresearch.net**<br>**east** |
| Database and Log Folders | Type the folder locations specified by your design | The design for Trey Research specifies that the database folder remain in the default location: **C:\Winnt\Ntds**, and that the log folder is placed on a separate partition: **D:\Logs** |

| | | |
|---|---|---|
| Shared System Volume | Confirm or type the location specified by your design | **C:\Winnt\Sysvol** |
| DNS Registration Diagnostics | DNS Registration Diagnostics will indicate that it cannot find the name and address of the DNS server with which this domain controller will be registered. This is because the pre-created delegation record points to the local computer and DNS has not been installed on the domain controller at this point.<br><br>Select the option to **Install and configure the DNS server on this computer and set this computer to use this DNS server as its preferred DNS server.** | |
| Permissions | Select the security level specified by your design:<br><br>• Permissions compatible with pre-Windows 2000 server operating systems<br><br>• Permissions compatible only with Windows 2000 or Windows Server 2003 operating systems | Because Trey Research currently has services running on Windows NT 4.0–based servers under the context of the Local System account, they selected **Permissions compatible with pre-Windows 2000 server operating systems**. |
| Directory Service Restore Mode Administration Password | In the **Password** and **Confirm password** boxes, type any strong password | |

Verify that all information on the Summary page is accurate, and then click **Finish.** After the Active Directory Installation Wizard finishes, you will be prompted to restart the computer. The installation will not be complete until the computer restarts.

For more information about installing and removing Active Directory, see the *Active Directory Collection* of the *Windows Server 2003 Technical Reference* (or see the Active Directory Collection on the Web at http://www.microsoft.com/reskit).

After you install Windows Server 2003 Active Directory, enable Remote Desktop for Administration, formerly known as Terminal Services in Remote Administration mode, to enable administrators to log on remotely if necessary. To enable Remote Desktop for Administration, in Control Panel, double-click **System**, select the **Remote** tab, and then select **Allow users to connect remotely to this computer**.

# Verify the DNS Server Recursive Name Resolution

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

DNS server recursive name resolution is configured automatically during the Active Directory installation process. If your design specifies a different configuration, you can use the DNS snap-in or Dnscmd.exe to modify these settings. Use the DNS snap-in to verify DNS server recursive name resolution based on the information in Table 8.6.

**Table 8.6 Information to Verify DNS Server Recursive Name Resolution**

| Method | Configuration |
|---|---|
| Recursive name resolution by root hints | No additional configuration is necessary. When the DNS server specified as the Preferred DNS server during the installation process is correctly configured, the root hints are automatically configured. To verify the root hints by using the DNS snap-in:<br>1. In the console tree, right-click the domain controller name, and then click **Properties**.<br>2. In the **Properties** sheet for the domain controller, view the root hints on the **Root Hints** tab.<br>Root hints are the recommended method to use for recursive name resolution in a Windows Server 2003 environment. |
| Recursive name resolution by forwarding | Forward unresolved queries to specified DNS servers. To verify forwarding by using the DNS snap-in:<br>1. In the console tree, right-click the domain controller name, and then click **Properties**.<br>2. On the **Forwarders** tab, in the selected domain's Forwarders list, verify that the IP addresses match those specified by your design.<br>Forwarders should be used only if that is what your organization's design specifies. Root hints are the recommended method to use for recursive name resolution in a Windows Server 2003 environment. |
| No existing DNS infrastructure | No additional configuration is necessary.<br>In this environment, if you want to configure internal DNS servers to resolve queries for external names, configure this DNS server to forward unresolved queries to an external server, such as one in your perimeter network, or one hosted by an Internet service provider. |

# Perform Post-Upgrade Tests

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After the Active Directory Installation Wizard completes, verify the Active Directory installation. Review the Windows Server 2003 Event Viewer for any errors and use the DNS snap-in to verify that the DomainDnsZones was created under the DNS root zone.

You can also verify that Event ID 4500 has been logged in DNS Events to ensure that application directory partitions have been created.

Next, perform the tests defined in your test plan to test the Active Directory configuration and verify whether Active Directory is functioning correctly. For more information about developing a test plan, see "Develop a Test Plan" earlier in this chapter.

After performing post-upgrade tests and verifying that the upgrade of the Windows NT 4.0 PDC and the installation of Active Directory succeeded, complete the upgrade process by continuing to "Modify Security Policies" later in this chapter.

# Upgrade to a Single Domain Forest

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To complete the process for upgrading to a single domain forest, perform the following tasks:

1. Back up all domain data.
2. If you have an existing DNS infrastructure, delegate the DNS zone for the new Windows Server 2003 domain.
3. Configure protection against domain controller overload.
4. Upgrade the operating system of the Windows NT 4.0 PDC.
5. Install Active Directory.
6. Configure the site topology.
7. Configure the Windows Time Service.
8. Enable aging and scavenging for DNS.
9. Verify DNS server recursive name resolution.
10. Perform post-upgrade tests.

**Important**

- When upgrading to a single domain forest, any individual who is a member of the Domain Admins group in the existing Windows NT 4.0 domain will become a member of the Domain Admins and Enterprise Admins groups. Before upgrading the first Windows NT 4.0 domain, remove users whom you do not want to have full access to the entire forest from both the Administrators and Domain Admins groups.

# Back Up the Domain Data

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Back up your Windows NT 4.0 domain data before you begin the upgrade. This task varies according to the operations and procedures that already exist in your environment. It is recommended that you complete the following steps:

- Back up the PDC.
- Back up the BDC that you designated as the rollback server.
    - Test all backup media to ensure that the data can be restored successfully.

**Important**

- Before you begin the upgrade process, store the backup media in a secure offsite location designated by and accessible to the upgrade team.

# Delegate the DNS Zone for the Windows Server 2003 Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If your organization has an existing DNS infrastructure, review current network diagrams and DNS domain hierarchy diagrams. Also review the existing DNS zone configuration, replication, and resource records that are used for delegation and forwarding. To configure the DNS zone for the single domain forest, the DNS administrator of your existing DNS infrastructure delegates the zone matching the name of the new Windows Server 2003 domain to the DNS servers that are running on the domain controllers in the single domain forest.

**Important**

- When no DNS infrastructure exists, skip this step in the process for upgrading to a single domain forest and proceed to the next step, "Configure Protection Against Domain Controller Overload on Additional Domain Controllers" later in this chapter. The remainder of this step describes the process of configuring and delegating a zone in the existing DNS internal namespace.

In preparation for the deployment of the single domain forest, create a delegation for the DNS servers that will be running on the domain controllers in the Windows Server 2003 domain. Create the delegation by adding DNS name server (NS) and address (A) resource records to the parent DNS zone.

**Note**

- The delegation that occurs in this step references the first Windows Server 2003–based domain controller, which does not currently exist. The DNS service is installed and configured on the first Windows Server 2003–based domain controller in a later step.

**To delegate the DNS zone for the Windows Server 2003 domain**

1. Create a name server (NS) resource record in the parent zone. Use the full DNS name of the domain controller.

   ***forest_root_domain*** IN NS ***domain_controller_name***

2. Create a host address (A) resource record in the parent zone. Use the full DNS name of the domain controller.

   ***domain_controller_name*** IN A ***domain_controller_ip_address***

   For example, the DNS administrator for Fabrikam created the following DNS resource records in the parent zone, fabrikam.com:

   - **fabricorp** IN NS **SEA-FAB-DC01.fabricorp.fabrikam.com**
   - **SEA-FAB-DC01.fabricorp.fabrikam.com** IN A **172.16.16.2**

# Configure Protection Against Domain Controller Overload

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before installing Windows Server 2003 on the Windows NT 4.0 PDC, shield the domain controller by configuring it to emulate a Windows NT 4.0–based domain controller. By shielding the domain controller, clients running Windows 2000, Windows XP, and Windows Server 2003 will not recognize it as an Active Directory domain controller. Clients will authenticate with the new Windows Server 2003–based domain controller as if it were a Windows NT 4.0–based domain controller, protecting it from being overloaded with authentication requests from Active Directory clients.

Maintain the emulation setting until there are enough Windows Server 2003–based domain controllers in each site to service all Active Directory clients.

**Note**

- After removing the NT4Emulator registry entry, Windows 2000, Windows XP, and Windows Server 2003 clients will not immediately begin to use the Kerberos authentication protocol. This will be delayed until each client resets its secure channel or is restarted.

If no Windows 2000, Windows XP, or Windows Server 2003 clients are running in a particular site, or if the Windows Server 2003–based domain controller has the capacity to support the number of clients that are present in the site, this configuration is not needed.

**Caution**

- The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back up first and see the Windows Server 2003 Resource Kit Registry Reference.

**To configure emulation on a Windows NT 4.0–based domain controller before upgrade**

1. In the **Run** dialog box, type **regedit**, and press ENTER.
2. In the registry editor, navigate to HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters
3. Click **Edit**, click **New**, and then click **DWORD Value**.
4. For the new entry name, type **NT4Emulator**, and then press ENTER.
5. Double-click the name that you typed in the previous step.
6. In the **Edit DWORD Value** dialog box, type **1** in the **Value data:** box, and then click **OK**.
7. Click **Registry**, and then click **Exit** to close the registry editor.

Repeat this procedure as needed on each Windows NT 4.0–based domain controller that you plant to upgrade to a Windows Server 2003.

After you protect the PDC from becoming overloaded, you must neutralize the emulation on any additional domain controllers that you plan to upgrade. For the Active Directory installation to succeed, additional domain controllers in the same domain must be able to contact an Active Directory domain controller in their domain.

On Windows NT 4.0 BDCs, setting the NT4Emulator registry entry before the operating system upgrade will protect the domain controller from overload. Setting the NeutralizeNT4Emulator registry entry immediately afterward will allow the BDC to contact an Active Directory domain controller that has the NT4Emulator registry entry set and successfully install Active Directory. For more information about neutralizing Windows NT 4.0 emulation, see "Neutralize Windows NT 4.0 Domain Controller Emulation" later in this chapter.

After you upgrade all domain controllers, or you have enough Windows Server 2003–based domain controllers to authenticate the clients in your domain that are running Windows 2000, Windows XP, and Windows Server 2003, you can reverse this configuration by editing the registry again and removing the NT4Emulator registry entry.

# Upgrade the Operating System of the Windows NT 4.0 Primary Domain Controller (PDC)

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before upgrading the operating system to Windows Server 2003, use the Winnt32.exe command-line tool to detect any upgrade problems. This tool reports potential upgrade problems, such as inadequate hardware resources or compatibility problems.

**To determine potential upgrade problems**

- At the command line, connect to the I386 directory located at your installation source and type the following command:

```
winnt32 /checkupgradeonly
```

Resolve reported problems before performing the upgrade.

To install the operating system on the computer, insert the Windows Server 2003 operating system CD in the CD-ROM drive of the domain controller and select the option to install the operating system, or use an automated installation method. If the Windows Server 2003 media is shared on the network, run the Winnt32.exe command.

Complete the operating system installation by doing the following:

1. Select **Upgrade** for the Installation type.

2. Use NTFS to convert the partitions. The installation of Active Directory will not succeed if you do not have at least one NTFS partition available on which to locate the SYSVOL shared folder.

3. Verify that you are using a static IP address.

4. Configure DNS client settings by using the IP address of the closest DNS server for the **Preferred DNS Server** settings. If you have more than one DNS server, add the IP address of the next closest DNS server to the **Alternate DNS server** setting. If there are no other DNS servers, leave the alternate setting blank. These DNS client settings are temporary and will be changed during the installation of Active Directory.

5. Install Windows Support Tools, which are available in the \Support\Tools folder on the Windows Server 2003 operating system CD.

During the operating system upgrade the computer will restart three times. After you upgrade the operating system on a Windows NT 4.0 domain controller to Windows Server 2003, the computer is in an intermediate state, meaning that the computer is no longer a Windows NT 4.0–based domain controller, and it is not a Windows Server 2003–based member server or domain controller until Active Directory is installed. After the computer restarts for the last time, the Welcome to the Active Directory Installation Wizard appears.

# Install Active Directory by Continuing the Active Directory Installation Wizard

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Immediately proceed with the installation of Active Directory by continuing the Active Directory Installation Wizard. The Active Directory Installation Wizard creates the Active Directory database and moves objects from the Windows NT 4.0 SAM to the Active Directory database. In addition, on the first domain controller in a new domain, the wizard proceeds through the following tasks:

- Prompts the administrator to verify the installation and configuration of the DNS Server service.
- Configures DNS recursive name resolution forwarding by adding the IP addresses of the existing entries for **Preferred DNS server** and **Alternate DNS server** to the list of DNS servers on the **Forwarders** tab of the **Properties** sheet for the domain controller.
- Configures DNS recursive name resolution by root hints, by adding the root hints that are configured on the **Preferred DNS server** to the list of DNS servers on the **Root Hints** tab of the **Properties** sheet for the domain controller.
- Configures the **Preferred DNS server** to point to DNS server that is running locally on the domain controller, and configures the **Alternate DNS server** to point to the closest DNS server.
- Creates two application directory partitions that are used by DNS. The DomainDnsZones application directory partition holds domain-wide DNS data, and the ForestDnsZones application directory partition holds forest-wide DNS data.
- Prompts the administrator to select the forest functional level.

Table 8.7 lists information to install Active Directory on a Windows NT 4.0 PDC, and lists sample data for installing Active Directory on the first domain controller in the single domain forest for Fabrikam, SEA-FAB-DC01.

**Table 8.7 Information to Install Active Directory on a Windows NT 4.0 PDC**

| Wizard Page or Dialog Box | Action | Example |
|---|---|---|
| Create New Domain | Select **Domain in a new forest** | |
| New Domain Name | Type the full DNS name of the domain | **Fabricorp.fabrikam.com** |
| Forest Functional Level | Choose **Windows Server 2003 interim** | Because Fabrikam does not plan to add any Windows 2000–based domain controllers to their forest at any time they chose the **Windows Server 2003 interim** forest functional level. |
| Database and Log Folders | Type the folder locations specified by your design | The design for Trey Research specifies that the database folder remain in the default location: **C:\Winnt\Ntds**, and that the log folder is placed on a separate partition: **D:\Logs** |

| | | |
|---|---|---|
| Shared System Volume | Confirm or type the location specified by your design | **C:\Winnt\Sysvol** |
| DNS Registration Diagnostics | DNS Registration Diagnostics will indicate that it cannot find the name and address of the DNS server with which this domain controller will be registered. This is because the pre-created delegation record points to the local computer and DNS has not been installed on the domain controller at this point.<br><br>Select the option to **Install and configure the DNS server on this computer and set this computer to use this DNS server as its preferred DNS server.** | |
| Permissions | Select the security level specified by your design:<br><br>• Permissions compatible with pre-Windows 2000 server operating systems<br><br>• Permissions compatible only with Windows 2000 or Windows Server 2003 operating systems | Because Fabrikam currently has services running on Windows NT 4.0–based servers under the context of the Local System account, they selected **Permissions compatible with pre-Windows 2000 server operating systems** |
| Directory Service Restore Mode Administration Password | In the **Password** and **Confirm password** boxes, type any strong password | |

Verify that all information on the Summary page is accurate, and then click **Finish**. After the Active Directory Installation Wizard finishes, you will be prompted to restart the computer. The installation will not be complete until the computer restarts.

For more information about installing and removing Active Directory, see the *Active Directory Collection* of the *Windows Server 2003 Technical Reference* (or see the Active Directory Collection on the Web at http://www.microsoft.com/reskit).

After you install Windows Server 2003 Active Directory, enable Remote Desktop for Administration, formerly known as Terminal Services in Remote Administration mode, to enable administrators to log on remotely if necessary. To enable Remote Desktop for Administration, in Control Panel, double-click **System**, select the **Remote** tab, and then select **Allow users to connect remotely to this computer**.

# Configure the Site Topology

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you install Active Directory on the first domain controller in the forest, a site object named Default-First-Site-Name is created in the Sites container in Active Directory. The server object for the first domain controller is created in this site.

If no additional sites have been defined in Active Directory, the server object for all subsequent domain controllers will be added to the Default-First-Site-Name site object. However, if additional sites are defined in Active Directory and the IP address of the installation computer matches an existing subnet in a defined site, the domain controller is added to that site.

**Note**

- Domain controllers are only added to sites based on their IP address at the time of installation. After installation, if the IP address, subnet, or site information of a domain controller changes, an administrator must manually move the domain controller to the new site.

To simplify the placement of the domain controller into the appropriate site, configure your site topology before you install Active Directory on additional domain controllers. After all sites are created, a server object for each additional domain controller is created in the appropriate site according to its IP address.

Configure your Active Directory site topology as specified in your site topology design. For information about creating a site topology design, see "Designing the Site Topology" in this book. For more information about configuring your site topology, see "Configure Site Settings" and "Configure Replication Between Sites" in Help and Support Center for Windows Server 2003.

# Configure the Windows Time Service on the Forest Root Domain Controller

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When deploying a single domain forest, it is important to correctly configure the Windows Time Service on the forest root domain controller to meet your organization's needs. The Windows Time Service provides time synchronization to peers and clients, ensuring that there is consistent time throughout an enterprise.

By default, the first domain controller that is deployed holds the PDC emulator operations master role, and should be set to synchronize from a valid Network Time Protocol (NTP) source. If no source is configured, the service will log a message to the event log, and use the local clock when providing time to clients. Although internet NTP sources are valid for this configuration, it is recommended that a dedicated hardware device, such as a GPS, or Radio clock be employed in the interest of security.

It is recommended that you repeat this operation when the PDC emulator operations master role is transferred or seized in the forest root domain.

**To configure the Windows Time Service on first forest root domain controller**

1. Log on to the domain controller.

2. At the command line, type:

   ```
   W32tm /config /manualpeerlist:<peers> /syncfromflags:manual
   ```

   where <peers> is a space–delimited list of DNS and/or IP addresses. When specifying multiple peers, enclose the list in quotation marks.

3. Update the Windows Time Service configuration. At the command line, type:

   ```
   W32tm /config /update
   ```

   – or –

   ```
   Net stop w32time
   Net start w32time
   ```

### Note

- When specifying a manual peer, do not use the DNS name or IP address of a computer that uses the forest root domain controller as its source for time, such as another domain controller in the forest. The time service will not operate correctly if there are cycles in the time source configuration.

For more information about configuring and deploying the Windows Time Service, see the *Active Directory Collection* of the *Windows Server 2003 Technical Reference* (or see the Active Directory Collection on the Web at http://www.microsoft.com/reskit).

Videos about the Windows Time Service

# Enable Aging and Scavenging for Domain Name System (DNS)

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In a new single domain forest you will need to enable aging and scavenging on Windows Server 2003–based domain controllers running the DNS Server service to allow automatic cleanup and removal of stale resource records (RRs), which can accumulate in zone data over time.

With dynamic update, RRs are automatically added to zones when computers start on the network. However, in some cases, they are not automatically removed when computers leave the network. For example, if a computer registers its own host (A) RR at startup, and is later incorrectly disconnected from the network, its host (A) RR might not be deleted. If your network has mobile users and computers, this situation can occur frequently.

If left unmanaged, the presence of stale RRs in zone data might cause problems, including the following:

- If a large number of stale RRs remain in server zones, they can eventually take up server disk space and cause unnecessarily long zone transfers.
- DNS servers loading zones with stale RRs might use outdated information to answer client queries, potentially causing the clients to experience name resolution problems on the network.
- The accumulation of stale RRs at the DNS server can degrade its performance and responsiveness.

**Caution**

- By default, the aging and scavenging mechanism for the DNS Server service is disabled. Enable aging and scavenging only after you understand all parameters. Otherwise, the server could be accidentally configured to delete resource records that should not be deleted. If a resource record is accidentally deleted, not only will users fail to resolve queries for that resource record, but any user can create the resource record and take ownership of it, even on zones configured for secure dynamic update.
- For more information about how to configure aging and scavenging, see "Understanding aging and scavenging" in Help and Support Center for Windows Server 2003.

To enable the aging and scavenging features, and to configure the applicable server and its Active Directory–integrated zones, perform these tasks:

- Enable aging and scavenging at the server. These settings determine the effect of zone-level properties for any Active Directory–integrated zones loaded at the server.
- Enable aging and scavenging for selected zones at the DNS server. When zone-specific properties are set for a selected zone, these settings apply only to the applicable zone and its resource records. Unless these zone-level properties are otherwise configured, they inherit their defaults from comparable settings maintained in server aging/scavenging properties.

**To set aging and scavenging properties for the DNS server**

1. Log on to the computer that is running the DNS Server service with an account that is a member of the local Administrators group.
2. In the DNS console tree, right-click the applicable DNS server, and then click **Set Aging/Scavenging for all zones**.
3. Select the **Scavenge stale resource records** check box.
4. Modify other aging and scavenging properties as needed.

**To set aging and scavenging properties for a zone**

1. Log on to the computer that is running the DNS Server service with an account that is a member of the local Administrators group.

2. In the DNS console tree, right-click the applicable zone, and then click **Properties**.

3. On the **General** tab, click **Aging**, and then select the **Scavenge stale resource records** check box.

4. Modify other aging and scavenging properties as needed.

# Verify DNS Server Recursive Name Resolution When Upgrading to a Single Domain Forest

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

DNS server recursive name resolution is configured automatically during the Active Directory installation process. If your design specifies a different configuration, you can use the DNS snap-in or Dnscmd.exe to modify these settings. Use the DNS snap-in to verify DNS server recursive name resolution based on the information in Table 8.8.

**Table 8.8 Information to Verify DNS Server Recursive Name Resolution**

| Method | Configuration |
|---|---|
| Recursive name resolution by root hints | No additional configuration is necessary. When the DNS server specified as the Preferred DNS server during the installation process is correctly configured, the root hints are automatically configured. To verify the root hints by using the DNS snap-in:<br>1. In the console tree, right-click the domain controller name, and then click **Properties**.<br>2. In the **Properties** sheet for the domain controller, view the root hints on the **Root Hints** tab.<br>Root hints are the recommended method to use for recursive name resolution in a Windows Server 2003 environment. |
| Recursive name resolution by forwarding | Forward unresolved queries to specified DNS servers. To verify forwarding by using the DNS snap-in:<br>1. In the console tree, right-click the domain controller name, and then click **Properties**.<br>2. On the **Forwarders** tab, in the selected domain's Forwarders list, verify that the IP addresses match those specified by your design.<br>Forwarders should be used only if that is what your organization's design specifies. Root hints are the recommended method to use for recursive name resolution in a Windows Server 2003 environment. |
| No existing DNS infrastructure | No additional configuration is necessary.<br>In this environment, if you want to configure internal DNS servers to resolve queries for external names, then configure this DNS server to forward unresolved queries to an external server, such as one in your perimeter network, or one hosted by an Internet service provider. |

# Perform Post-Upgrade Tests After the Active Directory Installation Wizard Completes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After the Active Directory Installation Wizard completes, verify the Active Directory installation. Review the Windows Server 2003 event log for any errors and use the DNS snap-in to verify that the following two DNS zones were created under the DNS root zone:

- DomainDnsZones
- ForestDnsZones

You can also verify that Event ID 4500 has been logged in DNS Events to ensure that application directory partitions have been created.

Next, perform the tests defined in your test plan to test the Active Directory configuration and verify whether Active Directory is functioning correctly. For more information about developing a test plan, see "Develop a Test Plan" earlier in this chapter.

After performing post-upgrade tests and verifying that the upgrade of the Windows NT 4.0 PDC and the installation of Active Directory succeeded, complete the upgrade process by continuing to "Modify Security Policies" later in this chapter.

# Modify Security Policies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To ensure that clients running earlier versions of the Windows operating system can access domain resources in the new Windows Server 2003 domain, you might have to modify default security policies.

In order to increase security, Windows Server 2003–based domain controllers require by default that clients attempting to authenticate to them use SMB packet and secure channel signing. Clients running the Windows 95 operating system without the Directory Service Client Pack or Windows NT 4.0 with Service Pack 2 and earlier do not support SMB packet signing and will not be able to log on or access domain resources on the network. Clients running Windows NT 4.0 with Service Pack 3 and earlier do not support secure channel signing and will not be able to establish communications with a domain controller in their domain.

The most secure way to enable these clients to log on and access domain resources on the network is to apply either the appropriate service pack or the Directory Service Client Pack. If you cannot apply either of these, configure all Windows Server 2003–based domain controllers to not require SMB packet signing and secure channel signing. To do this, disable the following settings in the Default Domain Controllers Policy:

- **Microsoft network server: Digitally sign communications (always)**
- **Domain member: Digitally encrypt or sign secure channel data (always)**

**Important**

- If you modify these policies, the default security policies in your environment are weakened. However, this is necessary to ensure that some clients running earlier versions of Windows can access domain resources. After all the clients in your environment are running versions of Windows that support SMB packet and secure channel signing, you can re-enable these security policies to increase security. It is recommended that you upgrade your Windows clients as soon as possible.

**To make SMB packet and secure channel signing optional on Windows Server 2003–based domain controllers**

1. Open **Active Directory Users and Computers**, right-click the **Domain Controllers** container, and then click **Properties**.
2. Select the **Group Policy** tab, and then click **Edit**.
3. Under **Computer Configuration**, navigate to Windows Settings\Security Settings\Local Policies\Security Options.
4. In the details pane, double-click **Microsoft network server: Digitally sign communications (always)** and then click **Disabled** to prevent SMB packet signing from being required.
5. Click **OK**.
6. In the Details pane, double-click **Domain member: Digitally encrypt or sign secure channel data (always),** click **Disabled** to prevent secure channel signing from being required, and then click **OK**.
7. To apply the Group Policy change immediately, either restart the domain controller, or run the **gpupdate /force** command.

**Note**

- Modifying these settings in the Domain Controllers container will change the Default Domain Controllers Policy. Policy changes that are made here are replicated to all other domain controllers in the domain, requiring you to modify these policies only one time.

For more information about SMB packet signing and secure channel signing, see "Background Information for Upgrading to Windows Server 2003 Active Directory" earlier in this chapter.

For more information about security policies, see "Security Options" on the Microsoft Web site.

# Synchronize File Replication Services

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After upgrading the Windows NT 4.0 PDC, create a script to copy logon script and profile information from the NETLOGON shared folder on the new Windows Server 2003–based domain controller to the REPL$ share on the Windows NT 4.0 BDC that is providing export services to other Windows NT 4.0 BDCs in the domain.

**To create logon script and profile replication between Windows Server 2003–based and Windows NT 4.0–based domain controllers**

1. Create a user account on a Windows NT 4.0 BDC in the Windows Server 2003 domainby using User Manager for Domains and the information in Table 8.9.

   **Table 8.9 User Account Information for Logon Script and Profile Replication**

   | When Prompted For | Use |
   |---|---|
   | User name | LbridgeAcct |
   | Description | Account used by lbridge.cmd for replication. |
   | Password | *password* (where *password* is any password that meets the security requirements for your organization). |
   | Select **User Must Change Password At Next Logon** to clear the checkbox. | |

2. Use the information listed in Table 8.10 to ensure that the LbridgeAcct has the correct permissions on both the Windows Server 2003–based domain controller and on the Windows NT 4.0 BDC.

   **Table 8.10 Permissions for the LbridgeAcct User Account**

   | Folder | Permission |
   |---|---|
   | On the Windows NT 4.0 BDC, ensure that the LbridgeAcct is granted Full Control to the REPL$ share.<br><br>In Server Manager, select the computer configured as the export server, click **Computer**, and select **Shared Directories.** Select **REPL$**, and then click **Properties**. In the **Share Properties** dialog box, click **Permissions**, click **Add**, and then click **Show Users**. Select the LbridgeAcct. In the **Type of Access** drop-down list box, select **Full Control**. | Full Control |
   | On the Windows Server 2003–based domain controller in the new Windows Server 2003 domain, ensure that the LbridgeAcct is granted Read access to the NETLOGON shared folder.<br><br>Access the NETLOGON shared folder by typing *win_dc*\Netlogon (where *win_dc* is the name of the Windows Server 2003–based domain controller) in the Run dialog box. | Read |

3. Create a destination folder on the Windows Server 2003–based domain controller where you will install the **Lbridge.cmd** script and the **Robocopy.exe** tool.

4. Modify the path statement in Environment Variables to include the destination folder. Right-click **My Computer**, click **Properties**, click the **Advanced** tab, and then click **Environment Variables**. In the System Variables list, select **Path** and click **Edit**. Append the Variable value with the location of the destination folder (*;C:\destination folder*).

   The **Lbridge.cmd** script and **Robocopy.exe** tools are available on the *Windows Server 2003 Deployment Kit* companion CD.

5. On the Windows Server 2003–based domain controller, in Windows Explorer, right-click the Lbridge.cmd script, and then

click **Edit**. Edit as indicated in Table 8.11.

**Table 8.11 Modifications to the lbridge.cmd Script**

| Script Line | Change To |
|---|---|
| Set L-Destination=%1 | Set L-Destination=***winnt_dc*\REPL$** (where *winnt_dc* is name of the Windows NT 4.0 BDC hosting the LMRepl export server. |
| Call :Xcopy | @Rem Call :Xcopy |
| @Rem Call :Robocopy | Call :Robocopy |
| Echo Robocopy %L-Source%%L-Destination% /E /PURGE | Robocopy %L-Source%%L-Destination% /E /PURGE |

6. On the Windows Server 2003–based domain controller, open **Control Panel**, point to **Scheduled Tasks**, and then click **AddScheduled Task**.

7. Complete the Scheduled Task Wizard by using the information in Table 8.12. Accept the default settings when no information is supplied.

**Table 8.12 Scheduled Task Wizard Actions for Lbridge.cmd**

| Wizard Page | Action |
|---|---|
| Click the program you want Windows to run | Click **Browse**.<br><br>In the **Select Program to Schedule** dialog box, click lbridge.cmd. |
| Type a name for this task | Type **FRS - LMRepl Replication Bridge**. |
| Perform this task | Select **Daily**. |
| Start time | Enter the time and date that you want the replication to start. |
| Enter the user name | Type **LbridgeAcct**. |
| Enter the password | Type the password that you have chosen for LbridgeAcct. |
| Confirm the password | Confirm the password for LbridgeAcct. |
| Open advanced properties for this task when I click Finish | Select the check box. |

The **FRS - LMRepl Replication Bridge** dialog box opens.

8. In the **FRS - LMRepl Replication Bridge** dialog box, on the **Schedule** tab, click **Advanced**.

9. In the **Advanced Schedule Options** dialog box, select the **Repeat task** check box.

10. In the **Every** box, specify how often you want the script to run.

11. In the **Duration** box, specify how long you want the script to run, and then click **OK**.

12. In the **FRS - LMRepl Replication Bridge** dialog box, on the **Schedule** page, click **OK**.

To verify that the script ran successfully and replication is occurring from the Windows Server 2003–based domain controller to all Windows NT 4.0–based domain controllers, place a file called Test.txt into the

***Win_dc*\SYSVOL\sysvol*domainname*\scripts** folder. After replication is scheduled to take place, verify that the Test.txt file has replicated to the **\Winnt_dc\system32\REPL\Import\scripts** folder.

# Recreate Trusts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Trust relationships between Windows NT 4.0 domains use NetBIOS domain names. During the in-place upgrade of your Windows NT 4.0 environment, if some of your Windows NT 4.0 domains have trust relationships with other Windows NT 4.0 domains that are then upgraded into separate forests, those trust relationships between the domains in different forests remain, but continue to use the NetBIOS domain name. It is recommended that trust relationships between domains in different forests use the DNS name for the domain in order to gain better functionality in a Windows Server 2003 environment. To rename the trust relationship by using the DNS name for the domain, delete and recreate external trust relationships that exist between Windows NT 4.0 domains and Active Directory domains in different forests. Trusts that use NetBIOS names and exist between Windows NT 4.0 domains can be left in place.

# Use DNS Registration to Decrease the Workload on the PDC Emulator

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After upgrading the Windows NT 4.0 PDC, the domain controller hosts the PDC emulator operations master role. Of all the operations master roles, the PDC emulator role has the greatest effect on the domain controller that is hosting that role because the PDC emulator fulfills additional tasks in the domain, such as processing password changes, processing authentication requests if the password fails on the authenticating domain controller, and all write operations to the domain that are requested or performed by applications or by clients running Windows 2000, Windows XP, and Windows Server 2003.

In domains with more than 10,000 users, it might be necessary to reduce the number of authentication requests received by the PDC emulator and allow it to perform other tasks. If, after upgrading the Windows NT 4.0 PDC, CPU utilization is higher than 50 percent or if disk queues remain higher than two for several hours or days, reduce the number of client authentication requests that are received by the PDC emulator.

**Note**

- Other factors that can increase the workload on the PDC emulator include pre-Active Directory clients or applications that have been written to contact the PDC emulator.

To reduce the number of client authentication requests that are processed by the PDC emulator, adjust its weight or its priority in the DNS environment. If you want to proportionately reduce the number of client authentication requests received by the PDC emulator, adjust its weight. If you want to ensure that the PDC emulator does not receive any client authentication requests, adjust its priority.

Active Directory assigns a default value of 100 for the weight. By creating a new registry entry for the weight and assigning it a decreased value of 50, you can proportionately reduce the number of client authentication requests that are sent to the PDC. This ensures that the PDC will authenticate half of the number of clients that it would if the weight value remained at 100.

Active Directory assigns a default value of zero for the priority. By creating a new registry entry for the priority and assigning it an increased value of 200, you can ensure that the PDC will never receive client authentication requests unless it is the only accessible domain controller.

**Caution**

- The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the "Registry Reference" on the *Windows Server 2003 Deployment Kit* companion CD or on the Microsoft Web site.

**To change the weight for DNS SRV records by using the registry**

1. In the **Run** dialog box, type **regedit**, and then press ENTER.
2. In the registry editor, navigate to HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters
3. Click **Edit**, click **New**, and then click **DWORD value**.
4. For the new entry name, type **LdapSrvWeight**, and then press ENTER. (The value name is not case sensitive.)
5. Double-click the entry name you just typed.
6. In the **Edit DWORD Value** dialog box, select **Decimal** as the **Base** option.
7. Enter a value between 0 and 65535 (the recommended value is 50), and then click **OK**.
8. Click **File**, and then click **Exit** to close the registry editor.

Adjusting the priority of the domain controller also reduces the number of client referrals. However, rather than reducing it proportionally to the other domain controllers, changing the priority causes DNS to stop referring all clients to this domain controller unless all domain controllers with a lower priority setting are unavailable.

**Note**

- A lower value entered for **LdapSrvPriority** indicates a higher priority. A domain controller with an **LdapSrvPriority** setting of 100 has a lower priority than a domain controller with a setting of 10. Therefore, clients attempt to use the domain controller with the setting of 10 first.

**To change the priority for DNS SRV records by using the registry**

1. In the **Run** dialog box, type **regedit**, and then press ENTER.
2. In the registry editor, navigate to HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters
3. Click **Edit**, click **New**, and then click **DWORD value**.
4. For the new entry name, type **LdapSrvPriority**, and then press ENTER.
5. Double-click the entry name that you just typed.
6. In the **Edit DWORD Value** dialog box, select **Decimal** as the **Base** option.
7. Enter a value between 0 and 65535 (the recommended value is 200), and then click **OK**.
8. Click **File**, and then click **Exit** to close the registry editor.

For more information about adjusting the weight or the priority of the PDC emulator, see the Active Directory link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources. Search under "Administration and Configuration Guides" and download the *Active Directory Operations Guide*.

# Upgrade Additional Domain Controllers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you upgrade the operating system and install Active Directory on the Windows NT 4.0 PDC, add another Windows Server 2003–based domain controller to the domain as soon as possible. This provides redundancy for any clients running in the environment.

You can add additional domain controllers to the Windows Server 2003 domain by upgrading Windows NT 4.0–based BDCs and installing Active Directory, or by adding Windows Server 2003–based member servers to the domain and installing Active Directory on the member servers.

To complete the process for upgrading additional domain controllers, perform the following tasks:

1. Configure protection against domain controller overload.
2. Neutralize Windows NT 4.0 domain controller emulation.
3. Upgrade the operating system of Windows NT 4.0 BDCs.
4. Install Active Directory.
5. Install DNS on additional domain controllers.
6. Reconfigure the DNS Service.
7. Add Windows NT 4.0 BDCs to the Windows Server 2003 domain if necessary.
8. Perform post-upgrade tests.

# Configure Protection Against Domain Controller Overload on Additional Domain Controllers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To configure an additional domain controller against overload, perform the same steps that were performed to configure protection on the Windows NT 4.0 PDC. Configure the domain controller to emulate a Windows NT 4.0–based domain controller before you upgrade the operating system and install Active Directory.

**Caution**

- The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Windows Server 2003 Resource Kit Registry Reference.

**To configure emulation on a Windows NT 4.0–based domain controller before upgrade**

1. In the **Run** dialog box, type **regedit**, and then press ENTER.
2. In the registry editor, navigate to HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters
3. Click **Edit**, click **New**, and then click **DWORD Value**.
4. For the new entry name, type **NT4Emulator**, and then press ENTER.
5. Double-click the entry name that you typed in the previous step.
6. In the **Edit DWORD Value** dialog box, type **1** in the **Value data:** box, and then click **OK**.

Keep the registry editor open to perform the next step in the upgrade process.

# Neutralize Windows NT 4.0 Domain Controller Emulation

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

On all additional domain controllers, you must be sure to neutralize Windows NT 4.0 emulation before installing Active Directory. When deploying additional domain controllers, the computers must be able to contact an Active Directory domain controller during the installation of Active Directory. If the Active Directory domain controllers that you have already upgraded have been configured to protect against domain controller overload by setting the value of the NT4Emulator registry entry to one, the additional domain controllers will only recognize them as Windows NT 4.0–based domain controllers and the Active Directory installation will fail.

**Caution**

- The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Windows Server 2003 Resource Kit Registry Reference.

**To neutralize Windows NT 4.0 emulation**

1. In the registry editor, navigate to HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters
2. Click **Edit**, click **New**, and then click **DWORD Value**.
3. For the new entry name, type **NeutralizeNT4Emulator**, and then press ENTER.
4. Double-click the entry name that you typed in the previous step.
5. In the **Edit DWORD Value** dialog box, type **1** in the **Value data:** box, and then click **OK**.
6. Click **Registry**, and then click **Exit** to close the registry editor.

You can also administer Windows Server 2003–based domain controllers that have been configured to emulate a Windows NT 4.0–based domain controller from a workstation running Windows 2000 or Windows XP. If you intend to use a management workstation that is running Windows 2000 or Windows XP, you must first neutralize the emulation mode on the management workstation so that Windows Server 2003–based domain controllers will respond to it.

# Upgrade Windows NT 4.0 BDCs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can upgrade any Windows NT 4.0 BDC to a Windows Server 2003–based domain controller as long as it meets the hardware requirements for a domain controller running Windows Server 2003. For more information about the hardware requirements for Windows Server 2003–based domain controllers, see "Planning Domain Controller Capacity" in this book.

Before upgrading the operating system to Windows Server 2003, use the Winnt32.exe command-line tool to detect any upgrade problems. This tool reports potential upgrade problems, such as inadequate hardware resources or compatibility problems.

**To determine potential upgrade problems**

- At the command line, connect to the I386 directory located at your installation source and type the following command:

```
winnt32 /checkupgradeonly
```

Resolve reported problems before performing the upgrade.

To install the operating system on the computer, insert the Windows Server 2003 operating system CD in the CD-ROM drive of the domain controller and select the option to install the operating system, or use an automated installation method. If the Windows Server 2003 media is shared on the network, run the Winnt32.exe command.

To complete the operating system installation, perform these tasks:

1. Select **Upgrade** for the Installation type.

2. Use NTFS to convert the partitions. The installation of Active Directory will not succeed if you do not have at least one NTFS partition available on which to locate the SYSVOL shared folder.

3. Verify that you are using a static IP address.

4. On the first additional domain controller upgraded, configure DNS client settings by using the IP address of the PDC for the **Preferred DNS server** setting and do not specify an IP address in the **Alternate DNS server** setting.

   On all remaining domain controllers that are upgraded, configure DNS client settings by using the IP address of the PDC for the **Preferred DNS server** setting and use the IP address of the second domain controller upgraded for the **Alternate DNS server** setting.

   These DNS client settings are temporary and will be changed during the installation of Active Directory.

5. Install Windows Support Tools, which are available in the \Support\Tools folder on the Windows Server 2003 operating system CD.

During the operating system upgrade the computer will restart three times. After the computer restarts for the last time, the **Welcome to the Active Directory Installation Wizard** appears.

# Install Active Directory on the Additional Domain Controllers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The process for installing Active Directory on additional domain controllers is identical whether you upgraded to a regional domain controller in an existing domain or upgraded to a single domain forest. After upgrading the operating system on a Windows NT 4.0 additional domain controller to Windows Server 2003, the computer is in an intermediate state, meaning that the computer is no longer a Windows NT 4.0–based domain controller, nor is it a Windows Server 2003–based member server or domain controller.

The Active Directory Installation Wizard allows you to create an additional domain controller or a member server in the new domain. If you will be installing Active Directory by replicating the directory data over the network or from another media source, select the **Member Server** option in the Active Directory Installation Wizard. Selecting **Member Server** will configure the computer to be a Windows Server 2003–based member server, allowing you to install Active Directory at a later time.

**To install Active Directory on a Windows Server 2003–based member server**

- At the command Line, type **Dcpromo**.

  – or –

  Open **Administrative Tools**, and then click **Configure Your Server Wizard**. Select **Domain Controller (Active Directory)** to configure your domain controller. After the Configure Your Server Wizard finishes, the Active Directory Installation Wizard begins.

You can also install Active Directory by using the install from media feature, new in Windows Server 2003. Install from media allows you to pre-populate Active Directory with System State data backed up from an existing Windows Server 2003–based domain controller. This backup can be present on local CD, DVD, or hard disk partition. Installing from media drastically reduces the time required to install directory data by reducing the amount of data that is replicated over the network. Installing from media is most beneficial in environments with very large domains or for installing new domain controllers that are connected by a slow network link.

**To install Active Directory on a Windows Server 2003–based member server from media**

- Type **dcpromo /adv** in the **Run** dialog box.

  The wizard prompts you to choose a network share or a backup as the installation source. If you are installing from backup files, you must identify the location of the files. If the domain controller from which you restored the System State data was a global catalog server, you will have the option make this new domain controller a global catalog server. The wizard will then proceed with the installation.

For more information about installing and removing Active Directory, see the *Active Directory Collection* of the *Windows Server 2003 Technical Reference* (or see the Active Directory Collection on the Web at http://www.microsoft.com/reskit).

Table 8.13 lists information for installing Active Directory on additional domain controllers, as well as sample data for installing Active Directory on additional domain controllers in a regional domain in the existing Trey Research forest or in the Fabrikam single domain forest. Trey Research will install Active Directory immediately after upgrading the operating system. Fabrikam will use the **dcpromo /adv** command to install Active Directory on a member server by copying directory data over the network from a domain controller.

**Table 8.13 Installing Active Directory on Additional Domain Controllers**

| Wizard Page or Dialog Box | Action | Example |
|---|---|---|

| | | |
|---|---|---|
| Additional Domain Controller or Member Server | Select whether you want the computer to become a member server or an additional domain controller for the domain. | **Upgrading to a regional domain in an existing forest:**<br><br>Trey Research will select Additional domain controller to install Active Directory immediately.<br><br>**Upgrading to a single domain forest:**<br><br>Fabrikam will select Member Server. They will install Active Directory at a later time using the **dcpromo /adv** command. |
| Domain Controller Type | Select **Additional domain controller for an existing domain**. | **Upgrading to a regional domain in an existing forest:**<br><br>Trey Research will not see this wizard page.<br><br>**Upgrading to a single domain forest:**<br><br>When Fabrikam initiates the Active Directory Installation Wizard by using the **dcpromo /adv** command, this is the first wizard page that appears. |
| Copying Domain Information | Select either:<br><br>• Over the network from a domain controller<br><br>• From these restored backup files | **Upgrading to a regional domain in an existing forest:**<br><br>Trey Research will not see this wizard page because they chose to install Active Directory immediately following the operating system upgrade.<br><br>**Upgrading to a single domain forest:**<br><br>Fabrikam will copy domain information from the first domain controller that is deployed, SEA-FAB-DC01,which is in the same location as the new one. Therefore, they selected **Over the network from a domain controller** to copy the information in the shortest time. |
| Network Credentials | Type the user name and password of an account with sufficient privileges to install Active Directory on this computer, and the fully qualified domain name of the domain in which the computer will become an additional domain controller. | |
| Additional Domain Controller | Type the full DNS name of the forest root domain. | **Upgrading to a regional domain in an existing forest:**<br><br>Trey Research will not see this wizard page. It appears only if you are installing Active Directory over the network from a domain controller.<br><br>**Upgrading to a single domain forest:**<br><br>**Fabricorp.fabrikam.com** |
| Database and Log Folders | Type the folder locations specified by your design. | Database folder: **C:\Windows\NTDS**<br><br>Log folder: **D:\Logs** |
| Shared System Volume | Confirm or type the location specified by your design. | **C:\Windows\SYSVOL** |
| Directory Service Restore Mode Administration Password | In the **Password and Confirm password** boxes, type any strong password. | |

Verify that all information on the Summary page is accurate, and then click Finish. After the Active Directory Installation Wizard

finishes, you will be prompted to restart the computer. The installation will not be complete until the computer restarts.

**Note**

- All additional domain controllers added to a single domain forest should be configured as Global Catalog servers. For more information about global catalog server placement, see "Designing the Site Topology" in this book.

After you install Windows Server 2003 Active Directory, enable Remote Desktop for Administration, formerly known as Terminal Services in Remote Administration mode, to enable administrators to log on remotely if necessary. To enable Remote Desktop for Administration, in Control Panel, double-click **System**, select the **Remote** tab, and then select **Allow users to connect remotely to this computer**.

# Install DNS on Additional Domain Controllers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Install DNS on all Windows Server 2003–based domain controllers that are added to the domain.

**To install DNS on additional domain controllers using the Windows Components Wizard**

1. Click **Start**, point to **Settings**, and click **Control Panel**.
2. Double click **Add or Remove Programs**, and then click **Add/Remove Windows Components**.
3. In **Components**, select the **Networking Services** check box, and then click **Details**.
4. In **Subcomponents of Networking Services**, select the **Domain Name System (DNS)** checkbox, click **OK**, and then click **Next**.
5. If prompted, in **Copy files from**, type the full path to the distribution files and then click **OK**. The required files will be copied to your hard disk.

# Reconfigure the Domain Name System (DNS) Service

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After deploying additional domain controllers in either a new regional domain in an existing forest or in a single domain forest, do the following to reconfigure the DNS service:

- Configure the DNS client settings of the first and subsequent domain controllers

  After you have deployed an additional domain controller, modify the DNS client settings on the first domain controller. Because no other domain controllers were running when you deployed the first domain controller, modify the DNS client settings on the first domain controller to include the additional domain controller. As you deploy more domain controllers, you might also need to modify the Alternate DNS server setting specified on existing domain controllers to ensure that this setting points to the closest DNS server.

- Update the DNS delegation

  If you have delegated the DNS zone to an existing DNS server, update the DNS delegation for the domain after you install the DNS Server service on new domain controllers.

# Add Windows NT 4.0 BDCs to Windows Server 2003 Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you have applications in your environment that can run only on a Windows NT 4.0–based domain controller and if all the Windows NT 4.0 BDCs have been upgraded to Windows Server 2003 or the existing Windows NT 4.0 BDC in your environment becomes unavailable, you might need to add an additional Windows NT 4.0 BDC to your environment. You can do this by installing a new Windows NT 4.0 BDC in the domain. Prior to installing the new Windows NT 4.0 BDC in the domain, you must first add the new computer account to the Windows Server 2003 domain.

**Note**

- You will not be able to install a new Windows NT 4.0–based BDC in your environment if you have SMB packet signing and secure channel signing enabled. If these security policies are enabled in your environment, modify them before installing a new Windows NT 4.0–based BDC. For information about modifying security policies, see "Modify Security Policies" earlier in this chapter.

**To add a Windows NT 4.0 BDC to a Windows Server 2003 domain**

1. In Active Directory Users and Computers, right-click the **Domain Controllers** folder.
2. Point to **New**, and then click **Computer**.
3. Type the computer name of the BDC.
4. Ensure that the checkboxes are selected for **Assign this computer account as a pre-Windows 2000 Computer** and **Assign this computer account as a backup domain controller**.
5. Install the BDC in to the domain.

# Perform Post-Upgrade Tests on Domain Controllers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After each additional domain controller is deployed, verify that the upgrade was successful. Use the same tests and tools that you used to verify that the upgrade of the Windows NT 4.0 PDC was successful. For more information about developing a test plan, see "Develop a Test Plan" earlier in this chapter.

Also verify that DNS recursive name resolution is configured according to your organization's DNS design. For more information about verifying recursive name resolution, see "Verify DNS Server Recursive Name Resolution on the First Forest Root Domain Controller" earlier in this chapter.

# Complete Post-Upgrade Tasks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you upgrade all domain controllers in the domain to Windows Server 2003, complete the post-upgrade tasks. These tasks are the final step in the process for upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory, as shown in Figure 8.10.

**Figure 8.10 Completing Post-Upgrade Tasks**

# Eliminate Anonymous Connections to Domain Controllers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you upgrade all the servers in the domain hosting services that run as Local System and use Anonymous or null credentials when accessing a domain controller, such as Windows NT 4.0 RAS servers, remove the Everyone and Anonymous Logon groups from the Pre-Windows 2000 Compatible Access built-in group. This task increases the security of your domain by preventing anonymous connections to domain controllers.

**To remove groups from the Pre-Windows 2000 Compatible Access Group using the command line**

- At a command prompt, type:

```
net localgroup "Pre-Windows 2000 Compatible Access" GroupName /delete
```

When using the **net localgroup** command to add or delete any group or group member name that includes spaces, such as the Anonymous Logon group, you must enclose the group name in quotation marks.

# Raise Your Domain and Forest Functional Levels

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Although the Windows Server 2003 domain functional level provides a number of features and advantages, enable this functional level only when all your Windows NT 4.0 BDCs have been upgraded and you are certain that your environment is ready.

**Important**

- If you raise the domain and forest functional levels to Windows Server 2003, this action cannot be reversed and you cannot add Windows NT 4.0–based or Windows 2000–based domain controllers to the environment. Any existing Windows NT 4.0 or Windows 2000–based domain controllers in the environment will no longer function. Before you raise functional levels to take advantage of advanced Windows Server 2003 features, ensure that you will never need to install domain controllers that run Windows NT 4.0 or Windows 2000 in your environment.

After you determine that your environment is ready, use Active Directory Domains and Trusts to enable the Windows Server 2003 domain functional level.

After all domains are operating at the Windows Server 2003 functional level, raise the forest functional level to Windows Server 2003 to take advantage of all Windows Server 2003 forest-level features.

For more information about enabling functional levels and the features available at the Windows Server 2003 domain and forest functional levels, see "Enabling Advanced Windows Server 2003 Active Directory Features" in this book.

# Redirect the Users and Computers Containers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The default CN=Users and CN=Computers containers that are created when Active Directory is installed are not organizational units (OUs). Objects in the default containers are more difficult to manage because Group Policy cannot be applied directly to them. New user accounts, computer accounts, and security groups that are created by using earlier versions of user interface and command-line management tools, such as the net user and net computer commands, the net group command, the netdom add command where the /ou command is either not specified or supported, or Windows NT 4.0 tools such as User Manager for Domains, do not allow administrators to specify a target organizational unit and therefore create these objects in either the CN=Computers container or the CN=User container by default.

It is recommended that administrators who upgrade Windows NT 4.0–based and Windows 2000–based domain controllers to Windows Server 2003 redirect the well-known path for the CN=Users and CN=Computers to an OU that is specified by the administrator so that Group Policy can apply to containers that are hosting newly created objects.

**Important**

- The CN=Users and CN=Computers containers are computer-protected objects. You cannot (and must not) remove them for backward compatibility purposes. However, you can rename these objects.

In Windows Server 2003 Active Directory, when the domain functional level has been raised to Windows Server 2003, you can redirect the default CN=Users and CN=Computers containers to organizational units that you specify so that each can support Group Policy, making them easier to manage.

**To redirect the Users container**

1. In Active Directory Users and Computers, create an organizational unit container to which you will redirect users that were created with earlier versions of user interface and command-line management tools.
2. At the command line, change to the system32 directory by typing:

```
Cd %systemroot%\system32
```

3. At the %systemroot%\system32 directory, type:

```
Redirusr ou=
newuserou
,DC=
domainname
,dc=com
```

**To redirect the Computers container**

1. In Active Directory Users and Computers, create an organizational unit container to which you will redirect computer objects that were created with earlier versions of user interface and command-line management tools.
2. At the command line, change to the system32 directory by typing:

```
Cd %systemroot%\system32
```

3. At the %systemroot%\system32 directory, type:

```
Redircmp ou=
newcomputerou
```

```
,DC=
domainname
,dc=com
```

For more information about creating an organizational unit design, see "Designing the Active Directory Logical Structure" in this book.

# Complete the Upgrade

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Complete the following tasks to finalize the process:

- Review, update, and document the domain architecture to reflect any changes that you made during the in-place domain upgrade process.
- Review your operating procedures and administrative tasks to determine whether new Windows Server 2003 features, such as Group Policy objects or distributed administration, affect the operations environment. Be sure to document any changes that you identify.
- Remove the FRS script from the domain controller that you scheduled to provide the daily script export to an LMRepl server.
- After you ensure that your Windows Server 2003 Active Directory environment is operating successfully for a period of time, you can redeploy the rollback server that you reserved for the recovery process. If you do not need the Windows NT 4.0 BDC to achieve the required load balance among your domain controllers, maintain the rollback server for one week. Maintain the backup of the rollback server for a longer period of time to be safe.
- Some Windows NT 4.0 applications, such as Microsoft® Systems Management Server (SMS), can have an unpredictable effect on the domain when installed after the domain has been upgraded to Active Directory. Ensure that you are running SMS 2.0 and have installed Service Pack 4. For more information about SMS, see the SMS Downloads link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

After the above tasks have been completed successfully, you will have completed the in-place upgrade process.

# Additional Resources for Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information and tools related to this chapter.

**Related Information**

- "Restructuring Windows NT 4.0 Domains to an Active Directory Forest" in this book for more information about restructuring domains when upgrading from Windows NT 4.0 to Windows Server 2003.
- "Designing the Active Directory Logical Structure" in this book for more information about the Active Directory logical structure.
- "Designing the Site Topology" in this book for more information about Active Directory site topology.
- "Enabling Advanced Windows Server 2003 Active Directory Features" in this book for more information about enabling functional levels.
- "Deploying DNS" in *Deploying Network Services* for more information about deploying DNS.

**Related Tools**

- Adsiedit.exe

  The ADSI Edit tool (Adsiedit.exe) is a Microsoft Management Console snap-in that you can use to edit objects in the Active Directory database. For more information about Adsiedit.exe, in Help and Support Center for Windows Server 2003, click **Tools,** and then click Install Windows Support Tools.

- Ldp.exe

  Ldp.exe provides an interface to perform LDAP operations against Active Directory. For more information about Ldp.exe, in Help and Support Center for Windows Server 2003, click **Tools,** and then click Install Windows Support Tools.

**Related Help Topics**

For best results in identifying Help topics by title, in Help and Support Center, under the **Search** box, click **Set search options**. Under **Help Topics**, select the **Search in title only** check box.

- "Active Directory" in Help and Support Center for Windows Server 2003.
- "Install Windows Support Tools" under "Tools" in Help and Support Center for Windows Server 2003.
- "Configure Site Settings" in Help and Support Center for Windows Server 2003 for more information about creating site objects, subnet objects, and associating subnets with sites.
- "Understanding aging and scavenging" in Help and Support Center for Windows Server 2003 for more information about how to configure aging and scavenging of stale resource records.

**Related Job Aids**

- "Windows NT 4.0 Domain Controllers and Services" (DSSUPNT_1.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Windows NT 4.0 Domain Controllers and Services" on the Web at http://www.microsoft.com/reskit).

- "Windows NT 4.0 Hardware Configuration" (DSSUPNT_2.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Windows NT 4.0 Hardware Configuration" on the Web at http://www.microsoft.com/reskit).

- "Windows NT 4.0 Network Configuration" (DSSUPNT_3.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Windows NT 4.0 Network Configuration" on the Web at http://www.microsoft.com/reskit).

- "Windows NT 4.0 Domain Controller Role Assignment" (DSSUPNT_4.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Windows NT 4.0 Domain Controller Role Assignment" on the Web at http://www.microsoft.com/reskit).

- "Windows NT 4.0 Domain Controller Documentation" (DSSUPNT_5.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Windows NT 4.0 Domain Controller Documentation" on the Web at http://www.microsoft.com/reskit).

# Upgrading from Windows 2000 Domains to Windows Server 2003 Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Upgrading your network operating system from Microsoft® Windows® 2000 to Windows® Server 2003 requires minimal network configuration and typically has a low impact on user operations. The upgrade process is straightforward, efficient, and allows your organization to take advantage of the improved security that is offered by Windows Server 2003.

**In This Chapter**

# Overview of Upgrading Your Windows 2000 Domains to Windows Server 2003 Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

By upgrading your network operating system from Microsoft® Windows® 2000 Server to the Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; or Windows® Server 2003, Datacenter Edition operating system, you can maintain your current network and domain configuration while improving the security, scalability, and manageability of your network infrastructure.

Prior to upgrading your Windows 2000 domains, review your business objectives and decide how they relate to your existing Active Directory infrastructure. Although your objectives might not require other significant changes to your existing environment, the operating system upgrade is an opportune time to review your existing Active Directory design, including your Active Directory logical structure, site topology, and domain controller capacity. You might find opportunities for increased efficiencies and cost savings that you can incorporate into your upgrade process.

Additionally, ensure that you test your upgrade process in a lab and pilot program. For more information about lab testing and piloting, see "Planning an Active Directory Deployment Project" in this book.

When the domain upgrade process is complete, all domain controllers will be running Windows Server 2003, and the Active Directory domain and forest will be operating at the Windows Server 2003 functional level. At the Windows Server 2003 forest functional level, you can take advantage of all advanced Active Directory features. For more information about advanced Active Directory features related to Active Directory functional levels, see "Enabling Advanced Windows Server 2003 Active Directory Features" in this book.

**Note**

- For a list of the job aids that are available to assist you in upgrading from Windows 2000 Server to Windows Server 2003, see "Additional Resources for Upgrading from Windows 2000 Domains to Windows Server 2003 Domains" later in this chapter.

# Process for Upgrading Windows 2000 Domains to Windows Server 2003 Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Upgrading your Windows 2000 Active Directory environment to a Windows Server 2003 Active Directory environment involves completing several tasks. Figure 9.1 shows the tasks in the upgrade process.

**Figure 9.1 Upgrading Windows 2000 Domains to Windows Server 2003 Domains**

# Background Information for Upgrading Windows 2000 Domains to Windows Server 2003 Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you begin the process of upgrading your Windows 2000 Active Directory environment to Windows Server 2003 Active Directory, become familiar with some important issues that affect the upgrade process.

**Active Directory Preparation Tool**
To prepare your Windows 2000 forest and domains for upgrade to Windows Server 2003 Active Directory, or for the introduction of a new Windows Server 2003–based domain controller, you must use the Active Directory Preparation tool (Adprep.exe). Adprep.exe is located on the Windows Server 2003 and Windows Server 2003 Service Pack 1 (SP1) operating system CD.

Adprep.exe prepares the forest and domains for an Active Directory upgrade by performing a collection of operations prior to the installation of the first Windows Server 2003–based domain controller, including:

- Extending your current schema with new schema information that Adprep.exe provides, while preserving previous schema modifications in your environment.
- Resetting permissions on containers and objects throughout the directory for improved security and interoperability with new Windows Server 2003 domains.
- Copying administrative tools to manage new Windows Server 2003 domains to the local computer.

### Note

- Changes made by Adprep.exe do not affect the functioning of Windows NT 4.0–based or Windows 2000–based domain controllers.

For more information about using Adprep.exe to prepare your environment, see "Prepare Your Infrastructure for Upgrade" later in this chapter.

**Application Directory Partitions for DNS**
Application directory partitions provide storage for application-specific data that can be replicated to a specific set of domain controllers in the same forest. If you have at least one domain controller in your forest running Windows Server 2003 and the domain naming master is also running Windows Server 2003, you can take advantage of application directory partitions.

For example, you can use application directory partitions to store DNS data on Windows Server 2003–based domain controllers. DNS-specific application directory partitions are automatically created in the forest and in each domain when the DNS service is installed on new or upgraded Windows Server 2003–based domain controllers. If application directory partition creation fails during Active Directory installation, DNS attempts to create the partitions again every time that the service starts.

### Note

- The creation and deletion of application directory partitions, including the default DNS application directory partitions, requires that the domain naming master role holder reside on a Windows Server 2003–based domain controller.

The following DNS-specific application directory partitions are created during Active Directory installation:

- ForestDnsZones — A forest-wide application directory partition shared by all DNS servers in the same forest
- DomainDnsZones — Domain-wide application directory partitions for each DNS server in the same domain

**SRV resource records**
A Windows Server 2003–based domain controller's Net Logon service uses dynamic updates to register SRV resource records

in the DNS database, as described in "A DNS RR for specifying the location of services (DNS SRV)." For more information about this draft, see the Internet Engineering Task Force (IETF) web page. This SRV record is used to map the name of a service, such as the Lightweight Directory Access Protocol (LDAP) service, to the DNS computer name of a server that offers that service. In a Windows Server 2003 network, an LDAP resource record locates a domain controller. A workstation that is logging on to a Windows Server 2003 domain queries DNS for SRV records in the general form:

*_Service* **.**_ *Protocol* **.** *DnsDomainName*

where *Service* is the service requested, *Protocol* is the protocol requested, and *DnsDomainName* is the fully qualified DNS name of the Active Directory domain.

Active Directory servers offer the LDAP service over the TCP protocol; therefore, clients find an LDAP server by querying DNS for a record of the form:

**_ldap._tcp.** *DnsDomainName*

**Note**

- The service and protocol strings require an underscore (_) prefix to prevent potential collisions with existing names in the namespace.
