- Use the **Turn off automatic updates of adm files** policy setting for all Group Policy administrators to make sure that .adm files are not overwritten in the Sysvol by any Group Policy Object Editor session, and make sure that you are using the latest .adm files that are available from Microsoft.

**Note**

The Always use local adm files for Group Policy Object Editor policy is typically used with the Turn off automatic updates of adm files policy setting, (that is, when it is supported by the operating system from which you are running Group Policy Object Editor).

**Keyboard Shortcuts for Administrative Templates Node**
You can use the following keyboard shortcuts to navigate the Administrative Templates namespace:

- SHIFT+asterisk (*) (on the keypad only) automatically expands the current node and all of its child nodes.
- The plus sign (+) on the keypad expands one level.
- Minus (-) on the keypad collapses one level.
- Double-click a policy in the results pane to bring up the **Properties** page.

When the **Properties** page appears, move it out from in front of the Group Policy Object Editor window. Then, click back one of the **Policies** in the results pane. You can now use the cursor keys to navigate up and down the list. Notice that the information in the **Properties** page changes. This method also works for the text on the **Explain** tab. You can also use the Tab key to move back and forth between the tree pane and the results pane, while leaving the **Properties** page open.

# What's New for Administrative Template Files in Windows XP SP2

Applies To: Windows Server 2003

Windows XP SP2 includes modifications to tools used to administer Group Policy. This includes changes to the **LISTBOX ADDITIVE** behavior, which is implemented through an update to gptext.dll. This section includes details of these changes.

For information about managing new features released in Windows XP SP2, see Managing Windows XP Service Pack 2 Features Using Group Policy at http://go.microsoft.com/fwlink/?LinkId=31974.

**Changes to LISTBOX ADDITIVE**

Policy settings defined by the **LISTBOX** keyword allow you to manage multiple values under one registry key. When **LISTBOX** is used, the specified settings are written as a **REG_SZ** registry value type, which allows for multiple values to be stored within one registry key.

An example of the use of **LISTBOX** is the **Windows Firewall: Define Port Exceptions** policy setting, located in **Computer Configuration\Administrative Templates\Network\Network Connections\Windows Firewall**, under both the **Domain Profile** and **Standard Profile** nodes.

By default, when LISTBOX policy settings are used in multiple GPOs, the list of the values written to the registry is defined entirely by the last GPO applied ("last writer wins"). The additive keyword changes the behavior so that the aggregate values from multiple GPOs are applied. For example, suppose that you have two GPOs with the following values for the **Windows Firewall: Define Port Exceptions** policy setting:

- GPO x. Sets values A, B, and C.
- GPO y. Sets values D, E, and F.

Without the additive keyword, only the values D, E, and F in GPO y are applied to the registry of targeted computers. This is because GPO y is the last GPO applied. With the additive keyword, all of the values from both GPOs are applied: A, B, C, D, E, and F.

The LISTBOX ADDITIVE behavior in Windows XP with SP2 gives you more flexibility in determining the values that will be applied to targets in a given Active Directory container. For example, the ability to disable policy settings from lower precedent GPOs is a key tenet of Group Policy management. Prior to Windows XP with SP2, the disabled behavior had no effect for policy settings that used LISTBOX ADDITIVE. Furthermore, prior to Windows XP with SP2, LISTBOX ADDITIVE was only found in several, rarely used policy settings affecting offline files. In Windows XP with SP2, LISTBOX ADDITIVE is used more prominently including policy settings that affect Windows Firewall and Internet Explorer.

Therefore, in Windows XP with SP2, the disabled behavior now functions as expected: removing any entries inherited from other lower precedent GPOs.

For example, suppose GPOs with values A, B, and C is normally applied to all computers in a domain. But, as an OU administrator, you wish to prevent these values from taking effect on computers in your OU. You can create a new GPO to disable values A, B, and C. This is illustrated in the following example:

- GPO x. Enables values A, B, and C for all computers in the domain.
- GPO z. Disables values A, B, and C. for all computers in your OU.
- GPO y. Enables values D, E, and F for all computers in the domain.

In this scenario, the values D, E, and F are applied to the computers in your OU.

Because, the disabled functionality only works when using the latest version of the gptext.dll, all policy settings that use LISTBOX ADDITIVE are enclosed by the #if version > 5 ...#end if construct. This eliminates the possibility of having multiple administrators experiencing different disabled behavior if they are using earlier versions of gptext.dll. Consequently, the policy settings that use LISTBOX ADDITIVE are *not* visible when editing a GPO from a computer running Windows Server 2003,

Windows XP with SP1, or Windows 2000 operating systems.

If you have administrative workstations that are not using Windows XP with SP2, you will need to install a hotfix in order to manage these policy settings. For more information, see the "'String too long...' Hotfix for Earlier Operating Systems or Service Packs" section later in this document.

**Managing Policy Settings on Earlier Operating Systems or Service Packs**
The .adm files that use the LISTBOX ADDITIVE syntax do not fully load on earlier versions of the Group Policy Object Editor (gpedit), which is present by default in Windows Server 2003, Windows XP with SP1, and Windows 2000. If attempted, multiple error messages will appear when the system.adm and inetres.adm files are loaded in earlier versions of gpedit.

The error message is "The following entry in the [strings] section is too long and has been truncated." This occurs because earlier versions of gpedit cannot correctly handle the "#if version >= 5 / #endif" construct in the inetres.adm and system.adm files. Although clicking **OK** on all the pop-up error messages does result in the .adm files loading correctly, the new Windows XP SP2 policy settings that use the LISTBOX syntax will not be displayed. (This problem does not occur on computers running Windows XP with SP2 or computers that have been updated with the latest version of gpedit.)

This issue is of particular significance because of the way .adm files are distributed through a domain. By default, when a GPO is opened, a comparison is made between the timestamps of the .adm files stored in the GPO being edited and those on the local computer. If the local .adm files have a more recent timestamp then they are uploaded to the domain controller and replicated throughout the domain. From that point, all earlier versions of gpedit use the new .adm files. This scenario is illustrated in the following steps.

1. Install Windows XP SP2 on the administrative computer.

2. Open existing GPO in Group Policy Object Editor. The .adm file stored on the administrative computer is uploaded to domain controller. GPO is "upgraded" to Windows XP SP2.

3. This .adm file is replicated to all domain controllers in the domain.

4. If the GPO is opened by other administrative workstations in the domain that are not running Windows XP with SP2 or the latest version of gpedit, error messages appear.

**"String Too Long..." Hotfix for Earlier Operating Systems and Service Packs**
If you or other administrators in your organization are going to manage policy settings on computers running earlier operating systems or service packs (for example, Windows Server 2003 or Windows XP with SP1), you need to install a hotfix in order for policy settings to appear correctly in the Group Policy Object Editor.

These hotfixes are available for the following:

- Windows Server 2003

- Windows XP with SP1

- Windows 2000

To obtain these hotfixes, see article 842933, ""The following entry in the [strings] section is too long and has been truncated" error message when you try to modify or to view GPOs in Windows Server 2003, Windows XP Professional, or Windows 2000," in the Microsoft Knowledge Base at http://go.microsoft.com/fwlink/?LinkId=4441.

If you are going to manage policy settings from workstation computers running Windows XP with SP2 only, you will be able to manage policy settings without applying any hotfixes. For example, you will be able to run the Group Policy Object Editor and view all the new policy settings delivered with Windows XP SP2.

**Important**

Opening a GPO on a computer running Windows XP with SP2 causes all other administrative workstations to use the new .adm files (note that no changes need be made to the GPO for this to occur). This will generate error messages when earlier versions of gpedit are loaded. For more information about this issue, see article 842933, ""The following entry in the [strings] section is too long and has been truncated" error message when you try to modify or to view GPOs in Windows Server 2003, Windows XP Professional, or Windows 2000," in the Microsoft Knowledge Base at http://go.microsoft.com/fwlink/?LinkId=4441.

By installing the hotfix for Windows Server 2003, Windows XP with Service Pack 1, and Windows 2000, you ensure that the Windows XP SP2 .adm files load correctly on these platforms.

# Language Reference for Administrative Template Files

Applies To: Windows Server 2003

This section includes a complete reference guide for using the .adm language to create policy settings.

Each .adm file can contain zero or more policy settings, and each policy setting in turn can contain zero or more parts. The .adm language includes the following components:

- Comments
- Strings
- CLASS
- CATEGORY
- POLICY
- PART
- ITEMLIST
- ACTIONLIST

**.Adm File Language Versions**

You can specify that any part of your .adm file be evaluated only in specific versions of the Group Policy editing tools. Table 5 lists the versions of the Group Policy editing tools.

**Table 5 Versions of Group Policy Editing Tools**

| Operating System(s) | Version | Type |
|---|---|---|
| Windows XP SP2 | 5.0 | Group Policy |
| Windows Server 2003 and Windows XP | 4.0 | Group Policy |
| Windows Server 2000 | 3.0 | Group Policy |
| Windows NT® 3.x and 4.x | 2.0 | System Policy |
| Windows 95 | 1.0 | System Policy |

**Comments**

You can use two methods to add comments to an .adm file. You can precede the comment either with a semicolon (;) or with two forward slashes (//). You can place comments at the end of any valid line.

**Strings**

To add strings to an .adm file, precede the text with two exclamation points (!!). At the end of the .adm file, all strings must be defined in the [strings] section. The strings must be enclosed in quotation marks ("). Optionally, you can enclose a variable name or hard-coded string in quotation marks.

**Example**

```
POLICY 34]!!LimitSize
   EXPLAIN!!LimitSize_Explain   ; This string is stored in the strings section
   TIP1 "Limit Profile Size to"   ; This string is hard coded

[strings]
LimitSize="Limit profile size"
LimitSize_Explain="Limits the size of user profiles"
```

**Best Practice**
Place all strings in the [strings] section of the .adm file. This facilitates conversion of the .adm file to other languages (that is, for localization), as you only need to modify the [strings] section of an .adm file to port it to different languages.

**CLASS**
This component defines where your policy setting is displayed in the Group Policy Object Editor.

The first entry in the .adm file is the keyword **CLASS**. This specifies whether the subsequent entries should be displayed under the **Computer Configuration** or **User Configuration** node of Group Policy Object Editor.

**Syntax**
The **CLASS** syntax is as follows:

```
CLASS name
```

**Name**
This defines the name of the **CLASS**, which must be MACHINE or USER.

If the .adm file contains a **CLASS** other than the valid classes (MACHINE or USER), the errors are ignored when loaded in Group Policy Object Editor.

**Example**
The following examples illustrate the use of the CLASS component.

```
CLASS MACHINE
CLASS USER
```

| **Note** |
| --- |
| You can define multiple CLASS USER or CLASS MACHINE sections in an .adm file. When the file is processed, all the CLASS USER sections are merged, and all CLASS MACHINE sections are merged. However, for ease of ongoing .adm file management, it is recommended that you define CLASS USER or CLASS MACHINE once. |

**CATEGORY**
After you define the **CLASS** component, you can use the **CATEGORY** component to display a node name under which your policy setting is displayed in the Group Policy Object Editor.

| **Note** |
| --- |
| You can create child nodes by nesting a CATEGORY within another CATEGORY. |

**Syntax**
To specify a **CATEGORY**, use the following syntax.

```
CATEGORY!!name
    KEYNAME key name
    [policy definition statements]
END CATEGORY
```

**name**
The **CATEGORY** name as it should appear in the Group Policy Object Editor list box. Optionally, you can enclose the variable name in quotation marks ("). Names with spaces must be enclosed in quotation marks.

**key name**
The key name is an optional path to the registry key to use for the **CATEGORY**.

Do not use **HKEY_LOCAL_MACHINE** or **HKEY_CURRENT_USER** in the registry path as the preceding **CLASS** statement specifies the keys to use. If you specify a key name, all child categories, policies, and parts will use this key name, unless they specifically provide a key name of their own. Names with spaces must be enclosed in double quotation marks.

If a key name is not specified and if no higher level category specifies a key name, each policy in this category must specify its own key name: otherwise, the key name for the next category that does specify a key name will be used.

**policy definition statements**
A **CATEGORY** can include zero or more **POLICY** statements. A **POLICY** definition statement cannot appear more than once within a single category, as shown in the following sample code.

**Example**

```
CLASS USER

; The following categories will be displayed
; under User Configuration

CATEGORY !!Desktop
   KEYNAME "Software\Policies\System"

   ; <INSERT POLICIES HERE>

   CATEGORY !!InternalApps
   KEYNAME "Software\Policies\InternalApps"

    ; <INSERT POLICIES HERE>

   END CATEGORY
END CATEGORY

[strings]
Desktop="Desktop Settings"
InternalApps="Line of Business Apps settings"
```

**Supported Tag**

The Group Policy Object Editor uses the **Supported** tag to populate the **Requirements** field. This tag informs the Group Policy administrator about the platforms or applications for which the policy setting is supported. For example, many of the policy settings included in the System.adm file use a **Supported** tag that specifies a specific service pack release. Often, the string used for the Supported tag will make reference to multiple operating system or service packs.

While operating system components generally use an operating system or service pack reference in this field, applications – which can be updated outside the release of a service pack – can refer to a specific version of an application. The **Supported** tag is an essential element in the data presented to Group Policy administrators to ensure they are equipped with the right information to make informed decisions about the use of the policy setting.

Because your .adm file may be localized, it is highly recommended that the **Supported** tag use the **!!Stringname** construct, which allows the referenced string to be localized easily. In addition, since the **Supported** tag is only supported in Windows XP and later operating systems, it should be enclosed within a **Version** construct, as follows (this ensures that the Windows 2000 version of Group Policy Object Editor does not attempt to interpret the **Supported** tag):

```
#if version >= 4
        SUPPORTED!!SUPPORTED_MyApplication
    #endif
```

**CATEGORY Keywords**

The valid keywords for **CATEGORY** are:

- **KEYNAME**
- **CATEGORY**
- **POLICY**
- **END**
- **SUPPORTED**

| **Note** |
| --- |
| If you have a CATEGORY defined with a default KEYNAME in it, and the same category is found again later in the .adm file, that same default KEYNAME is still in effect. This means that you can get an error message about KEYNAME being defined twice, when it was actually just defined in the same category earlier. To remove the error condition, remove the duplicate category entry. |

**POLICY**
To identify a policy setting that the user can modify, use the keyword **POLICY**. The policy and its associated controls are displayed in a dialog box that administrators use to set the state of the policy. You can use multiple **POLICY** key names under one **KEYNAME**.

The following examples illustrate the syntax of POLICY.

**Syntax**

```
POLICY name
   [KEYNAME key name]
   [EXPLAIN help string]
   [VALUENAME value name]
   [CLIENTEXT guid]
   [part definition statements]
END POLICY
```

**name**
The name of the policy as it should be displayed in the Group Policy Object Editor namespace.

**key name**
This is an optional path to the registry key to use for the category. Do not include **HKEY_LOCAL_MACHINE** or **HKEY_CURRENT_USER** in the registry path as the preceding CLASS statement determines which of these keys is used.

If you specify a key name, all **PART** definition statements will use this key name unless they specifically provide a key name of their own.

If a key name is not specified and if no higher level category specifies a key name, each policy in this category must specify its own key name: otherwise, the key name for the next category that does specify a key name will be used.

**help string**
The Help string is the text displayed in the **Explain** tab of the dialog box for the policy setting.

**value name**
Value name is the registry value to modify. Selecting this option sets the value as a REG_DWORD of 1. Clearing the option removes the registry value. To specify values other than the default values, use the **VALUEON** and **VALUEOFF** statements directly following the corresponding **VALUENAME** statement. These statements are specified as follows:

```
VALUEON on value
VALUEOFF off value
```

When you use these statements, the behavior is modified such that if the administrator selects the option, the value is set to on value. If the administrator clears the option, the value is set to off value.

**guid**
This is an optional value that specifies the globally unique identifier (GUID) of the snap-in extension.

**part definition statements**
A policy can contain zero or more **PART** statements to specify various options, including drop-down list boxes, text boxes, and text in the lower pane of the Group Policy Object Editor.

**POLICY Example**

```
CLASS MACHINE

CATEGORY!!DiskQuota

   KEYNAME "Software\Policies\MS\DiskQuota"

   POLICY!!DQ_Enable
      EXPLAIN !!DQ_Enable_Help
      VALUENAME "Enable"
         VALUEON  NUMERIC 1
         VALUEOFF NUMERIC 0
      CLIENTEXT {3610eda5-77ef-11d2-8dc}

      PART!!DQ_EnableTip1    TEXT
      END PART
   END POLICY

END CATEGORY
```

```
[strings]
DiskQuota="Disk Quotas"
DQ_Enable="Enable disk quotas"
DQ_Enable_Help="Enables and disables disk quota management"
DQ_EnableTip1="Enable disk quotas for all NTFS volumes"
```

**POLICY Keywords**
The valid keywords for POLICY are:

- **KEYNAME**
- **PART**
- **VALUENAME**
- **VALUEON**
- **VALUEOFF**
- **ACTIONLISTON**
- **ACTIONLISTOFF**
- **END**
- **HELP**
- **CLIENTEXT**
- **POLICY**

**PART**
Use **PART** to specify various options, such as drop-down list boxes, text boxes, and text in the lower pane of Group Policy Object Editor.

For a simple policy where you only need to set a registry key to either 1 or 0, you do not need to use **PART**. PART allows a richer system administrator experience, and collects more information from the administrator through simple controls.

**Syntax**

```
PART name part-type type-dependent data
  [KEYNAME key name]
  [VALUENAME value name]
END PART
```

**name**
Specifies the **PART** name as it should appear in Group Policy Object Editor. You can enclose it in quotation marks ("). Names with spaces must be enclosed in quotation marks (").

**part-type**
A policy **PART type**. Table 6 lists the valid types for **POLICY**.

**Table 6 Policy PART Types**

| Type | Description |
|---|---|
| CHECKBOX | Displays a check box. The value is set in the registry with the **REG_DWORD** type. The value is other than zero if the check box is selected and zero if it is not selected. |
| COMBOBOX | Displays a combo box. |

| | |
|---|---|
| DROPDOWNLIST | Displays a combo box with a drop-down list style. The user may choose only one of the entries supplied. |
| LISTBOX | Displays a list box with Add and Remove buttons. This is the only PART type that can be used to manage multiple values under one key. |
| EDITTEXT | Displays a text box that accepts alphanumeric text. The text is set in the registry with either the REG_SZ or the REG_EXPAND_SZ type. |
| TEXT | Displays a line of static text. There is no associated registry value with this PART type. |
| NUMERIC | Displays a text box with an optional spin control that accepts a numeric value. The value is set in the registry with the REG_DWORD type. |

**type-dependent data**
This is information about the **PART**.

**key name**
This is an optional path to the registry key to use. Do not include **HKEY_LOCAL_MACHINE** or **HKEY_CURRENT_USER** in the registry path as the preceding **CLASS** statement determines which of these keys is used.

If no key name is specified, the previous key name in the hierarchy is used.

**value name**
The value name indicates the registry value to modify. Selecting this option sets the value to a REG_DWORD of 1, and clearing the option removes the registry value. If you want to specify values other than the default values, use the **VALUEON** and **VALUEOFF** statements directly following the corresponding **VALUENAME** statement. You specify these statements as follows:

```
VALUEON on value
VALUEOFF off value
```

**Keywords**
The valid keywords for **PART** are:

- **CHECKBOX**
- **TEXT**
- **EDITTEXT**
- **NUMERIC**
- **COMBOBOX**
- **DROPDOWNLIST**
- **LISTBOX**
- **END**
- **CLIENTEXT**
- **PART**

**Using PART Types to Add Controls to the User Interface**
Using the valid keywords along with the **PART** component allows you to add text and various user interface controls to the properties page of the policy.

Because much of the syntax is related, the next section presents a task-based approach to writing the syntax for these **PART** types used to create the user interface elements above.

Using the different **PART** types, you can add text and controls to enhance a policy setting. These types need to be used with the **PART** component as previously defined.

**CHECKBOX PART Type**

This **PART** type displays a check box on the **Property** page of a policy setting. The value is set in the registry with the REG_DWORD type. The default behavior is as follows:

- By default the check box is not selected.
- A check box writes the value 1 to the registry if it is selected and 0 if it is not selected.

**Syntax**

```
PART text CHECKBOX
   VALUENAME value name
END PART
```

**text**

This represents the text to be displayed on the right of the check box that you are creating. You can hard code it and enclose it in quotation marks (") or you can make the string a variable by putting **!!** in front of the variable name.

**value name**

Indicates the registry value to which the selected value will be written. Selecting the option sets the value as a REG_DWORD of 1. Clearing the option removes the registry value. To specify values other than the default values, use the **VALUEON** and **VALUEOFF** statements directly following the corresponding **VALUENAME** statement. These statements are specified as follows:

```
VALUEON on value
VALUEOFF off value
```

When you use these statements, the behavior is modified such that if the administrator selects the option, the value is set to on value. If the administrator clears the option, the value is set to off value.

To override the default behavior:

To have the check box selected by default use **DEFCHECKED**. In the preceding sample, the syntax would be:

```
PART !!SampleChkBox_NotChked CHECKBOX
         DEFCHECKED
           VALUENAME "test1"
    END PART
```

You can use **VALUEON** and **VALUEOFF**. This example accomplishes the following::

- Writes the string "Enabled" to the registry when the check box is selected.
- Writes a numeric value of 12 when the check box is not selected.

```
    PART !!SampleChkBox_NotChked CHECKBOX
         VALUENAME "test1"
         VALUEON "Enabled"
         VALUEOFF NUMERIC 12
       END PART
```

To modify more than one registry key, use an ACTIONLIST.

The valid keywords for **CHECKBOX** are:

- KEYNAME
- VALUENAME
- VALUEON
- VALUEOFF
- ACTIONLISTON

- ACTIONLISTOFF
- DEFCHECKED
- CLIENTEXT
- END

**TEXT PART Type**
The **PART** type **TEXT** can be used to display text on the **Property** page of a policy setting. Text uses the following syntax.

```
PART text TEXT
END PART
```

**text**
Text that is to be displayed is entered here. You can hard code it and enclose it in quotation marks ("), or you can make the string a variable by putting **!!** before the variable name.

The following example illustrates the use of **TEXT**. The **Disable Active Desktop** policy deactivates Active Desktop and prevents users from enabling or disabling Active Desktop, or from modifying the configuration.

**TEXT Example**

```
POLICY !!NoActiveDesktop

   KEYNAME "Software\Microsoft\Windows\CurrentVersion\Policies\Explorer"
   EXPLAIN!!NoActiveDesktop_Help
     VALUENAME "NoActiveDesktop"

     PART !!NoActiveDesktop_Tip    TEXT
     END PART

END POLICY
```

The valid keyword for **TEXT** is **END**.

**EDITTEXT PART Type**
The **EDITTEXT** option allows the user to input alphanumeric text into an edit field. The text is set in the registry with the REG_SZ type.

**Syntax**

```
PART !!text EDITTEXT
   VALUENAME value name
END PART
```

**text**
Text to be displayed is entered here. You can hard code it and enclose it in quotation marks (") or you can make the string a variable by putting two explanation points (**!!**) before the variable name. This text is displayed on the left side of the edit box.

**value name**
The value name indicates the registry value to which the users input entered in the Edit Text box will be written.

Table 7 lists the options for **EDITTEXT.**

**Table 7 Options for EDITTEXT**

| Option | Description |
|---|---|
| DEFAULT value | Specifies the initial string to place in the edit field. If this option is not specified, the field is initially empty. |
| MAXLEN value | Specifies the maximum length of a string. The string in the edit field is limited to this length. |
| REQUIRED | Specifies that the Group Policy Object Editor does not allow a policy containing this PART to be enabled, unless a value has been entered for this PART. |

| | |
|---|---|
| OEMCONVERT | Sets the ES_OEMCONVERT style in the edit field so that typed text is mapped from ASCII to OEM and back. ES_OEMCONVERT converts text entered in the edit control. The text is converted from the Windows character set (ASCII) to the OEM character set and then back to the Windows set. This ensures proper character conversion when the application calls the CharToOem <JavaScript:hhobj_1.Click()> function to convert an ASCII string in the edit control to OEM characters. This style is most useful for edit controls that contain file names. |
| EXPANDABLETEXT | Specifies that the text is set in the registry with the REG_EXPAND_SZ type. By default, the text is set in the registry with the REG_SZ type |

The valid keywords for **EDITTEXT** are:

- **KEYNAME**
- **VALUENAME**
- **DEFAULT**
- **REQUIRED**
- **MAXLENGTH**
- **OEMCONVERT**
- **END**
- **EXPANDABLETEXT**
- **CLIENTEXT**

**EDITTEXT Example**

An example of use of the **PART** component with **EDITTEXT** and **TEXT** follows:

```
CLASS USER
CATEGORY !!DesktopLockDown

  KEYNAME "Software\Policies\System"
   POLICY !!Wallpaper
    EXPLAIN !!Wallpaper_Explain

     PART !!Wallpaper_Tip1       TEXT
     END PART

     PART !!Wallpaper_Filename   EDITTEXT
        VALUENAME Wallpaper
        MAXLEN 60
     END PART

   END POLICY

END CATEGORY

[strings]
DesktopLockDown="Desktop Settings"
Wallpaper="Desktop Wallpaper"
Wallpaper_Explain="Used to set the desktop wallpaper"
Wallpaper_FileName="Filename"
Wallpaper_Tip1="Specify UNC Path for selected wallpaper"
```

In the preceding example, the text entered into the edit field is written to the registry key **HKEY_CURRENT_USER\Software\Policies\System\Wallpaper**. The text can be a maximum of 60 characters.

When this policy setting is **Not Configured** or **Disabled**, this key is not written.

**EXPANDABLETEXT Example**
The following example writes a value to registry with data type REG_EXPAND_SZ.

For example:

```
PART!!MyVariable    EDITTEXT EXPANDABLETEXT
VALUENAME ValueToBeChanged
END PART
```

**REQUIRED Example**
The following example generates an error if the user does not enter a value when required.

```
PART!!MyVariable    EDITTEXT REQUIRED
  VALUENAME ValueToBeChanged
END PART
```

**MAXLEN Example**
The following example specifies the maximum length of text.

```
PART!!MyVariable    EDITTEXT
  VALUENAME ValueToBeChanged
  MAXLEN 4
END PART
```

**DEFAULT Example**
The following example specifies a default value. This can be used for text or numeric data.

```
PART!!MyVariable    EDITTEXT
  DEFAULT !!MySampleText
  VALUENAME ValueToBeChanged
END PART
```

**NUMERIC PART Type**
Displays an edit field with an optional spinner control (an up-down control) that accepts a numeric value.

**NUMERIC Syntax**

```
PART text NUMERIC
   VALUENAME value name
   MIN value
   MAX value
   DEFAULT value
   SPIN value
END PART
```

**text**
This represents the text to be displayed on the right of the spin control that you are creating. You can hard code it and enclose it in quotation marks (") or you can make the string a variable by putting !! before the variable name.

**value name**
Indicates the registry value to which the selected value will be written.

**NUMERIC Default Behavior**
The default behavior for the **NUMERIC** PART type is as follows:

- The value is set in the registry as a REG_DWORD type.
- You can optionally have the value written as a REG_SZ type by using the **TXTCONVERT** keyword.

Table 8 shows the options for the NUMERIC type.

**Table 8 Options for NUMERIC**

| Option | Description |
|---|---|
| DEFAULT value | Specifies the initial numeric value for the edit field. If this option is not specified, the field is initially empty. |

| | |
|---|---|
| MAX value | Specifies the maximum value for the number. The default value is 9999. |
| MIN value | Specifies the minimum value for the number. The default value is 0. |
| REQUIRED | Specifies that the Group Policy Object Editor does not allow a policy containing this PART to be enabled unless a value has been entered for this PART. |
| SPIN value | Specifies increments to use for the spinner control. The default is SPIN 1. SPIN 0 removes the spinner control. |
| TXTCONVERT | Writes values as REG_SZ strings ("1", "2", or "128") rather than as binary values. |

The valid keywords for **NUMERIC** are:

- KEYNAME
- VALUENAME
- MIN
- MAX
- SPIN
- DEFAULT
- REQUIRED
- TXTCONVERT
- END
- CLIENTEXT

**Examples of NUMERIC Use**

The following example illustrates use of the **NUMERIC PART** type using the **DEFAULT** option.

```
PART!!MyVariable    NUMERIC
  DEFAULT 5
  VALUENAME ValueToBeChanged
END PART
```

The following example illustrates use of the minimum and maximum valid values for a variable.

```
PART!!MyVariable    NUMERIC
  MIN 100
  MAX 999
  DEFAULT 55
  VALUENAME ValueToBeChanged
END PART
```

The following example illustrates use of the **NUMERIC PART** type using **SPIN**. In this case, increments of 100 are used for the spin control.

```
PART !!ProfileSize    NUMERIC REQUIRED SPIN 100

        VALUENAME "MaxProfileSize"
        DEFAULT 30000
        MAX     30000
        MIN     300
END PART
```

The following example illustrates use of the **NUMERIC PART** type using the **TXTCONVERT** option, which writes values as **REG_SZ** strings (such as "60") instead of binary values.

```
PART !!ScreenSaverTimeOutFreqSpin    NUMERIC DEFAULT 900

        MIN 0 MAX 599940 SPIN 60
        TXTCONVERT
        VALUENAME "ScreenSaveTimeOut"
END PART
```

**COMBOBOX PART Type**

This **PART** type displays a combo box. It accepts the same options as **EDITTEXT**, as well as the **SUGGESTIONS** option, which begins a list of suggestions to be placed in the drop-down list. **SUGGESTIONS** are separated with spaces and must be enclosed in quotation marks (") when a value includes spaces. If a suggestion name includes white space, it must be enclosed in quotation marks. The list ends with **END SUGGESTIONS**.

**Example**

The following example illustrates the use of the **SUGGESTIONS** option.

```
SUGGESTIONS
  Alaska Alabama Mississippi "New York"
END SUGGESTIONS
```

**Keywords**

The valid keywords for **COMBOBOX** are:

- **KEYNAME**
- **VALUENAME**
- **DEFAULT**
- **SUGGESTIONS**
- **REQUIRED**
- **MAXLENGTH**
- **OEMCONVERT**
- **END**
- **NOSORT**
- **EXPANDABLETEXT**
- **CLIENTEXT**
- **END**

**DROPDOWNLIST PART Type**

Displays a combo box with a drop-down list style. The user may choose only one of the entries supplied.

| **Note** |
| --- |
| GPMC requires that you define the key name and value name before you specify DROPDOWNLIST. |

**DROPDOWNLIST Syntax**

**DROPDOWNLIST** uses the following syntax.

```
PART !!text DROPDOWNLIST
   ITEMLIST
     NAME name VALUE value
     ..
     NAME name VALUE value
```

```
   END ITEMLIST
END PART
```

**text**
This represents the text to be displayed on the right of the spin control that you are creating. You can hard code it and enclose it in quotation marks (") or you can make the string a variable by putting **!!** in front of the variable name.

**name**
This is text that will be displayed in the drop-down list for a particular item.

**value**
The value to be written to the specified registry key if this item is selected. Values are assumed to be strings, unless they are preceded by **NUMERIC**. The following example shows both string and numeric values:

```
VALUE "Some value"
VALUE NUMERIC 1
```

The valid keywords for **DROPDOWNLIST** are:

- KEYNAME
- VALUENAME
- REQUIRED
- ITEMLIST
- END
- NOSORT
- CLIENTEXT

**LISTBOX PART Type**
The LISTBOX **PART** component specifies various options such as drop-down list boxes, text boxes, and text in the lower pane of the Group Policy Object Editor. **LISTBOX** accepts the options shown in Table 9.

**Table 9 LISTBOX Options**

| LISTBOX Option | Description |
|---|---|
| ADDITIVE | By default, the content of list boxes overrides any values set in the target registry. This means that a control value is inserted in the policy file that causes existing values to be deleted before the values set in the policy file are merged. If this option is specified, existing values are not deleted, and the values set in the list box is in addition to whatever values exist in the target registry. |
| EXPLICITVALUE | This option makes the user specify the value data and the value name. The list box shows two columns, one for the name and one for the data. This option cannot be used with the VALUEPREFIX option. |
| VALUEPREFIX prefix | The prefix you specify is used in determining value names. If a prefix is specified, the prefix and an incremented integer are used, instead of the default value naming scheme described previously. For example, a prefix of "SampleName" generates the value names "SampleName1", "SampleName2", and so on. The prefix can be empty (""), which causes the value names to be "1", "2", and so on. |

By default, only one column appears in the list box, and for each entry a value is created whose name and value are the same. For instance, a "name" entry in the list box creates a value called "name" that contains data called "name". When using a **LISTBOX**, use the **ADDITIVE** keyword unless you have a specific reason not to do so.

The valid keywords for **LISTBOX** are:

- **KEYNAME**

- **VALUEPREFIX**
- **ADDITIVE**
- **NOSORT**
- **EXPLICITVALUE**
- **EXPANDABLETEXT**
- **END**
- **CLIENTEXT**

| **Note** |
| --- |
| Windows XP SP2 fixed issues relating to the LISTBOX ADDITIVE functionality. For more information, see the "Changes to LISTBOX ADDITIVE" section in this document. |

**ACTIONLIST**
You can use an action list to specify a set of arbitrary registry changes to make in response to a control being set to a particular state.

**Syntax**
The **ACTIONLIST** syntax is as follows:

```
ACTIONLIST
[KEYNAME key name]
VALUENAME value name
VALUE value
END ACTIONLIST
```

**key name**
This is an optional path to the registry key. Do not include HKEY_LOCAL_MACHINE or HKEY_CURRENT_USER in the registry path as the preceding CLASS statement determines which of these keys is used. If no key name is specified, the previous key name in the hierarchy is used.

**value name**
Indicates the registry value to modify. Selecting this option sets the value to a REG_DWORD of 1, and clearing the option removes the registry value. If you want to specify values other than the default values, use the VALUEON and VALUEOFF statements directly following the corresponding VALUENAME statement. You specify these statements as follows:

```
VALUEON on value
VALUEOFF off value
```

**value**
Values are treated as strings unless they are preceded by NUMERIC, as in the following examples:

```
VALUE "Some value"
VALUE NUMERIC 1
```

If **VALUE** is followed by **DELETE** (for example, **VALUE DELETE**), the registry entry is deleted.

Table 10 lists the two variants for **ACTIONLIST** that can be used with **POLICY** and **CHECKBOX**.

**Table 10 Variants for ACTIONLIST**

| Variant | Description |
| --- | --- |
| ACTIONLISTON | Specifies an optional action list to be used if the check box is selected. |
| ACTIONLISTOFF | Specifies an optional action list to be used if the check box is not selected. |

**ACTIONLIST Example**
The following example illustrates the use of **ACTIONLISTON** and **ACTIONLISTOFF**.

```
POLICY  "Deny connections requests"
    EXPLAIN "If enabled, TS will stop accepting connections"
    ACTIONLISTON
       VALUENAME "fDenyTSConnections"    VALUE NUMERIC 1
    END ACTIONLISTON
    ACTIONLISTOFF
       VALUENAME "fDenyTSConnections"    VALUE NUMERIC 0
    END ACTIONLISTOFF
END POLICY
```

**Additional Elements**
The .adm language supports the following elements:

**KEYNAME**
The **KEYNAME** keyword is used within a **CATEGORY** to define which key within the registry is modified as a result of an action here. **KEYNAME** should be followed by the registry path to the key that contains the value that you want to change. Do not include **HKEY_LOCAL_MACHINE** or **HKEY_CURRENT_USER** in the registry path as the preceding CLASS statement determines which of these keys is used.

If the **KEYNAME** contains a space, you must enclose the string in quotation marks (").

**VALUENAME**
Defines the options available within a **POLICY**. First identify the registry value that is to be modified as a result of using the keyword **VALUENAME**. For example, **VALUENAME** MyFirstValue.

The following example illustrates the use of **VALUENAME**. The Disable Boot / Shutdown / Logon / Logoff status messages policy prevents the display of system status messages.

```
POLICY!!DisableStatusMessages
    KEYNAME "Software\Microsoft\Windows\CurrentVersion\Policies\System"
       EXPLAIN!!DisableStatusMessages_Help
       VALUENAME "DisableStatusMessages"
END POLICY
```

Unless you specify otherwise, the value is written in the following format when the user checks or clears the option:

- Checked. Uses a REG_DWORD type with a value of 1.
- Cleared. Removes the value.

You can specify options other than these defaults by using **VALUEOFF** and **VALUEON**. If the option is to be selected within the lower pane of the Group Policy Object Editor, the **VALUENAME** needs to be within a **PART** scope.

**CLIENTEXT**
The **CLIENTEXT** keyword is used to specify which client-side extension to the Group Policy Object Editor needs to process the particular settings on the client computer. By default, the registry extension processes all settings configured under the Administrative Templates node. The **CLIENTEXT** keyword changes the default behavior and causes the specified extension to process these settings after the registry extension has placed them in the registry.

**CLIENTEXT** must be used within either the **POLICY** scope or the **PART** scope and should follow the **VALUENAME** statement.

The following example illustrates use of **CLIENTEXT**.

```
POLICY !!DQ_Enforce

            #if version >= 4
                 SUPPORTED !!SUPPORTED_Win2k
            #endif

            EXPLAIN !!DQ_Enforce_Help
                 VALUENAME "Enforce"
                 VALUEON  NUMERIC 1
            VALUEOFF NUMERIC 0
            CLIENTEXT {3610eda5-77ef-11d2-8dc5-00c04fa31a66}
```

```
        END POLICY
```

The GUID that follows the **CLIENTEXT** keyword is the GUID of the client-side extension. The client-side extensions are listed in the registry under **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\WindowsNT \CurrentVersion\Winlogon\GPExtensions**.

**VALUEON and VALUEOFF**

You can use **VALUEON** and **VALUEOFF** to write specific values based on the state of the option. To enable this functionality, you can write the .adm file as described in the following examples:

```
KEYNAME key name
   POLICY!!MyPolicy
     VALUENAME ValueToBeChanged
     VALUEON "Turned On" VALUEOFF "Turned Off"
   END POLICY
```

```
KEYNAME key name
   POLICY!!MyPolicy
     VALUENAME ValueToBeChanged
     VALUEON 5 VALUEOFF 10
   END POLICY
```

**Using Simple Policies and Policies with the VALUEOFF and VALUEON Statements**

This section presents two examples that illustrate the difference between using the default policy states and specifying **VALUEON** and **VALUEOFF** statements. There is a significant difference between the two example policies.

**Example 1**

In this example, no explicit **VALUEON** or **VALUEOFF** statements are used. This means that the Administrative Templates use the default behavior when the user changes the state of this policy.

```
POLICY!!EnableSlowLinkDetect
    EXPLAIN !!EnableSlowLinkDetect_Help
    KEYNAME "Software\Policies\Microsoft\Windows\System"
    VALUENAME "SlowLinkDetectEnabled"
END POLICY
```

Table 11 lists the default behavior.

**Table 11 Example 1 Policy Defaults**

| State | Behavior |
|---|---|
| Policy setting enabled | A DWORD with the value 1 is written to the registry. |
| Policy setting disabled | The registry value is deleted. |
| Policy setting not configured | Nothing is changed in the registry. |

Note the policy-disabled state. The value is not written to the registry with the value of 0—instead it is explicitly deleted. This means that a component reading the policy will not find the value in the registry, and will fall back to using the default in the code.

**Example 2**

In this example, the state values are explicitly defined, so when the user changes the policy, the Administrative Templates use these values.

```
POLICY!!EnableSlowLinkDetect
    EXPLAIN!!EnableSlowLinkDetect_Help
    KEYNAME "Software\Policies\Microsoft\Windows\System"
    VALUENAME "SlowLinkDetectEnabled"
        VALUEON NUMERIC 1
        VALUEOFF NUMERIC 0
END POLICY
```

Table 12 lists the behaviors in Example 2.

**Table 12 Example 2 Policy Defaults**

| State | Behavior |
|---|---|
| Policy setting enabled | A DWORD with the value 1 is written to the registry. |
| Policy setting disabled | A DWORD with the value 0 is written to the registry. |
| Policy setting not configured | Nothing is changed in the registry. |

**EXPLAIN**

The **EXPLAIN** keyword is used to provide online Help text for a specific Group Policy. In Windows 2000, the **Properties** page for each policy setting includes an **Explain** tab, which provides details about the policy settings.

Each Group Policy that you create should include one **EXPLAIN** keyword, followed by at least one space, and then the **EXPLAIN** string in quotation marks (") or a reference to the Help string. For example:

```
POLICY!!Pol_NoConfigCache
#if VERSION >= 3
EXPLAIN!!Pol_NoConfigCache_Help
#endif
    VALUENAME "NoConfigCache"
    PART!!Lbl_NoConfigCacheHelp1       TEXT
END PART
END POLICY
       .....

[Strings]
Pol_NoConfigCache_Help="Prevents users from changing the automatic
synchronization behavior at logoff."
```

In the preceding example, Help is offered for one of the Offline Files options. The **EXPLAIN** keyword wrapped in the **#if VERSION** allows this .adm file to be used with the Windows 2000 Group Policy Object Editor (version 3).

**Line Breaks**

To start text on a new line or to create a line break, use this syntax:

```
\n = Starts a new line
\n\n = Creates a line break
```

**#If Version for Version Comparison**

The **IF VERSION** conditional statement is used to control the display of certain policy settings and features in the Administrative Templates node, based on the version of the Group Policy Object Editor that you are using. **IF VERSION** allows for part of the .adm files to be conditionally parsed and ignored by earlier versions of the Group Policy Object Editor tool. For example, the SUPPORTED tag is not supported on versions of the Group Policy Object Editor earlier than version 4. For this reason any statement using the SUPPORTED tag should be enclosed by #If Version...#endif.

You can specify that any part of your .adm file be evaluated only in specific versions of the Group Policy editing tools, as shown in Table 5, in the "*.Adm File Language Versions*" section of this document.

To compare versions, use the following syntax:

```
#if Version (operator) x
#endif
```

The valid operators are listed in Table 13.

**Table 13 Valid Operators for the Version Statement Number**

| Operator | Signifies |
|---|---|
| > (GT) | Greater than. For example, a > b means a is greater than b. |
| < (LT) | Less than. For example, a < b means a is less than b. |
| == (EQ) | Equal. For example, a == b means a is equal to b. |
| != (NE) | Not equal. |
| >= (GTE) | Greater than or equal to. For example, a >= b means a is greater than or equal to b. |

| | |
|---|---|
| <= (LTE) | Less than or equal to. For example, a <= b means a is less than or equal to b. |

**.Adm File String/Tag Limits**

Various restrictions apply to .adm files and settings. Table 14 provides a complete list of these restrictions.

**Table 14**

| File String | Tag Limits |
|---|---|
| Maximum string length for Explain text | 4096 |
| Maximum string length for Category Explain text | 255 |
| Maximum string length for EDITTEXT string | 1023 |

# Windows Server 2003 Group Policy Infrastructure

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Intended for system administrators, architects, and others who need to create and manage Group Policy settings, this paper explains Group Policy infrastructure and shows how the new Group Policy Management Console (GPMC) fits into this infrastructure. The paper includes detailed information about Group Policy processing as well as many best practices useful to the Group Policy administrator.

Introduced in Windows® 2000 Server, Group Policy provides directory-based desktop configuration management. With Group Policy, you can specify settings for registry-based policies, security, software installation, scripts, folder redirection, Remote Installation Services, and Internet Explorer maintenance. The Windows Server 2003 family of operating systems, extends Group Policy in a number of ways— through GPMC, which includes scripting interfaces, Group Policy Results, Group Policy Modeling, and more.

The Group Policy settings that you create are contained in a Group Policy object (GPO). By linking a GPO with selected Active Directory® service system containers—sites, domains, and organizational units—you can apply these settings to the users and computers in those Active Directory containers. To create GPOs, you use GPMC in conjunction with the Group Policy Object Editor, an MMC snap-in, also known previously as the Group Policy snap-in, Group Policy Object Editor, or GPedit.

**Administrative Requirements for Using Group Policy**

In order to use of all of its features, Group Policy requires Active Directory and client computers running Windows 2000 or later. To set Group Policy for a selected Active Directory container, you must have a Windows 2000 or Windows Server 2003 domain controller installed, and you must have read and write permission to access the system volume of domain controllers (Sysvol folder) and modify rights to the currently selected directory container. The system volume folder is automatically created when you install a domain controller (or promote a server to domain controller).

| **Note** |
| --- |
| Group Policy depends on Active Directory; therefore, it is crucial to understand Active Directory and its structure. It is highly recommended that you familiarize yourself with Active Directory concepts before implementing Group Policy. To learn about Active Directory, see the Active Directory white papers at http://www.microsoft.com/ad. Information about planning and implementing Active Directory is available from the Windows Deployment and Resource Kits page at http://www.microsoft.com/reskit. |

**GPMC System Requirements**

GPMC can manage both Windows 2000 and Windows Server 2003 domains with Active Directory. In either case, the computer on which the tool itself runs must be running Windows Server 2003 or Windows XP Professional (with Windows XP Service Pack 1 and the Microsoft .NET Framework). Note: When installing GPMC on Windows XP Professional with SP1, a post SP1 hotfix is required. This hotfix (Q326469) is included with GPMC. GPMC Setup prompts you to install Windows XP hotfix Q326469 if it is not already present.

**Feedback on this Paper**

# What's New About Group Policy in Windows Server 2003

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This section summarizes new features in Windows Server 2003 Group Policy. The biggest change for Group Policy in Windows Server 2003 is the introduction of GPMC, the new solution for Group Policy management that helps you manage an enterprise more cost-effectively. It consists of a new Microsoft Management Console (MMC) snap-in and a set of scriptable interfaces for managing Group Policy. GPMC is available for download from the Microsoft GPMC Web site at http://www.microsoft.com/windowsserver2003/gpmc. This paper assumes you are using GPMC.

**Group Policy Management Console**
GPMC simplifies the management of Group Policy by providing a single place for managing core aspects of Group Policy. It addresses the top Group Policy deployment requirements by providing the following functionality:

- A user interface that makes Group Policy much easier to use.
- Backup/restore of GPOs.
- Import/export and copy/paste of GPOs and Windows Management Instrumentation (WMI) filters.
- Simplified management of Group Policy–related security.
- HTML reporting for GPO settings and Resultant Set of Policy (RSoP) data.
- Scripting of policy-related tasks that are exposed within this tool (not scripting of settings within a GPO).

GPMC is used to create, view, and manage GPOs while the Group Policy Object Editor is used to edit GPOs.

More information about GPMC is contained throughout this paper. For additional information about GPMC including step-by-step instructions for completing tasks, see the following resources:

- Group Policy Administration using the Group Policy Management Console. This white paper provides additional technical details of functionality in GPMC.
- GPMC Help. Available when you install GPMC, this provides step-by-instructions for GPMC tasks and addresses key concepts in GPMC.
- Microsoft GPMC Web site at http://www.microsoft.com/windowsserver2003/gpmc/. This site provides links to the latest GPMC resources including downloading information.

**New policy settings**
Windows Server 2003 includes more than 200 new policy settings. The new Windows Server 2003 policy settings allow administrators to control the behavior of:

- System restore, error reporting, PC Health.
- Terminal server.
- Networking such as SNMP, Quality of Service (QoS), personal firewall, and dialup connections.
- DNS and net logon.
- Roaming user profiles and Group Policy.
- Control panel.

- Windows Media® Player.
- Wireless configuration.
- Software restriction policy.

**Administrative Templates Changes**
For Administrative Templates policy settings, Group Policy Object Editor provides explain text directly in the Web view of the console. You also can find this explain text by double-clicking the policy setting and then clicking the **Explain text** tab. In either case, this text shows operating system requirements, defines the policy setting, and includes any specific details about the effect of enabling or disabling the policy setting.

Because new Administrative Template policy settings have been added that only work on specific versions of the operating system such as Windows XP Professional or Windows Server 2003, you can view only the Administrative Template policy settings that might be applied in your users' work environment, based on the "supported" keyword in each Administrative Template (.adm) file. For example, you may want to edit only policy settings that could be applied on client computers running Windows 2000 Service Pack 3. In Group Policy Object Editor, you can specify these options in the **Filtering** dialog box, available by clicking a node in the Administrative Templates section, clicking the **View** menu, and then clicking **Filtering**. For more information, see the section "Using Administrative Templates" in this paper.

**Command Line Refresh of Policy**
Administrators can now refresh policy settings from the command line using Gpupdate, which replaces **secedit /refreshpolicy** in Windows 2000. Gpupdate gives administrators better control and flexibility in refreshing policy. For more information, see the section "Refreshing Policy from the Command Line" in this paper.

**WMI Filtering**
WMI makes a large amount of data, such as hardware and software inventory, settings, and configuration information, available for a target computer. WMI retrieves data from the registry, drivers, file system, Active Directory, SNMP, Windows Installer, SQL, networking, and Exchange. WMI Filtering in Windows Server 2003 allows you to create queries based on this data. These queries (also called WMI filters) determine which users and computers receive all of the policy configured in the GPO where you create the filter. This functionality lets you target Group Policy based on a significant number of different properties of the target. In most organizations only senior administrators would actually create WMI filters; other administrators would simply access the WMI filters that have been created for their domain. For more information, see the section "WMI Filtering" in this paper.

**Tools for Best Practice Organizational Unit Design**
Redirusr.exe (for user accounts) and Redircomp.exe (for computer accounts) are two new tools included with Windows Server 2003 that enable you to change the default location where new user and computer accounts are created so you can more easily scope GPOs directly to newly created user and computer objects. By running Redirusr.exe and Redircomp.exe once for each domain, the domain administrator can specify the organizational units into which all new user and computer accounts are placed at the time of creation. For more information, see the section "Redirecting the Users and Computers Containers in Windows Server 2003 Domains in this paper.

**Forest Trust**
The Windows Server 2003 family introduces a new feature called Forest Trust that enables you to authenticate and authorize access to resources from separate, networked forests. With trusts established between forests, you can manage Group Policy throughout your enterprise, which provides greater flexibility especially in large organizations. For more information, see the section "Using Group Policy Features Across Forests" in this paper.

**Domain Rename**
The ability to rename a domain provides you with the flexibility to make important changes to your forest structure and namespace as the needs of your organization change. Renaming domains can accommodate acquisitions, mergers, name changes, or reorganizations. Domain rename allows you to:

1. Change the DNS and NetBIOS names of any domain in the forest (including the forest root domain).
2. Restructure the position of any domain in the forest (except the forest root domain).

You can only rename domains in a forest where all of the domain controllers are running Windows Server 2003 and the forest functional level has been raised to Windows Server 2003. For more information, see Windows Server 2003 Domain Rename Tools at http://www.microsoft.com/windowsserver2003/downloads/domainrename.mspx.

**Restore GPOs tool**
This is a new command-line tool intended for failure recovery. The tool, dcgpofix.exe, restores the default GPOs to their original state (that is, the default state after initial installation). For more information, see "Troubleshooting Windows Server 2003 Group Policy" available from the Microsoft GPMC Web site at http://www.microsoft.com/windowsserver2003/gpmc/.

**Wireless Support**
A new Wireless Network (IEEE 802.11) Policies Group Policy extension allows you to configure wireless network settings that are part of Group Policy for Computer Configuration. Wireless network settings include the list of preferred networks, Wired Equivalent Privacy (WEP) settings, and IEEE 802.1X settings. These settings are downloaded to targeted domain members, making it much easier to deploy a specific configuration for secure wireless connections to wireless client computers.

**Software Restriction Policy Settings**
Software restriction policy settings address the need to regulate unknown or untrusted software. With the rise in the use of networks, the Internet, and e-mail for business computing, users find themselves exposed to new software in a variety of ways. Users must constantly make decisions about running unknown software. Viruses and Trojan horses often intentionally misrepresent themselves to trick users into running them. It is difficult for users to make safe choices about which software they should run.

With software restriction policy settings, you can protect your computing environment from untrusted software by identifying and specifying which software is allowed to run. You can define a default security level of unrestricted or disallowed for a GPO so that software is either allowed or not allowed to run by default. You can make exceptions to this default security level by creating rules for specific software. For example, if your default security level is set to disallowed, you can create rules that allow specific software to run. For more information, see the section "Software Restriction Policy Settings" in this paper.

**Internet Explorer Enhanced Security Configuration**
Internet Explorer Enhanced Security Configuration, also known as Internet Explorer hardening, is enabled by default on computers running Windows Server 2003. It can be managed using Group Policy in an enterprise environment to ensure consistent trusted sites and security settings on targeted server computers or to disable the feature on specific servers. For example, you may wish to ensure that Internet Explorer Enhanced Security Configuration is reapplied on a specific computer if the local administrator on that computer turns it off using the Optional Component Manager in the **Windows Components Wizard** (available from **Add or Remove Programs**.) In addition, it's likely that you will want to manage computers or groups of computers in your organization by defining a set of trusted sites and/or a specific security level for sites in the **Internet** or **Trusted sites** zones. For more information, see "Using Group Policy and Internet Explorer Enhanced Security Configuration" later in this document and Managing Internet Explorer Enhanced Security Configuration, available from the Microsoft Group Policy Web site at http://www.microsoft.com/grouppolicy.

# Overview of Group Policy Infrastructure and Mechanics

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Group Policy uses a document-centric approach to creating, storing, and associating policy settings. Similar to the way in which Microsoft Word stores information in .doc files, Group Policy settings are contained in GPOs. GPOs are linked to the following Active Directory containers: sites, domains, or organizational units. The settings within the GPOs are then evaluated by the affected clients, using the hierarchical nature of Active Directory.

**Linking Group Policy Objects to Active Directory Containers**
GPOs cannot be linked directly to users, computers, or security groups. They can only be linked to sites, domains and organizational units.

A given GPO can be linked to more than one site, domain, or organizational unit. Conversely, a given site, domain, or organizational unit can have multiple GPOs linked to it. In the case where multiple GPOs are linked to a particular site, domain, or organizational unit, you can prioritize the order of precedence in which these GPOs are applied.

By linking GPOs to sites, domains, and organizational units, you can implement Group Policy settings for as broad or as narrow a portion of the organization as you want:

- A GPO linked to a site applies to all users and computers in the site.
- A GPO applied to a domain applies directly to all users and computers in the domain and by inheritance to all users and computers in child organizational units. Note that policy is not inherited across domains.
- A GPO applied to an organizational unit applies directly to all users and computers in the organizational unit and by inheritance to all users and computers in child organizational units.

To link a GPO to a site, domain, or organizational unit, use GPMC. In the console tree, locate the site, domain or organizational unit and then choose **Link an Existing GPO** or **Create and Link a GPO Here**.

Note that GPOs are stored in domains not in organizational units. For example, if you create and link a new GPO for an organizational unit, GPMC is actually completing two steps at once: creating a GPO in the domain and then linking that GPO to that organizational unit. The link is not a component of the GPO; it is a component of the container to which it is linked. Therefore, if you want to delegate the ability to manage links for a given container, it must be delegated on that container, not the GPO. In the GPMC tree view, GPO links on a given container are shown as child nodes of that container.

Although you can link a site, domain, or organizational unit to a GPO in another trusted domain, this is not generally recommended for performance reasons because of the potential delay of processing GPOs at logon.

**Group Policy Hierarchy**
By default, Group Policy is inherited and cumulative, and it affects all computers and users in an Active Directory container. GPOs are processed according to the following order:

1. **Local GPO**. Each computer has exactly one GPO that is stored locally, shared by all users of that computer. This processes for both computer and user Group Policy processing.
2. **Site**. Any GPOs that have been linked to the site that the computer belongs to are processed next. Processing is in the order that is specified by the administrator, on the **Linked Group Policy Objects** tab for the site in GPMC. The GPO with the lowest **link order** is processed last, and therefore has the highest precedence.
3. **Domain**. Processing of multiple domain-linked GPOs is in the order specified by the administrator, on the **Linked Group Policy Objects** tab for the domain in GPMC. The GPO with the lowest **link order** is processed last, and therefore has the highest precedence.
4. **Organizational units**. GPOs that are linked to the organizational unit that is highest in the Active Directory hierarchy are processed first, then GPOs that are linked to its child organizational unit, and so on. Finally, the GPOs that are linked to the organizational unit that contains the user or computer are processed.

At the level of each organizational unit in the Active Directory hierarchy, one, many, or no GPOs can be linked. If several GPOs are linked to an organizational unit, their processing is in the order in which GPOs are linked to the organizational unit. For example, if you link three GPOs to an organizational unit the first GPO you added has the highest precedence and overwrites the settings of all other GPOs. Alternatively, you can specify the order on the **Linked Group Policy Objects** tab for the organizational unit in GPMC.

This order means that the local GPO is processed first, and GPOs that are linked to the organizational unit of which the computer or user is a direct member are processed last, which overwrites settings in the earlier GPOs if there are conflicts. (If there are no conflicts, then the earlier and later settings are merely aggregated.)

In GPMC, you can view the precedence order of inherited GPOs for a given site, domain or organizational unit by navigating to the Group Policy Inheritance tab for any site, domain, or organizational unit.

**Managing Inheritance of Group Policy**

You can further control precedence and how GPO links are applied to specific domains, sites, or organizational units by:

- **Changing the link order.** Within each domain, site, and organizational unit, the link order controls when links are applied. To change the precedence of a link, you can change the link order, moving each link up or down in the list to the appropriate location. The link with the higher order (with 1 being the highest order) has the higher precedence for a given site, domain, or organizational unit. For example, if you add six GPO links and later decide that you want the last one that you added to have highest precedence, you can move the GPO link to the top of the list. However, the link order of an inherited GPO cannot be altered.

- **Blocking Group Policy inheritance.** You can block policy inheritance for a domain or organizational unit. Using block inheritance prevents GPOs linked to higher sites, domains, or organizational units from being automatically inherited by the child-level. By default, children inherit all GPOs from the parent, but it is sometimes useful to block inheritance. For example, if you want to apply a single set of policies to an entire domain except for one organizational unit, you can link the required GPOs at the domain level (from which all organizational units inherit policies by default), and then block inheritance only on the organizational unit to which the policies should not be applied. Blocking does not affect Local GPOs.

- **Enforcing a GPO link.** You can specify that the settings in a GPO link should take precedence over the settings of any child object by setting that link to **Enforced** (formerly known as "no override"). GPO-links that are enforced cannot be blocked from the parent container. Without enforcement from above, the settings of the GPO links at the higher level (parent) are overwritten by settings in GPOs linked to child organizational units, if the GPOs contain conflicting settings. With enforcement, the parent GPO link always has precedence. Note that **Enforce** policy options always take precedence over Block Inheritance.

- **Disabling a GPO link**. By default, processing is enabled for all GPO links. You can completely block the application of a GPO for a given site, domain, or organizational unit by disabling the GPO link for that domain, site, or organizational unit. Note that this does not disable the GPO itself, and if the GPO is linked to other sites, domains or organizational units, they will continue to process the GPO, if their links are enabled.

- **Disabling user and/or computer settings**. A GPO may have its user settings disabled, its computer settings disabled, or all settings disabled. By default, neither user settings nor computer settings are disabled on a GPO.

| **Note** |
| --- |
| A GPO link may be **enforced**, or **disabled**, or both. By default, a GPO link is neither enforced nor disabled. If the link is enforced and disabled, the disabled link has precedence. |

Figure 1 below shows a sample domain structure to illustrate how GPOs can be applied to containers in Active Directory.

**Figure 1. Group Policy and Active Directory**

**Filtering the Scope of the Group Policy Object**
You can further refine which groups of computers and users a particular GPO influences by using security groups or WMI filtering.

**Security Filtering**
Security filtering is a way of refining which users and computers will receive and apply the settings in a GPO. Using security filtering, you can narrow the scope of a GPO so that it applies only to a single group, user, or computer by specifying that only certain security principals within a container where the GPO is linked apply the GPO. Security filtering determines whether the GPO as a whole applies to groups, users, or computers; it cannot be used selectively on different settings within a GPO.

In order for the GPO to apply to a given user or computer, that user or computer must have both **Read** and **Apply Group Policy (AGP)** permissions on the GPO, either explicitly, or effectively though group membership.

By default, all GPOs have **Read** and **AGP** both **Allowed** for the Authenticated Users group. The Authenticated Users group includes both users and computers. This is how all authenticated users receive the settings of a new GPO when it is applied to an organizational unit, domain or site. Therefore, the default behavior is for every GPO to apply to every Authenticated User. By default, Domain Admins, Enterprise Admins, and the local system have full control permissions, without the Apply Group Policy ACE. However, administrators are members of Authenticated Users, which means that they will receive the settings in the GPO by default.

You can change these permissions to limit the scope to a specific set of users, groups, or computers within the organizational unit, domain, or site. Group Policy Management manages these permissions as a single unit, and displays the security filtering for the GPO on the GPO Scope tab. Using GPMC, you can add and remove groups, users, and computers to be used as security filters for each GPO. In addition, security principals used for security filtering also appear on the **Delegation** tab for a GPO as having **Read (from Security Filtering)**, since they have read access to the GPO.

To modify security filtering, you add or remove groups in the Security Filtering section on the Scope tab of a GPO. In practice, you don't have to set the two access control entries (ACEs), because GPMC sets both for you when you set security filtering. In addition, The **Read** and **AGP** permissions are visible separately, and able to be set independently of one another, through the access control list (ACL) editor. In GPMC, the **Security Filtering** section of the **Scope** tab of a GPO shows only whether the GPO will apply. If you want to see the permissions separately, you can open the ACL editor by clicking the **Advanced** button on the **Delegation** tab for the GPO.

To prevent a GPO from applying to a specified group requires removal of the AGP ACE from that group. In the ACL editor, if you remove the AGP ACE (clear the **Allow check box**) for Authenticated Users, you can then explicitly grant this permission to individual security groups that should receive the policy settings. Alternatively, you could set AGP to **Deny** for certain classes of users, such as administrators, that will never need that policy.

| **Note** |
| --- |
| Use the **Deny** ACE with caution. A **Deny** ACE setting for any group has precedence over any **Allow** ACE given to a user or computer because of membership in another group. |

**Best Practice:** If you disallow Apply Group Policy for a GPO for some users, consider also disallowing Read access to those users. When the Read ACE is allowed and the Apply Group Policy is not, the GPO is still processed by the user even though it is not applied to the user. Therefore, to improve performance, you should remove the Read Access Control Entry to prevent the

user from processing the GPO. In addition, removing Read access increases security. With Read access allowed, it is possible for an inquisitive user with considerable knowledge of Active Directory to read the contents of that GPO, even if it's not applied to them. This may not be desirable in some cases, such as a GPO for a human resources group. It might be advisable to limit Read access on GPOs that affect the HR users to only those users.

Security groups and DACLs are also used to delegate control of GPOs, as explained in the section "Delegating Group Policy."

**Note**

Granting Read and AGP is not sufficient to ensure that the GPO is processed for a user or computer. The GPO also has to be linked to a site, domain or organizational unit containing the user or computer, directly or through inheritance.

A GPO with security filtering set to Read and AGP doesn't necessarily apply to all security principals that have security filtering. It only applies to them if those user or computer objects are in the container or child container that is linked to the GPO.

The location of a security group in Active Directory is irrelevant to security filtering and, more generally, irrelevant to Group Policy processing.

**WMI Filtering**

WMI filters allow you to dynamically determine the scope of GPOs based on attributes of the target computer.

When a GPO that is linked to a WMI filter is applied on the target computer, the filter is evaluated on the target computer. If the WMI filter evaluates to false, the GPO is not applied (except if the client computer is running Windows 2000, in which case the filter is ignored and the GPO is always applied). If the WMI filter evaluates to true, the GPO is applied.

WMI makes data about a target computer available for administrative use. Such data can include hardware and software inventory, settings, and configuration information. For example, WMI exposes hardware configuration data such as CPU, memory, disk space, and manufacturer, as well as software configuration data from the registry, drivers, file system, Active Directory, the Windows Installer service, networking configuration, and application data.

A WMI filter consists of one or more queries based on this data. If all queries are true, the GPO linked to the filter will be applied. The queries are written using the WMI Query Language (WQL), a SQL-like language. Queries can be combined with AND and OR logical operators to achieve whatever effect the administrator wants. Each query is executed against a particular WMI namespace. When you create a query, you must specify the namespace. The default is root\CIMv2, which is appropriate for most WMI queries. For more information, see Windows Management Instrumentation in the Microsoft Platform SDK at http://msdn.microsoft.com/library/default.asp?url=/library/en-us/wmisdk/wmi/wmi_start_page.asp.

The WMI filter is a separate object from the GPO in the directory. To apply a WMI filter to a GPO, you link the filter to the GPO. This is shown in the WMI filtering section on the Scope tab of a GPO. Each GPO can have only one WMI filter, however the same WMI filter can be linked to multiple GPOs.

WMI filters, like GPOs, are stored on a per-domain basis. A WMI filter and the GPO it is linked to must be in the same domain.

**Note**

Client support for WMI filters exists only on Windows XP, Windows Server 2003, and later operating systems.
Windows 2000 clients will ignore any WMI filter and the GPO is always applied, regardless of the WMI filter.

WMI filters are only available in domains that have at least one Windows Server 2003 domain controller. In an environment consisting only of Windows 2000 domains, the WMI filter node in GPMC is not shown.

Here are some sample uses of WMI Filters.

- Services – computers where DHCP is turned on.
- Registry – computers that have this registry key populated.
- Hardware inventory – computers with a Pentium III processor.
- Software inventory – computers with Visual Studio® .NET installed.
- Hardware configuration – computers with network adapters on interrupt level 3.

- Software configuration – computers with multi-casting turned on.
- Associations – computers that have any service dependent on SNA service.
- Ping – computers that can ping Server1 in less than 100 milliseconds.

WMI filtering allows administrators to filter the application of a GPO by attaching one set of Windows Query Language query to a GPO. The queries can be written to query WMI for multiple items. If the query returns true for all queried items, then the GPO will be applied to the target user or computer. The WMI filter applies to every setting in the GPO, so you will want to create separate GPOs specifically for WMI filtering.

There are two distinct parts to WMI filtering in Windows Server 2003:

- Server administration of WMI filters. This includes GPMC, changes to the Group Policy Object Editor, and filter specifications.
- Client side processing. (WMI supports batch processing of WMI filters.)
- For more information about WMI filtering including sample filters for specific scenarios, see "Appendix C" in this paper.

**MMC Snap-in Extension Model**

The nodes of the Group Policy Object Editor are also MMC snap-in extensions. These extensions include Administrative Templates, Scripts, Security Settings, Software Installation, Folder Redirection, Remote Installation Services, and Internet Explorer Maintenance. Extension snap-ins may in turn be extended. For example, the Security Settings snap-in includes several extension snap-ins. Developers can also create their own MMC extensions to the Group Policy Object Editor to provide additional policy settings.

For more information about creating MMC extensions, see the Microsoft Management Console section of the Microsoft Platform SDK documentation at: http://www.microsoft.com/msdownload/platformsdk/sdkupdate/.

By default, all the available Group Policy Object Editor extensions are loaded when you start the Group Policy Object Editor. You can modify this default behavior by creating a custom MMC console, or by using policy settings to control the behavior of MMC itself. MMC options are accessed under the **User Configuration\Administrative Templates\Windows Components\Microsoft Management Console** node. For more information, see:

"Specifying Group Policy to Control the Behavior of MMC and Snap-ins", later in this document.

**Group Policy Object Editor Namespace**

The root node of the Group Policy Object Editor is displayed as the name of the GPO and the domain to which it belongs, in the following format:

*GPO Name [DomainName.com] Policy*

For example:

Default Domain Policy [HQ-RES-DC-01.Contoso.com] Policy

**Computer Configuration and User Configuration**

Below the root node, the namespace is divided into two parent nodes: Computer Configuration and User Configuration. These are the parent nodes that you use to configure Group Policy settings. Computer-related Group Policy is applied when the operating system boots and during the periodic refresh cycle, explained later in this document. User-related Group Policy is applied when users log on to the computer and during the periodic refresh cycle.

**Extensions to the Group Policy Object Editor**

Three nodes exist under the Computer Configuration and User Configuration parent nodes: Software Settings, Windows Settings, and Administrative Templates. The Software Settings and Windows Settings nodes contain extension snap-ins that extend either or both of the Computer Configuration or User Configuration nodes. Most of the extension snap-ins extend both of these nodes, but frequently with different options. The Administrative Templates node namespace contains all policy settings pertaining to the registry; it can be extended by using .adm files.

The Group Policy extension snap-ins include:

- **Administrative Templates**. This extension contains all registry-based policy settings, including those for the

Windows 2000 and Windows Server 2003 operating systems and their components as well as any registry-based policy settings provided by applications. You use these policy settings to mandate registry settings that control the behavior and appearance of the desktop, the operating system components, and applications that provide registry-based policy. This node uses .adm files to specify the registry settings that can be modified through the Group Policy Object Editor user interface. For more information about .adm files, see "Administrative Templates" later in this paper.

- **Security Settings**. The Security Settings extension is used to set security options for computers and users within the scope of a GPO. You can define local computer, domain, IP security settings, wireless configuration, and software restriction policy settings. For more information about security settings, see "Security Settings" and "Appendix A: Security Settings and User Rights" later in this paper.

- **Software Installation**. You can use the Software Installation snap-in to centrally manage software in your organization. You can assign and publish software to users and assign software to computers. For more information about software installation, see "Software Installation", later in this document.

- **Scripts**. Scripts are used to automate tasks at computer startup and shutdown, and at user logon and logoff. You can use any language supported by Windows Script Host. These include the Microsoft Visual Basic® development system, Scripting Edition (VBScript), JavaScript, PERL, and MSDOS®-style batch files (.bat and .cmd). See "Scripts", later in this document and Microsoft Windows Script Web site at http://www.microsoft.com/scripting for more information.

- **Remote Installation Services**. Remote Installation Services (RIS) is used to control the behavior of the Remote Operating System Installation feature as displayed to client computers. See "Remote Installation Services", later in this document.

- **Internet Explorer Maintenance**. Internet Explorer Maintenance is used to manage and customize Internet Explorer on computers running Windows 2000 or later. You can also export settings for Windows 95, Windows 98, and Windows NT® 4.0-based client computers (the settings are exported into an .ins and .cab file format for those platforms). Administrators can set options for Browser UI, connections, URLs, proxy settings, security zones, Favorites, and other options. See "Internet Explorer Maintenance", later in this document.

- **Folder Redirection**. You can use folder redirection to redirect special directories on Windows 2000 or Windows Server 2003 from their default user profile location to an alternate location on the network. These special folders include My Documents, Application Data, Desktop, and the **Start** menu. See "Folder Redirection", later in this document.

For more information about extending the functionality of the Group Policy Object Editor see "Implementing Registry-Based Group Policy" at http://www.microsoft.com/windows2000/techinfo/howitworks/management/rbppaper.asp.

**Client-side Extensions to Group Policy**

Some of the Group Policy Object Editor extensions also include *client-side extensions*. These extensions are DLLs that are responsible for implementing Group Policy at the client computers. For more information about the client-side extensions, see the "Client-side Processing of Group Policy" section later in this paper.

**Group Policy Storage**

A GPO is a virtual object. The policy setting information of a GPO is actually stored in two locations: the Group Policy container (GPC) and the Group Policy template (GPT). The Group Policy container is an Active Directory container that stores GPO properties, including information about version, GPO status, and a list of components that have settings in the GPO. The Group Policy template is a directory structure within the file system that stores Administrative Template-based policy settings, security settings, script files, and information regarding applications that are available for Software Installation. The Group Policy template is located in Sysvol in the \Policies sub-directory for its domain. GPOs are identified by their globally unique identifiers (GUIDs) and stored at the domain level. Replication of a GPO to other domain controllers happens through two different mechanisms. The Group Policy container is replicated by using Active Directory replication, whereas the Group Policy template is replicated using File Replication service (FRS). The settings from a GPO are only applied when the Group Policy container and Group Policy template are synchronized. For additional information about storage of Group Policy information, see"Appendix B: Group Policy Storage", later in this paper.

# Migrating GPOs Across Domains

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Taking a GPO in a given domain and creating a new GPO that contains the same set of policies in a different domain is a central function of GPMC.

Although the collection of settings in a GPO is logically a single entity, the data for a single GPO is stored in multiple locations and in a variety of formats; some data is contained in Active Directory and other data (of various types) is stored on the Sysvol file share on the domain controllers. This means that copying GPOs is not as simple as taking a directory and copying it from one computer to another.

In addition to the complex way in which GPO data is stored, certain policy data may be valid in one domain but be invalid in the domain that the GPO is being copied to. For example, Security Identifiers (SIDs) stored in security policy settings are often domain specific. In addition, Universal Naming Convention (UNC) paths for folder redirection or software installation policies may not work properly if the data in the GPO is copied without modification to a different domain.

**Migration Tables**

The solution is to modify these references in the GPO that are domain-specific, during the import or copy operation, so that the settings in the destination GPO are written with the appropriate information for the destination domain. GPMC supports this capability using migration tables.

A migration table is a file that maps references to users, groups, computers, and UNC paths in the source GPO to new values in the destination GPO. A migration table consists of one or more mapping entries. Each mapping entry consists of a type, source reference, and destination reference. If you specify a migration table when performing an import or copy, each reference to the source entry will be replaced with the destination entry when writing the settings into the destination GPO.

The migration table will apply to any references in the settings within a GPO, whether you are performing an import or copy operation. In addition, during a copy operation, if you choose the option to preserve the discretionary access control list (DACL) on the GPO, the migration table will also apply to both the DACL on the GPO and the DACLs on any software installation settings in the GPO.

Migration tables store the mapping information as XML, and have their own file name extension, .migtable. You can create migration tables using the Migration Table Editor (MTE). The MTE is a convenient tool for viewing and editing migration tables without having to work in, or be familiar with, XML. The MTE is associated with the .migtable extension so that when you double click a migration table, it opens in the MTE. The MTE is installed with GPMC. You can also create and edit migration tables using any XML editor or using the GPMC scripting interfaces.

**GPMC as the Solution for Migrating GPOs**

There are four operations that GPMC provides to allow for archival and recovery of GPOs, and for migrating GPOs from one environment to another:

- **Copy**. A copy operation allows you to transfer settings from an existing GPO in Active Directory directly into a new GPO. The new GPO created during the copy operation is given a new GUID and is unlinked. You can use a copy operation to transfer settings to a new GPO in the same domain, another domain in the same forest, or a domain in another forest. Because a copy operation uses an existing GPO in Active Directory as its source, trust is required between the source and destination domains. Copy operations are suited for moving Group Policy between production environments, and for migrating Group Policy that has been tested in a test domain or forest to a production environment, as long as there is trust between the source and destination domains.

- **Backup**. Backing up a GPO copies the data in the GPO to the file system. The backup function also serves as the export capability for GPOs. A GPO backup can be used to restore the GPO to the backed-up state, or to import the settings in the backup to another GPO.

- **Import**. The Import operation transfers settings into an existing GPO in Active Directory using a backed-up GPO in the file system location as its source. Import operations can be used to transfer settings from one GPO to another GPO within the same domain, to a GPO in another domain in the same forest, or to a GPO in a domain in a different forest. The import operation always places the backed-up settings into an existing GPO. It erases any pre-existing settings in the destination GPO. Import does not require trust between the source domain and destination domain. Therefore it is useful for transferring settings across forests and domains that don't have trust. Importing settings into a GPO does not affect its DACL, links on sites domains or organizational units to that GPO, or a link to a WMI filter.

- **Restore**. Restoring a GPO re-creates the GPO from the data in the backup. A restore operation can be used in both of the following cases: the GPO was backed up but has since been deleted, or the GPO is live and you want to roll back to a known previous state.

Each of these operations can be performed through the GPMC user interface, or through the GPMC scripting model.

For more information, see the following resources:

- Group Policy Administration using the Group Policy Management Console White paper. Provides technical details of functionality in GPMC.

- Migrating GPOs Across Domains with GPMC. Explains how to migrate GPOs from one domain to another using GPMC.

- **GPMC Help**. Available when you install GPMC, this provides step-by-instructions for GPMC tasks and addresses key concepts in GPMC.

# Scripting Group Policy Tasks

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

GPMC provides a comprehensive set of COM interfaces for scripting many Group Policy-related operations. The interfaces are documented in the Group Policy Management Console SDK, which is located at **%programfiles%\gpmc\scripts\gpmc.chm** on any computer where you installed GPMC. (The Group Policy Management Console SDK is only available in English.)

When you install GPMC, a set of sample scripts illustrating the use of these interfaces are installed to the **%programfiles%\gpmc\scripts** directory.

The sample scripts address real-world administrative problems and scenarios. You can perform various tasks such as finding all GPOs in a domain that have duplicate names or generating a list of all GPOs in a domain whose settings are disabled or partially disabled.

| **Note** |
| --- |
| Scripted control of individual settings inside a GPO is not provided. |

# Delegating Group Policy

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

One of the features of Active Directory is its ability to delegate control of portions of the directory service. This section explains how Group Policy fits in with the delegation of sites, domains, and organizational units.

With GPMC, the following tasks can be delegated:

- Create GPOs in a domain.
- Set permissions on a GPO.
- Set policy-related permissions on site, domain or organizational unit.
    - Link GPOs to a given site, domain or organizational unit.
    - Perform Group Policy Modeling analyses on a given domain or organizational unit (but not on a site).
    - Read Group Policy Results data for objects in a given domain or organizational unit (but not on a site).
- Create WMI filters in a domain.
- Set permissions on a WMI filter.

GPMC simplifies delegation by managing the various ACEs required for a task as a single bundle of permissions for the task. If you want to see the ACL in detail, you can click the **Advanced** button on the **Delegation** tab.

The underlying mechanism for achieving delegation is the application of the appropriate DACLs to GPOs and other objects in Active Directory. This mechanism is identical to using security groups to filter the application of GPOs to various users, as described earlier in this paper.

You can also specify Group Policy to control the behavior of MMC and MMC snap-ins. For example, you can use Group Policy to manage the rights to create, configure, and use MMC consoles, and to control access to individual snap-ins.

**Using Security Groups to Delegate Group Policy**

The following table lists the default security-permission settings for a GPO:

| Groups or Users | Security permission |
|---|---|
| Authenticated User | Read with Apply Group Policy ACE |
| Domain Admins<br>Enterprise Admins<br>Creator Owner<br>Local System | Full control without Apply Group Policy ACE. |

| Note |
|---|
| By default, administrators are also authenticated users, which means that they have the **Apply Group Policy** attribute set. If this is not desired, administrators have two choices: |

- Remove Authenticated Users from the list on the security tab of the GPO, and add a new security group with the Apply Group Policy and Read attributes set to **Allow**. This new group should contain all the users that this Group Policy is intended to affect.

- Set the Apply Group Policy attribute to **Deny** for the Domain and Enterprise Admins, and possibly the Creator Owner groups. This will prevent the GPO from being applied to members of those groups. Remember that an ACE set to **Deny** always takes precedence over **Allow**. Therefore, if a given user is a member of another group that is set to explicitly **Allow** the Apply Group Policy attribute for this GPO, it will still be denied.

**Managing Group Policy Links for a Site, Domain, or Organizational Unit**

The **Group Policy** tab in the **Properties** page for a site, domain, or organizational unit allows the administrator to specify which GPOs are linked to this site, domain, or organizational unit. This property page stores the user's choices in two Active Directory properties called **gPLink** and **gPOptions**. The **gPLink** property contains the prioritized list of GPOs and the **gPOptions** property contains the **Block Policy Inheritance** setting.

To manage GPO links to a site, domain, or organizational unit, you must have read and write access to the **gPLink** and **gPOptions** properties. By default, Domain Admins have this permission for domains and organizational unit, and only Enterprise Admins and Domain Admins of the forest root domain can manage links to sites.

Active Directory supports security settings on a per-property basis. This means that a non-administrator can be given read and write access to specific properties. In this case, if non-administrators have read and write access to the **gPLink** and **gPOptions** properties, they can manage the list of GPOs linked to that site, domain, or organizational unit.

**Creating GPOs**

By default, only Domain Admins, Enterprise Admins, and Group Policy Creator Owners can create new GPOs. Creating GPOs is a user right of the Group Policy Creator Owners (GPCO) group by default but can be delegated to any group or user. There are two methods to grant a group or user this right:

- Add the user or group to membership of the **Group Policy Creator Owners** group. This was the only method available prior to GPMC.

- Explicitly grant the group or user permission to create GPOs. This method is newly available with GPMC.

You can manage this permission using the **Delegation** tab on the **Group Policy Objects** container for a given domain in GPMC. This tab shows the groups that have permission to create GPOs in the domain, including the GPCO group. From this tab, you can modify the membership of existing groups with this permission, or add new groups.

The ability to grant users permissions to create GPOs without using GPCO was added to facilitate the delegation of GPO creation to users outside the domain. Because the Group Policy Creator Owners group is a domain global group, it cannot contain members from outside the domain. Thus, prior to GPMC, this task could not be delegated to members outside the domain.

It is recommended that for users and groups within the domain, you continue to use the GPCO group to grant them GPO creation rights. If you require that users outside the domain have the ability to create GPOs, then create a new domain local group in the domain ("GPCO - External"), grant that group GPO creation rights in the domain, and then add external domain users to that group.

Adding a user to the membership of GPCO, or granting the user GPO creation permissions directly using the new method available in GPMC, is identical in terms of permissions. Users have the ability to create GPOs in the domain, but do not have permissions on GPOs created by other users. For example, granting a user the ability to create GPOs in the domain does not give the user the ability to edit or delete existing GPOs, or the ability to link the GPO to a site, domain or organizational unit.

Note that when an administrator creates a GPO, the Domain Admins group becomes the Creator Owner of the GPO. The ability to link GPOs to a site, domain or organizational unit is a permission that is specific to that site, domain or organizational unit. When delegating to non-administrators, you should also consider delegating the ability to manage the links for a specific organizational unit. The reason is that by default, non-administrators cannot manage links.

In GPMC, this permission can be managed using the Delegation tab on the site, domain or organizational unit when you click the **Link GPOs** option in the permission drop-down list box. At the individual permission level in Active Directory, this allows Read and Write access to the gPLink and gPOptions attributes on the site, domain, or organizational unit. By default, only Domain Admins and Enterprise Admins have this permission.

**Editing Group Policy Objects**

To edit a GPO, the user must have both read and write access to the GPO. (However, read-only support for opening a GPO is provided in GPMC). To edit a GPO, the user must be one of the following:

- An administrator.
- A Creator Owner.
- A user with delegated access to the GPO. That is, an administrator, or the Creator Owner, must have provided to this user both read and write access to the GPO.

By default, Domain Admins, Enterprise Admins, the operating system, and the GPO Creator Owner can edit GPOs because they have full control of GPOs without the **Apply Group Policy** attribute.

**Delegating an individual GPO**

There are five permission options on GPOs in GPMC user interface. Each corresponds to a set of individual NT permissions. The correspondence is summarized in the following table.

| Option in GPMC user interface | Corresponding NT permission in ACL Editor |
|---|---|
| Read | Allow **Read** Access on the GPO |
| Edit settings | Allow **Read**, **Write**, **Create Child Objects**, and **Delete Child Objects**. |
| Edit, delete, and modify security | Allow **Read**, **Write**, **Create Child Objects**, **Delete Child Objects**, **Delete**, **Modify Permissions**, and **Modify Owner**. This essentially grants full control on the GPO, except that the **Apply Group Policy** permission is not set. |
| Read (from Security Filtering) | This setting cannot be set directly, but appears on the delegation tab if the user has **Read** and **Apply Group Policy** permissions to the GPO. |
| Custom | Any other combination of permissions, including the use of **Deny** will show up as **Custom** in the display. GPMC can only set custom permission sets by clicking the Advanced button and opening the ACL editor. |

Permissions on a GPO are managed from the Delegation tab of that GPO.

**Specifying Group Policy to Control the Behavior of MMC extensions**

Windows Server 2003 Group Policy includes several policy settings designed to control the behavior of MMC snap-ins. For example, you can use Group Policy to manage the rights to use MMC snap-ins.

**Restricting Access to a List of Permitted Snap-ins**

Administrators can specify which MMC snap-ins may be run by the affected user and which may not. This may be specified to be inclusive, which only allows a set of snap-ins to run, or it may be set as exclusive, which does not allow a set of snap-ins to run.

To create a list of permitted snap-ins for users, enable the **Restrict users to the explicitly permitted list of snap-ins** policy. When this policy is enabled, only permitted snap-ins can be run. If this policy is disabled or not configured, all snap-ins are permitted, except those you explicitly prohibit.

This policy is available in the Group Policy console under the **User Configuration\Administrative Templates\Windows Components\Microsoft Management Console** node.

**Controlling Access to a Snap-in**

To restrict or explicitly permit access to a particular snap-in, navigate to **User Configuration\Administrative Templates\Windows Components\Microsoft Management Console\Restricted\Permitted snap-ins\Group Policy** in the console tree. In the details pane, double-click the snap-in that you want to permit or restrict, and then select an option. For more information about these policy settings, select a policy setting, and view the description in the Web view or click the explain tab in the Properties dialog box for the policy setting.

Administrators can enable the **Restrict the user from entering author mode** policy in order to prevent users from using MMC in author mode. This policy is available in the Group Policy console under the **User Configuration\Administrative Templates\Windows Components\Microsoft Management Console** node.

**Creating Custom Group Policy Object Editor Consoles**

You can create custom Group Policy MMC consoles (.msc files), which include only a subset of the Group Policy Object Editor

extensions. You can combine this with the use of the policy settings above to provide a customized tool. For example, you could create a custom Group Policy console that includes only the Security Settings extension. This allows you to define Group Policy settings in a modular fashion.

To set access permissions, use the **Security** tab on the **Properties** page of the selected GPO. These permissions allow or deny specified groups access to the GPO.

# Group Policy Extension Snap-ins

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Group Policy extension snap-ins constitutes the main nodes in the Group Policy Object Editor namespace; they are all loaded by default when the Group Policy Object Editor is started. You can modify which extensions are loaded by creating custom consoles for Group Policy, and by specifying policy settings for MMC. For more information, see "Creating Custom Group Policy Snap-in Consoles" and "Specifying Group Policy to Control the Behavior of MMC and Snap-ins" in this document.

This section presents additional information about the following topics:

- Administrative Templates
- Security Settings
- Software Installation
- Scripts (Startup/Shutdown and Logon/Logoff)
- Folder Redirection
- Internet Explorer Maintenance
- Remote Installation Services

**Administrative Templates**

Administrative templates, (or .adm files), enable administrators to control registry settings using Group Policy. Windows comes with a predefined set of Administrative template files, which are implemented as text files (with an .adm extension), that define the registry settings that can be configured in a GPO. These .adm files are stored in two locations by default: inside GPOs in the Sysvol folder and in the %windir%\inf directory on the local computer.

As new versions of Windows are released, new policy settings are added. In addition to supporting these new settings, each successive version of Windows supports all registry policy settings that were available in earlier versions of Windows. For example, the Windows Server 2003 family supports all registry policy settings available in Windows 2000 and Windows XP.

Note that .adm files are Unicode files which consist of a hierarchy of categories and subcategories that define how the options are displayed through the Group Policy Object Editor and GPMC. They also indicate the registry locations where changes should be made if a particular selection is made, specify any options or restrictions (in values) that are associated with the selection, and in some cases, indicate a default value to use if a selection is activated.

It is important to understand that .adm files are not the actual settings that are deployed to client operating systems. The adm file is simply a template file that provides the friendly name for the setting and an explanation. This template file is used to populate the user interface. The settings that are deployed to clients are contained in the registry.pol file inside the GPO. On Windows XP and Windows Server 2003, each registry setting contains a "Supported on" tag that indicates which operating system versions support that policy setting. If a setting is specified and deployed to a client operating system that does not support that setting, the settings are ignored.

Because all successive iterations of .adm files include settings from earlier versions, and because there is no harm if a new setting is applied inadvertently to a computer running an earlier operating system that does not support that setting, it is recommended to always create and edit GPOs from a computer that has the latest .adm files available. Note that the behavior for handling .adm files in GPMC and the Group Policy Object Editor differs.

Windows Server 2003 includes the following .adm files: System.adm, Inetres.adm, Conf.adm, Wmplayer.adm, and Wuau.adm, which contain all the settings initially displayed in the Administrative Templates node.

| .Adm file | Contains | For Use on | Description |
|---|---|---|---|

| | | | |
|---|---|---|---|
| System.adm | Settings to configure the Operating System | Windows 2000 or Windows Server 2003 | Loaded by default. |
| Inetres.adm | Settings to configure Internet Explorer | Windows 2000 or Windows Server 2003 | Loaded by default. |
| Conf.adm | Settings to configure NetMeeting v3 | Windows 2000 or Windows Server 2003.<br>**Note**<br>This tool is not available on Windows XP 64-Bit Edition and the 64-bit versions of the Windows Server 2003 family. | Loaded by default. |
| Wmplayer.adm | Settings to configure Windows Media Player | Windows XP, Windows Server 2003.<br>**Note**<br>This tool is not available on Windows XP 64-Bit Edition and the 64-bit versions of the Windows Server 2003 family. | Loaded by default. |
| Wuau.adm | Settings to configure Windows Update | Windows 2000 SP3, Windows XP SP1, Windows Server 2003 | Loaded by default. |

**Handling .adm files in Group Policy Object Editor**

- Windows Server 2003, Group Policy Object Editor uses .adm files to display available registry-based policy settings in the Administrative Templates section of a GPO. This includes Group Policy for the Windows Server 2003 operating system and its components and for applications.

- By default it attempts to read .adm files from the GPO (from the Sysvol on the domain controller). Alternatively, the .adm file can be read from the local workstation computer. This behavior can be controlled by a policy setting.

- By default, if the version of the .adm file found on the local computer is newer (based on the time stamp of the file) than the version on the Sysvol, the local version is copied to the Sysvol and is then used to display the settings. This behavior can be controlled by a policy setting.

- If the GPO contains registry settings for which there is no corresponding .adm file, these settings cannot be seen in the Group Policy Object Editor. However, the policy settings are still active and will be applied to users or computers targeted by the GPO.

- Policy settings pertaining to a user who logs on to a given workstation or server are written to the **User** portion of the registry database under **HKEY_CURRENT_USER**. Computer-specific settings are written to the **Local Machine** portion of the registry under **HKEY_LOCAL_MACHINE**.

**Handling .adm files in GPMC**

- GPMC uses .adm files to display the friendly names of policy settings when generating HTML reports for GPOs, Group Policy Modeling, and Group Policy Results.

- By default, GPMC uses the local .adm file, regardless of time stamp. If the file is not found, then GPMC will look in the GPO's directory on Sysvol.

- The user can specify an alternate path for where to find .adm files. If specified, this takes precedence over the previous locations.

- GPMC never copies the .adm file to the Sysvol.

For more information, see Recommendations for Managing Group Policy Administrative Template (.adm) Files at

http://support.microsoft.com/default.aspx?scid=kb;en-us;816662.

**Using Administrative Templates**
For Administrative Templates policy settings, the Group Policy Object Editor provides explain text directly in the Web view of the console. You also can find this explain text by double-clicking the policy setting and then clicking the Explain text tab. In either case, this text shows operating system requirements, defines the policy setting, and includes any specific details about the effect of enabling or disabling the policy setting.

**New policy settings**
Windows Server 2003 includes more than 200 new policy settings. The new Windows Server 2003 policy settings allow administrators to control the behavior of:

- System restore, error reporting, PC Health.
- Terminal Server.
- Networking such as SNMP, QoS, personal firewall, and dialup connections.
- DNS and net logon.
- Roaming user profiles and Group Policy.
- Control panel.

To filter settings based on the "supported on" information: Open the Group Policy Object Editor, click **View**, and then click **Filtering**. Select the versions you want to show and click **OK**.

| **Note** |
| --- |
| Showing only policy settings that can be fully managed is the default setting. You can also show policy settings by supported-on information and show only configured policy settings. In Windows Server 2003, the command **Only show configured policy settings** is now contained in the Filtering dialog box, shown above. |

**True Policy Settings Compared with Group Policy Preferences**
In Windows 2000 and later, all shipping policy settings set registry keys and values in one of the following locations:

- **HKLM\Software\Policies** (preferred location).
- **HKLM\Software\Microsoft\Windows\CurrentVersion\Policies**.
- **HKCU\Software\Policies** (preferred location).
- **HKCU\Software\Microsoft\Windows\CurrentVersion\Policies**.

Policy settings that are stored in these specific locations of the registry are known as *true policies*. Storing settings here has the following advantages:

- These trees are secure and cannot be modified by a non-administrator.
- When Group Policy changes, for any reason, these trees are cleaned, and the new policy settings are then rewritten.

This prevents the behavior that was often present in Windows NT 4.0, whereby System Policies resulted in persistent settings in the user and computer registry. The policy remained in effect until the value was reversed, either by a counteracting policy or by editing the registry. These settings are stored outside the approved registry locations above and are known as *preferences*.

All the policy settings in the System.adm, Inetres.adm, Conf.adm, Wmplayer,adm, and Wuau.adm files use registry settings in the Policies trees of the registry. This means that they will *not* cause persistent settings in the registry when the GPO that applies them is no longer in effect.

By default, only true policy settings are displayed in the Group Policy Object Editor. The following .adm files are loaded:

- System.adm: contains operating system settings
- Inetres.adm: contains Internet Explorer restrictions
- Conf.adm: contains NetMeeting settings
- Wmplayer,adm: contains Windows Media Player settings
- Wuau.adm: contains Windows Update settings

| **Note** |
| --- |
| Because of the persistent nature of non-policy settings, they should be avoided.<br><br>It is still possible for administrators to add an additional .adm file that sets registry values outside of the Group Policy trees mentioned previously. These settings might be more appropriately referred to as preferences because the user, application, or other parts of the system can also change them. In this case, the administrator is ensuring that this registry key or value is set in a particular way. Although it is possible to add any .adm file to the namespace, if you use an .adm file from a previous version of Windows, the registry keys are unlikely to have an effect; or they actually set preference settings and mark the registry with these settings; that is, the registry settings persist. |

**Creating Custom .adm Files**

It is possible to create new .adm files. For example when an application adds Group Policy support, a new .adm file may be necessary to describe the location of the appropriate registry keys and the UI exposed by the Group Policy Object Editor. Through the Group Policy Object Editor, the administrator can optionally add in additional .adm files to the GPO which, by default, will then be copied to the domain controller into the GPO directory.

To view custom .adm files in the Group Policy Object Editor:

- Right click any administrative template node, select **View** and then click **Filtering**. In the filtering dialog box, clear the check box for **Only show policy settings that can be fully managed** and click **OK**.

**Viewing Group Policy Preferences**

By default only the settings that are contained in the genuine Group Policy trees (the trees that correspond to the reserved Group Policy registry areas) are visible in the console.

To eliminate use of non-policies, you can enable the policy setting, **Enforce Show Policies Only**, available in **User Configuration\Administrative Templates**, under the **System\Group Policy** nodes.

If you enable this setting, the **Show Policies Only** command is turned on, and administrators cannot turn it off. As a result, Group Policy displays only true settings; preferences do not appear. If you disable this setting or do not configure it, the **Show Policies Only** command is turned on by default, but administrators can view preferences by turning off the **Show Policies Only** command.

In Group Policy, preferences are indicated by a red icon to distinguish them from true policy settings, which are indicated by a blue icon.

**Impact of GPO Replication**

By default, when you add a new domain to the console, GPMC uses the PDC emulator in that domain to help ensure that all administrators are using the same domain controller. For managing sites, GPMC uses the PDC emulator in the user's domain by default. You can change the default choice of domain controller using the Change Domain Controller dialog box in GPMC. If you are located at a remote site with a slow connection to the default domain controller, you may want to do this.

It is important for administrators to consider the choice of domain controller in order to avoid replication conflicts particularly because both Active Directory and FRS use multi-master replication. This is especially important to consider because GPO data resides in both Active Directory and on Sysvol, and two independent replication mechanisms must be used to replicate GPO data to the various domain controllers in the domain. If two administrators are simultaneously editing the same GPO on different domain controllers, it is possible for the changes written by one administrator to be overwritten by another administrator, depending on replication latency.

| **Important** |
| --- |
| If multiple administrators manage a common GPO, it is recommended that all administrators use the same domain controller when editing a particular GPO, to avoid collisions in FRS.<br><br>Because the Group Policy template is replicated to all domain controllers, the size of the .adm files can have an impact on network bandwidth, particularly where domain controllers are separated by slow links. |

**Security Settings**

You can define a security configuration within a GPO. A security configuration consists of settings applied to one or more security areas supported on Windows 2000 Professional, Windows XP Professional or Windows Server 2003. The specified security configuration is then applied to computers as part of the Group Policy application.

The Security Settings extension of the Group Policy Object Editor complements existing system security tools such as the **Security** tab on the **Properties** page (of an object, file, directory, and so on), and **Local Users** and **Groups** in **Computer Management**. You can continue to use existing tools to change specific settings, whenever necessary.

The security areas that can be configured for computers include the following:

- **Account Policies**. These are computer security settings for password policy, lockout policy, and Kerberos policy in domains on Windows 2000 and Windows Server 2003.

- **Local Policies**. These include security settings for audit policy, user rights assignment, and security options. Local policy allows you to configure who has local or network access to the computer and whether or how local events are audited.

- **Event Log**. This controls security settings for the Application, Security, and System event logs. You can access these logs using the Event Viewer.

- **Restricted Groups**. This allows you to control who should and should not belong to a restricted group, as well as which groups a restricted group should belong to. This allows administrators to enforce security policy settings regarding sensitive groups, such as Administrators or Payroll. For example, it may be decided that only Joe and Mary should be members of the Administrators group. Restricted groups can be used to enforce that policy. If a third user is added to the group (for example, to accomplish some task in an emergency situation), the next time policy is enforced, that third user is automatically removed from the Administrators group.

- **System Services**. These control startup mode and security options (security descriptors) for system services such as network services, file and print services, telephone and fax services, Internet and intranet services, and so on.

- **Registry**. This is used to configure security settings for registry keys including access control, audit, and ownership. When you apply security on registry keys, the Security Settings extension follows the same inheritance model as that used for all tree-structured hierarchies in Windows 2000 and Windows Server 2003 (such as Active Directory and NTFS). Microsoft recommends that you use the inheritance capabilities to specify security only at top-level objects, and redefine security only for those child objects that require it. This approach greatly simplifies your security structure and reduces the administrative overhead that results from a needlessly complex access-control structure.

- **File System**. This is used to configure security settings for file-system objects, including access control, audit, and ownership.

- **Public Key Policies**. You use these settings to:

    - Specify that computers automatically submit a certificate request to an enterprise certification authority and install the issued certificate.

    - Create and distribute a certificate trust list.

    - Establish common trusted root certification authorities.

    - Add encrypted data recovery agents and change the encrypted data recovery policy settings.

- **IP Security Policies on Active Directory**. IP Security (IPSec) policy can be applied to the GPO of an Active Directory object. This propagates that IPSec policy to any computer accounts affected by that GPO.

- **Wireless Networking**. This lets you configure wireless network settings that are part of Group Policy for Computer Configuration. Wireless network settings include the list of preferred networks, WEP settings, and IEEE 802.1X settings. These settings are downloaded to targeted domain members, making it much easier to deploy a specific configuration for secure wireless connections to wireless client computers.

- **Software Restriction Policies**. This lets you protect your computer environment from untrusted code by identifying and specifying which applications are allowed to run. With software restriction policies, you can:

    - Control the ability of programs to run on your system. For example, if you are concerned about users receiving viruses through e-mail, you can apply a policy setting that does not allow certain file types to run in the e-mail attachment directory of your e-mail program.

    - Permit users to run only specific files on multi-user computers. For example, if you have multiple users on your computers, you can set up software restriction policy settings in such a way that users do not have access to any software but those specific files that are necessary for their work.

    - Decide who can add trusted publishers to your computer.

    - Control whether software restriction policy settings affect all users or just certain users on a computer.

    - Prevent any files from running on your local computer, organizational unit, site, or domain. For example, if your system has a known virus, you can use software restriction policy settings to stop a computer from opening the file that contains the virus.

    | **Note** |
    | --- |
    | Software restriction policy settings should not be used as a replacement for antivirus software. |

- You can configure security settings policies in **Computer Configuration\Windows Settings\Security Settings** in the Group Policy Object Editor.

**Default Security Templates**

Windows 2000 and Windows Server 2003 include three default security templates called *Basic*. These new default security settings are applied to Windows 2000 or Windows Server 2003 systems that have been installed onto an NTFS partition. When Windows 2000 or Windows Server 2003 is installed onto a FAT file system, security cannot be applied.

The following Basic security templates are used:

- Basicwk.inf for workstations.

- Basicsv.inf for member servers.

- Basicdc.inf for domain controllers.

The Basic security templates specify default Windows 2000 or Windows Server 2003 security settings for all security areas, with the exception of User Rights and Groups. These templates can be applied to Windows 2000 or Windows Server 2003 systems using the Security Configuration and Analysis MMC snap-in or by using the **Secedit.exe** command-line tool.

**Incremental Security Templates**

Windows 2000 and Windows Server 2003 include several incremental security templates. By default, these templates are stored in %systemroot%\Security\Templates. These predefined templates can be customized using the Security Templates MMC snap-in and can be imported into the Security Settings extension of the Group Policy Object Editor.

These security templates were constructed based on the assumption that they would be applied to computers running Windows 2000 or later and that are configured with Windows 2000 or later default security settings. In other words, these templates *incrementally* modify the default security settings. They do not include the default security settings plus the modifications.

The following table lists the incremental security templates included in Windows 2000 and Windows Server 2003.

| **Security Configuration** | **Computer** | **Templates** | **Description** |
|---|---|---|---|
| Compatible | Workstation, and server | Compatws.inf | For customers who do not want their users to run as Power Users (by default all users are Power Users on Windows 2000 Professional and Windows XP Professional), the Compatible configuration opens up the default permissions for the Users group so that legacy applications are more likely to run. For example, Office 97 should run successfully when users are logged on as a User to a computer running Windows 2000, Windows XP, or Windows Server 2003 that has had the Compatible security template applied over the default settings. Note that this is not considered a secure environment. |
| Secure | Workstation, server, and domain controller | Securews.inf and Securedc.inf | The Secure configuration provides increased security for areas of the operating system that are not covered by permissions. This includes increased security settings for Account Policy, Auditing, and some well-known security-relevant registry keys. Access control lists are not modified by the secure configurations because the secure configurations assume that default Windows 2000, Windows XP, or Windows Server 2003 security settings are in effect. |
| Highly Secure | Workstation, server, and domain controller | Hisecws.inf and Hisecdc.inf | The Highly Secure configuration is provided for Windows 2000, Windows XP, or Windows Server 2003-based computers that operate in native (or pure) Windows 2000 or Windows Server 2003 environments only. In this configuration, it is required that all network communications be digitally signed and encrypted at a level that can only be provided by Windows 2000 or later. Thus, a Windows 2000 highly secure computer cannot communicate with a client running Windows 95, Windows 98, or Windows NT. |

For information about the default security settings contained in the Default Domain Policy GPO and Default Domain Controller Policy GPO, see "Appendix A: Security Settings and User Rights" later in this paper.

**Using Software Installation and Maintenance**

You can use the software installation and maintenance feature to install software applications at computer startup, user logon, or on demand. You can also use this feature to upgrade deployed applications, remove earlier applications that are no longer required, and deploy service packs and operating system upgrades. They can ensure that a person cannot install any software from local media, such as a CD-ROM or disk.

This feature also provides for the following situations:

- If users inadvertently delete files from an application it will repair itself.
- If users move from one computer to another their software will always be available to them.
- If users do not have an application installed on their computer and they try to open a document associated with that application, the application will automatically be installed and the document will open.

Deploying software through Group Policy requires applications to use the Windows Installer service, which provides much more than just the capability to install applications. It also protects the integrity of the application against inadvertent mishaps with local files. For example, if a user attempted to use a copy of Microsoft Word that was missing some essential files, the Windows Installer service would reinstall the files from the install point, the next time that the application is launched.

In addition, Windows Installer-based applications that are deployed using Group Policy can install with elevated privileges, meaning users don't have to be administrators on their local machines to install software that you, as a network administrator, want them to have.

Application repair follows the same logic as on-demand installation. Whenever an application authored by Windows Installer is invoked, the Windows Installer service checks to ensure that the appropriate files are available; if required, files or settings are

repaired automatically.

You use Group Policy to define software installation options that specify which applications are to be deployed, upgraded, or removed from a computer. You can apply software installation policies to groups of users or to groups of computers, depending on your organization's needs. There are two methods by which you can install applications on users' computers: assigning and publishing.

**Assigning Applications**
You can assign applications to either a user or a computer using Group Policy. When you assign applications to a computer, the application is automatically installed the next time the computer is started. When you assign applications to a user with Group Policy, the administrator can choose to either have the application installed on-demand when the user selects the application or in-full when the user next logs on:

- **On Demand.** If the application is installed on demand, the user's computer is set up with a Start menu shortcut, and the appropriate file associations are created in the registry. To the user, it looks and feels as if the application is already present. However, the application is not fully installed until the user needs the application. When the user attempts to open the application or a file associated with that application, Windows Installer checks to make sure that all the files and parameters of the application are present for the application to properly execute. If they are not present, Windows Installer retrieves and installs them from a predetermined distribution point. Once in place, the application opens.

- **Full Install.** The full-install option is useful for specific groups of users such as frequent travelers who might require all available applications to be fully installed before they travel. With full install, a user's applications are installed at logon.

Assigning applications makes them resilient — they are available no matter what the user does; for example, if the user removes an application, it will automatically be reinstalled on demand.

**Publishing Applications**
When you publish an application, it appears in Add or Remove Programsin Control Panel. Users can choose to install published applications. Installation can also be configured to occur automatically when a user attempts to open a file that requires a specific published application. You publish applications when the software is not absolutely necessary for users to perform their jobs.

In order to obtain the full benefits of publishing technology, all published applications should be authored to install using the Windows Installer service. Although you can still publish non-Windows Installer service applications using .ZAP files, you won't get the benefits of elevated privileges as explained earlier, and of course, you won't get the benefits of using Windows Installer either.

A .zap file is a text file that provides a pointer to the setup package, which enables the application to be listed in **Add or Remove Programs**.

For more information, see the "Software Installation and Maintenance" white paper at http://go.microsoft.com/fwlink/?linkid=13293 and the Step-by-Step Guide to Software Installation and Maintenance at http://www.microsoft.com/windows2000/techinfo/planning/management/swinstall.asp.

**Scripts**
With the Scripts extensions, you can assign scripts to run when the computer starts or shuts down or when users log on or off their computers. For this purpose, you can use Windows Script Host to include both Visual Basic® Scripting Edition (VBScript) and Jscript® development software script types.

Windows 2000 and later include Windows Script Host, a language-independent scripting host for 32-bit Windows platforms. For more information about Windows Script Host, see the Microsoft Windows Script Web site at http://www.microsoft.com/scripting.

The names of scripts and their command lines (in the form of registry keys and values) are stored in the Registry.pol file, described in "Registry.pol Files" later in this document.

**Types of Scripts**
The five script types are as follows:

- Group Policy logon scripts.

- Group Policy logoff scripts.

- Group Policy startup scripts.

- Group Policy shutdown scripts.

- Legacy logon scripts (those specified on the User object). This includes support for Windows Script Host scripts. Windows Script Host supports scripts written in VBScript or JavaScript. This means that you can now enter a command line like *sample.vbs* in the logon script path of the user object.

| **Note** |
| --- |
| Windows XP Professional, Windows 2000, and the Windows 98-based clients will properly run .vbs and .js scripts. To run .vbs and .js scripts on Windows NT 4.0 and Windows 95 clients, you must embed the scripts in batch (.bat) files. The scripts continue to run in a normal window. There is a policy that allows for scripts to be run as hidden or minimized. |

**Specifying Policy Settings for Script Behavior**

The following table lists the Group Policy options that are available to control the behavior of scripts.

| **Policy in Computer Configuration\Administrative Templates\System\Logon** | **Description** |
| --- | --- |
| Run logon scripts synchronously | When this option is enabled, the system waits until the script finishes running before it starts Windows Explorer. Note that an equivalent option for this is available under the User Configuration node. The policy setting you specify in the Computer Configuration node has precedence over that set in the User Configuration node. |
| Run startup scripts asynchronously | By default, startup scripts run synchronously and hidden, which means the user cannot logon until the scripts complete. In some corporations, the administrator might want the scripts to run asynchronously since they could take a long time to complete. This policy allows the administrator to change the default behavior. |
| Run startup scripts visible | If this option is enabled, startup scripts run in a command window. |
| Run shutdown scripts visible | If this option is enabled, shutdown scripts run in a command window. |
| Maximum wait time for Group Policy scripts | This policy setting lets you change the default script time out period. (By default, scripts will time-out after 600 seconds). The range is 0 to 32000 seconds. |

| **Policy in User Configuration\Administrative Templates\System\Logon\Logoff** | **Description** |
| --- | --- |
| Run logon scripts synchronously | When you enable this option, Windows waits for the scripts to finish running before it starts Windows Explorer.<br><br>Note that an equivalent option for this is available under the Computer Configuration node. The policy setting you specify in the Computer Configuration node has precedence over that set in the User Configuration node. |
| Run legacy logon scripts hidden | If this option is enabled, legacy logon scripts will run in hidden mode. |
| Run logon scripts visible | If this option is enabled, logon scripts run in a command window. |
| Run logoff scripts visible | If this option is enabled, logoff scripts run in a command window. |

| **Note** |
| --- |
| Scripts that run hidden (and to a lesser degree minimized) can cause an errant script or one that prompts for user input to wait for 600 seconds. This is the default wait-time value and may be changed using a Group Policy. During this time, the system appears to be hung up. In the case of a script running in a minimized window, if the user selects the window, its processing can be stopped. |

**Best Practice**: For easier manageability, it is a good idea to use Group Policy scripts and to avoid using legacy logon scripts, if at all possible. Rather than using a single monolithic script with lots of internal logic branching, Group Policy-based logon scripts allow for use of tiered and modular scripts targeted to the desired set of users.

**Folder Redirection**
The Folder Redirection extension is used to redirect any of the following special folders in a user profile to an alternate location (such as a network file share):

- Application Data
- Desktop
- My Documents
    - My Pictures
- Start Menu

For example, you could redirect a user's My Documents directory to \\Server\Share\%username%. By redirecting the My Documents directory, you can provide the following advantages:

- Ensure that users' documents are available when they roam from one computer to another.
- Reduce the time it takes to log on to and log off from the network. The My Documents folder is part of the Roaming User Profile (RUP), which means that the My Documents folder and its contents are copied back and forth between the client computer and the server when users log on and log off. Relocating the My Documents folder outside of the user profile can significantly decrease that time.
- Store user data on the network (rather than on the local computer). The data can then be managed and protected by the Information Technology department.
- Make users' network-based My Documents folder available to users when they are disconnected from the corporate network by using Offline Folder technologies.

**Folder Redirection Improvements for Windows XP and Windows Server 2003**
This section provides information about the differences between Windows 2000 and Windows Server 2003.

**User Interface changes**
The Folder Redirection user interface has been simplified for Windows Server 2003. The main goals of these changes were to simplify the use of Folder Redirection by removing the requirement that administrators be familiar with environment variables such as %USERNAME%.

In addition to the simplified UI, several new redirection options have been added:

- **Create a directory for each user under the root path**. Rather than having to enter a UNC path such as \\server\share\%username%\MyDocuments, the administrator can simply type in the path to the file share such as \\server\share, and Folder Redirection will automatically append the user name and the directory name when the policy is applied. This removes the need for administrators to be familiar with environment variables, and minimizes the chances of errors and spelling mistakes.
- **Redirect to home directory (My Documents Only)**. Windows Server 2003 and Windows XP allow you to redirect a user's My Documents folder to their home directory. This option is intended only for organizations that have a legacy deployment of home directories and want to transition users to the My Documents metaphor while maintaining compatibility with their existing home directory environment. **You should only select this option if you have already deployed home directories in your organization.**
- Folder redirection treats redirection to the home directory as a special case and certain checks are skipped:
    - Redirection to the home directory is only supported on Windows XP and Windows Server 2003 computers.

Redirection to the home directory policy will fail to apply on Windows 2000 computers.

- No security check is performed and no setting of access permissions is done. The administrator must set restrictive permissions on the directory to ensure that proper access is granted. The **Grant the user exclusive rights to My Documents** check box on the settings page of the property sheet is disabled.

- No ownership checks are made. Normally folder redirection will fail if a user is not the owner of the directory they are being redirected to. Because redirection to the home directory is intended for use in a legacy environment, this ownership check is skipped.

- Users must have the home folder property correctly set on their user object. The folder redirection client side extension retrieves the actual path for the user's home directory from the user object at logon time. Users affected by Folder Redirection Policy must have this path correctly set or folder redirection will not apply.

- **Redirect to a specific path**. This option is intended to allow an administrator to redirect folders to an alternate local drive/partition, or to enter unusual configurations not anticipated by the new user interface. Functionally it works in exactly the same way as the Windows 2000 folder redirection user interface.

- **Redirect to the local user profile**. This option is intended to allow an administrator to redirect the selected folder to the default location in the local user profile, for example: %userprofile%\<Folder Name>. This setting can be used to remove redirection for a particular folder, without removing the GPO. Note: Setting the redirection option to "Not Configured" (or "No Administrative policy specified" in the Windows 2000 UI) **does not** redirect the folder to the local profile, this option means that Folder Redirection is not configured – *if a folder was previously redirected it will continue to be redirected to the previous location*. If an administrator wanted to return the folder to the local user profile they can use this redirection setting.

**My Pictures no longer shown in the Folder Redirection Node**
To simplify the user interface and to help support the best practice that the My Pictures folder should always follow the My Documents folder, the My Pictures folder is not shown in the Folder Redirection node for new GPO's. If you have previously redirected the My Pictures folder separately, the My Pictures node will still appear.

**Redirected Folders automatically made available offline**
By default in Windows XP and Windows Server 2003, any redirected shell folders such as My Documents, Desktop, Start Menu, and Application Data are automatically made available offline. This is in contrast to Windows 2000, which required administrators to configure the "Administratively assigned offline files" policy setting to ensure all files in the redirected folders were always available offline. This setting was difficult to use with advanced folder redirection, and involved extra administrative overhead.

The default behavior can be overridden by enabling the **Do not automatically make redirected folders available offline** policy. This setting can be found in the Group Policy Object Editor in the **User Configuration\Administrative Templates\Network\Offline Files** section.

Note that on Windows Server 2003 Offline files are disabled by default.

More information about Folder Redirection will be available in the white paper, "User Data and Settings Management" at http://www.microsoft.com/grouppolicy.

**Internet Explorer Maintenance**
The Internet Explorer Maintenance extension snap-in includes policy settings to manage the following:

- **Browser User Interface**. You use these options to customize the browser's appearance. For example, you can specify settings for the browser title bar, toolbar button options, and so on.

- **Connection Settings**. You can preset and manage the connection settings, such as local area network (LAN) and dial-up options.

- **Custom URLs**. You can specify which URLs are displayed by the browser, for example, for the Home page, those on the Favorites list, and for the Search page.

- **Security**. You can preset security settings such as security zones, content ratings, and Authenticode. (A browser can be

configured to allow only signed code to be downloaded. Authenticode is the Microsoft version of object signing; it provides a basis for verifying the origin and integrity of an object, as well as links to policies of a certification authority).

- **Program Associations**. You can specify which Internet programs to use by default for Internet-related tasks such as reading e-mail or viewing newsgroups.

**Exporting Internet Explorer Settings for Earlier Clients**

Administrators can export Internet Explorer policy settings into an auto-configuration package (an .ins file and its associated .cab files) to be used to apply these settings to Windows 95, Windows 98, and Windows NT 4.0 clients. The exported packages are auto-configuration packages. Before the original Group Policy Object Editor was created in Windows 2000, Internet Explorer settings were applied to Internet Explorer clients using auto-configuration packages after Internet Explorer installation. Using GPOs is the preferred method of applying Internet Explorer policy settings on clients running Windows 2000 or later, although Windows 2000 and Windows Server 2003 support auto-configuration packages.

**Managing Internet Explorer Maintenance Advanced Settings**

You can manage advanced settings for Internet Explorer such as setting a size limit for users' Temporary Internet files. In order to do this, you need to first enable **Preference Mode** for Internet Explorer Maintenance. By default, the **Preference Mode** option is hidden. You access this option by right-clicking **Internet Explorer Maintenance** node and selecting **Preference Mode** on the shortcut menu.

This adds an **Advanced** node to the results pane. This node contains settings for managing Temporary Internet files and other UI features. Note that switching to **Preference Mode** disables some of the Internet Explorer Maintenance nodes. If a setting name has **Preference Mode** appended to it, it can be used in that mode; otherwise, it means that setting is disabled. For example, the **Connection Settings (Preference Mode)** option under the **Connection** node can be used in **Preference Mode** as indicated by its labeling in the UI, whereas the **User Agent String** option (note the exclusion of **Preference Mode**) cannot be used in **Preference Mode** and this is reflected in its labeling.

For more information, see this Microsoft Knowledge Base article, How to Set Advanced Settings In Internet Explorer by Using Group Policy Objects.

**Using Internet Explorer Customization Wizard and Internet Explorer Profile Manager**

Besides the Internet Explorer Maintenance Group Policy options mentioned above, it is also possible to customize Internet Explorer before deployment and to manage Internet Explorer on other operating systems by using the Internet Explorer Administration Kit (IEAK) at http://www.microsoft.com/windows/ieak/default.asp.These tools provide options for System Policies and restrictions that administrators can use to specify desktop, shell, and security settings, for example.

**Remote Installation Services**

Remote Installation Services is an optional component that is included in the Windows Server operating system and works with other Windows Server 2003 technologies to implement the Remote Operating System Installation feature. Administrators use Remote Operating System Installation to remotely install a copy of the Windows XP Professional operating system on supported computers. (Computers that are PC98-compliant ship with a PXE Remote Boot ROM.) Administrators use the Remote Installation Services extension of Group Policy to specify which options are presented to users by the Client Installation Wizard, for example, Automatic Setup, Custom Setup, and Restart Setup.

Client computers that are enabled with Pre-boot Execution Environment (PXE) remote-boot technology access the RIS server to install the operating system, and then the Remote Installation Services server checks for Group Policy that affects remote installation options defined for the user. The Boot Information Negotiation Layer (BINL) service running on the RIS server performs this work. It impersonates the user who logs on to the RIS client-side pre-boot user interface, and evaluates the GPOs to determine the resulting policy. Based on the resulting policy, it determines which screens to send to the pre-boot RIS client code for display to the user.

# Group Policy Modeling and Results

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Group Policy Modeling and Group Policy Results is a feature of Group Policy that makes implementation, troubleshooting, and planning of Group Policy easier. When multiple GPOs apply to a given user or computer, they can contain conflicting policy settings. For most policy settings, the final value of the policy setting is set only by the highest precedence GPO that contains that setting. Group Policy Modeling and Group Policy Results uses the Resultant Set of Policy (RSoP) infrastructure, available on Windows XP and Windows Server 2003, to present the final set of policy that is applied as well as settings that did not apply as a result of policy inheritance.

Specifically, RSoP helps you determine the following:

- The final value of the setting that is applied as a result of all the GPOs.
- The final GPO that set the value of this setting (also known as the winning GPO).

Precedence details that show any other GPOs that attempted to set this setting and the value that each GPO attempted to set for that policy setting.

**Group Policy Results**
This represents the actual policy data that is applied to a given computer and user. It is obtained by querying the target computer and retrieving the RSoP data that was applied to that computer. The Group Policy Results capability is provided by the client operating system and requires Windows XP, Windows Server 2003 or later. Outside of GPMC, Group Policy Results is referred to as RSoP - logging mode.

**Group Policy Modeling**
This is a simulation of what would happen under circumstances specified by an administrator. Group Policy Modeling requires that you have at least one domain controller running Windows Server 2003 because this simulation is performed by a service running on a domain controller that is running Windows Server 2003. With Group Policy Modeling, you can either simulate the RSoP data that would be applied for an existing configuration, or you can perform "what-if" analyses by simulating hypothetical changes to your directory environment and then calculating the RSoP for that hypothetical configuration. For example, you can simulate changes to security group membership, or changes to the location of the user or computer object in Active Directory. Outside of GPMC, Group Policy Modeling is referred to as RSoP - planning mode. Note that although Windows 2000 does not provide the RSoP infrastructure, Group Policy Modeling can be used as an effective way to simulate the affect of Group Policy on Windows 2000 computers.

**Using GPMC Reports**
In GPMC, resultant set of policy data is obtained using Group Policy Modeling or Group Policy Results wizards. GPMC provides an HTML report of the RSoP data. This report shows the final value of the winning settings and the winning GPO that set that value. When you create a Group Policy Modeling or Group Policy Results report, the report is shown in GPMC under the appropriate node. Right-clicking this report and choosing **Advanced View** opens the RSoP snap-in, which provides additional information, enabling you to verify precedence for a policy setting. In the RSoP snap-in, the dialog box for a policy setting contains a Precedence tab, which shows all GPOs that attempted to set a particular setting and the value for each GPO.

**RSoP Architecture**
Figure 2 below shows the high-level architecture of RSoP for Group Policy Results and Group Policy Modeling.

**Figure 2. RSoP high-level architecture**

Take for example, a standard logon procedure in Windows 2000: a client computer logs onto the network and Winlogon runs. The domain controller passes a list of pointers to the GPOs that are to apply. This list is passed to each of the client-side extensions (CSEs) such as Software Installation, Scripts, Security, Administrative Templates, and so on. Each CSE processes this list of GPOs.

Windows Server 2003 uses the same process but improves on Windows 2000 by collecting all the Group Policy processing information and storing it in a Common Information Model Object Management (CIMOM) database on the local computer. This information, such as the list, content and logging of processing details for each GPO, can then be accessed by tools using WMI.

In Group Policy Results, RSoP queries the CIMOM database on the target computer, receives information about the policies and displays it in GPMC. In Group Policy Modeling, RSoP simulates the application of policy using the Group Policy Directory Access Service (GPDAS) on a Domain Controller. GPDAS simulates the application of GPOs and passes them to virtual client-side extensions on the Domain Controller. The results of this simulation are stored to a local CIMOM database on the domain controller before the information is passed back and displayed in GPMC.

**Security and RSoP**
By default, access to Group Policy Results is restricted to enterprise, domain, and local administrators although users can still perform logging on their own computer. In Windows XP, non-administrators can run Group Policy Results for their computer and user account; in Windows Server 2003 non-administrators can only run Group Policy Results for their own user account. Group Policy Modeling is restricted to enterprise and Domain Admins. However, organizations can delegate access to Group Policy Results and Modeling using GPMC. For step-by-step instructions, see Group Policy Help.

**Group Policy Results and Modeling Examples**
Group Policy Results and Modeling allow administrators to solve problems for specific scenarios. Some examples are included below.

**Group Policy Results**
**What is the current state of Folder Redirection for the current user?**
Example: User Paul has four computers, and contacts help desk because they cannot find files on computer D that are on computer A, even though Paul is set up to use folder redirection. The administrator runs Group Policy Results and sees that on computer D, redirection is different than the others because a different GPO applies.

**What is the current state of Folder Redirection for a sampling of users?**
Example: An administrator wants to profile different sets of users. Using Group Policy Results, the administrator picks a sample user from each user group and uses the RSoP information to model redirection within the organization.

**Why did this happen?**
Example: An administrator is confused as to why Paul's documents are being redirected to the SuperUsers server. The administrator uses Group Policy Results to look at the current redirection path, and the GPO and security group that caused the redirection.

The administrator notices that of the three GPOs specifying folder redirection policy, the winning GPO has the advanced option set to redirect users in different security groups to different locations. The administrator notices that Paul is a member of both the VanillaUsers group and the SuperUsers group and realizes that this caused Paul's folders to be redirected to the SuperUsers server.

**Group Policy Modeling**
**Precedence Details**
In processing Group Policy, administrators determine which GPOs were in conflict to configure folder redirection for this user.

**Change of Site**
Example: An administrator can model site and domain changes for individual users or using a sample target to assess what would happen to an entire group of users under different combinations of sites, domains, and so forth. By comparing what should be seen, by what actually exists under the new GPO structure, the administrator can avoid problems before the move actually takes place.

Example: User Jane is going to move from one department to another. The administrator uses Group Policy Modeling to model the move under the different site condition and finds out that a GPO conflict exists that redirects Jane's folder to an alternate location.

**Change of Folder Redirection Mode**
An Administrator wants to configure folder redirection to use the advanced options to redirect users to alternate locations based on their security group membership. The administrator uses Group Policy Modeling to configure Group Policy for the desired folder redirection behavior.

By comparing the current results of folder redirection for the users, with the results of the desired changes, the administrator can avoid problems before the move actually takes place.

**RSoP Schema**

For information about the RSoP schema, see the RSoP SDK, available as part of the Microsoft Windows Platform SDK at http://www.microsoft.com/downloads/details.aspx?FamilyId=A55B6B43-E24F-4EA3-A93E-40C0EC4F68E5&displaylang=en.

# Group Policy Processing

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As described earlier in this paper, Group Policy is processed in the following order: Local Group Policy object (Local GPO), then GPOs linked to containers in this order: site, domain, and organizational units, including any nested organizational units (starting with the organizational unit further from the user or computer object). This means that the local Group Policy object is processed first, and the organizational unit to which the computer or user belongs (the one that it is a direct member of) is processed last. All of this is subject to the following conditions:

- WMI or security filtering that has been applied to GPOs.
- Any domain-based GPO (not local GPO) may be enforced by using the **Enforce** option so that its policies cannot be overwritten. When more than one GPO has been marked as enforced, the GPO that is highest in Active Directory hierarchy takes precedence.
- At any domain or organizational unit, Group Policy inheritance may be selectively designated as **Block Inheritance**. However, blocking inheritance does not prevent policy from **enforced** GPOs from applying; this is because enforced GPOs are always applied, and cannot be blocked.

| **Note** |
| --- |
| Every computer has a single local GPO that is always processed regardless of whether the computer is part of a domain or is a stand-alone computer. The Local GPO can't be blocked by domain-based GPOs. However, settings in domain GPOs always take precedence since they are processed after the Local GPO. |

**Initial Processing of Group Policy**

Group Policy for computers is applied at computer startup. For users, Group Policy is applied when they log on. By default, the processing of Group Policy is synchronous, which means that computer Group Policy is completed before the CTRL+ALT+DEL dialog box is presented, and user Group Policy is completed before the shell is active and available for the user to interact with it. (As explained below, Windows XP with Fast Logon enabled lets users logon while Group Policy is processed in the background.)

**Synchronous and Asynchronous Processing**

Synchronous processes can be described as a series of processes where one process must finish running before the next one begins. Asynchronous processes, on the other hand, can run on different threads simultaneously because their outcome is independent of other processes.

You can change the default processing behavior by using a policy setting for each GPO so that processing is asynchronous instead of synchronous. However, this is not recommended because it can cause unpredictable or undesirable side effects. For example, if the policy has been set to remove the **Run** command from the **Start** menu, it is possible under asynchronous processing that a user could logon prior to this policy taking effect, so the user would initially have access to this functionality. To provide the most reliable operation, it is recommended that you leave the processing as synchronous.

**Fast Logon in Windows XP Professional**

By default in Windows XP Professional, the Fast Logon Optimization feature is set for both domain and workgroup members. This results in the asynchronous application of policies when the computer starts and when the user logs on. This application of policies is similar to a background refresh process and can reduce the length of time it takes for the Logon dialog box to display and the length of time it takes for the shell to be available to the user. An administrator can change the default by using the Group Policy Object Editor.

Fast Logon Optimization is always off during logon under the following conditions:

- When a user first logs on to a computer.
- When a user has a roaming user profile or a home directory for logon purposes.
- When a user has synchronous logon scripts.

Note that under the preceding conditions, computer startup can still be asynchronous. However, because logon is synchronous under these conditions, logon does not exhibit optimization.

The following table summarizes the default processing of policy on Windows XP.

| Client | Application at startup/log on | Application at refresh |
|---|---|---|
| Windows 2000 | Synchronous | Asynchronous |
| Windows XP Professional | Asynchronous | Asynchronous |

Windows XP clients support Fast Logon Optimization in any domain environment. To turn off Fast Logon Optimization, you can use the following policy setting:

Computer Configuration\Administrative Templates\System\Logon\ Always wait for the network at computer startup and logon

| Note |
|---|
| Fast Logon Optimization is not a feature of Windows Server 2003. |

**Folder Redirection and Software Installation Policies**

Note that when logon optimization is on, a user may need to log on to a computer twice before folder redirection policies and software installation policies are applied. This is because application of these types of policies require the synchronous policy application. During a policy refresh (which is asynchronous), the system sets a flag that indicates that the application of folder redirection or a software installation policy is required. The flag forces synchronous application of the policy at the user's next logon.

**Time Limit for Processing of Group Policy**

Under synchronous processing, there is a time limit of 60 minutes for all of Group Policy to finish processing on the client. Any client-side extensions that are not finished after 60 minutes are signaled to stop, in which case the associated policy settings may not be fully applied. An errant extension may not be able to respond; in either case the Group Policy engine goes into asynchronous processing mode. This means that the Group Policy engine is no longer blocked while waiting for a running (likely errant) extension and continues to process; it leaves the extension(s) running and does not terminate it (them). There is no setting to control this time-out period or behavior.

**Background Refresh of Group Policy**

In addition to the initial processing of Group Policy at startup and logon, Group Policy is applied subsequently in the background on a periodic basis, and can also be triggered on demand from the command line.

During a background refresh, a client side extension will by default only reapply the settings if it detects that a change was made on the server in any of its GPOs or its list of GPOs. This is done for performance reasons.

Not all Group Policy extensions are processed during a background refresh. Software Installation and Folder Redirection processing occurs only during computer startup or when the user logs on. This is because processing periodically could cause undesirable results. For example, for Software Installation, if an application is no longer assigned, it is removed. If a user is using the application while Group Policy tries to uninstall it or if an assigned application upgrade takes place while someone is using it, errors would occur.

| Note |
|---|
| The script's extension is processed during background refresh, however the scripts themselves are only ran at startup, shutdown, logon, and logoff, as appropriate. |

**Periodic Refresh Processing**

Group Policy is processed periodically. By default, this is done every 90 minutes with a randomized offset of up to 30 minutes. You can change these default values by using a Group Policy setting in Administrative Templates. Setting the value to zero minutes causes the refresh rate to be set to seven seconds.

| Note |
|---|

Setting a short refresh interval in a production environment is not recommended. This is because a policy refresh causes the Windows shell to be refreshed, which in turn causes all open shortcut menus to close, a brief flicker of the screen, and so on. In addition, it causes computers to contact domain controllers more frequently, increasing the load on the domain controllers. However, setting a shorter interval may be useful in test or demonstration scenarios.

To change the policy refresh interval setting, edit the **Default Domain Controllers** Group Policy object, which is linked to the **Domain Controllers** organizational unit. The **Group Policy Refresh Interval for Computers** setting is located under **Computer Configuration\Administrative Templates\System\Group Policy** node.

For domain controllers, the default period is every five minutes. **Group Policy Refresh Interval for Domain Controllers** setting is available under **Computer Configuration\Administrative Templates\System\Group Policy** node.

**On-Demand Processing**
You can also trigger a background refresh of Group Policy on demand from the client. However, the application of Group Policy cannot be pushed to clients on demand from the server.

**Messages and Events**
When Group Policy is applied, a **WM_SETTINGCHANGE** message is sent, and an event is signaled. Applications that can receive window messages can use it to respond to a Group Policy change. Those applications that do not have a window to receive the message (as with most services) can wait for the event.

**Refreshing Policy from the Command Line**
Gpupdate refreshes local Group Policy settings and Group Policy settings that are stored in Active Directory, including security settings. This command supersedes the now obsolete **/refreshpolicy** option for the **secedit** command.

**Syntax**
Gpupdate [/target:{computer | user}] [/force] [/wait:*Value*] [/logoff] [/boot]

**Parameters**
/target:{computer | user}

Processes only the *Computer* settings or the current *User* settings. By default, both the computer settings and the user settings are processed.

/force

Ignores all processing optimizations and reapplies all settings.

**/wait:** *Value*

Number of seconds that policy processing waits to finish. The default is 600 seconds. 0 equals no wait, and -1 equals wait indefinitely.

/logoff

Logs off after the refresh has completed. This is required for those Group Policy client-side extensions that do not process on a background refresh cycle but that do process when the user logs on, such as user Group Policy Software Installation and Folder Redirection. This option has no effect if there are no extensions called that require the user to log off.

/boot

Restarts the computer after the refresh has completed. This is required for those Group Policy client-side extensions that do not process on a background refresh cycle but that do process when the computer starts up, such as computer Group Policy Software Installation. This option has no effect if there are no extensions called that require the computer to be restarted.

/synch

Causes the next foreground policy application to be done synchronously. Foreground policy applications occur at computer boot and user logon. You can specify this for the user, computer, or both using the /Target parameter. The /Force and /Wait parameters will be ignored if specified.

/?

Displays help at the command prompt.

**Slow Links and Remote Access Issues**
Special considerations apply when processing Group Policy over slow links or remote access.

| Note |
| --- |
| Note that while these issues are related, they are distinct, and the processing of Group Policy is different for each. In particular, *remote access* does not necessarily imply a slow link, nor does a LAN necessarily imply a fast link. A slow link is by default based on the algorithm described in the section below. Windows Server *remote access* is part of the integrated Routing and Remote Access Service; it connects remote or mobile users to corporate networks, allowing users to work as if their computers are physically connected to the network. Users run remote access software to connect to a remote access server, which is a computer running Windows Server and the Routing and Remote Access Service. The remote access server authenticates the user and services sessions until terminated by the user or network administrator. The remote access connection enables all services typically available to a LAN-connected client, such as file and print sharing, messaging, and Web server access. |

**Group Policy and Slow Links**

When Group Policy detects a slow link, it sets a flag to indicate to client-side extensions that a policy setting is being applied across a slow link. Individual client-side extensions can determine whether or not to apply a policy setting over the slow link.

The default settings are as follows:

- Security Settings—ON (and cannot be turned off).
- Administrative Templates—ON (and cannot be turned off).
- Software Installation—OFF.
- Scripts—OFF.
- Folder Redirection—OFF.

For all but the Administrative Templates snap-in and security settings snap-in, a policy is provided for switching the slow link processing settings.

**Setting Policy for Slow-Link Definition**

You can use Group Policy to set the definition of a slow link for computers and users, and for user profiles.

For Group Policy, Windows 2000 and Windows Server 2003 use an IP ping algorithm to ping the server, rather than measuring the file system performance method that was used in Windows NT 4.0. Note: Slow link detection requires the Internet Control Message Protocol (ICMP). If ICMP cannot be used to communicate with the domain controllers, policy processing will not work, in which case you should disable slow link detection.

A slow link is, by default, based on the following algorithm (where ms = milliseconds):

1. Ping the server with 0 bytes of data and time the number of milliseconds. This value is time#1. If it is less than 10 ms, exit (assume a fast link).
2. Ping the server with 2 KB of uncompressible data, and time the number of milliseconds. This value is time#2. The algorithm uses a compressed .jpg file for this.
3. DELTA = time#2 - time#1. This removes the overhead of session setup, with the result being equal to the time to move 2 KB of data.
4. Calculate Delta three times, adding to TOTAL each DELTA value.
5. TOTAL/3 = Average of DELTA, in milliseconds.
6. 2 * (2 KB) * (1000 millisec/sec) / DELTA Average millisec = X
7. X = (4000 KB/sec) / DELTA Average
8. Z Kilobits per second (Kbps) = (4000 KB/sec) / DELTA Average) *(8 bits/byte)

9. Z Kbps = 32000 kbps/Delta Avg.

Two KB of data have moved in each direction (this is represented by the leading factor two on the left side in step six above) through each modem, Ethernet card, or other device in the loop once.

The resulting Z value is evaluated against the policy setting. A default of less than 500 Kbps is considered a slow link; otherwise it is a fast link. This value may be set through Group Policy in the Administrative Templates node.

To specify policy settings for Group Policy slow link detection for computers, you use the **Computer Configuration\Administrative Templates\System\Group Policy** node. To set this policy for users, you use the **User Configuration\Administrative Templates\System\Group Policy** node. The connection speed is set for kilobits per second (Kbps).

For User Profiles, the **Slow network connection time-out for user profiles** policy is located in the **Computer Configuration\Administrative Templates\System\Logon** node. This policy has support for both pinging the server and checking the performance of the file system. This is because user profiles can be stored anywhere, and that server may or may not have IP support. Therefore, the user profile code first tries to ping the server. If the server does not have IP support, it falls back to measuring the file system's performance. You must specify connection speeds in both kilobytes per second (Kbps) and milliseconds (ms) when setting this policy.

**Application of Group Policy During a Remote Access Connection**

Group Policy is applied during a remote access connection as follows:

When using the **Logon using dial-up connection** check box on the logon prompt, both User and Computer Group Policy is applied, provided the computer is a member of the domain that the remote access server belongs to or trusts. However, computer-based software installation settings are not processed. This is because normally computer policy would have been processed before the logon screen, but since no network connection is available until logon, the application of computer policy is done as background refresh at the time of logon.

When the logon is done with cached credentials, and then a remote access connection is established, Group Policy is not applied during logon. For example, if users connecting through a VPN connection are logging in via cached credentials, folder redirection settings will not be processed, because folder redirection policy can only be processed at user logon, not in the background refresh.

Group Policy is not applied to computers that are members of a foreign domain or a workgroup. Although the connection may still be made, access to domain resources may be affected (because of mismatched IPSec security).

**Client-side Processing of Group Policy**

The client-side extensions are loaded on an as-needed basis when a client computer is processing policy. The client computer first gets a list of Group Policy objects. Next, it loops through all the client-side extensions and determines whether each client-side extension has any data in any of the GPOs. If a client-side extension has data in a GPO, the client-side extension is called with the list of Group Policy objects that it should process. If the client-side extension does not have any settings in any of the GPOs, it is not called.

**Computer Policy for Client-Side Extensions**

A computer policy exists for each of the Group Policy client-side extensions (located in Computer Configuration\Administrative Templates\System\Group Policy). Each policy includes a maximum of three options (check boxes). Some of the client-side extensions include only two computer policy options; in those cases, this is because the third option is not appropriate for that extension.

The computer policy options are:

- **Allow processing across a slow network connection**. When a client-side extension registers itself with the operating system, it sets preferences in the registry, specifying whether it should be called when policy is being applied across a slow link. Some extensions move large amounts of data, so processing across a slow link can affect performance (for example, consider the time involved in installing a large application file across a 56 Kbps modem line). An administrator can set this policy to mandate that the client-side extension should run across a slow link, regardless of the amount of data.

- **Do not apply during periodic background processing**. Computer policy is applied at boot time, and then again in the background, approximately every 90 minutes thereafter. User policy is applied at user logon, and then approximately every 90 minutes after that. The **Do not apply during periodic background processing** option gives the administrator the ability to override this logic and force the extension to either run or not run in the background.

| Note |
| --- |
| The Software Installation and Folder Redirection extensions process policy only during the initial run because it is risky to process policy in the background. For example, with Software Installation application upgrades, applications are installed during the initial run and not in the background. If it were done in the background, a user could be running an application, and then have it uninstalled and a new version installed. The application could also have a shared component that is in use by another application. This would prevent the installation from completing successfully. |

- **Process even if the Group Policy Objects have not changed**. By default, if the GPOs on the server have not changed, it is not necessary to continually reapply them to the client, since the client should already have all the settings. However, local administrators may be able modify the parts of the registry where Group Policy settings are stored. In this case, it may make sense to reapply these settings during logon or during the periodic refresh cycle to get the computer back to the desired state.

  For example, assume that you have used Group Policy to define a specific set of security options for a file. Then the user (with administrative credentials) logs on and changes it. The Group Policy administrator may want to set the policy to process Group Policy even if the GPOs have not changed so that the security is reapplied at every boot. This also applies to applications. Group Policy installs an application, but the end user can remove the application or delete the icon. The process gives the administrator the ability to restore the application at the next user logon, even if the Group Policy objects have not changed option.

Note that, by default, security settings are applied every 16 hours (960 minutes) even if a GPO has not changed. It is possible to change this default period by using the following registry key:

```
HKLM\Software\Microsoft\Windows NT\CurrentVersion\Winlogon\GPExtentions\{82...}
\MaxNoGPOListChangesInterval, REG_DWORD, in number of minutes.
```

The following table lists the client-side extensions that include only two computer policy options, as well as the reason for this.

| Client-side extension | Missing policy check box | Reason |
| --- | --- | --- |
| Registry | Slow link (Allow processing across a slow network connection) | Registry policy is always applied because it controls the other client-side extensions. |
| Security Settings | Slow link (Allow processing across a slow network connection) | To ensure that security settings are in effect, they must always be applied, even across a slow link. |
| Folder Redirection | Background processing (Do not apply during periodic background processing) | Users' files could be in use while they are logged on. |
| Software Installation | Background processing (Do not apply during periodic background processing) | Users' software could be in use while they are logged on. |

**Policy Settings for Group Policy**

You can use administrative templates to configure how you use Group Policy. Policy settings are located in the following areas of the Group Policy Object Editor:

- **Computer Configuration\Administrative Templates\System\Group Policy**

- **User Configuration\Administrative Templates\System\Group Policy**

- For details on these policy settings, double-click the policy in the details pane, and then in the policy **Properties** dialog box, click the **Explain** tab.

# Group Policy Replication and Domain Controller Selection (Group Policy Infrastructure)

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In a domain that contains more than one domain controller, Group Policy information takes time to propagate, or replicate, from one domain controller to another. Low bandwidth network connections between domain controllers slow replication. The Group Policy infrastructure has mechanisms to manage these issues.

Each GPO is stored partly in the Sysvol on the domain controller and partly in Active Directory. GPMC and Group Policy Object Editor present and manage the GPO as a single unit. For example, when you set permissions on a GPO in GPMC, GPMC is actually setting permissions on objects in both Active Directory and the Sysvol. It is not recommended that you manipulate these separate objects independently outside of GPMC and the Group Policy Object Editor. It is important to understand that these two separate components of a GPO rely on different replication mechanisms. The file system portion is replicated through File Replication Service (FRS), independently of the replication handled by Active Directory.

Lack of synchronization between the Group Policy template (data stored on Sysvol) and Group Policy container (data stored in Active Directory) portions of the Group Policy object can occur temporarily because of the differences in the replication schemes used by Active Directory and FRS.

For those Group Policy extensions that store data in only one data store (either Active Directory or Sysvol), this is not an issue, and Group Policy is applied as it can be read. Such extensions include Administrative Templates, Scripts, Folder Redirection, and most of the Security Settings.

For any Group Policy extension that stores data in both storage places (Active Directory and Sysvol), the extension must properly handle the possibility that the data is unsynchronized. This is also true for extensions that need multiple objects in a single store to be atomic in nature, since neither storage location handles transactions.

An example of an extension that stores data in Active Directory and Sysvol is Software Installation. The script files are stored on Sysvol and the Windows Installer package definition is in Active Directory. If the script exists, but the corresponding Active Directory components are not present, then nothing is done. If the script file is missing, but the package is known in Active Directory, application installation fails gracefully and will be retried on the next processing of Group Policy.

The tools used to manage Active Directory and Group Policy, such as GPMC, the Group Policy Object Editor, and Active Directory Users and Computers all communicate with domain controllers. If there are several domain controllers available, changes made to objects like users, computers, organizational units, and GPOs may take time to appear on other domain controllers. The administrator may see different data depending on the last domain controller on which changes were made and which domain controller they are currently viewing the data from.

For example, if you create a GPO on one domain controller and immediately attempt to link it on another domain controller, the operation could fail. In each domain, GPMC uses the same domain controller for all operations in that domain, in order to avoid any synchronization issues. This includes all operations on GPOs, organizational units, and security groups in that domain. In addition, when the Group Policy Object Editor is opened from GPMC, it will also use the same domain controller in use by GPMC. Finally, GPMC uses the same domain controller for all operations on sites within a given forest. This domain controller for sites is used to read and write information about the links to GPOs that exist on any given site; information regarding the GPO itself is obtained from the domain controller of the domain hosting the GPO. This domain controller is used to read and write information about the links to GPOs that exist on any given site; information regarding the GPO itself is obtained from the domain controller of the domain hosting the GPO.

By default, when you add a new domain to the console, GPMC uses the PDC emulator in that domain to help ensure that all administrators are using the same domain controller. For managing sites, GPMC uses the PDC emulator in the user's domain by default. You can change the default choice of domain controller using the Change Domain Controller dialog box in GPMC. If you are located at a remote site with a slow connection to the default domain controller, you may want to do this.

It is important for administrators to consider the choice of domain controller in order to avoid replication conflicts particularly because both Active Directory and FRS use multi-master replication. This is especially important to consider because GPO data resides in both Active Directory and on Sysvol, and two independent replication mechanisms must be used to replicate GPO data to the various domain controllers in the domain. If two administrators are simultaneously editing the same GPO on different domain controllers, it is possible for the changes written by one administrator to be overwritten by another administrator, depending on replication latency.

**Important**

If multiple administrators manage a common GPO, it is recommended that all administrators use the same domain controller when editing a particular GPO, to avoid collisions in FRS.

#### Options governing selection of a domain controller for GPMC

In GPMC, when you right-click a domain or the sites container and click **Change Domain Controller**, you see a **Change Domain Controller** dialog box. The domain controller options for GPMC are:

- **The one with the Operations Master token for the PDC emulator**. This is the default and preferred option.
- **Use any available domain controller.** This is the least safe option.
- **Use any available domain controller that is running Windows Server 2003 or later.** This option is useful if you are restoring deleted GPOs that contain software installation settings. If possible, it is recommended to perform restoration of GPOs containing software installation settings on domain controllers running Windows Server 2003.
- **This domain controller.** This option allows you to choose a specific domain controller from a list of domain controllers in the domain.

If you are changing the domain controller for a site, you can also choose any available trusted domain from the **Look in this domain** drop-down list box in the **Change Domain Controller** dialog box.

When you open the Group Policy Object Editor from GPMC it always uses the same domain controller that is targeted in GPMC for the domain where that GPO is located.

- All of these options may be overridden by a using policy setting, as described next. These settings are available in the **User Configuration\Administrative Templates\System\Group Policy** node of the Group Policy Object Editor.

#### Specifying a Domain Controller by Using Group Policy

Domain Admins can use a policy to specify how Group Policy chooses a domain controller—that is, they can specify which domain controller option should be used. In such cases, the option to choose a domain controller is unavailable since a policy is in place that overrides any setting that the user chooses. This policy allows Domain Admins to mandate that all administrators must use the PDC emulator, for example.

The **Group Policy domain controller selection** policy setting is available in the Administrative Templates node for User Configuration, in the **System\Group Policy** sub-container.

# Local Group Policy (Group Policy Infrastructure)

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can set local Group Policy for any computer, whether or not it participates in a domain. To set local Group Policy, you use the Group Policy Object Editor focused on the local computer. You can access the Group Policy Object Editor tool by typing **mmc** at the command prompt, adding the Group Policy Object Editor to MMC console, and focusing the Group Policy Object Editor on the local computer. Group Policy is processed in this order: local GPO first, followed by Active Directory linked GPOs (site, domain, organizational unit, and any nested organizational units).

**Local Group Policy Object**

On all computers, an Local GPO exists—this is just the Group Policy template portion. The location of the Local GPO is \%SystemRoot%System32\GroupPolicy. Each Group Policy extension snap-in queries the Group Policy engine to get the GPO type, and then decides if it should be displayed.

The following table indicates whether or not the Group Policy Object Editor extensions open when the Group Policy Object Editor is focused on the Local GPO.

| Group Policy Object Editor extension | Loaded when Group Policy Object Editor focused on Local GPO |
|---|---|
| Security Settings | Yes |
| Administrative Templates | Yes |
| Software Installation | No |
| Scripts | Yes |
| Folder Redirection | No |
| Internet Explorer Maintenance | Yes |

**Local Group Policy Object and DACLs**

There is no **Apply Group Policy** ACE for the local GPO; therefore, if you have Read access to the Local GPO, the local GPO applies to you. The implication is that it's difficult to have to choose whom the Local GPO should apply to (for example, the Local GPO also applies to the administrator). Everyone with Read access to the Local GPO who logs on gets the Local GPO. If this is not what you want, a work-around exists. You can set the Read ACE to Deny for a specific user, and then the Local GPO doesn't apply to that user. This is useful for administrators who don't want to be subject to the Local GPO settings. However, without Read access, administrators cannot see the contents of the Local GPO.

**Viewing Policy settings When the Group Policy Object Editor is Focused on the Local Computer**

When administrators run the Group Policy Object Editor focused on a local computer, this shows the information in the local GPO, not the cumulative effect of what has been applied to the computer or user. For Windows Server 2003, it shows the settings that a local administrator has set for that computer and all users of that computer. In the evaluation process, when the computer is joined to a domain, all the policy settings are subject to being overwritten by domain-based policy (any policy set in the site, domain, or organizational unit).

**Local Group Policy Object Processing**

When a computer is joined to a domain with Active Directory and Group Policy implemented, a local Group Policy object is processed. Note that Local GPO policy is processed even when the **Block Policy Inheritance** option has been specified.

Local Group Policy objects are always processed first, and then domain policy is processed. If a computer is participating in a domain and a conflict occurs between domain and local computer policy, domain policy prevails. However, if a computer is no longer participating in a domain, Local GPO policy is applied.

**Modifying the Local GPO on a Domain-based Computer**

If you modify the Local Group Policy object for a computer that is participating in a domain while the computer is disconnected from the network, the change is applied only after the computer is reconnected to the network. This is caused by two facts: the entire domain hierarchy must first be evaluated to find the resultant set of policy settings that apply to the computer and domain user, and domain-based Group Policy settings always take precedence over local Group Policy settings. Therefore, the computer can use only the existing policy settings (no new policy changes can be evaluated) until the computer is reconnected to the network.

# Group Policy Loopback Support

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Group Policy is applied to the user or computer, based upon where the user or computer object is located in Active Directory. However, in some cases, users may need policy applied to them, based upon the location of the computer object, not the location of the user object. The Group Policy *loopback* feature gives the administrator the ability to apply user Group Policy, based upon the computer that the user is logging onto.

To describe the loopback feature, we'll use an example. In this scenario, you have full control over the computers and users in this domain because you have been granted Domain Admin privileges.

The following illustration shows the Reskit domain, which is used to work through this example.

**Figure 3. The Reskit domain**

Normal user Group Policy processing specifies that computers located in the Servers organizational unit have the GPOs A3, A1, A2, A4, and A6 applied (in that order) during computer startup. Users of the Marketing organizational unit have GPOs A3, A1, A2, and A5 applied (in that order), regardless of which computer they log on to.

In some cases this processing order may not be what you want to do, for example, when you do not want applications that have been assigned or published to the users of the Marketing organizational unit to be installed while they are logged on to the computers in the Servers organizational unit. With the Group Policy loopback feature, you can specify two other ways to retrieve the list of GPOs for any user of the computers in the Servers organizational unit:

- **Merge mode**. In this mode, the computer's GPOs have higher precedence than the user's GPOs. In this example, the list of GPOs for the computer is A3, A1, A2, A4, and A6, which is added to the user's list of A3, A1, A2, A5, resulting in A3, A1, A2, A5, A3, A1, A2, A4, and A6 (listed in lowest to highest priority).

- **Replace mode**. In this mode, the user's list of GPOs is not gathered. Only the list of GPOs based upon the computer object is used. In this example, the list is A3, A1, A2, A4, and A6.

You can set the loopback feature by using the **User Group Policy loopback processing mode** policy under Computer Settings\Administrative settings\System\Group Policy.

The processing of the loopback feature is implemented in the Group Policy engine, which is the part of Group Policy that runs in the Winlogon process. When the Group Policy engine is about to apply user policy, it looks in the registry for a computer policy, which specifies which mode user policy should be applied in.

**Using Loopback for Terminal Services**

You can apply GPOs to Terminal Servers exclusively with the use of a GPO Loopback policy. This policy directs the system to apply the set of GPOs for the computer to any user who logs on to the computer affected by this policy. This policy is intended for special-use computers, such as those in public places, laboratories, and classrooms, where you must modify the user policy

based on the computer that is being used. Without Loopback, the user's GPOs determine which user policies apply. If this policy is enabled, the location of a user's computer object is the main factor in determining which set of GPOs are to be applied.

**Loopback Processing and Security Filtering**

In security filtering, if you have used the Deny ACL to explicitly prevent a policy setting from applying to a computer, the setting could still apply in loopback replace mode because the user's security principal remains unaffected by the Deny ACL computer settings.

# Design Considerations for Organizational Unit Structure and Use of Group Policy Objects

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This section discusses issues you need to consider when planning and implementing your organizational unit structure, and highlights recommendations for the use of GPOs.

**Organizational Unit Structure**
The Group Policy architecture is flexible and allows for many types of design. The guiding principle as you design your organizational unit structure should be to create a structure that is easy to manage and troubleshoot. There are two key reasons to create an organizational unit:

- To enable delegation of administration.
- To scope the application of GPOs.

In general, do not try to model your organizational unit structure based on your business organization. Rather, design your organizational unit structure based on how you administer your business. Information about planning for Active Directory is available in Best Practice Active Directory Design for Managing Windows Networks at http://www.microsoft.com/technet/prodtechnol/ad/windows2000/plan/bpaddsgn.asp.

In most organizations, organizational unit structure is likely to fall into one of the following categories:

- Flat organizational unit structure: 1 or 2 levels
- Narrow organizational unit structure: 3 to 5 levels
- Deep organizational unit structure: more than 5 levels

For organizations with simple administration requirements, it is recommended that administrators use a simple model in which a flat organizational unit structure is used and GPOs are linked at the domain or organizational unit level. Limited use of security groups or WMI filtering to filter GPOs is recommended. If you need additional flexibility, it is suggested that you reconsider your organizational unit structure.

For organizations with moderate administration requirements, it is recommended that administrators use a narrow organizational unit structure and GPOs are linked at the site, domain, or organizational unit level as necessary. Limited use of the Block Policy Inheritance options, the Enforce Policy options, security groups or WMI filtering to filter GPOs is recommended.

For organizations with complex administration requirements, the Active Directory namespace may use flat, narrow, or deep organizational unit structures. In such cases, administrators should consider the following issues:

- Flat organizational unit model: use security groups and DACLs or WMI filtering to filter effects of GPOs as a primary method, and Block Policy Inheritance and Enforce Policy options as secondary methods.
- Narrow organizational unit model: link to GPOs at site, domain, and organizational unit. As a secondary method, use Block Policy Inheritance and Enforce Policy options, and security groups and DACLs, or WMI filtering for filtering effects of GPOs.
- Deep organizational unit model: link to GPOs at site, domain, and organizational unit with security groups filtering and DACLs or WMI filtering. As a secondary method, use Block Policy Inheritance and Enforce Policy options.

**Design Principles**
This section presents general guidelines for using GPOs and policy features, and includes examples of GPO design.

**Administration of Group Policy Objects**
Delegation of authority, separation of administrative duties, central versus distributed administration, and design flexibility are important factors you'll need to consider when designing Group Policy and selecting which scenarios to use for your organization.

How you design your organizational unit structure and GPOs will depend on the administrative requirements and roles in your corporation. For example, if administrators are organized according to their duties (such as security administrators, logon administrators, and so on), you may find it useful to define these policy settings in separate Group Policy objects.

Delegation of authority will depend largely on whether you use centralized or distributed administration in your corporation. Based on their particular corporate requirements, network administrators can use security groups and Discretionary Access Control List permissions to determine which administrator groups can modify policy settings in GPOs. Network administrators can define groups of administrators (for example, Software Installation administrators), and then provide them read and write access to selected GPOs, allowing the network administrator to delegate control of the GPO settings. Administrators who have read and write access to a Group Policy object can by default control all of the contents of that Group Policy object; however, you can restrict access by setting policy to control which MMC snap-ins can be loaded by that user, as described earlier in the "Delegating Group Policy" section.

**Separate Users and Computers into Different organizational units**
It's recommended that you separate users and computers into separate organizational units. This is useful for these reasons:

- This simplifies GPO design because you need to focus on only configuration of either user or computers.
- Typically users and computers are administered differently, perhaps by different groups within your organization, which facilitates administration.
- You can reduce Group Policy processing time because you can disable the unused half of the GPO. It is possible to disable only the User or Computer portion of the GPO. To do this, right-click the GPO, click **Properties**, click either **Disable Computer Configuration settings** or **Disable User Configuration settings**, and then click **OK**. These options are available on the GPO **Properties** page, on the **General** tab.
- This type of design is required to enable loopback processing. See the "Group Policy Loopback Support" section for more information.
- For increased security and ease of administration, you should specify different organizational units for all new user and computer accounts when they are created, as explained below.

**Redirecting the Users and Computers Containers in Windows Server 2003 Domains**
New user and computer accounts are created in the CN=Users and CN=Computers containers by default. It is not possible to apply Group Policy directly to these containers, although they inherit GPOs linked to the domain.

Redirusr.exe (for user accounts) and Redircomp.exe (for computer accounts) are two new tools included with Windows Server 2003 that enable you to change the default location where new user and computer accounts are created so you can more easily scope GPOs directly to newly created user and computer objects. These tools are located in %windir%\system32. By running Redirusr.exe and Redircomp.exe once for each domain, the domain administrator can specify the organizational units into which all new user and computer accounts are placed at the time of creation. This allows administrators to manage these unassigned accounts by using Group Policy before the administrators assign them to the organizational unit in which they are finally placed. You might want to consider restricting the organizational units used for new user and computer accounts by using Group Policy to increase security around these accounts.

For more information about redirecting users and computers, see article 324949, "Redirecting the Users and Computers Containers in Windows Server 2003 Domains," in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

For more information about the redirusr.exe and redircomp.exe tools, see the Redirecting Users and Computers link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Best Practice Organizational Unit Structure**
Because you cannot apply Group Policy directly to the CN=Users and CN=Computers containers, if you wanted to define policy settings for users and computers to be stored in their default container you needed to do so on the root of the domain. To prevent policy settings that are defined on a superior container (the root of the domain) from applying to users, computers, and groups in subordinate CN and organizational unit containers, you needed to define complex ACLs on the policy setting in

the root of the domain.

The solution for Windows 2000 and Windows Server 2003 domains is to deploy the best-practice organizational unit structure where Users, Computers, Groups, Service Accounts and Admin accounts are each in their own organizational unit.

The following list describes the benefits of using the best-practice organizational unit structure:

- It permits administrators to link GPOs directly to the containers that are hosting users and computers.
- It permits administrators to match GPOs to objects of a common object class. For example, User or Computer policy settings can be linked directly to organizational units that are hosting user or computer accounts.
- It permits non-administrators to apply policy on containers that are not hosting security-sensitive users and groups such as Domain Admins, Schema Admins, or Enterprise Admins.
- It can minimize the effect if an organizational unit is accidentally deleted (this assumes that the parent container is correctly protected).
- It permits you to restore users and groups independently of each other in recovery scenarios. User accounts must exist before the restoration of the group. Having users and groups reside in different containers permits you to restore them and mark them as authoritative independently of each other.

Note that the CN=USERS and CN=COMPUTERS containers are computer-protected objects. You cannot (and must not) remove them for backward compatibility purposes although they can be renamed.

The best-practice organizational unit structure works well for storing existing users, computers, and groups in Active Directory because those objects can be moved into the appropriate organizational unit container on Windows 2000 and Windows Server 2003 domains regardless of its domain or forest functional level. New user accounts, computer accounts, and security groups that are created with earlier-version APIs used by GUI and command-line management tools do not allow administrators to specify a target organizational unit. As a result, these objects will initially be created in the CN=Users and CN=Computers containers until they are moved by the administrator or an administrator-defined script.

For more information about best-practice organizational unit structure see the "Creating an Organizational Unit Design" section of the Best Practice Active Directory Design for Managing Windows Networks at http://www.microsoft.com/technet/prodtechnol/ad/windows2000/plan/bpaddsgn.asp

**Functional Compared with Geographical Organizational Unit Structure**
When organizing organizational units, there are two basic models to start with: functional and then geographical, or geographical and then functional. The key is never to implement a structure that forces an artificial layering, which means that the organizational unit structure for computers may be very different than that for users—it all depends on how they are administered.

**Minimize the Number of Group Policy Objects Associated with Users or Computers**
You should note that the number of GPOs that are applied to a user affects the logon processing time. (Similarly, the number of GPOs applied to a computer affects boot time). The greater the number of associated GPOs, the longer logon will take to process them. During logon time, each GPO from the user's site, domain, and organizational unit hierarchy is applied, provided the user has both the Read ACE and the Apply Group Policy ACE. Note that if the Apply Group Policy ACE is not set, but the Read ACE is, the GPO will still be processed (although not applied), thus impacting logon time. Therefore, if you implement filtering based on security groups, you should also clear Read Access for those users that you clear Apply Group Policy for.

**Minimize the Use of the Block Policy Inheritance Feature**
As mentioned previously, you can prevent Group Policy settings of parent Active Directory containers from affecting users and computers in lower-level parent Active Directory containers. This is a useful and powerful feature that you should use judiciously only when a particular situation requires it. Blocking the inheritance of policy from parent Active Directory containers can complicate troubleshooting policy.

**Minimize the Use of the Enforce Feature**
You can also ensure that the policy settings you specify in a given GPO at a higher-level parent Active Directory container are enforced on lower-level parent Active Directory containers by using the Enforce option. Only use this powerful feature when circumstances require it. Overuse of this feature with other related features, such as Block Policy Inheritance, can complicate troubleshooting policy.

**Use Loopback Processing Only When Necessary**

You can set User Configuration per computer and thus override user-specific policy settings with computer-specific policy settings. This is useful when you want to provide a specific desktop configuration regardless of which users log on to the computer, such as a kiosk or other public terminal. To set User Configuration per computer, you would use the Administrative Templates node under **Computer Configuration** in the Group Policy Object Editor. For more information about this feature, see Group Policy Loopback Support.

**Avoid Using Cross-Domain GPO Assignments**
Although you can assign GPOs from different domains to a single Active Directory container if a particular situation requires it, you should note that in such cases Group Policy processing would be slower. This is because domain boundaries are crossed.

**Avoid Editing the Default Domain GPO**
Instead of editing the default domain GPO, create a new GPO, link it to the domain GPO, and set the new GPO to have precedence over the default domain GPO.

**Design Examples**
This section presents several models of GPO design. These examples are not intended as guidelines, but they do illustrate various ways to approach GPO design. In most corporate environments, administrators may use a combination of these or similar models, tailored to their business requirements.

The key overriding approaches are either functional or geographic models. The rest are usually variants of those.

**Layered GPO Design Model**
The objective of this design model is to create GPOs based on a layered approach. This approach optimizes maintenance of GPOs and facilitates delegation.

The following graphic illustrates an example of this model.

Layered GPO model

**Monolithic GPO Design Model**
The objective of this design is to create GPOs based on a monolithic design—an approach that reduces the number of GPOs that apply to a user and/or computer but may not be optimal for delegation.

The following graphic illustrates an example of the monolithic GPO model.

Monolithic GPO model

**Single Policy Type GPO Design Model**
The objective of this design is to create GPOs that deliver a single type of Group Policy, for example, policy for security settings. Such a design optimizes separation of duties for administrators; however, it may increase the number of GPOs that are applied to a given user or computer.

Each GPO delivers only one type of policy (security GPOs are different from script Group Policy objects, for example). Large corporations often create separate administrator groups based on administrative duties; this scenario would be useful in such corporate environments.

The following graphic illustrates an example of the single policy type GPO model.

Single Policy GPO Model

**Multiple Policy Types GPO Design Model**
The objective of this design is to create GPOs that deliver multiple types of policy. This is a hybrid of the single policy and monolithic models. Each GPO delivers several types of policy settings.

For example, you can create a GPO that includes Group Policy settings for software settings and application deployment and create another GPO that includes security and scripts settings, and so on. A GPO design that supports multiple policy types is useful in delegating administration environments and can reduce the number of GPOs that apply to a user and/or computer.

The following graphic illustrates an example of the multiple policy types GPO model.

Multiple Policy Types GPO

**Teams or Matrix Organizations GPO Model**
This model applies to organizations that leverage the virtual team concept. Individuals within the organization form teams to perform a task or project and each individual is a member of multiple teams. Each team has specific Group Policy requirements. The organizational unit architecture does not reflect the team structure. This model works by using security filtering.

The following graphic illustrates an example of the team GPO design model.

**Public Computing Environment GPO Model**

This scenario applies to environments were you want the computer Group Policy settings to always have precedence over the user Group Policy settings. This scenario is useful for training classes and kiosk-type environments in which you want to provide the same desktop environment regardless of which user logs on to the computer.

The following graphic illustrates an example of the GPO design for a public computing environment. The loopback policy feature with **Replace mode** is used in this example. See "Group Policy Loopback Support" in this document for more information.

Normal Group Policy processing specifies that users in the Sales organizational unit get these GPOs: Domain Policy GPO, Accounting GPO, and Sales GPO. With the loopback policy enabled in **Replace mode**, when users from the Sales organizational unit log on to a computer in the Kiosks organizational unit, the user will process *only* these GPOs: Domain Policy GPO, Accounting GPO, Resources GPO, and Kiosks Loopback Policy GPO—the users' list of GPOs is not gathered in this case. More specifically, the user settings specified in the Kiosks organizational unit (and those inherited) are the *only* GPOs processed for the user logging onto computers in that organizational unit. Those in the Users organizational unit tree are not processed.

**Delegation with Central Control**

This model applies to organizations that choose to delegate administration of GPOs, but would like to enforce certain Group Policy settings throughout the domain (for example, specific security policy settings).

The following graphic illustrates an example of GPO delegation with centralized control, and use of the **Enforce** option.

**Delegation with Distributed Control**

This scenario applies to organizations that want to allow administrators of organizational units to prevent Group Policy settings from being applied to their organizational unit. Administrators of an organizational unit can block Group Policy settings that have been assigned at higher levels in the hierarchy from applying to his or her organizational unit. However, administrators cannot block Group Policy settings that are marked as *Enforce*.

This feature allows organizations to minimize the number of domains without sacrificing autonomy.

# Deployment Considerations

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Administering a Mix of Windows 2000 and Windows Server 2003 Domains**
GPMC exposes features that are available in the underlying operating system. Because new features have been added to Group Policy since Windows 2000, certain features will only be available in GPMC depending on the operating system that has been deployed on the domain controllers. This section describes these dependencies. In general, there are three key issues that determine whether a feature is available in GPMC:

- Whether the forest supports the Windows Server 2003 schema for Active Directory. Certain features are only available once the schema is upgraded. This is the first step that must be taken before any Windows Server 2003 domain controller can be deployed in an existing Windows 2000 forest. The schema is a forest-wide configuration and is upgraded by running **ADPrep /ForestPrep**. ADPrep is a utility included on the Windows Server 2003 CD. Note that it is possible to have the Windows Server 2003 schema in a forest with all Windows 2000 domain controllers.

- Whether there is at least one domain controller in the forest that is running Windows Server 2003. Group Policy Modeling must be performed on a domain controller running Windows Server 2003.

- Whether a domain contains the Windows Server 2003 domain configuration. This is implemented once **ADPrep /DomainPrep** is run in that domain. This is the first step that must be taken before any Windows Server 2003 domain controller can be deployed in an existing Windows 2000 domain.

Note that there is no dependency from the Group Policy perspective on whether a domain is in native mode or mixed mode.

**Delegation of Group Policy Results and Group Policy Modeling**
In order to delegate either Group Policy Modeling or Group Policy Results, the Active Directory schema in the forest must be the Windows Server 2003 schema. Note that you can use Group Policy Results even without this schema, but only users with local administrative credentials on the target computer can remotely access Group Policy Results data. Thus, if the forest does not have the Windows Server 2003 schema, the delegation pages in GPMC for organizational units and domains will not show these permissions.

**Group Policy Modeling**
Group Policy Modeling is a simulation that is performed by a service that can only run on a domain controller running Windows Server 2003 or later. As long as there is at least one domain controller running Windows Server 2003 in the forest, you can use Group Policy Modeling. GPMC will only show the Group Policy Modeling node in the user interface if the Windows Server 2003 schema is present.

**WMI Filtering**
WMI filters are only available in domains that have the Windows Server 2003 configuration. Although none of the domain controllers need to be running Windows Server 2003, you must have run ADPrep /DomainPrep in this domain. Also note that WMI filters are only evaluated by clients running Windows XP, Windows Server 2003, or later. WMI filters associated with a GPO will be ignored by Windows 2000 clients and the GPO will always be applied on Windows 2000.

If ADPrep /DomainPrep has not been run in a given domain, the WMI Filters node will not be present, and the GPO scope tab will not have a WMI filters section.

**Upgrading Windows 2000 Domains to Windows Server 2003 Domains and Interaction with Group Policy Modeling**
Group Policy Modeling is a new feature of Windows Server 2003 that simulates the resultant set of policy for a given configuration. The simulation is performed by a service that runs on Windows Server 2003 domain controllers. In order to perform the simulation in cross-domain scenarios, the service must have read access to all GPOs in the forest.

In a Windows Server 2003 domain (whether it is upgraded from Windows 2000 or installed as new), the Enterprise Domain Controllers group is automatically given read access to all newly created GPOs. This ensures that the service can read all GPOs in the forest.

However, if the domain was upgraded from Windows 2000, any existing GPOs that were created before the upgrade do not have read access for the Enterprise Domain Controllers group. When you click a GPO, GPMC detects this situation and notifies the user that Enterprise Domain Controllers do not have read access to all GPOs in this domain. To solve this problem, you can use one of the sample scripts provided with GPMC, GrantPermissionOnAllGPOs.wsf. This script can update the permissions for

all GPOs in the domain. To use this script:

Ensure that the person running this script is either a Domain Admin or has permissions to modify security on all GPOs in the domain.

Open a command prompt and navigate to the **%programfiles%\gpmc\scripts** folder by typing:

**CD /D %programfiles%\gpmc\scripts**

Type the following:

**Cscript GrantPermissionOnAllGPOs.wsf "Enterprise Domain Controllers" /Permission:Read /Domain:value**

The value of domain parameter is the DNS name of the domain.

**Using Group Policy Features Across Forests**

The Windows Server 2003 family introduces a new feature called Forest Trust that enables you to authenticate and authorize access to resources from separate, networked forests. With trusts established between forests, you can manage Group Policy throughout your enterprise, which provides greater flexibility especially in large organizations. This section describes Group Policy behavior in an environment with forest trust enabled:

- It is not possible to link a GPO to a domain in another forest.
- With Forest trust, it is possible that a user in Forest B could log onto a computer in Forest A. In this case, when the computer starts up, it will process policy for the computer configuration from Forest A, as usual. When a user from Forest B logs on, where they receive their policy settings from depends on the value of the **Allow Cross-Forest User Policy and Roaming Profiles** policy setting.
    - When this setting is **Not Configured**, no user-based policy settings are applied from the user's forest. Instead, loopback Group Policy processing will be applied, using the GPOs scoped to the computer. Users will receive a local profile instead of their roaming profile.
    - When this setting is **Enabled**, the behavior is exactly the same as Windows 2000 Server: User policy is applied from the user's forest and a roaming user profile is allowed from the trusted forest.
    - When this setting is **Disabled**, the behavior is the same as **Not Configured**.

This setting is available on Windows Server 2003 located at: **Computer Configuration\Administrative Templates\System\Group Policy\Allow Cross-Forest User Policy and Roaming Profiles.**

- It is possible to deploy Group Policy settings to users and computers in the same forest, but have those settings reference servers in other trusted forests. For example, the file shares that host software distribution points, redirected folders, logon scripts, and roaming user profiles could be in another trusted forest.
- Group Policy Modeling requires that both the user and the computer be in the same forest. If you want to simulate a user from Forest A logging on to a computer in Forest B, you must perform two separate Group Policy Modeling simulations: one for the user configuration and the other for the computer configuration.
- Delegation across forests is supported for managing Group Policy. For example, you can delegate to someone in Forest B the ability to perform Group Policy Modeling simulations on objects in Forest A.

**Group Policy and Active Directory Sites**

GPOs that are linked to site containers affect all computers in a forest of domains. Site information is replicated and available between all the domain controllers within a domain and all the domains in a forest. Therefore, any GPO that is linked to a site container is applied to all computers in that site, regardless of the domain (in the forest) to which they belong. This has the following implications:

- It allows multiple domains (within a forest) to get the same GPO (and included policy settings), although the GPO only lives on a single domain and must be read from that domain when the affected clients read their site policy.
- If child domains are set up across wide area network (WAN) boundaries, the site setup should reflect this. If it does not,

the computers in a child domain could be accessing a site GPO across a WAN link.

- To manage site GPOs, you need to be either an Enterprise Admin or Domain Admin of the forest root domain.

- You may want to consider using site-wide GPOs for specifying policy for proxy settings and network-related settings.

In general, it is recommended that you link GPOs to domains and organizational units rather than sites.

**Using Group Policy and Internet Explorer Enhanced Security Configuration**
Windows Server 2003 includes a new default security configuration for Internet Explorer, called Internet Explorer Enhanced Security Configuration, also known as Internet Explorer hardening.

You can manage Internet Explorer Enhanced Security Configuration by:

- **Enabling or disabling Internet Explorer Enhanced Security Configuration.** This is commonly used in situations where you want to ensure that Internet Explorer Enhanced Security Configuration is always enabled. For example, Internet Explorer Enhanced Security Configuration might need to be reapplied on a specific computer if the local administrator on that computer disables it using the Optional Component Manager in the Windows Components Wizard (available from Add or Remove Programs.)

- **Restricting who can manage trusted sites and other Internet Explorer security settings on a server**. This is commonly used when you want to ensure that all servers have the same Internet Explorer Enhanced Security Configuration settings. For example, you might want to configure Internet Explorer Enhanced Security Configuration so that machined-based security settings are applied to each server rather than user-based security settings.

- **Adding trusted Web sites and UNC paths to one of the trusted security zones.** This is commonly used when you want to allow users access to specific Web sites and corporate resources, but still reduce the risk of users downloading or running malicious content.

Enhanced Security Configuration impacts the Security Zones and Privacy settings within the Internet Explorer Maintenance settings of a GPO. The Security Zones and Privacy settings can either be enabled with Enhanced Security Configuration or not.

When you edit settings for Security Zones and Privacy settings in a GPO from a computer where Enhanced Security Configuration is enabled, that GPO will contain Enhanced Security Configuration-enabled settings. When you look at the HTML report for that GPO, the Security Zones and Privacy heading will be appended with the text (Enhanced Security Configuration enabled).

When you edit settings for Security Zones and Privacy settings in a GPO from a computer where Enhanced Security Configuration is not enabled , that GPO will contain Enhanced Security Configuration-disabled settings. ESC is not enabled on any computer running Windows 2000 or Windows XP, nor on computers running Windows Server 2003 where ESC has been explicitly disabled.

Enhanced Security Configuration settings deployed through Group Policy will only be processed on and applied by computers where Enhanced Security Configuration is enabled. Enhanced Security Configuration settings will be ignored on computers where Enhanced Security Configuration is not enabled (all computers running Windows 2000 and Windows XP, and Windows Server 2003 computers where Enhanced Security Configuration has been explicitly disabled). The converse is also true: A GPO that contains non- Enhanced Security Configuration settings will only be processed on and applied by computers where Enhanced Security Configuration is not enabled.

For more information, see Managing Internet Explorer Enhanced Security Configuration, available from the Microsoft Group Policy Web site at http://www.microsoft.com/grouppolicy.

# IntelliMirror Features without Active Directory

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The full functionality of IntelliMirror® management technologies requires Active Directory and Group Policy. However, in an environment without Active Directory and Group Policy, some of the capabilities are available. You can still implement the following IntelliMirror features to manage clients running Windows 2000 or later:

- Roaming User Profiles and Logon Scripts
- Folder Redirection
- Internet Explorer Maintenance
- Administrative Templates (registry-based policy)

**Roaming User Profiles and Logon Scripts**
When using either a Windows NT 4.0 domain or Active Directory, both roaming user profiles and logon scripts are configured on the user object.

**Folder Redirection**
You can redirect special folders to alternate locations, either to a local or network location. You do this by modifying the values under the following registry key:

**HKCU\Software\Microsoft\Windows\CurrentVersion\Explorer\Shell Folders**

Each value is of type **REG_SZ**, and the data is the redirected path (either local or UNC). The table below lists the folders that may be redirected and their associated value name.

| Folder | Name |
|---|---|
| My Documents | Personal |
| My Pictures | My Pictures |
| Application Data | AppData |
| Desktop | Desktop |
| Start Menu | Start Menu |

**Internet Explorer Maintenance**
Instead of using Group Policy to control Internet Explorer settings, administrators can use the Internet Explorer Administration Kit (IEAK) to apply settings to Internet Explorer clients using auto-configuration packages.

**Applying Administrative Templates (Registry-Based Policy)**
Domain-based Group Policy processing requires that the User and/or Computer objects be located in Active Directory. If the User or Computer objects are located in a Windows NT 4.0 domain, then Windows NT 4.0 System Policy will be processed for whichever of these objects is located in that domain—this could be the Computer or User object, or both. System Policy is defined as the policy mechanism used natively in Windows NT 4.0; it is a set of registry settings that together define the computer resources available to a group of users or an individual. (Also be aware that the local GPO is always processed prior to any System Policy.)

**Setting Registry-based Policy in a Windows NT 4.0 Domain**
A client running Windows 2000 or Windows XP Professional will process System Policy if either the user or computer account are in a Windows NT 4.0 domain. The client looks for the Ntconfig.pol file used by Windows NT 4.0-style System Policy. By default, it looks for this file in the NETLOGON file share of the authenticating Windows NT 4.0 domain controller.

# Migrating Policy-Enabled Clients from Windows NT 4.0 to Windows 2000 or Windows Server 2003

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This section discusses behavior of Group Policy and System Policy in relation to migration to Windows 2000 or Windows Server 2003.

**Windows NT 4.0 and Windows 2000 Policy Setting Comparison**
Group Policy differs greatly from System Policy in Windows NT 4.0. Although Group Policy does include the functionality from Windows NT 4.0 System Policy, it also provides policy settings for scripts, software installation, security settings, Internet Explorer maintenance, folder redirection, and Remote Installation Services.

In Windows NT 4.0 (and Windows 95 and Windows 98), System Policies:

- Are applied to domains.
- May be further controlled by user membership in security groups.
- Are not secure.
- Persist in users' profiles (this is sometimes referred to as *tattooing* the registry), as explained earlier in this paper This means that after a registry setting is set using Windows NT 4.0 System Policies, the setting persists until the specified policy is reversed or the user edits the registry.
- Are limited to desktop lockdown.

In Windows 2000 and Windows Server 2003, Group Policy:

- Represents the primary method for enabling centralized Change and Configuration Management. You can use Group Policy to manage registry-based policy, software installation options, security settings, scripts (for computer startup and shutdown, and for user logon and logoff), Internet Explorer maintenance, folder redirection, and Remote Installation Services.
- Can be linked to sites, domains, and organizational units.
- Affects all users and computers in the specified Active Directory container (site, domain, or organizational unit) by default.
- May be further controlled by user or computer membership in security groups.
- May be further controlled by use of WMI filtering.
- Settings are secure.
- Default policy settings do not persist in the registry.
- Can be used for tightly managed desktop configurations and to enhance the user's computing environment.

The Windows NT 4.0 effect of persistent registry settings can be problematic when a user's group membership is changed. An advantage of Windows 2000Group Policy is that this does not occur. When a GPO no longer applies, registry settings written to the following secure registry locations are removed:

- HKLM\Software\Policies

- HKLM\Software\MS\Windows\CurrentVersion\Policies
- HKCU\Software\Policies
- HKCU\Software\MS\Windows\CurrentVersion\Policies

**Migrating to Windows 2000 or Windows Server 2003**
Migrating Windows NT 4.0-based clients and servers to Windows 2000 or Windows Server 2003 in various combinations causes different behavior for Group Policy. In a pure Windows 2000 or later environment where both the user and computer accounts are in a Windows 2000 or later domain, Windows 2000 or later clients process only Group Policy. System Policy is not processed. However, Windows 2000 or Windows XP clients can process System Policy in cases where either the user account and/or the computer account is not located in a Windows 2000 or Windows Server 2003 domain.

In many organizations it may be impractical to upgrade all Windows NT 4.0-based servers and client computers simultaneously to Windows Server 2003 and Windows XP. In this case, it is important that you know how Group Policy and Windows NT 4.0 System Policy are affected during and after the migration process. This section presents information about the effects of migration on Group Policy.

**Client Computers**
Group Policy applies only to computers running Windows 2000 or later. There is no mechanism to process Group Policy on clients running Windows NT 4.0, Windows 95, Windows 98, and Windows Millennium Edition.

**Upgrading Computer or User Accounts from Windows NT 4.0 to Windows Server 2003**
When migrating from Windows NT 4.0, it's recommended to perform a clean installation of Windows Server 2003. To facilitate a clean installation, you can use the User State Migration Tool to migrate the users' data and settings to the new installation.

For more information about migrating from Windows NT 4 System Policy, see Windows 2000 Group Policy white paper at http://go.microsoft.com/fwlink/?linkid=203.

**Using Group Policy in a Mixed Environment of Windows 2000 and Windows XP Clients**
**Active Directory with Windows 2000 and Windows XP Clients**
This section explains issues to consider when using Group Policy in a Windows 2000 Server or Windows Server 2003 environment where some or all of the clients are running Windows XP Professional or Windows 2000.

**Comparing IntelliMirror Features on Windows 2000 and Windows XP**
The following tables show how IntelliMirror features compare on computers running Windows 2000 Professional and Windows XP Professional.

### Comparing Clients under Windows Server 2003 Active Directory

| Feature | Supported in Windows 2000 Client | Supported in Windows XP Client |
|---|---|---|
| Group Policy | Yes | Yes |
| GPMC | No. But Windows 2000 clients can be managed with GPMC running on Windows Server 2003 | Yes |
| Local Group Policy | Yes | Yes |
| System policy | Yes | Yes |
| Roaming profiles | Yes | Yes |
| Folder redirection | Yes (No home directory redirect) | Yes |
| Software installation | Yes | Yes |
| Internet Explorer Maintenance | Yes | Yes |

| | | |
|---|---|---|
| Security Settings | Yes | Yes |
| Software restriction policies | No | Yes |

**Comparing clients under Windows 2000 Active Directory**

| Feature | Supported in Windows 2000 | Supported in Windows XP |
|---|---|---|
| Group Policy | Yes | Yes |
| GPMC | No. But Windows 2000 clients in a Windows 2000 domain can be managed with GPMC installed on a computer running Windows XP or a member server running Windows Server 2003. | Yes |
| Local Group Policy | Yes | Yes |
| System policy | Yes | Yes |
| Roaming profiles | Yes | Yes |
| Folder redirection | Yes (No home directory redirect) | Yes |
| Software installation | Yes | Yes |
| Internet Explorer Maintenance | Yes | Yes |
| Security Settings | Yes | Yes |
| Software restriction policies | No | Yes (via Local Group Policy Object) |

**Comparing Clients Under Windows NT Server 4.0**

| Feature | Supported in Windows 2000 | Supported in Windows XP |
|---|---|---|
| System policy | Yes | Yes |
| Group Policy | No | No |
| Local Group Policy | Yes | Yes |
| Roaming profiles | Yes | Yes |
| Folder redirection | No | No |
| Software installation | No | No |
| Internet Explorer Maintenance | Yes, with Internet Explorer Administration Kit (IEAK) | Yes, with IEAK. |

| | | |
|---|---|---|
| Security Settings | No | No |
| Software restriction policies | No | No |

**Folder Redirection and Software Installation**
Because background refresh is the default behavior in Windows XP, Folder Redirection and Software Installation may require as many as three logons to apply changes.

This behavior exists because Folder Redirection and Software Installation cannot apply during an asynchronous or background application of policy. Folder Redirection can only apply when processed synchronously.

Here is a sample scenario showing how polices are applied:

1. An administrator deploys a software package to User A.

2. User A logs on fast and receives a background (asynchronous) application of policy.

3. Because the policy application was asynchronous, the software that was set to be installed cannot be installed at this time. Instead the machine is tagged, indicating that software needs to be installed.

4. The next time the user logs on, the machine instead logs on the user synchronously to allow the software package to be installed. (This is the same behavior as Windows 2000). This results in one extra logon for the software to be installed.

In the case of Advanced folder redirection, because policy is evaluated based on security group membership three logons will be required: the first logon to update the cached user object (and security group membership), the second logon for policy to detect the change in security group membership and require a foreground policy application, and the third logon to actually apply folder redirection policy in the foreground.

| **Note** |
|---|
| When a client running Windows XP logs onto a Windows 2000 or Windows Server 2003 Active Directory, all Software Installation policy settings for Windows 2000 clients will be applied and work successfully on the Windows XP client. |

**Internet Explorer Maintenance**
There are no changes in Internet Explorer Maintenance across Windows XP and Windows 2000.

**Roaming Profiles**
Users with roaming profiles can roam between Windows 2000 and Windows XP-based workstations without any changes in behavior. The new profile registry policy settings only work on Windows XP. If you apply these settings to a client running Windows 2000, they will have no effect.

**Security Settings**
Software Restrictions Policies were introduced in Windows XP. If you apply software restriction policy to a client running Windows 2000 it will have no effect. The software restriction policy registry settings will be written to the registry, but the Windows 2000 client will not know how to interpret them.

**64 bit Integration Issues**
If you apply a 64-bit package to Windows 2000 or a 32-bit version of Windows XP, it will not be advertised by default; however, you can override this behavior using the 64-bit deployment options in the Application Deployment Editor (ADE). If you apply a 64-bit package to a 64-bit version of Windows XP, it will be successfully advertised.

# Appendix A: Security Settings and User Rights

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This appendix lists the Security Settings that are defined by default in the Default Domain Policy GPO. This GPO is created when the first domain controller in the domain is installed by the Active Directory Installation Wizard. If this first domain controller is upgraded from a Windows NT 4.0 domain controller, then the values defined for the Windows NT 4.0 domain are used instead.

These domain-wide account policy settings (Password Policy, Account Lockout Policy and Kerberos Policy) are enforced by the domain controller computers in the domain; therefore, all domain controllers always retrieve the values of these account policy settings from the Default Domain Policy GPO.

| **Policy** | **Default Value** | **Comment** |
|---|---|---|
| **Password Policy** | | |
| Enforce password history | 1 password remembered | |
| Maximum password age | 42 days | |
| Minimum password age | 0 days | |
| Minimum password length | 0 characters | |
| Passwords must meet complexity requirements | Disabled | |
| Store password using reversible encryption for all users in the domain | Disabled | |
| **Account Lockout Policy** | | |
| Account Lockout Threshold | 0 | |
| **Kerberos Policy**<br>Since Kerberos support was not available in previous versions of Windows NT, the following Kerberos policy settings are always defined for the first domain controller of a Windows 2000 or Windows Server 2003 domain, regardless of whether it was upgraded or not. | | |
| Enforce user logon restrictions. | Enabled | |
| Maximum lifetime that a user ticket can be renewed | 7 days | |
| Maximum user ticket lifetime | 10 hours | |
| Maximum service ticket lifetime | 600 minutes | |
| Maximum tolerance for synchronization of computer clocks | 5 minutes | |
| **Security Options** | | |

| | | |
|---|---|---|
| Automatically logoff users when logon time expires | Disabled | This is a domain-wide setting even though it appears under the Security Options area. |

**Security Settings in the Default Domain Controllers Policy**

This section lists the Security Settings that are defined by default in the Default Domain Controller Policy GPO. This GPO is created when the first domain controller in the domain is installed via the Active Directory Installation Wizard. If this first domain controller is upgraded from a Windows NT 4.0 domain controller, then the values defined for the Windows NT 4.0 domain are used instead.

By default, these settings apply to all domain controllers in the domain.

| Policy | Default Value | Comment |
|---|---|---|
| **Security Options** | | |
| Digitally sign server-side communication when possible | Enabled | |
| **Audit Policy** | | |
| Audit Account Logon events | No Auditing | |
| Audit Account Management | No Auditing | |
| Audit Directory Service Access | No Auditing | |
| Audit Logon Events | No Auditing | |
| Audit Object Access | No Auditing | |
| Audit Policy Change | No Auditing | |
| Audit Privilege Use | No Auditing | |
| Audit Process Tracking | No Auditing | |
| Audit System Events | No Auditing | |
| **User Rights Policy** | | |
| Access this computer from the network | Administrators, Authenticated Users, Everyone | If the following groups were given this right prior to running the Active Directory Installation Wizard, then they are removed: Backup Operators, Guests, Guest, and Users.<br><br>If a Windows NT 4.0 domain controller is upgraded as the first Windows Server 2003 domain controller, then the Authenticated Users group is automatically given this right. |
| Act as part of the operating system | | |
| Add workstations to the domain | Authenticated Users | This User Right is for the support of legacy APIs. You can also allow users to create computer accounts by using this User Right. Authenticated Users can only create 10 computer accounts using this User Right. |

| | | |
|---|---|---|
| Back up files and directories | Administrators, Backup Operators, Server Operators | |
| Bypass traverse checking | Administrators, Authenticated Users, Everyone | If the following groups were given this right prior to running the Active Directory Installation Wizard, then they are removed: Backup Operators, Users. |
| Change the system time | Administrators, Server Operators | |
| Create a pagefile | Administrators | |
| Create a token object | | |
| Create permanent shared objects | | |
| Debug programs | Administrators | |
| Force shutdown from a remote system | Administrators, Server Operators | |
| Generate security audits | | |
| Increase quotas | Administrators | |
| Increase scheduling priority | Administrators | |
| Load and unload device drivers | Administrators | |
| Lock pages in memory | | |
| Log on as a batch job | | |
| Log on as a service | | |
| Log on locally | Account Operators, Administrators, Backup Operators, Server Operators, Print Operators | If the following groups were given this right prior to running the Active Directory Installation Wizard, then they are removed: Authenticated Users, Guests, Guest, Users, and Everyone. |
| Manage auditing and security log | Administrators | |
| Modify firmware environment variables | Administrators | |
| Profile single process | Administrators | |
| Profile system performance | Administrators | |
| Replace a process-level token | | |
| Restore files and directories | Administrators, Backup Operators, Server Operators | |

| | | |
|---|---|---|
| Shut down the system | Account Operators, Administrators, Backup Operators, Server Operators, Print Operators | If the following groups were given this right prior to running the Active Directory Installation Wizard, then they are removed: Authenticated Users, Guests, Guest, Users, and Everyone. |
| Take ownership of files or other objects | Administrators | |
| Deny Logon Locally | | |

**Help for Windows NT 4.0 Administrators**

This section provides information to help administrators who have been using User Manager to configure security policy settings in the past move to the new model of Group Policy for editing and configuring security policy settings.

**Changing Password Policy for the Domain**

**To change password policy for the domain, open the Default Domain GPO from the Administrative Tools menu:**

1. Click **Start**, point to **Programs**, click **Administrative Tools**, and then click **Domain Security Policy**.

2. In the **Domain Security Policy** console, expand **Security Settings**, expand **Account Policies**, expand **Password Policy**, and then select the policy you want to modify in the results pane. You can then make changes.

**Changing Auditing Policy or User Rights for Domain Controllers**

To change the Audit policies or User Rights defined for domain controllers, open the **Default Domain Controllers GPO** from the Administrative Tools menu:

1. Click **Start**, point to **Programs**, click **Administrative Tools**, and then click **Domain Controller Security Policy**.

2. In the **Domain Controller Security Policy** console, expand **Security Settings**, expand **Local Policies**, click either **Audit Policy** or **User Rights Assignment**, and then select the policy you want to modify in the results pane.

**Changing local Password Policy on member Workstations or Servers (Non-Domain Controllers)**

Because the **Default Domain Policy GPO** applies to all computers in the domain and because domain-level policy settings override local policy settings, member workstations and servers apply the Default Domain password policy settings to their local account databases by default. If this does not meet your requirements, then the permissions on the **Default Domain GPO** have to be reconfigured so that member computers that you do not want to receive this policy do not have the **Apply Group Policy** permission on the **Default Domain GPO**. After the permissions are configured so that the member computer does not have access to the default domain policy, local policy settings will no longer be overridden by the password policy settings defined in the **Default Domain GPO**.

**To modify Local Password Policy security settings using the Local Security Policy UI:**

1. Click **Start**, point to **Programs**, click **Administrative Tools**, and then click **Local Security Policy**.

2. In the **Local Security Settings** console, expand **Security Settings**, expand **Account Policies**, click **Password Policy**, and then select in the results pane the policy you want to edit.

**Frequently Asked Questions about Security Settings**

**Is it possible to define different account policies (Password, Lockout, or Kerberos Policies) for different organizational units?**

No. All domain controllers for a domain enforce the account policy settings that are defined in the Default Domain Policy. Domain controllers ignore password, lockout, or Kerberos policy settings defined at an organizational unit or Local GPO level.

**After modifying a local security setting, the change does not take effect. What is happening?**

The Group Policy model specifies that any policy settings configured locally may be overridden by like policy settings specified in the domain. The **Local Security Settings** UI lists the local security setting and the effective security setting for each policy item. (You can access the **Local Security Settings** UI by clicking **Start**, pointing to **Programs**, clicking **Administrative Tools**, and selecting **Local Security Policy**). If the effective security setting is different from the local security setting, it implies that there is a policy from the domain that is overriding your setting.

**After modifying a domain-level-policy security setting, the change does not take effect. What is happening?**

The Group Policy model applies domain-level policy changes periodically; therefore, it is likely that the policy changes made in the directory have not been made to your computer yet. To trigger a policy propagation on a local computer, type the following at the command line:

```
secedit /refreshpolicy MACHINE_POLICY
```

This will cause any changes made to domain-level policy settings to be applied to the local computer. To force a reapplication of policy to domain-level policy settings, regardless of whether there has been a change or not, type the following at the command line:

```
secedit /refreshpolicy MACHINE_POLICY /enforce
```

You can determine whether or not security was applied successfully by viewing the Application Event Log. If an error occurred during the process of applying security policy, you can get detailed information by setting the following **REG_DWORD** to **0x02**:

```
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Winlogon\GPExtensions\
{827D319E-6EAC-11D2-A4EA-00C04F79F83A}\ExtensionDebugLevel
```

When this value is set, the Security Templates will log policy-processing information in the Winlogon.log file at %windir%\Security\Logs\Winlogon.log.

**What is the Add Workstation to Domain Logon right, and how does it relate to delegating similar permissions on the directory?**

The **Add Workstation to Domain** user right is supported for applications that use earlier SAM (Security Accounts Manager) NET APIs to create computer accounts. Users that have this right are allowed to create 10 computer accounts in the Active Directory **Computers** container using these earlier APIs. When a user creates a computer account using this user right, the Domain Admins group becomes the owner of the computer object. Note that this right is *not* recognized when LDAP is used to create computer accounts.

In Windows 2000 and later, the recommended way to allow a user or group to create computer accounts is by granting that user or group the permission to **Create Computer Objects** on the desired container. This can be accomplished in GPMC. When a computer account is created using access control permissions, the actual creator of the object becomes the owner of that object.

| **Note** |
| --- |
| The create-computer-object permission should not be granted indiscriminately. Allowing users to create computers in the domain is similar to allowing users to create user accounts in the domain. Unlike Windows NT 4.0, Windows Server 2003 computer objects can be used to do network authentication and, hence, to access resources over the network. Users that have access permissions to create computer objects are also not subject to any quota restrictions. That is, they can create any number of computer accounts. |

The best security practice would be to grant only trusted users (by using a group) the permission to create computer objects. At the time the computer object is created, the creator can define which users are allowed to use that computer object to join their physical computer to the domain.

# Appendix B: Group Policy Storage

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Group Policy objects store information in two locations: a Group Policy container and a Group Policy template.

**Group Policy Container**
The Group Policy container is an Active Directory container that stores GPO properties; it includes sub-containers for computer and user Group Policy information. The Group Policy container has the following properties:

- **Version information.** This is used to ensure that the information is synchronized with the Group Policy template information. Indicates the number of changes made to the GPO.
- **Status information.** This indicates whether the GPO is enabled or disabled.
- **List of components (extensions) that have settings in the GPO.**
- **File System path.** The UNC path to the Sysvol folder.
- **Functionality version.** This is the version of the tool that created the GPO. Currently, this is version 1.

For example, the Group Policy container stores information used by the Software Installation snap-in to describe the state of the software available for installation. This data repository contains data for all applications, interfaces, and APIs that provide for application publishing and assigning.

**Group Policy Template**
Group Policy objects also store Group Policy information in a folder structure called the Group Policy template that is located in the System Volume folder of domain controllers (Sysvol) in the \Policies sub-folder. The Group Policy template is the container where Security Settings, Administrative Template-based policy settings, applications available for Software Installation, and script files are stored.

When you modify a GPO, the directory name given to the Group Policy template is the GUID of the GPO that you modified. For example, assume that you modified a GPO associated with a domain called Seattle. The resulting Group Policy template folder would be named as follows (the GUID is an example):

```
%systemroot%\sysvol\<SYSVOL>\Seattle.yourcompanyname.com\Policies\{47636445-af79-11d0-
91fe-080036644603}
```

where the second *sysvol* is shared as Sysvol. (The default location of the Sysvol folder is %systemroot%).

**Gpt.ini File**
At the root of each Group Policy template folder is a file called Gpt.ini. For local Group Policy objects, the Gpt.ini file stores information indicating the following:

- Which client-side extensions of the Group Policy Object Editor contain User or Computer data in the GPO.
- Whether the User or Computer portion is disabled.
- Version number of the Group Policy Object Editor extension that created the Group Policy object.

For the local GPO, the Gpt.ini file contains the following information:

```
[General]
gPCUserExtensionNames //Includes a list of GUIDs that tells the client
side engine which Client
                      Side Extensions have User data in the GPO.
                      The format is: [{GUID of Client Side Extension}{GUID of MMC
                      extension}{GUID of second MMC extension if appropriate}]
[repeat first
                      section as appropriate].
```

```
GPCMachineExtensionNames //Includes a list of GUIDs that tells the
client side engine which
                         Client Side Extensions have Machine data in the GPO.

Options..//Refers to GPO options such as User portion disabled or
Machine portion disabled.

GPCFunctionalityVersion //The Version number of the Group Policy
extension tool that created
                       the Group Policy object.
```

**Gpt.ini for Active Directory GPOs**
The Gpt.ini file for Active Directory GPOs contains the following entries, which are stored in Active Directory:

```
Version=0  //Version number of the Group Policy Object
DisplayName //Display name of the GPO
```

**Local Group Policy Objects**
A local Group Policy object exists on every computer, and by default it contains only security policy (that is, other types of policy settings are not configured by default). The local GPO is stored in %systemroot%\System32\GroupPolicy, and it has the following ACL permissions:

- Administrators: full control
- Operating system: full control
- User: read

**Group Policy Template Subfolders**
The Group Policy template folder contains the following subfolders:

- **User**. Includes a Registry.pol file that contains the registry settings to be applied to users. When a user logs on to a computer, this Registry.pol file is downloaded and applied to the **HKEY_CURRENT_USER** portion of the registry.

  The **User** folder may contain the following subfolders (depending on the GPO contents):

  - **Applications**. Contains the advertisement files (.aas files) used by the Windows installer. These are applied to users.
  - **Documents and Settings**. Contains the Fdeploy.ini file, which includes status information about the Folder Redirection options for the current user's special folders.
  - **Microsoft\RemoteInstall**. Contains the OSCfilter.ini file, which holds user options for operating system installation through Remote Installation Services.
  - **Microsoft\IEAK**. Contains settings for the Internet Explorer Maintenance Snap-in.
  - **Scripts\Logon**. Contains all the user logon scripts and related files for this GPO.
  - **Scripts\Logoff**. Contains all the user logoff scripts and related files for this GPO.

- **Machine**. Includes a Registry.pol file that contains the registry settings to be applied to computers. When a computer initializes, this Registry.pol file is downloaded and applied to the **HKEY_LOCAL_MACHINE** portion of the registry.

  The **Machine** folder may contain the following subfolders (depending on the GPO):

  - **Scripts\Startup**. Contains the scripts that are to run when the computer starts up.
  - **Scripts\Shutdown**. Contains the scripts that are to run when the computer shuts down.

- **Applications**. Contains the advertisement files (.aas files) used by the Windows installer. These are applied to computers.

- **Microsoft\Windows NT\Secedit**. Contains the Gpttmpl.inf file, which includes the default security configuration settings for a Windows 2000 domain controller.

- **Adm**. Contains all of the .adm files for this GPO.

The User and Machine folders are created at install time, and the other folders are created as needed when policy is set.

**Registry.pol Files**
The Administrative Templates snap-in extension of Group Policy saves information in the Group Policy template in Unicode files referred to as Registry.pol files; they are stored in the Group Policy template. These files contain the customized registry settings that you specify (by using the Group Policy Object Editor) to be applied to the Computer (**HKEY_LOCAL_MACHINE**) or User (**HKEY_CURRENT_USER**) portion of the registry.

Two Registry.pol files are created and stored in the Group Policy template, one for **Computer Configuration**, which is stored in the **\Machine** subdirectory, and one for **User Configuration**, which is stored in the **\User** subdirectory.

When you use the Administrative Templates extension of the Group Policy Object Editor to define customized registry settings, two Registry.pol files are created and stored in the Group Policy template. One Registry.pol file is for Computer Configuration-related registry settings and is stored in the **\Machine** sub-directory, and the other is for User Configuration settings and is stored in the **\User** sub-directory.

The Registry.pol file consists of a header and registry values.

The header contains version information and signature data, both **DWORD** values:

```
REGFILE_SIGNATURE 0x67655250
REGISTRY_FILE_VERSION 00000001 (increments each time the file format changes)
```

The registry values begin with an opening bracket ([) and end with a closing bracket (]):

```
[key;value;type;size;data]
```

where:

*Key* is the path to the registry key to use for the category. Do not include **HKEY_LOCAL_MACHINE** or **HKEY_CURRENT_USER** in the registry path. The location of the file determines which of these keys is used.

The following value has special meaning for this field:

- ****DeleteKeys**—a semi-colon-delimited list of values to delete.

  For example: ****DeleteKeys NoRun;NoFind**.

*Value* is the name of the registry value. The following values have special meaning for this field:

- ****DeleteValues**—a semi-colon-delimited list of values to delete. Use as a value of the associated key.

- ****Del.valuename**—deletes a single value. Use as a value of the associated key.

- ****DelVals**—deletes all values in a key. Use as a value of the associated key.

*Type* is a data type. The field can be any of the standard registry value types, for example:

- REG_DWORD

- REG_EXPAND_SZ

- REG_SZ

Note that although the file format supports all the registry data types (such as **REG_MULTI_SZ**), the Administrative Templates node does not support these registry types: **REG_BINARY, REG_MULTI_SZ.**

*Size* is the size of the data field in bytes. For example, 4.

*Data* is the raw information. For example, 4 bytes of data 0x00000001.

It is possible that the *valuename*, *type*, *data*, and *size* could be missing or 0. In this case, only the key should be created.

This pattern of [] entries continues until the end of the file.

The following special values are used for deleting keys and values:

- ****DeleteKeys** // Semi-colon-delimited list of keys to delete.

  For example: ****DeleteKeys REG_SZ NoRun;NoFind.**

- ****DeleteValues** // Semi-colon-delimited list of values to delete.

  Used as a value of the designated key.

- ****Del.valuename** // Deletes a single value name.

  Used as a value of the designated key.

- ****DelVals** // Deletes all values in a key.

  Used as a value of the designated key.

The Registry.pol file contains data to be written to the registry based on the settings specified with the Group Policy Object Editor, and the names of any scripts and their command lines (in the form of registry keys and values).

**How Registry.pol Files Are Created**
The following section outlines how to form Registry.pol files:

- When you start the Group Policy Object Editor, a temporary registry tree is created that consists of two nodes: **USER** and **MACHINE**.

- As you navigate the Administrative Templates node of the Group Policy Object Editor, .adm file nodes are displayed. The .adm files within the Group Policy Object Editor nodes are loaded dynamically when a particular node is selected, and the .adm file is then cached.

- When a policy is selected in the details pane (the right side of MMC console window), the temporary registry is queried to determine whether the selected policy already has registry values assigned to it; if it does, those values are displayed in the **Policy** dialog box.

  If the selected policy does not have a registry value assigned to it, the default value from the .adm file or from the associated MMC snap-in extension is used.

- After you modify a policy, the registry values that you specify are written to the appropriate portion of the temporary registry (either **MACHINE** or **USER**).

- When you close the Group Policy Object Editor, the temporary registry hives are exported to the Registry.pol files in the appropriate folders of the Group Policy template.

- The next time you start the Group Policy Object Editor for the same Group Policy Object for which you have previously set Group Policy settings, the registry information from the corresponding Registry.pol files is imported into the temporary registry tree. Therefore, when you view the policy settings, they reflect the current state.

# Appendix C: WMI Filtering

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**How WMI Works**
The WMI filters are evaluated on the client computer after the list of potential GPOs have been determined and filtered based on Security Group membership.

When a filter is applied to a GPO, it will be evaluated on the client computer. The GPO will only be applied if the entire query results in TRUE. Note that a GPO will be processed if no WMI filter has been selected.

During RSoP, in planning mode evaluation, a simulation of the client side processing occurs, producing a result based on the specified WMI Filters evaluation to TRUE.

For example:

- If no WMI filter is selected, all WMI filters are assumed to evaluate to true; therefore, all GPOs will apply.
- If a filter specified in the RSoP wizard matches a given GPO, the GPO will be evaluated.
- In the RSoP wizard, the wizard will show all the filters based on the list of GPOs that apply to a computer or user. If a filter is removed from the filter list, it is assumed to evaluate to false and the GPO that is associated with the filter will not apply.

**Active Directory Schema additions**
A new property called "gPCWQLFilter" has been added to the properties of a GPO. It includes the namespace path and GUID that represents the WMI filter.

**Using WMI in Mixed Environments**
Clients running Windows 2000 or earlier versions do not have support for WMI filters. They may however be affected by a GPO that has specified a WMI filter. In this case, the client will process the GPO as if the filter evaluated to TRUE because it has no way of knowing if it were FALSE.

However, a mixed environment supports the schema changes required to enable WMI filters. Windows Server 2003-based servers with WMI filter-enabled GPOs will continue to handle Windows 2000 clients as they did previously.

WMI filters are only available in domains that have at least one Windows Server 2003 domain controller. In an environment consisting only of Windows 2000 domains, the WMI filter node in GPMC is not shown.

**Examples of WMI Filters**
This section illustrates some scenarios in which administrators use WMI filtering to achieve a specific goal.

**Software inventory-based targeting (Ored set)**
A company purchases a site license for a new bounds-checker tool that helps software developers write more reliable code. Because the bounds-checker only works with Visual Basic®, Visual C, and Visual C++,® the administrator wants to assign the package only on computers running any of these programs.

The administrator chooses the following filter:

Root\cimv2;Select * from Win32_Product where name = "MSIPackage1" OR name = "MSIPackage2" OR name = "MSIPackage32"

| **Note** |
| --- |
| it may be more reliable to use IdentifyingNumber |

**Software inventory-based targeting( Anded set)**
A software company discovers that the interaction of three software products causes instabilities on the system. The company develops a hot fix but only wants to install it on computers where this interaction is possible.

The administrator chooses the following filter:

root\cimv2;Select * from Win32_Product where name = "MSIpackage1"

root\cimv2;Select * from Win32_Product where name = "MSIPackage2"

root\cimv2;Select * from Win32_Product where name = "MSIPackage3"

| **Note** |
| --- |
| it may be more reliable to use IdentifyingNumber. |

**Operating system-based targeting**
An administrator wants to deploy an enterprise monitoring policy but needs to limit the target set to computers running either Windows 2000 Server or Advanced Server.

The administrator chooses the following filter:

Root\CimV2; Select * from Win32_OperatingSystem where Caption = "Microsoft Windows 2000 Advanced Server" OR Caption = "Microsoft Windows 2000 Server"

**Hardware inventory-based targeting**
An administrator wants to deploy a new connection-manager but needs to avoid wasting space on desktop computers without modems where the connection manager would be useless. An administrator can deploy the package across the enterprise with the following WMI-filter:

Root\CimV2;Select * from Win32_POTSModem

**Resource-based targeting**
To encourage field engineers and consultants to use documentation, a company wants to make Help systems available directly on users' hard disks. But because users complain that the Help files consume too much space, a manager decides to only deploy the documentation on computers that have at least 600 megabytes (MB) available.

An administrator can accomplish this with the following WMI filter:

Root\CimV2; Select * from Win32_LogicalDisk where FreeSpace > 629145600 AND Description <> "Network Connection"

**Computer-based targeting**
An administrator wants to set up a policy to encrypt all "My Documents" folders on notebook computers. The administrator determines that all the company's notebook computers are Toshiba Tecra models 800 and 810.

To set up the policy, an administrator uses the following WMI filter:

Root\CimV2; Select * from Win32_ComputerSystem where manufacturer = "Toshiba" and Model = "Tecra 800" OR Model = "Tecra 810"

**Asset tag-based targeting**
An administrator wants to set hardware inventory monitoring policy for all computers with an "asset tag" of 300,000-355555.

To set up the policy, an administrator uses the following WMI filter:

Root\Cimv2 ; Select * from Win32_SystemEnclosure where SMBIOSAssetTag > '300000' AND SMBIOSAssetTag < '355555'

**Hardware configuration-based targeting**
An administrator wants to target a policy for all computers that have a network adapter on interrupt number 11. The administrator chooses the following filter:

Root\cimv2; Associators of {win32_IRQResource.IRQNumber=11} where resultclass = Win32_NetworkAdapter

**Configuration-based targeting**
An administrator wants to avoid turning on "netmon" on computers enabled with multicasting turned on. The administrator chooses the following filter:

Select * from Win32_NetworkProtocol where SupportsMulticasting = true

**File attribute-based targeting**
An administrator only wants to disable sharing of folders on systems where at least one of "My Documents" directories are not

encrypted. The administrator chooses the following filter:

Root\cimv2 ; Select * from Win32_Directory where filename ='my documents' AND encrypted = false

**Time zone-based targeting**
An administrator needs to target a policy on all servers located on the East Coast of the United States. The administrator chooses the following filter:

Root\cimv2 ; Select * from win32_timezone where bias =-300

**Hot fix-based targeting**
An administrator only wants to apply a policy on computers that have a specific hot fix. The administrator chooses the following filter:

Root\cimv2 ; select * from Win32_QuickFixEngineering where HotFixID = 'q147222'

**Further Information**
The WMI SDK has a tool called cimstudio. This allows users to find a class, searching by name, description, property name, and so forth. Users can then experiment with queries on the class and optimize it before creating a new filter. For more information, see Windows Management Instrumentation in the Microsoft Platform SDK at http://msdn.microsoft.com/library/default.asp?url=/library/en-us/wmisdk/wmi/wmi_start_page.asp.

# Glossary (Group Policy Infrastructure)

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This section presents terminology used in this document.

**Active Directory**

The Windows 2000 Server and Windows Server 2003 directory service that stores information about all objects on the computer network and makes this information easy for administrators and users to find and apply. With Active Directory, users can gain access to resources anywhere on the network with a single logon. Similarly, administrators have a single point of administration for all objects on the network, which can be viewed in a hierarchical structure.

**administrative templates (.adm files)**

Template files that provide settings pertaining to Windows 2000, Windows NT 4.0, and Windows 95, Windows 98, and Windows Millennium Edition operating system and registry structure. The .adm file specifies the registry settings that can be modified through the Group Policy Object Editor user interface. The .adm file consists of a hierarchy of categories and subcategories that together define how the options are displayed through the Group Policy Object Editor user interface. It also indicates the registry locations where changes should be made if a particular selection is made, specifies any options or restrictions (in values) that are associated with the selection, and in some cases, specifies a default value to use if a selection is activated.

**Administrative Templates snap-in extension**

A Group Policy Object Editor extension that includes all registry-based Group Policy, which you use to define settings that control the behavior and appearance of the desktop, including the operating system and applications. The Administrative Templates snap-in extension includes functionality for managing disk quotas.

**application assignment**

You can assign applications to either a user or a computer using Group Policy. When you assign applications to a computer, the application is automatically installed the next time the computer is started. When you assign applications to a user with Group Policy, the administrator can choose to either have the application installed on-demand when the user selects the application or in-full when the user next logs on:

- **On Demand.** If the application is installed on demand, the user's computer is set up with a Start menu shortcut, and the appropriate file associations are created in the registry. To the user, it looks and feels as if the application is already present. However, the application is not fully installed until the user needs the application. When the user attempts to open the application or a file associated with that application, Windows Installer checks to make sure that all the files and parameters of the application are present for the application to properly execute. If they are not present, Windows Installer retrieves and installs them from a predetermined distribution point. Once in place, the application opens.

- **Full Install.** The full-install option is useful for specific groups of users such as frequent travelers who might require all available applications to be fully installed before they travel. With full install, a user's applications are installed at logon.

**application publishing**

In Windows 2000 and Windows Server 2003, you can use the Software Installation snap-in extension of the Group Policy Object Editor to *publish* applications to users. Published applications are those that the administrator makes available for on-demand use.

Published applications have no presence on the users' computers. That is, no shortcuts or Start menu references to the application are present on the desktop. A published application is advertised to Active Directory. The advertised attributes are used to locate the application and all the information required for installing it. After the application is advertised in Active Directory, users can activate it by document association, just as an assigned application. Users can also set up the program using the Add or Remove Programs Control Panel tool on their desktop.

**.cab file**

A .cab file contains one or more files, all of which are downloaded together in a single compressed cabinet file. Included in the cabinet is an .inf file that provides further installation information. The .inf file may refer to files in the .cab and to files at other URLs.

**discretionary access control list (DACL)**

A part of the security descriptor that specifies the groups or users that can access an object, as well as the types of access (permissions) granted to those groups or users. *See also* security descriptor.

**disk quotas**

Within the Administrative Templates node of the Group Policy Object Editor are policy options for managing disk quotas, which administrators can use to monitor and limit disk space use for NTFS volumes formatted as NTFS version 5.0. After you enable disk quotas, you can set options for disk quota limits and warnings.

**domain**

A grouping of servers and other network objects under a single name. Domains provide the following benefits:

- You can group objects into domains to help reflect your company's organization in your computer network.
- Each domain stres only the information about the objects located in that domain. By partitioning the directory information this way, Active Directory scales up to as many objects as you need to store information about on your network.
- The administraor of a domain has absolute rights to set policy settings within that domain only.

**domain trees**

You can combine multiple domains into structures called domain trees. The first domain in a tree is called the root of the tree, and additional domains in the same tree are called child domains. A domain immediately above another domain in the same tree is referred to as the parent of the child domain.

All domains within a single domain tree share a hierarchical naming structure. Domains that share a common root share a contiguous namespace. Domains in a tree are joined together through two-way, transitive trust relationships. These trust relationships are two-way and transitive, therefore, a domain joining a tree immediately has trust relationships established with every domain in the tree.

**Folder Redirection snap-in extension**

A Group Policy Object Editor extension that you use to place the Windows 2000 or Windows Server 2003 special folders in network locations other than their default location (%systemroot%\Documents and Settings\%userprofile%) on the local computer.

**globally unique identifier (GUID)**

A 128-bit integer that identifies a particular object class and interface. GUIDs are virtually guaranteed to be unique. A GUID can be generated using either the uuidgen.exe utility from the Platform Software Development Kit, or the GUIDgen tool included in the Microsoft Visual C++® development system. For more information about GUIDs, see the OLE Programmer's Reference, Volume One; the Platform Software Development Kit documentation; and Inside OLE, 2d ed. by Kraig Brockschmidt, Redmond, Wash.: Microsoft Press, 1995.

**Group Policy**

A component used in Windows 2000 and Windows Server 2003 to define options for managed desktop configurations for groups of users and computers. To specify Group Policy options, you use GPMC in conjunction with the Group Policy Object Editor.

**Group Policy engine**

The part of Group Policy that runs in the Winlogon process.

**Group Policy Management Console (GPMC)**

An MMC console to view and edit Group Policy properties, generate reports, copy, import, backup, restore, and to select GPOs for editing. GPMC lets administrators manage Group Policy for multiple domains and sites within a given forest, all in a simplified user interface with drag-and-drop support. Operations are fully scriptable, which lets administrators customize and automate management.

**Group Policy object**

The Group Policy settings that you create by using the Group Policy Object Editor are contained in a GPO, which is in turn associated with selected Active Directory containers: sites, domains, and organizational units (organizational units).

**Group Policy Object Editor**

To edit a specific desktop configuration for a particular group of users and computers, you use the Group Policy Object Editor, also known previously as the Group Policy snap-in, Group Policy Object Editor, or GPedit.

You can specify Group Policy settings for the following:

- Registry-based policy settings—Includes Group Policy for the Windows 2000 and Windows Server 2003 operating systems and their components and for applications. To manage these settings, use the Administrative Templates node of the Group Policy Object Editor.
- Security settings—Includes options for local computer, domain, and network security settings.
- Software Installation and Maintenance options—Used to centrally manage application installation, updates, and removal.
- Script options—Includes scripts for computer startup and shutdown and user logon and logoff.
- Folder Redirection options—Allows administrators to redirect users' special folders to the network.
- Internet Explorer Maintenance—Used to manage and customize Internet Explorer on Windows 2000- and Windows Server 2003-based computers.
- Remote Installation Services—Used to control the behavior of the Remote Operating System Installation feature as displayed to client computers

**Group Policy Modeling**

This is a simulation of what would happen under circumstances specified by an administrator. Group Policy Modeling requires that you have at least one domain controller running Windows Server 2003 because this simulation is performed by a service running on a domain controller that is running Windows Server 2003. With Group Policy Modeling, you can either simulate the RSoP data that would be applied for an existing configuration, or you can perform "what-if" analyses by simulating hypothetical changes to your directory environment and then calculating the RSoP for that hypothetical configuration. For example, you can simulate changes to security group membership, or changes to the location of the user or computer object in Active Directory. Outside of GPMC, Group Policy Modeling is referred to as RSoP - planning mode.

**Group Policy Results**

This represents the actual policy data that is applied to a given computer and user. It is obtained by querying the target computer and retrieving the RSoP data that was applied to that computer. The Group Policy Results capability is provided by the client operating system and requires Windows XP, Windows Server 2003 or later. Outside of GPMC, Group Policy Results is referred to as RSoP - logging mode.

**IntelliMirror**

IntelliMirror refers to the ability to provide users with consistent access to their applications, application settings, roaming user profiles, and user data, from any managed computer—even when they are disconnected from the network. IntelliMirror is delivered via a set of Windows features that enable IT administrators to implement standard computing environments for groups of users and computers.

IntelliMirror can significantly boost user productivity and satisfaction by doing the following:

- Allowing users to continue working efficiently in intermittently connected or disconnected scenarios by enabling uninterrupted access to user and configuration data under these conditions.
- Delivering a consistent computing environment to users from any computer when their desktop or laptop computer is unavailable or in scenarios where users are not assigned a specific computer.
- Minimizing data loss by enabling centralized backup of user data and configuration files by the IT organization.
- Minimizing user downtime by enabling automated installation and repair of applications.
- Implementing IntelliMirror also boosts administrator efficiency and reduces IT costs by doing the following:

- Eliminating the need to manually configure user settings, install applications, or transfer user files to provide users access to their computing environments on any computer.
- Enabling scenarios where users don't have an assigned computer but log in to any available computer in a pool of computers. This helps reduce hardware and administration costs.
- Easing the IT task of implementing centralized backup of user files while satisfying need for these files to be available on the user's computer.
- Reducing support costs by using Windows Installer to automatically repair broken application installations.
- IntelliMirror is implemented by means of a set of Windows features, including Active Directory, Group Policy, Software Installation, Windows Installer, Folder Redirection, Offline Folders, and Roaming User Profiles.

**Internet Explorer Maintenance**

A Group Policy extension snap-in that includes policy settings to manage the following: Browser User Interface, Connection Settings, Custom URLs, Security, and Program Associations.

**Microsoft Management Console (MMC)**

A common console framework for system-management applications. The primary goal of the Microsoft Management Console is to support simplified administration and lower cost of ownership through tool integration, task orientation, support for task delegation, and overall interface simplification. MMC console hosts the administrative tools (these are called MMC snap-ins); the console itself provides no management functionality.

**Migration table**

A migration table is a file that maps references to users, groups, computers, and UNC paths in the source GPO to new values in the destination GPO. A migration table consists of one or more mapping entries. Each mapping entry consists of a type, source reference, and destination reference. If you specify a migration table when performing an import or copy, each reference to the source entry will be replaced with the destination entry when writing the settings into the destination GPO. Migration tables store the mapping information as XML, and have their own file name extension, .migtable. You can create migration tables using the Migration Table Editor (MTE). The MTE is a convenient tool for viewing and editing migration tables without having to work in, or be familiar with, XML. The MTE is associated with the .migtable extension so that when you double click a migration table, it opens in the MTE. The MTE is installed with GPMC.

**MMC snap-in**

Tools that extend MMC console and provide administrative functionality. A snap-in functions independently from other snap-ins.

**MMC extension snap-in**

A tool that enhances the functionality of a parent snap-in. An extension depends on a parent snap-in for contextual data.

**organizational unit (organizational unit)**

A type of directory object contained within domains. organizational units are logical containers into which you can place users, groups, computers, and even other organizational units.

**registry**

A database in which Windows NT internal configuration information and computer- and user-specific settings are stored.

**registry hive**

A section of the registry that is saved as a file. The registry subtree is divided into hives (named for their resemblance to the cellular structure of a beehive). A hive is a discrete body of keys, subkeys, and values.

**Remote Installation Services**

A component that administrators can use to remotely install a local copy of the Windows 2000 Professional or Windows XP Professional on supported computers throughout their organization. Administrators can deploy a new version of an operating system upgrade to large numbers of clients at one time from a centralized location.

Administrators can use Group Policy to specify the client installation options that groups of users can access. These options are determined by the specific Remote operating system Installation Group Policy settings that administrators define for the site, domain, or organizational unit to which the users belong, in conjunction with the specific security group or user account.

**Resultant Set of Policy (RSoP)**

RSoP allows administrators to see the effect of Group Policy on a targeted user or computer. RSoP is an infrastructure leveraged by GPMC to enable Group Policy Results and Group Policy Modeling. In Group Policy Results, administrators assess what has applied to a particular target. In Group Policy Modeling, administrators can see how policy settings would be applied to a target and then examine the results before deploying a change to Group Policy.

**Roaming user profile**

A copy of the local user profile stored on a server share. This profile is downloaded every time that a user logs on to any computer on the network, and any changes made to a roaming user profile are synchronized with the server copy upon logoff. See also user profile.

**schema**

The formal definition of all object classes, and the attributes that make up those object classes, that can be stored in the directory. Active Directory includes a default schema, which defines many object classes, such as users, groups, computers, domains, organizational units, and security policy settings. The Active Directory schema is dynamically extensible; this means that you can modify the schema by defining new object types and their attributes and by defining new attributes for existing objects. You can do this either programmatically with the Schema Manager snap-in tool included with Windows NT Server.

**scripts**

Batch files (.bat) or executable (.exe) files that run when a computer starts up or shuts down or when a user logs on or off at any type of workstation on the network. Windows 2000 and Windows Server 2003 support Windows Script Host Visual Basic Scripting Edition (VBScript) and Jscript, while continuing to support MS-DOS command scripts and executable files.

**security descriptor**

A set of access-control information attached to every container and object on the network. A security descriptor controls the type of access allowed to users and groups. Administrators assign security descriptors to objects stored in Active Directory in order to control access to resources or objects on the network.

A security descriptor lists the users and groups that are granted access to an object (a file, printer, or service, for example), and the specific permissions assigned to those users and groups. *See also* discretionary access control list *and* system access control list.

**Security Settings extension snap-in**

A Group Policy extension snap-in that you use to define security configuration for computers within a GPO. A security configuration consists of settings applied to each security area supported for Windows 2000 or Windows XP Professional and Windows 2000 Server and Windows Server 2003. This configuration is included within a GPO.

**site**

In Windows 2000 and Windows Server 2003 you register your network's physical topology by defining sites. A site is defined as one or more IP subnets. Windows 2000 and Windows Server 2003 uses site information to direct requests from one computer to be fulfilled by another computer at the same site. For example, when a workstation logs on, Active Directory uses the TCP/IP address of the workstation, along with the site information you have entered, to locate a domain controller on the local site. This local controller is used to service the workstation's requests.

**Scripts extension snap-in**

A Group Policy extension snap-in that you use to assign scripts to run at computer startup or shutdown or upon user logon or logoff.

**Software Installation extension snap-in**

A Group Policy extension snap-in that you use to centrally manage software distribution in your organization.

**system access control list (SACL)**

Part of a security descriptor that specifies which user accounts or groups to audit when accessing an object, the access events to be audited for each group or user, and a Success or Failure attribute for each access event, based on the permissions granted in the object's DACL.

**tattooing**

This refers to a registry setting that is set using Windows NT 4.0 System Policies, the setting persists until the specified policy is reversed or the user edits the registry.

**total cost of ownership (TCO)**

Refers to the administrative costs associated with computer hardware and software purchases, deployment and configuration, hardware and software updates, training, maintenance, and technical support.

**user profile**

A user profile describes the desktop computing configuration for a specific user, including the user's environment and preference settings. A profile is created the first time that a user logs on to a computer running Windows Server 2003, Windows XP, Windows 2000, or Windows NT Workstation. A user profile is a group of settings and files that defines the environment that the system loads when a user logs on. It includes all the user-specific configuration settings, such as program items, screen colors, network connections, printer connections, mouse settings, and window size and position. Profiles are not user policies and the user has a profile even if you don't use Group Policy.

**Windows Installer packages (.msi files)**

Packages that contain all the information necessary to describe to the Windows Installer how to set up an application in every conceivable situation: various platforms, different sets of previously installed products, earlier versions of a product, and numerous default installation locations. The Software Installation extension snap-in to the Group Policy Object Editor uses .msi packages.

**Windows Management Instrumentation (WMI)**

A management infrastructure that supports monitoring and controlling system resources through a common set of interfaces and provides a logically organized, consistent model of Windows operation, configuration, and status. WMI Filtering in Windows Server 2003 allows you to create queries based on this data. These queries (also called WMI filters) determine which users and computers receive all of the policy configured in the GPO where you create the filter.

# Multiple Forest Considerations in Windows 2000 and Windows Server 2003

Updated: April 8, 2004

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The goal of this paper is to present an overview of the effort and infrastructure that might be required to enable varying levels of collaboration among multiple forests that have domain controllers that are running Microsoft® Windows® 2000 Server or Microsoft® Windows Server™ 2003 operating systems. This paper enumerates the scenarios in which a multiforest environment might be necessary or desirable and analyzes the consequences of such an environment on the total cost of ownership of the enterprise.

**In This White Paper**

Who Should Read This Paper

Introduction (Multiple Forest Considerations in Windows 2000 and Windows Server 2003)

Multiforest Deployments

Additional Costs of Deploying Multiple Forests

Additional Configuration for Functionality Across Forests (Multiple Forest Considerations in Windows 2000 and Windows Server 2003)

Multiforest Feature Implementation and Cost Summary (Multiple Forest Considerations in Windows 2000 and Windows Server 2003)

# Who Should Read This Paper

Updated: April 8, 2004

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This paper is intended for architects and project managers who are designing an Active Directory deployment and have identified a potential need for multiple Active Directory forests, or who have an existing single-forest environment that must change to accommodate multiple forests. They can use this paper to help them understand the impact of deploying multiple Active Directory forests on total cost of ownership, and draw up their plans accordingly.

This paper is not intended to provide recommendations for when to deploy multiple forests or prescriptive guidelines for how to deploy multiple forests. The goal is to present a high-level view of the configuration changes that are required to enable collaboration between forests. Microsoft intends to issue a deployment guide that provides detailed instructions for implementing these configuration changes.

For more information about the conditions that warrant deploying multiple forests, see "Design Considerations for Delegation of Administration in Active Directory." You can view this document on the Microsoft® TechNet Web site at http://www.microsoft.com/technet/prodtechnol/windows2000serv/technologies/activedirectory/plan/addeladm.mspx.

For general Active Directory deployment planning information, see "Best Practice Active Directory Design for Managing Windows Networks." You can view this document on the Microsoft TechNet Web site at http://www.microsoft.com/technet/prodtechnol/windows2000serv/technologies/activedirectory/plan/bpaddsgn.mspx.

For information about deploying Microsoft® Exchange 2000 Server with Active Directory in a Windows 2000 Server environment, see "Best Practice Active Directory Design for Exchange 2000." You can download this document from the Microsoft Web site at http://go.microsoft.com/fwlink/?LinkId=10517.

# Introduction (Multiple Forest Considerations in Windows 2000 and Windows Server 2003)

Updated: April 8, 2004

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Active Directory infrastructure necessarily provides a certain amount of forestwide oversight that enables administrators in the forest root domain to manage schema data, configuration data, and domain controllers. The control granted to these administrators carries with it the potential for misuse by malicious administrators. In addition, where autonomy or isolation is required, the level of security afforded by a single domain might not be adequate. In particular, large organizations might have organizational, legal, or operational requirements that warrant dividing control between separate forests.

The need to deploy multiple forests might be recognized and accommodated during initial deployment planning, or might occur as an unplanned requirement of an organizational change after deployment. Both cases have important ramifications, as follows:

- Planned multiforest deployment: During planning for multiple forests, be sure that you carefully weigh the advantages against the added costs of implementation.
- Unplanned multiforest deployment: If business decisions result in a merger, acquisition, or divestiture that creates a need to add one or more forests to the deployed environment, be prepared for a gradual process of implementing multiple forests and enabling collaboration across forests.

The division of a Windows deployment into multiple Active Directory forests must be undertaken with the understanding that some of the functionality that is available by default in a single Active Directory forest requires additional configuration in a multiforest deployment.

| **Note** |
| --- |
| Some single-forest functionality is not available in multiforest deployments for applications using Active Directory. For example, certain mailbox-related features are not available in multiforest deployments that implement Microsoft Exchange 2000 Server, and require a workaround solution. For information about these features and solutions, see "Features that are Unavailable Across Forests" later in this paper. |

To coordinate the data and services of multiple forests to serve a single organization, the following functionality requires additional configuration:

- Domain Name System (DNS) name resolution across forest boundaries.
- Microsoft Exchange 2000 Server and later functionality, including synchronization of address list information across multiple forests and synchronization of free and busy calendar information.
- Access to resources across the forests.
- Infrastructure data synchronization across the forest boundaries.
- Application data synchronization across multiple forests.

| **Note** |
| --- |
| This paper does not provide step-by-step configuration instructions. Microsoft intends to issue a deployment guide to address deployment information. |

In this paper, the rationale for each additional configuration is explained, as well as an overview of the planned and unplanned conditions for, and effects of, deploying multiple forests.

**What This Paper Does Not Cover**

It is not a goal of this paper to provide recommendations for when to deploy multiple Active Directory forests rather than a single Active Directory forest. If you are planning to deploy multiple forests, it is assumed that you have analyzed operational, organizational, and legal requirements for Active Directory and have determined that one or more requirements are consistent with creating multiple Active Directory forests.

Preliminary reading to examine these conditions includes the following:

- For a detailed explanation of the conditions that warrant partitioning a Windows network between multiple forests to achieve service autonomy, service isolation, or data isolation, see "Design Considerations for Delegation of Administration in Active Directory." You can view this document on the Microsoft TechNet Web site at http://www.microsoft.com/technet/prodtechnol/windows2000serv/technologies/activedirectory/plan/addeladm.mspx.

- For general Active Directory deployment planning information, see "Best Practice Active Directory Design for Managing Windows Networks." You can view this document on the Microsoft TechNet Web site at http://www.microsoft.com/technet/prodtechnol/windows2000serv/technologies/activedirectory/plan/bpaddsgn.mspx.

- In addition, this paper does not provide:

- Prescriptive step-by-step instructions for how to configure features in multiple forests. Microsoft intends to issue a deployment guide with instructions for how to implement configuration changes.

- Recommendations for whether to merge or "bridge" multiple forests when companies merge, or instructions for how to do so.

- Instructions for how to spin off a separate forest in preparation for a divestiture.

# Multiforest Deployments

Updated: April 8, 2004

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The decision to deploy multiple forests is often associated with the need to manage directory services independently (autonomy) or to manage data or services without threat of interference (isolation). In Microsoft® Windows NT® 4.0 operating system deployments, the domain is the ultimate component and is discrete in its management and its boundaries. With the introduction of Active Directory® in Microsoft Windows® 2000, a new category of *forest* was introduced, and the forest has service and data implications for all domains.

Availability of service and data isolation or autonomy in an Active Directory domain depends not only on the administrator of that domain and forest administrators, but also on other domain administrators within a forest.

When designing your forest, keep in mind that administrative independence has a cost and that you must carefully consider the tradeoff between autonomy or isolation versus interoperation and collaboration.

**Management Autonomy and Isolation**

Management of Active Directory can be divided into two general categories:

- Service management: Configuration and delivery of the directory service.
- Data management: Creation and management of directory contents (account management, organizational unit administration).

Active Directory provides tools for the delegation of control over these areas of management, and delegation can occur at several levels, including forest, domain, and organizational units. At each of these levels and for each of their respective service or data categories, the need for independence can vary widely, depending on the nature of the organization.

In most cases, an appropriate and adequate level of control can be delegated within a single forest by using domains and organizational units to manage data and by the ability to trust service managers at the forest root level. However, the following requirements for independence can exceed the limitations of single-forest delegation of control:

- Service autonomy: Provides the ability to independently manage and manipulate the schema and configuration containers. The need for this level of control is usually driven by organizational structure or operational requirements. For example, one division of a company wants to install directory-enabled applications that extend the schema without depending on approval by the central Information Technology (IT) department.
- Service isolation: Provides the assurance that no administrator outside the organization can interfere with the operation of the directory service. The need for this level of control is usually driven by legal or operational requirements. For example, suppose a hosting company needs to place domain controllers on a customer's premises. If a breach of domain controller security can affect service delivery in the rest of the forest, that customer's operations can be separated into its own forest to better protect other clients of the directory service.
- Data isolation: Provides the assurance that no service administrators outside of a limited scope of administrators can control or view any subset of data on a domain controller or on member computers joined to the forest. The need for this level of control is usually based on a legal requirement. For example, a financial institution might be required by law to limit access to data that belongs to clients in a particular jurisdiction to the users, computers, and administrators in that jurisdiction.

**Unplanned Deployments**

The need for multiforest deployment is not always planned in advance. A change from a single-forest deployment to a multiforest deployment might be required to accommodate the following business decisions:

- Mergers and acquisitions: Assuming the merged or acquired organizations operate one or more existing forests, you might need to enable collaboration between users and resources from the different parts of the new and original organizations.
- Divestitures: When a decision is made to divest your company of certain portions of the organization, you can create a

forest to accommodate the users and resources in the departments that are being transferred in advance of the actual organizational spin-off and enable collaboration between the original forest or forests and the spun-off forest.

- Grass-roots deployments: In the event that one or more divisions within your organization deploy their own forest without consulting the central IT department, consider the following courses of action:

    - If no central forest has yet been deployed by the IT department, use the existing forest as the main forest for the entire organization, provided the existing forest satisfies your Active Directory design requirements.

    - If an IT forest already exists, merge the IT forest and the grass-roots forest into a single, central IT forest.

    - If an IT forest already exists, implement a multiforest deployment.

**Levels of Collaboration**
The level of collaboration determines which functionality needs to be enabled across the forests and, as a result, determines part of the additional cost associated with deploying multiple forests. As the first step in evaluating the cost of enabling functionality across forests, assess the level of collaboration that your business requires. Use the following example scenarios to help determine the functionality you want to enable on the basis of the needed levels of collaboration.

**Scenario 1: Organizations Share Only Address List Information**
For organizations that require operational and organizational independence, collaboration needs are minimal. For example, a holding company for banks manages businesses that remain competitors. Because the businesses compete, they do not merge to a single forest, modify the messaging system, nor share any resources. Employees of these banks, however, need the ability to look up the phone numbers, office locations, and perhaps managerial information of personnel in the other divisions of the company, and to communicate by e-mail.

These organizations have the following operating conditions and requirements:

- No resource sharing.

- No authentication of users across forests.

- Independent Exchange Server organizations, but commonly viewable global address list between the forests.

In this scenario, the only collaboration requirement is the need to view address information of the users in different forests. The only configuration that is required for this scenario is to enable Exchange address list synchronization between the forests. The cost of this added functionality is that of deploying and operating a directory data synchronization product such as Microsoft Identity Integration Server 2003. An integrated address list synchronization solution works in conjunction with Microsoft Identity Integration Server 2003 to implement address list synchronization.

For more information about implementing address list synchronization, see “Synchronizing Exchange Data Across Forests” later in this paper.

**Scenario 2: Organizations Share Schedule Information**
In this scenario, in addition to the ability to view address list information, users in the separate forests need to schedule meetings with each other and to use other workflow applications that use Exchange public folders. An example of an organization that requires this type of collaboration is a holding company that includes multiple companies (for example, pharmaceutical companies) that compete with each other. For this reason, the companies require separate forests, messaging system, and prevention of resource access from outside of the forests. At the same time, however, they must conduct joint research projects. These joint research projects involve experts from different organizations working together in virtual teams. To enable these experts to schedule meetings and conference calls with each other, the organization decides to synchronize public folders, which also include free and busy calendar information, to make it viewable outside of the forest boundaries.

For businesses that have separate Exchange organizations, this level of collaboration has the following requirements:

- No resource sharing.

- No authentication of users across forests.

- Address list synchronization as described in Scenario 1.

- Free and busy information synchronization (public folder synchronization).

Synchronizing free and busy information involves synchronizing Exchange public folders across forests. The information that is required for scheduling meetings is stored only in public folders on Exchange servers, and not in Active Directory. The solution for enabling this functionality is to use a public folder synchronization tool to synchronize the contents of the Exchange system public folders between forests.

For more information about synchronizing public folders, see "Synchronizing Exchange Data Across Forests" later in this paper.

**Scenario 3: Organizations Share Resources**
In this scenario, the organizations need to be able to assign access to resources in one forest to groups of users in another forest. In addition, users need to be able to look up other users throughout the organization by using the global address list, and to view free and busy calendar information to enable them to schedule meetings with people in different forests.

This scenario is commonly used in the following real-life cases:

1. Two organizations merge and their management decides to eventually merge directory or messaging infrastructures, or both. Because merging directory and messaging infrastructures is a time-consuming process, the IT department is tasked with enabling single sign-on capability for resource access outside of a forest and to simulate the experience of single-forest messaging, in which address lists are viewable and free and busy information is available for all users in both forests.

2. Two organizations merge, but unfortunately domain controllers of one organization are located in less secure location(s) than domain controllers of the other organization. The IT department of the less secure organization does not accept the level of physical security of domain controllers in the more secure organization. For this reason, these administrators decide to not merge their directory and messaging infrastructures. At the same time, businesses of these two organizations need close collaboration, which requires single sign-on capability for resource access outside of a forest and the same messaging experience that is available in a single forest.

3. An enterprise has deployed a test selfhost forest where new configurations, operations, and applications are deployed before they are deployed in the main production forest. All employees are equally trusted and need access to various resources in both forests, and therefore users must have access to the same resources, regardless of which forest contains a user's account. Although deploying a single messaging system is feasible in an environment where employees are equally trusted, this organization chooses to deploy Exchange Server in each forest to completely simulate the main production forest environment. In this way, they can identify any disruptions to messaging before any new configurations, operations, or applications are deployed in the main production forest.

This level of collaboration includes:

- Bridged DNS infrastructures.

- Separate Exchange organizations, but a commonly viewable global address list.

- Free and busy information synchronization between Exchange organizations in separate forests.

- Resource sharing among users across both forests:

    - Controlled sharing or full sharing.

    - Security groups can have members from both forests.

    - Access control lists (ACLs) can list security principals from both forests.

- Single sign-on between forests: User logon experience is the same for access to resources in any forest.

Solutions for this scenario involve configuring DNS to locate servers in the different forests. Enabling resource access requires trust relationships between domains in different forests as well as appropriate groups and permissions for resource sharing.

For the forest functional level of Windows Server 2003, forest trust relationships are available that enable bidirectional, transitive trust relationships between all domains in the respective forests. For Windows 2000 forests or Windows Server 2003 forests that have a functional level other than Windows Server 2003, you must manually create explicit trust relationships between specific domains to enable resource sharing.

| ⚠**Caution** |
| --- |
| External trust relationships between Windows 2000 domains in different forests are created with security identifier (SID) filter quarantining turned off by default. If you plan to implement external trust relationships, see article Q289243, "Forged SID Could Result in Elevated Privileges in Windows 2000," in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://go.microsoft.com/fwlink/?LinkId=291. |

For more information about bridging DNS, see “Enabling DNS Name Resolution Across Different Forests” later in this paper. For more information about enabling resource sharing and single sign-on between forests, see “Enabling Resource Access Across Forests” later in this paper. For more information about address list synchronization, see “Synchronizing Exchange Data Across Forests” later in this paper.

**Scenario 4: Organizations are Completely Integrated and Share a Single Exchange Organization**

To reduce the cost of providing a messaging solution, administrators might agree to deploy a single Exchange 2000 organization to serve an entire enterprise, in which case their messaging infrastructure does not need to be synchronized. This solution offers tighter integration because a single Exchange Server organization can span multiple forests without additional configuration.

An example of a tightly integrated multiforest organization is a factory that has assembly lines that must never be stopped because the consequences of stopping the assembly line could be devastating for the organization. Considering the mission-critical role of the assembly line, and because the functionality of the assembly line depends on an Active Directory-integrated application, the IT team deploys a separate assembly-line forest that has no external dependencies. For example, this forest might have no dependency on network connectivity, or perhaps it cannot accept the level of service that is provided for the corporate forest in terms of the time required for the IT department to respond to failures.

Some users have accounts in the assembly-line forest. These users roam throughout the company on a regular basis and they use laptops that are joined to the assembly-line forest. They often need access to file shares on the Distributed File System (DFS) servers in the corporate forest and to use printers that are located in the corporate forest. In addition to the DNS integration and resource sharing that is described in Scenario 3, the following functionalities can also be configured to accommodate the needs of these roaming users:

- Site and subnet synchronization.
- Printer information.

For more information about site and subnet information, see “Synchronizing Sites and Subnets” later in this paper. For more information about making printer information available across forests, see “Locating Printers Across Forests” later in this paper.

# Additional Costs of Deploying Multiple Forests

Updated: April 8, 2004

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The most significant disadvantage to deploying multiple forests is the added costs involved with providing additional teams and training for multiple deployments, as well as additional configuration. When you deploy multiple forests as opposed to a single forest, additional costs include:

- Design: Different teams need to design their individual forest, which requires the cost of educating additional IT professionals and the cost of their time invested in the design process itself.
- Implementation: Different teams need to deploy, monitor, and operate a separate forest, which requires the cost of training more IT professionals and the cost of their time invested in these activities.
- Collaboration across forests: Extra cost might be associated with collaborating on the configuration and monitoring of the additional features that are not required for a single-forest deployment, including:
    - Collaboration between forest administrators and possibly domain administrators.
    - Additional software and hardware.
- Training for additional configuration requirements.
- The actual configuration of the specific features that are required to implement single-forest functionality across forests.

If deploying multiple forests is an option rather than a requirement, then prior to deployment you must be sure that the advantages of service autonomy, service isolation, or data isolation outweigh these additional costs.

# Additional Configuration for Functionality Across Forests (Multiple Forest Considerations in Windows 2000 and Windows Server 2003)

Updated: April 8, 2004

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Although most of the operations performed by users and administrators in a multiforest deployment rely on functionality within their own forests, some operations require additional configuration to extend the underlying functionality across the forest boundaries.

In addition to administrative collaboration that is involved in cooperatively operating multiple forests, the following features require additional configuration to enable collaboration across forests:

- DNS name resolution: Enable DNS name resolution between forests to provide domain controller and resource location functionality.
- Access to resources:
    - Establish trust relationships between user domains and resource domains.
    - Configure the access control lists (ACLs) of resources to allow access to appropriate groups from different forests, and create new groups to accommodate forest roles across forests.
- Synchronization of sites and subnets: Enable each forest to recognize the entire scope of the network. To allow clients in one forest to locate the nearest domain controller in another forest and enable access to DFS file shares with minimum network traffic, configure the same sites and subnets in all forests.
- Storage and retrieval of application data: Provide computers of all forests with the ability to access application data in any forest.
- Printer location: Synchronize printer information.
- Exchange Server integration: Enable address list synchronization and free and busy calendar information.

The topics in this section contain discussion of the essentials of each configuration at a high level but do not provide specific configuration instructions. Microsoft intends to issue a deployment guide with instructions for how to enable the functionality described in this section.

**Enabling DNS Name Resolution Across Different Forests**
Successful Active Directory deployment requires DNS for name resolution. The ability to resolve an IP address from the DNS name of a computer is necessary for the location of domain controllers and resources by users and computers.

**Issue**
With multiple forests, name resolution is required to function between forests so that users and computers in one forest can locate resources and domain controllers in the other forest.

Best practices for designing the DNS namespace and providing DNS support for deployment of a single Active Directory forest are provided in the "Best Practice Active Directory Design for Managing Windows Networks." You can view this document on the Microsoft TechNet Web site at http://go.microsoft.com/fwlink/?LinkId=10478. In the process of designing your multiforest Active Directory deployment, follow these recommendations for each individual forest. After you have completed the DNS design for each individual Active Directory forest, you must analyze the requirements to enable name resolution across the forest boundaries.

The ability to resolve the names from the namespace of a different forest is required by the following activities:

- User or computer needs to locate a resource (for example, an Exchange server, file share, or service) that is hosted on a

computer that is joined to a different forest.

- User or computer needs to locate a domain controller in a different forest for the purpose of authenticating to a resource in that forest.

In most scenarios, you will need to ensure name resolution across different forests.

**Solution**
The need for additional DNS configuration to enable name resolution across forests depends on your current DNS infrastructure and on any DNS design that might be planned for new Active Directory forests. The most common DNS scenarios are described below and relevant configuration requirements are enumerated for each.

If a user in a fictitious organization A (Org A) needs to locate resources in organization B (Org B), or vice versa, different configuration changes apply for each of the following scenarios:

- In Figure 1, Org A has a root DNS server that hosts the root (".") zone. In  In Figure this scenario, a delegation is set up on the root DNS server that hosts the root zone in Org A. This delegation consists of a host (A) resource record and a name server (NS) resource record for the DNS servers that host the highest-level DNS domain in Org B. The effect of these resource records is that queries originating in Org A for names within the namespace of Org B are referred to the DNS servers in Org B. Figure 1 shows the delegation from Org A to Org B.

**Figure 1 Delegation from DNS server hosting root zone in Org A to enable resolution of names in Org B**

- In Figure 2, Org A has no root zone, but DNS servers running a member of the Windows Server 2003 operating systems are configured to forward queries up the namespace, eventually to the Internet. In this scenario, conditional forwarding must be configured on a DNS server in Org A to forward queries ending with a particular suffix (in this case, the suffix of Org B) to DNS servers in Org B. DNS servers in Org A can forward to any level in the namespace of Org B. Figure 2 shows conditional forwarding from Org A to Org B.

**Figure 2 Conditional forwarding from Org A to Org B**

| Note |
| --- |
| Conditional forwarding is available only in Windows Server 2003. |

- In Figure 3, Org B has no root zone and DNS servers in Org B are running a member of the Windows 2000 Server family. To enable DNS servers in Org B to respond to queries for names within the namespace of Org A, DNS servers hosting high-level zones in the namespace hierarchy can be configured to host secondary zones that contain the highest-level zone data of Org A servers. As shown in Figure 3, the Org B servers that host these secondary zones must perform zone transfers from Org A DNS servers to ensure that the secondary zones for names in Org A are updated.

**Figure 3 Secondary zone for Org A in Org B**

**Enabling Resource Access Across Forests**

Access to resources in different forests requires appropriate trust relationships, user and group management, and access control in the trusting domains. Resource sharing between domains is discussed in "Designing the Active Directory Structure" in the *Deployment Planning Guide of the Microsoft® Windows® 2000 Server Resource Kit*. The model of resource access and management for multiple Windows Server 2003 forests is very similar, with a few basic differences.

**Issue**

When users in Forest A need access to resources in Forest B, the resource administrators in Forest B can add the accounts of users in Forest A to the access control list (ACL) on the resource. Assuming that there are a large number of users who need the same access to a resource, it is not feasible to add the individual account of every user to the ACL on every resource that is required by each user. Rather, a more scalable management model is required to allow users in Forest A to access resources in Forest B.

**Solution**

The model that allows users to access resources across forests is very similar to the model for allowing users in different domains in the same forest to have access to resources across domains. The most efficient management model is as follows:

- Create trust relationships between domains in different forests, as follows:

  - To enable resource sharing between all domains in two Windows Server 2003 forests, create a forest trust between the forest root domains. This trust relationship, which is available in Windows Server 2003 forests, enables two-way transitive trust between all domains in two forests. Forest trust relationships are not transitive beyond the two forests that share the trust.

    | **Note** |
    | --- |
    | A transitive trust relationship flows throughout a set of domains, such as a domain tree, and forms a relationship between a domain and all domains that trust that domain. For example, if domain A has a transitive trust with domain B, and domain B trusts domain C, then domain A trusts domain C. Transitive trusts can be one-way or two-way, and they are required for Kerberos-based authentication and Active Directory replication. |

- To enable resource sharing between specific domains in different forests, create external one-way, non-transitive domain trust relationships (explicit trusts) between the specific domains.

- To represent the sets of users who need access to the same type of resources, create role-based global groups in every domain and forest that contains these users.

  | **Note** |
  | --- |
  | You might already have such groups created in some forests. |

- Create universal groups that correspond to the global groups.

- Add multiple global groups to a universal group so that you can assign permissions to related resources in multiple forests.

  | **Note** |
  | --- |
  | Universal groups are not available as security groups in Windows 2000 mixed-mode domains or in Windows Server 2003 domains that have a domain functional level of Windows 2000 mixed. They are available for distribution groups. For information about Active Directory functional levels, see Help and Support Center for Windows Server 2003. |

- Create resource-based domain local groups in every domain for the resources in that domain that need to be accessed from outside the forest.

- Add universal groups (or global groups in mixed-mode domains) from all such forests to the domain local groups across the organization, and use the domain local groups to assign permissions on the resources within the respective domains.

When a new user account needs access to a resource in a different forest, add the account to the respective global group. When a new resource needs to be shared across forests, add the appropriate domain local group to the ACL for that resource. In this way, access is enabled for resources on the basis of group membership.

Figures 4 and 5 compare and contrast this model in single versus multiple forests and in Windows 2000 versus Windows Server 2003. In Figure 4, Forest A has Windows 2000 domains that are in mixed mode and therefore universal groups are not available. Global groups from Domain A and Domain C are added to the domain local group in Domain B, and that group is added to the ACL on the Domain B resource and permissions are assigned to the group that provide the appropriate level of access. The multiforest deployment follows the same model for three forests as is used for three domains in the single-forest deployment.

The scenarios in Figure 4 apply to domains and forests that do not have universal groups available to them. Domains that do not have the ability to use universal groups can be:

- Windows 2000 domains that have the domain mode of mixed.
- Windows Server 2003 domains that have the domain functional level of Windows 2000 mixed.

In Figure 4, group abbreviations are as follows:

- Global group (GG).
- Domain local group (DLG).

**Figure 4 Resource sharing when universal groups are not available**

In Figure 5, multiple global groups are added to a single universal group, which is added to the domain local group. In a single forest, one universal group per role is all that's required. In multiple forests, a universal group can be created for each forest that has users that need access to a resource in a different forest. This approach is useful when multiple global groups from the same forest need access to the same local resource.

The scenarios in Figure 5 apply to domains in which universal groups are available. Domains that have the ability to use universal groups are:

- Windows 2000 domains that have the domain mode of native.
- Windows Server 2003 domains that have the domain functional level of Windows 2000 native or Windows Server 2003.

In Figure 5, group abbreviations are as follows:

- Global group (GG).
- Domain local group (DLG).
- Universal group (UG)

**Figure 5 Resource sharing when universal groups are available**

**Adding Groups to Domain Local Groups vs. Computer Local Groups**

As a general rule, the practice of adding domain local groups to global groups and adding global groups to universal groups is effective when a large number of users must be granted access to several resources. When the number of users is few, you can add them directly to the universal group or to the resource.

In addition, when you have a choice of adding universal groups or global groups to a domain local group or to a computer local group, use the computer local group instead of the domain local group. The reason to do so is that when an access token is constructed, domain local groups, global groups, and universal groups of which the security principal is a member are included in the token. Thus, entries in the token include nested group memberships, which means that if user A is a member of group G and group G is member of group GR, the access token for user A will contain both group G and group GR. A maximum of 1,500 entries can be added to an access token, and if a user belongs to too many groups, this limit can be reached. However, computer local groups are not nested.

Therefore, if resource access is being enabled on a per-computer basis and the number of computers is not very large, using computer local groups avoids potentially nested memberships of a domain local group and is the better practice.

For example, if you want to allow a user to administer an Exchange server, adding their account or group to the computer local group on the Exchange server is more effective than creating a domain local group, adding that domain local group to the Exchange Admins group or to the ACL on the Exchange server object and setting permissions, and then adding the user's account or group to the domain local group.

**Security Considerations for Resource Access Across Forests**

Even when you create multiple forests for data isolation, service isolation, or both, trust relationships with other forests (or individual domains from other forests) can be created and users can be added to groups in other forests so that they can be granted access to resources. However, do not include users from other forests in any of the following groups:

- Groups that are responsible for service management or that can manage the membership of service administrator groups.
- Groups with administrative control over computers that store protected data.
- Groups that have access to protected data, or groups responsible for the management of user or group objects that have access to protected data.

Including users from another forest in any of these groups constitutes a potential security breach of the other forest that can lead to disclosure of protected data or service interruptions.

For information about these administrative groups, see "Design Considerations for Delegation of Administration in Active Directory." You can view this document on the Microsoft TechNet Web site at http://go.microsoft.com/fwlink/?LinkId=10516.

**Synchronizing Sites and Subnets**

Site and subnet information represents the physical topology of the network and is not related to the Active Directory

structure. Active Directory can determine the location of computers on the network according to the relationship of their respective IP addresses to a range of addresses defined by a subnet object in Active Directory. Subnets are associated with sites, and sites identify areas of good network connectivity. Sites are usually connected by Wide Area Network (WAN) links. For this reason, an ideal connection is one that does not cross site boundaries (traffic does not traverse a WAN link). Site and subnet information enables computers that are running Windows 2000, Microsoft® Windows® XP, or a member of the Windows Server 2003 operating systems to locate the following computers and services in the same site or a nearby site:

- Domain controller, global catalog server, or Key Distribution Center (KDC).
- Distributed File System (DFS) server that hosts a requested resource.

**Issue**

When site and subnet information in both forests is identical, or the Netlogon optimization is leveraged, computer and service location is optimized according to site (see article 916474 (http://go.microsoft.com/fwlink/?LinkId=166344) in the Microsoft Knowledge Base). The ability to locate computers and services in the same site or a nearby site depends in part on whether the appropriate site and subnet information is available in Active Directory.

It is important to note that establishing synchronization of site and subnet information is not an immediate requirement of implementing multiple forests. You can establish site and subnet synchronization at any point throughout the lifetime of a multiforest deployment, or you can decide to not establish it. If you decide to establish synchronization of site and subnet information, the question of how soon to establish it depends on the impact of not having an identical site topology between forests or not having Netlogon optimized.

For example, suppose an organization has Forest A and Forest B, and site and subnet information is not synchronized between them. The following scenarios describe the effects on the performance of three common operations that are affected by site awareness:

- Logon process
- File downloads
- Authentication

Use these scenarios to help determine whether the reduction in network traffic or request execution time, or both, outweigh the additional effort that is required to synchronize site and subnet information across the forests.

**Logon Process Across Forests**

When a user from Forest A logs on to a computer in Forest B, the logon process requires location of a domain controller from the user's domain in Forest A. If the site of the computer from Forest B is not specified in Active Directory in Forest A, the computer might locate any (rather than the closest) domain controller from the user's domain in Forest A. If the connection to the domain controller is made over a WAN, then this logon process adds traffic to the WAN (the amount of traffic depends on the number of Group Policies and logon scripts, as well as the size of the roaming profile). This connection generates traffic during logon as well as logoff and usually ranges from 100 kilobytes (KB) to a few hundred KB. Depending on the WAN bandwidth that is available for logon traffic, logon duration over the WAN might be increased. If these drawbacks are acceptable, especially if you anticipate that most users will be logging on to computers in their own forest, then site and subnet information might not be important enough to warrant synchronizing the data between forests.

**File Download Across Forests**

When a user who is logged on to a computer that is joined to Forest B requests a file that is hosted by multiple DFS servers, the nearest one being a server that is joined to Forest A, the DFS server that is contacted for the download depends on whether site and subnet information for Forest A is available in Forest B. If the site of this DFS server is not specified in Forest B, then the file might be downloaded from an arbitrary (potentially remote) DFS server. If the site of the DFS server is available in Forest B, the server in Forest A can be located.

| **Note** |
| --- |
| DFS enhancements in Windows Server 2003 ensure that files are downloaded from the next closest DFS server that hosts the desired file and is joined to Forest B. |

Downloading a file from a remote DFS server increases network traffic over a WAN (the amount of traffic is determined by the size of the file to be downloaded) and potentially increases the download time (the delay depends on bandwidth available to

download the file). If these drawbacks are acceptable, especially if you anticipate that users download files only from the DFS servers in their own forest, then synchronizing site and subnet information might not be important.

**Authentication Across Forests**
When a user needs to authenticate to a resource in a different forest, the user's computer or domain controller (depending on the authentication mechanism that is used) must contact a domain controller in the domain of the resource. Domain controller location is optimized by the closest site across forests only when identical site and subnet information is configured in Active Directory in both forests. However, if the traffic that is generated by authentication of the user does not cause significant delay, then it is not critical that a local domain controller be contacted.

**Solution**
The initial solution for mirroring site and subnet information is to create the same site and subnet objects in all forests. After these objects have been created, two methods can be used to ensure that site and subnet information is maintained identically in both forests:

- Use a directory data synchronization product (for example, Microsoft Identity Integration Server 2003) to synchronize the data when site and subnet information changes in one forest. This approach is characterized by a high level of automation and requires practically no administrator involvement after Microsoft Identity Integration Server 2003 configuration is in place. However, this approach is not acceptable in scenarios where service isolation is required (the service administrators in the destination forest do not trust the service administrators from the source forest).

- Establish a business process by which network administrators inform service administrators in each forest when site and subnet information changes, and the service administrators then update the information in their respective forests. This approach is most appropriate for the customers who have service isolation requirements for separate forests. However, this approach requires a high level of administrator overhead to create mirrored information in multiple forests.

Microsoft intends to issue a deployment guide that will describe the site and subnet objects and attributes that need to be synchronized to mirror network topology information.

**Retrieving Application Data Across Forests**
A rapidly growing family of applications is using Active Directory to store and retrieve application-specific data. Application architecture assumes that application-specific data is stored in a well-known (for service providers and consumers) Active Directory location that is populated by the service providers or administrators.

**Issue**
When clients of the service or application data need to obtain the data or locate the service, they perform a search against Active Directory and retrieve the data. Most clients assume that they are joined to the same forest as the service provider. In multiple forest deployments, this condition is not always true.

For example, service providers for service App1 are running on computers that are joined to Forest A and they register the information that enables clients to locate these service providers only in Forest A. In this case, if a client in Forest B queries Active Directory to discover a service provider for service App1, the query fails and the client cannot locate a service provider.

Clients do not always use the data stored in Active Directory to locate service providers. Sometimes a client or other service provider needs to retrieve data from Active Directory but does not need to locate any other service provider. The following solutions apply to both scenarios.

**Solution**
Two approaches can be used to give clients the ability to find information in Active Directory in a different forest:

- Deploy service providers in each forest.

- Synchronize the data across the forests.

Making a choice between the two approaches depends on the following requirements of the application:

- Load sharing.

- Discovery of the nearest service provider.

- Autonomy or isolation, or both (for security purposes).

**Deploy Additional Service Providers**
The following scenario describes a condition that requires deploying additional service providers on the basis of different application requirements.

**Load requirements**
If service providers that are deployed in one forest cannot sustain the load of requests from clients from multiple forests, then deploying additional service providers might be necessary. Deploying them in all individual forests eliminates a need to synchronize this application-specific data across the forests.

**Synchronize Data Across Forests**
The following scenario describes a condition that requires synchronizing data across multiple forests on the basis of different application requirements.

**Nearest service provider**
For some network-traffic-intensive or response-time-sensitive applications, it is important to ensure that a client locates the nearest service provider. In this case, deploying one or a few service providers to serve an entire network that spans multiple sites might not be appropriate. You might need to deploy at least one service provider per forest per site, but if multiple forests span the overlapping set of sites, then duplicating service providers for each forest might unnecessarily increase the cost of hardware and support of the service providers. In this case, synchronizing the application-specific data across different forests allows clients from one forest to locate the nearest service providers, even though the clients belong to a different forest. For an example of the service providers that can be used by all clients in the same site regardless of their forest affiliation, see "Locating Printers Across Forests" later in this paper.

**No Sharing of Application Data Across Forests**
In the following cases, providing application data across forests is not feasible.

**Autonomy or isolation**
For some applications, in addition to availability of the service and proximity of the service providers, some administrators might have additional requirements of autonomy. If, for example, an application or service owner in one division (that also has its own forest) requires special configuration of the service provider (not matching the configuration in other parts of organization), then users in this forest might not use the service providers in other forests and must rely on only the service providers in the same forest. In this case, there is no reason to synchronize the application-specific data between the forests.

In addition to autonomy or isolation requirements, the owner of a service might also have security reasons for requiring that users and computers use only the service providers from their own forest. Remember that service administrators in a different forest have full control over the services and data stored on the computers joined to their forest. If you cannot allow delivery of your service to depend on another forest (for example, if the other forest is compromised), then you must not synchronize the service-specific data to your forest.

**Considerations for Using Microsoft Identity Integration Server 2003 to Synchronize Application-Specific Data Between Forests**
If you decide to synchronize some application-specific data between forests, the recommended synchronization solution is Microsoft Identity Integration Server 2003. The solution involves the following administrative cooperation:

- The Microsoft Identity Integration Server 2003 administrator configures Microsoft Identity Integration Server 2003 to perform synchronization of the application-specific data.
- The application owner provides the Microsoft Identity Integration Server 2003 administrator with the description of the objects and attributes that need to be synchronized between the forests.
- The forest administrators indicate to Microsoft Identity Integration Server 2003 administrators the directory locations that the information should be read from and written to.

In collaboration with application administrators, administrators of the individual forests must decide relative to each application if they want to participate in data synchronization. This decision should be based on a need to share application-specific data with other forests, to use application-specific data from other forests, and on security requirements.

**Credentials for Writing Application Data**
When a forest administrator decides to allow Microsoft Identity Integration Server 2003 to write application-specific data for a specific application, the administrator must decide which credentials Microsoft Identity Integration Server 2003 should use to write this data. The recommended method is to create a user account that uses its credentials exclusively to allow Microsoft Identity Integration Server 2003 to write this data. The administrator does not have to create separate credentials for each application and might use the same set of credentials for data that is used by different applications.

**Security Considerations for Writing Application Data**

A forest administrator must also add appropriate write permissions to the container into which Microsoft Identity Integration Server 2003 will write the data. Depending on security requirements, the destination forest administrator might need to ensure that these credentials do not enable one to overwrite data from a different forest.

Even if you trust the Microsoft Identity Integration Server 2003 administrator to appropriately configure the synchronization server and you completely eliminate the possibility that the Microsoft Identity Integration Server 2003 administrator could be rogue, the possibility of the administrator being coerced still exists. To minimize the risk that a Microsoft Identity Integration Server 2003 administrator could jeopardize the functionality of an entire individual forest, the forest administrator, in addition to creating a dedicated organizational unit in which synchronized objects are created, should ensure that write permission granted to Microsoft Identity Integration Server 2003 to create, update, and delete data is limited to only this organizational unit, and no other portion of the forest.

Restricting access to a single organizational unit eliminates the possibility that Microsoft Identity Integration Server 2003 can overwrite any data outside of the organizational unit. If this approach is taken, the forest administrator must inform the Microsoft Identity Integration Server 2003 administrator of the location of this organizational unit in the forest hierarchy and ensure that any requirements of the application to read and write to various objects on the directory are fulfilled. For example, some applications expect the data to be in specific locations of the Active Directory hierarchy, and only in those locations.

| **Note** |
| --- |
| If you are using Microsoft Metadirectory Services version 2.2, Microsoft recommends that you hire a Microsoft Consulting Services (MCS) consultant who specializes in Microsoft Metadirectory Services 2.2 to configure Microsoft Metadirectory Services 2.2 to enable data synchronization. |

**Locating Printers Across Forests**

The presence of printer objects in Active Directory enables a computer that has an account in that forest to browse for printers that have specific characteristics (for example, printers that support color printing or stapling) and that are located near the computer.

**Issue**

In the multiforest scenario, a user might be logged on to a computer that is in the same physical location as a printer, but the computer account and printer information exist in different forests. In this case, the user can locate a printer in a different forest only by providing the print server and printer name. You might want to allow users to browse for printers on the basis of their proximity and without regard to forest membership.

**Solution**

It is possible for a user to configure a computer to use a particular printer by specifying the printer name, which requires no additional configuration on the part of the forest administrator. However, if you want to enable users in one forest to browse for printers in a different forest, then consider using Microsoft Identity Integration Server 2003 to synchronize printer data between the forests, as described in “Retrieving Application Data Across Forests” earlier in this document.

Microsoft intends to issue a deployment guide with instructions for how to enable this functionality.

**Synchronizing Exchange Data Across Forests**

Exchange 2000 Server uses Active Directory to store configuration and user information and to provide user authentication and permissions management. In multiforest deployments where more than one Exchange organization is deployed, additional configuration is required to synchronize mail-related data of multiple Exchange organizations among the multiple forests.

**Exchange Organizations and Active Directory**

An *Exchange organization* consists of one or more Exchange servers, and each Exchange organization is specific to one Active Directory forest. Exchange servers rely on access to the global catalog for address information. Because each forest has a separate global catalog, an Exchange organization is associated with only one forest.

However, multiple forests can use the same Exchange organization for mail service. A single Exchange organization that serves multiple forests does not require additional configuration across forests because the Exchange organization uses only one forest for its Active Directory storage and services.

Although user accounts in different forests can use the same Exchange organization to send and receive mail among users in all forests, the servers of a single Exchange organization cannot access information from more than one Active Directory. To enable multiple forests that each deploy separate Exchange organizations to function as a single business organization, additional configuration is required to synchronize the Exchange mail recipients in the respective Active Directories.

The ability to access address information from different forests requires that shadow (or proxy) versions of all mail recipients be created and maintained by synchronization in each relevant directory. With these shadow objects in place, when an

Exchange server queries a single directory, it can view information about mail recipients that originate in its forest as well as those that have been created as shadow objects.

**Single Exchange Organization**

Whether a single Exchange organization serves one forest or more than one forest, the Exchange organization is still associated with only one of the forests, called the *Exchange forest*. Users that have accounts in one forest might have mailboxes in the same forest or in a different forest; however, mailboxes are always in the same forest as the Exchange servers because mailbox data is stored on the Exchange servers.

For example, in a scenario where Forest A and Forest B share a single Exchange organization, Exchange servers are installed only in Forest B. User A has a user account in Forest A and User A's mailbox is stored in forest B. To associate the user in Forest A with the user's mailbox in Forest B, a disabled user account is created for User A in Forest B and the mailbox is associated with it. User A's mail is stored on Exchange servers in Forest B and an attribute on the disabled account references User A's account in Forest A. This type of Exchange environment is known as the *resource forest model*.

Figure 6 shows an Exchange organization that has mailboxes on Exchange servers in one forest and user accounts in a different forest. In this scenario, the user objects in Forest A have corresponding disabled user accounts that represent their respective Exchange mailboxes in Forest B, which hosts the Exchange servers.

Single Exchange Organization

**Figure 6 Single Exchange organization with users and mailboxes in different forests**

Single Exchange organizations can have users in more than one forest, as shown in Figure 7.

**Figure 7 Single Exchange organization that serves multiple forests**

**Multiple Exchange Organizations**

When the same enterprise deploys Exchange servers in multiple forests, each Exchange organization has a separate Exchange forest and therefore a separate global catalog and global address list. Additional configuration is required to enable users in each forest to be able to look up address list information in the other forests. To achieve this goal, mail recipient information from multiple Exchange organizations must be synchronized.

Figure 8 shows a multiforest enterprise that deploys Exchange servers in multiple forests.

**Figure 8 Multiple Exchange organizations and multiple forests**

**Note**

It is not a goal of this document to prescribe best practices to design Active Directory for Exchange 2000 Server. For more information about designing Active Directory for Exchange 2000 Server in a Windows 2000 Server environment, see "Best Practice Active Directory Design for Exchange 2000." You can download this document from the Microsoft Web site at http://go.microsoft.com/fwlink/?LinkId=10517.

For deployments in which multiple Exchange organizations serve separate forests in the same multiforest enterprise, additional configuration might be needed in order to enable:

- Viewing the global address list in all forests.
- Viewing free and busy calendar information in all forests.

The configuration information in this paper encompasses all scenarios in which Exchange Server is deployed in more than one forest, but not necessarily in every forest in the enterprise.

**Address List Synchronization**

In a multiforest environment with a single Exchange organization, all user accounts reference global catalog servers in the Exchange forest to gain access to the global address list. Although the users are in different forests, Exchange uses a single global address list for these users and therefore no synchronization of address list information is needed.

In a multiforest environment with multiple Exchange organizations, each Exchange forest has its own address list and therefore synchronization is required to present the same view of address list data across the forests.

The global address list is a list of entities in a forest that can receive mail. Mail recipients can be user accounts (both enabled and disabled accounts), contacts, distribution lists, security groups, and folders. Exchange administrators can also create different views of the global list of mail recipient information to generate logical groupings of recipients, which are viewable as address lists.

Every Outlook client is configured with the name of an Exchange server. When an Outlook client user opens the Address Book, or when a user composes a message and types a name or an address in the To: field, the Outlook client uses the global catalog server that is specified by its Exchange server to search the contents of the global address list or other address lists.

**Issue**

Outlook clients must use global catalog servers and Exchange servers in only one forest to look up addresses. For this reason, the clients in one forest can view address lists of another forest in the same Exchange organization, but not of a forest in a different Exchange organization. Therefore, the following issues must be addressed in a multiforest deployment that has multiple Exchange organizations:

- Users in one forest need to be able to look up Address Book data, including mail addresses of objects in a different forest.
- The Exchange client must be able to resolve all addresses in its own forest.

Figure 9 shows two Active Directory forests with Exchange servers in each forest and an example of a mail-enabled user in each forest. The global address list (GAL) of each respective forest does not contain users from the other forest. For this reason, a query by an Exchange client does not find address lists for the other forest.

**Figure 9 Two forests with separate Exchange global address lists (GALs)**

In the configuration that is shown in Figure 9, separate Exchange organizations are deployed in two forests. In this case, before any additional configuration occurs, Forest A does not contain an account for Fred, who resides in Forest B. Likewise, Forest B does not contain an account for John, who resides in Forest A. Therefore, when the user of the Outlook client that is referencing the Exchange server that is configured to use the global address list in Forest A opens the Address Book, Fred is not found in the Address Book. John also cannot send mail to Fred by using an alias, but must use the full Simple Mail Transfer Protocol (SMTP) address for Fred.

The same restriction applies to the distribution lists and resources (for example, conference rooms) that reside in different forests. For example, if a distribution list exists in Forest A, then without this additional configuration, a user whose Outlook client is retrieving global address list information from the global catalog in Forest B does not see this distribution list in the Forest B Address Book.

**Solution**

To allow users to see mail recipients from another forest in the Address Book, the mail recipients must be synchronized between forests. In this scenario, the mail recipients are synchronized in both directions.

**Synchronizing users and groups between forests**

The solution that enables users in different forests to see the identities of each other in the Address Book is to create a proxy, or "shadow," version of mail-enabled objects in the forests that have Exchange 2000 Server deployed. The shadow version is represented by a contact object. In Figure 10, the mail account of John in Forest A is represented by the contact object John in Forest B, while the mail account of Fred in Forest B is represented by the contact object Fred in Forest A. Synchronization is performed by a directory data synchronization product such as Microsoft Identity Integration Server 2003.

**Figure 10 Mailbox synchronization between two forests**

In this example, if administrators of both forests want to allow users from Forest B to view the users from Forest A in the Address Book, then administrators can configure a directory synchronization server, such as Microsoft Identity Integration Server 2003, to perform the following operations:

- Search Forest A for all mail-enabled objects.
- Create corresponding contact objects in Forest B.

These operations can be scheduled to run periodically to dynamically update information in all forests when a mail-enabled object is added, deleted, or modified in its source forest. Upon completion of these operations, Exchange services (running every minute by default) in all forests that have an Exchange server installed will appropriately update existing address lists, including the global address list. Thereafter, when the user Fred in Forest B attempts to find the user John from Forest A by searching the Address Book, Fred successfully finds John because John is represented by a contact object in Forest B.

In addition, because routing information is included in the contact object, a user in Forest B can successfully send messages to John by specifying John's alias. The Exchange server locates the full SMTP address for the alias for the user John in the John contact object and properly forwards the message to the Exchange Server service that contains the mailbox of the user John.

Depending on the decision of the administrators of the source forest (the forest from which data is read) and the destination forest (the forest in which data is updated to match the appropriate data in the source forest), and assuming proper configuration, Microsoft Identity Integration Server 2003 can perform synchronization in one or both directions.

The process is very similar for contact objects that are synchronized out of this forest as well as mail-enabled security and distribution groups. As shown in Table 1, all of these object types are synchronized as contacts into other forests.

**Table 1**

| Source Directory | Target Directory |
|---|---|
| User | Contact |
| Contact | Contact |
| Group | Contact |

**Additional scenarios for address synchronization in forests without Exchange**
The scenarios described earlier apply to multiple forests that deploy separate Exchange organizations. Under the following conditions, address list synchronization might be deployed in forests that do not deploy Exchange servers:

- The attributes on the mailbox-enabled user account need to be propagated back to the forest with the logon user account. For example, if a human resources database typically updates phone numbers on the user account in the Exchange forest and other applications look up this information in the user account forest, then synchronization is required.

- Applications other than Outlook use the Address Book.

**Cost of global address list synchronization**
The cost of synchronizing the global address list and other address lists is that of implementing a directory data synchronization product such as Microsoft Identity Integration Server 2003. A single Microsoft Identity Integration Server 2003 server is required for every synchronization infrastructure that you want to implement. For example, if you decide to use a centralized Microsoft Identity Integration Server 2003 administrator who manages global address list synchronization for all of the forests, then the cost is that of running Microsoft Identity Integration Server 2003 on a single server computer plus a Microsoft Identity Integration Server 2003 administrator who will manage the process. However, if the forest administrators do not trust each other and want to run their own solutions, then each forest must have a Microsoft Identity Integration Server 2003 server with a Microsoft Identity Integration Server 2003 administrator who manages getting data into the forest.

**Which synchronization solution to use**
Any solution that enables synchronization of the objects described above can be used to synchronize address lists across multiple Exchange organizations. However, Microsoft highly recommends using Microsoft Identity Integration Server 2003. Microsoft Identity Integration Server 2003 is capable of synchronizing directory data between multiple Active Directory forests according to the business rules that are specified in the Microsoft Identity Integration Server 2003 configuration.

If you are using Microsoft Metadirectory Services (MMS) version 2.2, it is recommended that you hire a Microsoft consultant to perform the necessary configuration of MMS 2.2 to enable global address list synchronization.

Concurrent with shipping Microsoft Identity Integration Server 2003, Microsoft intends to provide a Global Address List (GAL) Synchronization Solution that automates the configuration of Microsoft Identity Integration Server 2003. The GAL Synchronization Solution significantly simplifies the configuration of Microsoft Identity Integration Server 2003 to perform global address list synchronization, including the creation of contact objects and distribution groups. The GAL Synchronization Solution performs configuration of that is expected to satisfy business rules of the majority of customers. At the same time, customers have the flexibility to modify Microsoft Identity Integration Server 2003 configuration on the basis of their individual business rules regarding global address list synchronization data. Detailed information about the GAL Synchronization Solution is to be included in the Multiforest Deployment Guide, which Microsoft intends to issue in the future.

**Administrative considerations for global address list synchronization**
To enable synchronization of global address list data by Microsoft Identity Integration Server 2003, administrators of the source and destination forests must provide information to the Microsoft Identity Integration Server 2003 administrators, as follows:

- The source forest administrator creates a user account that has read permission on the object that is to be synchronized. Credentials for this account will be used by Microsoft Identity Integration Server 2003 to read the objects from the source forest. The source forest administrator also specifies whether to allow group membership expansion.

- The destination forest administrator creates or identifies an organizational unit in which Microsoft Identity Integration Server 2003 will create the new contact objects. The administrator also creates a user account and grants permissions on the organizational unit to allow the account to create, delete, and update (write) objects in the organizational unit. To eliminate the possibility of tampering with destination and forest data outside of the organizational unit, allow write permissions only in the organizational unit that the administrator created for the purpose of creating synchronized

objects, and to specific attributes of accounts outside the organizational unit that are needed to preserve mail functionality.

| Note |
| --- |
| If the forest administrator decides to synchronize data both into and out of the forest, then the administrator should use the same user account credentials to perform both read and write operations. |

**Risk models for global address list synchronization**

There are two main risk models that apply to enabling global address list synchronization. The two models can coexist within the same organization. These risks apply in a more general context to all synchronization solutions.

- Individual forest administrators trust centralized Microsoft Identity Integration Server 2003 administrators to synchronize data between the forests. They are willing to risk the possibility that a centralized Microsoft Identity Integration Server 2003 administrator might maliciously or accidentally misconfigure Microsoft Identity Integration Server 2003. As a rule, individual forest administrators can and should protect their forest from data disclosure or tampering by ensuring that the user whose credentials are used by Microsoft Identity Integration Server 2003 to perform synchronization does not have permissions that would allow malicious activities. This approach is recommended.

- Individual forest administrators are not willing to risk the possibility that a centralized Microsoft Identity Integration Server 2003 administrator might maliciously or accidentally misconfigure Microsoft Identity Integration Server 2003. In this scenario, each individual forest administrator might deploy a Microsoft Identity Integration Server 2003 server that performs data synchronization from or into their forests, or both. The only cooperation required in this scenario is that the partner forest administrator must provide sufficient credentials to allow reading and writing the appropriate data. This approach is slightly more complex and might have a higher overhead, depending on the number of forests involved.

**Free and Busy Calendar Information Synchronization**

Calendar information enables users to schedule meetings by viewing the free and busy times in the schedules of meeting invitees. If frequent meetings are to be scheduled between members of different forests, the availability of schedule information might warrant synchronizing free and busy calendar data between Exchange organizations in different forests.

**Issue**

John has a mailbox in Forest A and wants to use Outlook to schedule a meeting with Fred, whose mailbox is in Forest B. John also wants to invite a group of people from Forest C. As shown in Figure 11, if John does not see the availability of users and groups in other forests, scheduling a meeting requires contacting them personally.

**Figure 11 Scheduling when calendar data is unavailable**

Free and busy calendar information is stored in the system public folders on Exchange 2000 servers, but not in Active Directory. For this reason, synchronizing global address list information between different forests is not sufficient to enable users that have mailboxes in one forest to view free and busy calendar information of users and resources that have mailboxes in Exchange organizations in other forests.

**Solution**

To enable users that have mailboxes in Forest A to view schedule information of users and resources that have mailboxes in the Exchange organizations in Forest B and Forest C, the system public folders data stored on the Exchange servers in Forest B

and Forest C must be included in the system public folders of the Exchange servers in Forest A. To enable such synchronization, Microsoft recommends using the Microsoft Exchange Interorg Replication Utility (also called the Public Folder [PF] Sync Tool). For information about using this tool, see article Q238573, "Installing and Configuring InterOrg Replication Utility," in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://go.microsoft.com/fwlink/?LinkId=291.

In most multiforest environments, a single synchronization server can accommodate multiple forests. Figure 12 shows a multiforest deployment that uses a single server that runs the PF Sync Tool to synchronize free and busy information among all three forests. In this scenario, each forest synchronizes data to and from two other forests.

**Figure 12 Free and busy information synchronized across three forests by one server**

**Migration Considerations**

In the environment that contains multiple Active Directory forests and potentially multiple Exchange organizations in different Active Directory forests, reorganizations or individual employee relocations will almost inevitably require you to migrate one or more of these: user accounts, computer accounts, groups, or mailboxes.

**User Migration**

User migration includes user accounts, groups, and computer accounts. To perform user account migration between forests, use Active Directory Migration Tool (ADMT). For information about using ADMT and to download ADMT, see "Active Directory Migration Tool Overview" in the Active Directory link on the Web Resources page at http://go.microsoft.com/fwlink/?LinkId=291.

**Mailbox Migration**

To perform migration of mailboxes between different Exchange organizations in different forests, use the Exchange Server Migration Wizard. For information about how to perform user mailbox account migration, see the Exchange online documentation.

If you need to migrate both user mailboxes and user accounts, perform the migration of the user account prior to migrating the user's mailbox.

**Considerations for Other Technologies**

Group Policy and Message Queuing features are not directly transferable across multiple Windows forests. Some workarounds are available, as described in "Group Policy" and "Message Queuing" later in this paper.

In addition, if you use trust relationships between domains in different forests or between two Windows Server 2003 forests, consideration for whether you want the ability to use user principal names (UPNs) to log on across forests can affect your decisions about the UPN suffixes you choose and the type of UPNs you create, as described in "Using the User Principal Name to Log On Across Forests" later in this paper.

**Group Policy**

Group Policy provides administrative control over users and computers. Group Policy can be applied to a domain, organizational unit, or site within the same forest. It is not possible to apply the same Group Policy object to users and computers in multiple forests.

If necessary, administrators of the forests can apply identical Group Policy objects to the domains, organizational units, or sites in different forests. For example, if you are managing merged organizations and have applied identical Group Policy objects to affect the users and computers in each domain in the original forest, you might want to apply identical Group Policy objects to all users and computers in each domain in the other (merged) forest.

Another scenario in which Group Policy management across forests is important is in the test-to-production scenario. For

example, for staging purposes, many customers maintain a separate test forest that closely resembles the production forest. After the policy deployment has been tested in the test environment, they want to reproduce this deployment in the production forest.

The Group Policy Management Console (GPMC) enables you to manage Group Policy across multiple forests by importing and copying Group Policy objects across forests. The GPMC will be available on the Microsoft Web site shortly after the release of Windows Server 2003. Although Group Policy Management can run only on the computers running Windows XP Professional and Windows Server 2003 operating systems, it can remotely manage Group Policy objects on domain controllers that are running a member of the Windows 2000 Server family with Service Pack 2 or greater.

**Message Queuing**
If you plan to deploy an application that uses Message Queuing (also known as MSMQ) and runs across the boundaries of multiple Active Directory forests, the application developer should the follow these recommendations:

- Use the direct format name for the target queues so that:
    - Message Queuing does not use Active Directory to resolve the target name.
    - The user cannot use Message Queuing built-in authentication and encryption features.
- If the application will run on a Windows XP or Windows Server 2003 platform, then use Message Queuing over HTTPS with client authentication.

For more information about Message Queuing, see Windows 2000 Server Help or Help and Support Center for Windows Server 2003.

**Using the User Principal Name to Log On Across Forests**
A user principal name (UPN) is a variation of a user account name that looks like an e-mail name but can be used to log on to a domain. The syntax is <*user name*>@<*string*>. UPNs allow you to use the same logon name across different domains in the same forest or in different forests.

UPNs are of two types:

- Implicit: Always of the form *userID@DNSDomainName*. For example, johns@corp.contoso.com is the UPN for the account of John Smith, whose user ID is johns and whose account is a member of the corp.contoso.com forest. The implicit UPN is always associated with the user's account, regardless of whether an explicit UPN is defined.
- Explicit: Always of the form *string@Anystring*, where both "string" and "Anystring" are explicitly defined by the administrator. For example, John Smith might have the UPN ITJS@coneast. Explicit UPNs are useful for situations in which the organization does not want to publicize the name of domains or the forest structure.

A UPN *suffix* is a string that indicates the namespace from which a UPN is derived. A UPN suffix includes everything to the right of the rightmost "at" (@) symbol in the full UPN. Everything to the left of the rightmost @ symbol is considered part of the user name, even if it contains another @ symbol. UPN suffixes can be either flat or hierarchical in structure, although they are typically used to identify flat namespaces.

UPNs are used primarily for interactive logons across domains. With multiple forests, UPN logons are available across forests under some conditions and not others. Under either of the following conditions, UPNs cannot be used to log on to a domain in a different forest:

- Shared UPN suffix: If two or more forests use the same UPN suffix, users cannot use UPNs to log on to a domain in the trusting forest. They can use the UPN only for logons within their own forest.
- Explicit UPN and external trust: When external trust relationships are created between domains in different forests, users in the respective domains cannot use explicitly created UPNs to log on to the trusting domains in the other forest. They can use only implicit UPNs.

Table 2 summarizes a user's ability to use a UPN to log on interactively across forests according to the different kinds of trust relationships that exist between domains in different forests and whether UPN suffixes are shared by multiple forests.

**Table 2 Ability to Use UPNs to Log On Across Forests**

| Trust Type | Explicit UPNs | Implicit UPNs | Shared UPN Suffixes |
|---|---|---|---|
| No trust relationships between domains in different forests | No | No | N/A |
| External trust relationship between domains in different forests | No | Yes | No |
| Forest trust relationship between Windows Server 2003 forests | Yes | Yes | No |

**Note**

Forest trust relationships are available between forests that have an Active Directory forest functional level of Windows Server 2003. For information about Active Directory functional levels, see Help and Support Center for Windows Server 2003.

In summary, if you want to share UPN suffixes among multiple forests but do not need the ability to log on interactively to a domain in another forest, you can use either external trust relationships or forest trust relationships.

To use UPNs to log on interactively across forests, use unique UPN suffixes for each forest. In this case, interactive logons are available as follows:

- If you use forest trust, you can use both explicit and implicit UPNs.
- If you use external domain trusts, you can use only implicit UPNs.

**Features that are Unavailable Across Forests**

Although experience with multiforest deployments shows that the features that cannot be enabled across different forests are not used by most customers in any case, the description of these features is included in this document to ensure a complete picture of the impact of deploying multiple forests.

**Delegating Mail Folders Across Forests**

Within a forest, you can delegate authority for a user to have access to the mail folders in another user's mailbox.

**Issue**

If mailboxes of two users are hosted by Exchange Server organizations in different forests, then a user in one forest cannot access the mail folders of a user in the other forest.

A typical example of this issue is executives who want to delegate the ability to manage their calendars to administrative assistants. If the mailboxes of such an executive and administrative assistant exist in Exchange Server organizations that are in different Active Directory forests, then such administrative delegation of this ability is not possible.

**Workaround**

Ensure that mailboxes of people who need access to the mail folders of others are in the same Exchange Server organization. Also, if a user needs access to mailboxes that are hosted by different Exchange Server organizations, you can create multiple mailboxes in the appropriate forests for the same user who needs access to other mailboxes. For example, in the case of the executives and administrative assistants described earlier, the administrative assistant requires an additional mailbox in the forest of the executive.

# Multiforest Feature Implementation and Cost Summary (Multiple Forest Considerations in Windows 2000 and Windows Server 2003)

Updated: April 8, 2004

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After reading this document, use the information in Table 3 to estimate the relative costs of implementing functionality across forests for your organization.

**Table 3 Features and Configuration Costs**

| Enabled Feature | Configuration Costs |
|---|---|
| View address list information | • Deploy Microsoft Identity Integration Server 2003 synchronization server<br>• Train and support synchronization administrator<br>• Create synchronization data container per target forest<br>• Create synchronization account per forest<br>• Enable permissions for synchronization<br>• Run GAL Sync tool |
| View free and busy calendar information | • All of “View address list information” configuration costs, plus:<br>• Deploy PF Sync server<br>• Train and support PF Sync administrator<br>• Confirm MAPI-capable Local Area Network (LAN) connection between Exchange organizations |
| Bridge DNS infrastructures | DNS configuration of one or more of the following:<br>• Delegations<br>• Conditional forwarding (Windows Server 2003 only)<br>• Secondary zones |

| | |
|---|---|
| Resource access | • Configure trust relationships:<br>  • Forest trust (Windows Server 2003 only)<br>  -Or-<br>  • External domain trust (Windows Server 2003 or Windows 2000)<br>• Create groups:<br>  • Role-based global groups<br>  • Resource-based domain local groups<br>  • Universal groups, if available<br>• Add global and/or universal groups to local groups<br>• Apply permissions to resources |
| Application data retrieval | • Configure additional service providers<br>-Or-<br>• Configure Microsoft Identity Integration Server 2003 to synchronize application data (see costs under "View address list information" in this table) |
| Printer location | • Configure clients with print locations<br>-Or-<br>• Configure Microsoft Identity Integration Server 2003 to synchronize printer application data (see costs under "View address list information" in this table) |

# NLB Basics

Updated: February 10, 2004

Applies To: Windows Server 2003 with SP1

**Q.** What is Network Load Balancing?

**A.** Network Load Balancing is a clustering technology offered by Microsoft as part of all Windows 2000 Server and Windows Server 2003 family operating systems. NLB uses a distributed algorithm to load balance network traffic across a number of hosts, helping to enhance the scalability and availability of mission critical, IP-based services, such as Web, Virtual Private Networking, Streaming Media, Terminal Services, Proxy, etc. It also provides high availability by detecting host failures and automatically redistributing traffic to operational hosts.

**Q.** What is a Cluster?

**A.** A cluster is a group of independent computers that work together to run a common set of applications and provide the image of a single system to the client and application. The computers are physically connected by cables and programmatically connected by cluster software. These connections allow computers to use problem-solving features such as failover in Server clusters and load balancing in Network Load Balancing (NLB) clusters.

# NLB and Other Clustering Technologies

Updated: February 10, 2004

Applies To: Windows Server 2003 with SP1

**Q.** What is the Difference Between NLB and Server Clusters?

**A.** A server cluster (MSCS) is a collection of servers that together provide a single, highly available platform for hosting applications. Applications can be failed over to ensure high availability in the event of planned downtime due to maintenance or unplanned downtime due to hardware, Operating System or application failures. Server clusters provide a highly available platform for applications such as SQL Server, Exchange Server data stores, file and print servers, etc. Server clusters are used for stateful applications that rely on some state context from one request to the next.

Network Load Balancing (NLB) clusters dynamically distribute the flow of incoming TCP and UDP traffic among the cluster nodes according to a set of traffic-handling rules. NLB clusters provide a highly available and scalable platform for applications such as IIS, ISA server, etc. NLB is used for stateless applications; i.e. those that do not build any state as a result of a request.

NLB and server clusters compliment each other in complex architectures: NLB is used for load balancing requests between front-end web servers while server clusters provide high availability for backend database access.

NLB and server clusters cannot be used on the same set of servers (see Question Can I use NLB and server clusters on the same set of servers?).

**Q.** Can I Use NLB and Server Clusters on the Same Set of Servers?

**A.** No, Microsoft Server clusters (MSCS) and Network Load Balancing (NLB) are not supported on the same set of nodes. Both Server clusters and Network Load Balancing clusters control and configure network adapters. Since they are not aware of each other, configuring one can interfere with the other.

# NLB for Scalability

Updated: February 10, 2004

Applies To: Windows Server 2003 with SP1

**Q.** How Large Should My Cluster Be?

**A.** The size of the cluster is determined by the application that is being hosted and load balanced and on the system resources on the host machines available to service client requests sent to the application. If you notice that client requests are slowing down as more and more clients make connection requests to the application, it may be time to add more hosts to the cluster. A single NLB cluster can have up to 32 hosts in it.

For more information and examples of how to determine the size of your cluster refer to Chapter 10 Designing Network Load Balancing of the Windows Server 2003 Deployment Guide, (http://go.microsoft.com/fwlink/?LinkId=4298).

**Q.** Are There Any Performance Concerns as My Cluster Grows?

**A.** Tests have shown the NLB performance begins to deviate from the linear as the cluster grows beyond 20 to 25 nodes. But, this really depends on the amount of traffic that the application sees in the form of client requests. The following graphs give a better idea of NLB performance as the cluster size and number of users increase.

**Web Load: GET requests for 10KB static web pages**

**Q.** We Expect Our Front-End Cluster to Grow Beyond 32 Nodes. Should I Use NLB Even Though it Has a Cluster Size Limit of 32 nodes?

**A.** NLB can be used to scale beyond 32 machines by using Round Robin DNS between multiple NLB Clusters. This is shown in the following figure.

# NLB for High Availability

Updated: February 10, 2004

Applies To: Windows Server 2003 with SP1

**Q.** How Does NLB Detect a Server Failure?

**A.** While servicing client requests, each NLB Cluster host emits heartbeats to the other hosts in the cluster. If a host fails and stops emitting heartbeats, then after a default time period of five seconds, the remaining hosts in the cluster undergo a process called convergence to remove the failed host from the cluster and have new client connection requests mapped to remaining hosts in the cluster. So, new connections made by the client get handled by one of the remaining hosts in the cluster.

**Q.** How Long Does it Take For a Failed Server to be Removed From the Cluster?

**A.** By default, five seconds are required to detect a failed host. Once a failure is detected, the convergence process takes an additional two and a half to three seconds to evict the failed host and redistribute its load to the surviving hosts.

# NLB Fundamentals - FAQ

Updated: February 10, 2004

Applies To: Windows Server 2003 with SP1

**Q.** Do the Heartbeat Packets Consume a Lot of Bandwidth?

**A.** No, the heartbeat packets, which are emitted every second by each host, consume less than 1,500 bytes.

**Q.** Do the Heartbeats Need to Go on a Back-End Network?

**A.** No, the heartbeat packets are always sent out on the same network interface on which data packets are received and sent. There is no need for an additional back-end network for the control (heartbeat) packets. In fact, in order to be able to detect connectivity failures on the load-balanced network adapter, NLB actually **requires** that heartbeats traverse the load-balanced network adapter.

**Q.** Is NLB a Kernel Component?

**A.** Yes, NLB has a kernel component called wlbs.sys. This is an intermediate NDIS driver. NLB also has user-mode components for management purposes.

**Q.** What are the Benefits of NLB Over Simple Round Robin Domain Name Service (RRDNS)?

**A.**

- Automatic recovery within 5 seconds
- More even load balancing

**Q.** How Does the NLB Load Balancing Algorithm Work?

**A.** NLB employs a fully distributed filtering algorithm to map incoming clients to the cluster hosts. This algorithm enables cluster hosts to independently and quickly make a load balancing decision for each incoming packet. It is optimized to deliver statistically even load balance for a large client population making numerous, relatively small requests, such as those typically made to Web servers. When the client population is small and/or the client connections produce widely varying loads on the server, the load-balancing algorithm is less effective. However, the simplicity and speed of NLBs algorithm allows it to deliver very high performance, including both high throughput and low response time, in a wide range of useful client/server applications. If *No Affinity* is set, NLB load balances incoming client requests so as to direct a selected percentage of new requests to each cluster host; the load percentage for each host is set in the NLB Properties dialog for each port range to be load balanced. The algorithm does not dynamically respond to changes in the load on each cluster host (such as the CPU load or memory usage). However, the load distribution is modified when the cluster membership changes, and load percentages are renormalized accordingly.

When inspecting an arriving packet, all hosts simultaneously perform a mapping to quickly determine which host should handle the packet. The mapping uses a randomization function that calculates a host priority based on their IP address, port, and other information. The corresponding host forwards the packet up the network stack to TCP/IP, and the other cluster hosts discard it. The mapping remains unchanged unless the membership of cluster hosts changes, ensuring that a given clients IP address and port will always map to the same cluster host. However, the particular cluster host to which the clients IP address and port map cannot be predetermined since the randomization function takes into account the current and past clusters membership to minimize remappings.

In general, the quality of load balance is statistically determined by the number of clients making requests. This behavior is analogous to dice throws where the number of cluster hosts determines the number of sides of a die, and the number of client requests corresponds to the number of throws. The load distribution improves with the number of client requests just as the fraction of throws of an N-sided die resulting in a given face approaches 1/N with an increasing number of throws. As a rule of thumb, with client affinity set, there must be at least five times more clients than cluster hosts to begin to observe even load balance.

The Network Load Balancing client affinity settings are implemented by modifying the statistical mapping algorithms input data. When client affinity is selected in the NLB Properties dialog, the clients port information is not used as part of the mapping. Hence, all requests from the same client always map to the same host within the cluster. Note that this constraint has no timeout value and persists until there is a change in cluster membership. When single affinity is selected, the mapping algorithm uses the clients full IP address. However, when Class C affinity is selected, the algorithm uses only the Class C portion (upper 24 bits) of the clients IP address. This ensures that all clients within the same Class C address space map to the

same cluster host.

**Q.** How Does NLB Cluster Convergence Work?

**A.** Convergence involves computing a new cluster membership list and recalculating the statistical mapping of client requests to the cluster hosts. There are two instances in which cluster traffic has to be remapped due to a change in cluster membership: when a host leaves the cluster and when a host joins the cluster. A convergence can also be initiated when several other events take place on a cluster, such as changing the load balancing weight on a host or implementing port rule changes.

**Removing a Member**. Two situations cause a host to leave the cluster or go offline. First, the host can fail, an event that is detected by the NLB heartbeat. Second, a system administrator can explicitly remove a host out of the load-balancing cluster or stop NLB on that host.

**The NLB heartbeat**. NLB uses a heartbeat mechanism to determine the state of the hosts that are load balanced. This message is an Ethernet-level broadcast that goes to every load-balanced cluster host.

NLB assumes that a host is functioning normally within a cluster as long as it participates in the normal exchange of heartbeat messages between it and the other hosts. If the other hosts do not receive a message from a host for several periods of heartbeat exchange, they initiate convergence. The number of missed messages required to initiate convergence is set to five by default (but can be changed).

During convergence, NLB reduces the heartbeat period by one-half to expedite completion of the convergence process.

**Server Failure**. When a cluster host fails, the client sessions associated with the host are dropped.

After convergence occurs, client connections to the failed host are remapped among the remaining cluster hosts, who are unaffected by the failure and continue to satisfy existing client requests during convergence. Convergence ends when all the hosts report a consistent view of the cluster membership and distribution map for several heartbeat periods.

**Q.** Can NLB Balance Load Based on CPU/Memory Usage?

**A.** No, NLB does not respond to changes in the server load (such as CPU usage or memory utilization) or the health of an application.

# Deployment Issues

Updated: February 10, 2004

Applies To: Windows Server 2003 with SP1

**Q.** What is the AOL Proxy or Megaproxy Problem? Does NLB Fix it?

**A.** All connections that originate from large enterprises or megaservices such as AOL or MSN pass through client-side proxies. However, there is no guarantee that two consecutive TCP connections originating from the same client would be sent out through the same proxy. Now, lets assume that an AOL client creates an SSL session with an NLB cluster on the other side of the Internet. To ensure that the session does not break, all TCP connections originating from this client that are part of the session must be sent to the same host in the cluster. To ensure this, the NLB cluster must be configured in Single Affinity Mode.

However, it is possible that multiple TCP connections originating from the same client on the AOL network may be sent to the NLB cluster through different client-side proxies. The NLB Cluster will view these two TCP connections as connections from different clients (because they would now have different source IP addresses) even though they have actually originated from the same host. Now, since NLB load balances connection requests based on the source IP address of the connection, these connections may get handled by different hosts in the cluster even though they are part of the same session, thus breaking the session. NLB does not fix this problem, though the problem may be mitigated by choosing Class C affinity, provided the AOL Proxy happens to use source IP addresses from a single Class C address range. Note that a well designed web application will should not fail if an SSL session is broken; instead it should negotiate a new SSL session, minimizing the impact on clients.

**Q.** Will I Get Even Load Balancing if Most Clients Connect to the NLB Cluster Through a Client-Side Proxy?

**A.** When connections coming from different clients pass through the same client-side proxy, they reach the NLB Cluster bearing the same source IP Address. This makes the NLB cluster believe that these connections are coming from a single machine. So, if the cluster is configured in Single Affinity mode, NLB will use only the Source IP Address of the incoming connections to achieve load balancing and since all these connections seem to come from the same IP address, they will all end up with the same host in the cluster. However, if the cluster is configured in No Affinity mode, NLB will use both the Source IP Address and the Source Port to achieve the load balancing, and so load will be distributed amongst all of the hosts.

**Q.** What is the Difference Between Multicast and Unicast Modes of Operation? Which One Should I Use in My NLB Installation?

**A.** NLB relies on the fact that incoming packets are directed to all cluster hosts and passed up to the NLB driver for filtering. In its default *unicast* mode of operation, this is achieved by NLB reassigning the station (MAC) address of the network adapter for which it is enabled and all cluster hosts are assigned the same MAC (media access control) address. In *multicast* mode, NLB assigns a layer-2 multicast address to the cluster adapter instead of changing the adapters station address.

Both modes of operation have their pros and cons. The advantages of *unicast* mode are that it works seamlessly with all routers and layer-2 switches (and layer-3 switches which are configured to operate in layer-2 mode). The disadvantages are:

- *Unicast* mode induces switch flooding, where all switch ports are flooded with NLB traffic, even ports to which non-NLB servers are attached;

- Since all hosts in the cluster have the same IP Address and the same MAC Address, there is no inter-host communication possible between the hosts configured in *unicast* mode.

*Multicast* allows inter-host communication because it adds a layer two multicast address to the cluster instead of changing it and this makes inter-host communication possible as the hosts retain their original unique MAC addresses and already have unique Dedicated IP Addresses. However, in *multicast* mode, the ARP reply sent out by a host in the cluster, in response to an ARP request, maps the clusters unicast IP Address to its multicast MAC Address. Such a mapping in an ARP reply is rejected by some routers and so administrator must add a static ARP entry in the router mapping the Cluster IP Address to its MAC Address

**Q.** How do I Reduce Switch Flooding Caused by Network Load Balancing?

**A.** For Windows 2000, the only choice is to isolate the NLB hosts. This can be done in one of two ways. First the hosts can be homed to their own LAN or Virtual LAN. This will work for either unicast or multicast modes. Second, for the multicast mode, the switch ports to which the hosts are attached can mapped to the cluster MAC address via static entries in the switchs Content-Addressable Memory (CAM) table.

Windows Server 2003 introduces a new feature, called *IGMP multicast*, as an additional means of limiting switch flooding. This mode can be used if the switch supports IGMP snooping. Note however, that this mode requires the cluster to be configured in

*multicast* mode.

**Q.** Does NLB Require Two Network Cards Per Host?

**A.** NLB does not require more than one network card per host. However, there are several scenarios in which a user may prefer to add another network card:

- **Inter-host communication in unicast mode**

  In *unicast* mode, each host in the cluster has the same IP Address and the same MAC Address making them look identical from a networking perspective. So, *unicast* mode has the side effect of disabling communication among the hosts of the cluster.

- **Separating the front-end traffic from the back-end traffic**

  The network adapter that has NLB bound to it can be used to handle incoming connections and connections to a bank-end database, for example, can be made from a separate back-end network adapter.

**Q.** Can NLB be used with network interface card teaming adapters?

**A.** Network interface card teaming solutions are offered by most major network adapter vendors and provide adapter fault tolerance (AFT). Network interface card teaming permits grouping network adapter ports for a connection to a single physical segment. If connectivity through one port is not working, another port is activated automatically. This operation is transparent to the operating system and other devices on the network.

NLB can be used with certain teamed adapters, however, this requires careful coordination between NLB and the teamed adapter configuration software. Refer to Knowledge Base article INFO: Using NIC Teaming Adapters with Network Load Balancing May Cause Network Problems (http://go.microsoft.com/fwlink/?LinkId=18366), for details.

**Q.** Can NLB be used instead of network interface card teaming software to provide adapter fault tolerance or increase throughput?

**A.** No, NLB cannot be used to team adapters (grouping adapter ports together). NLB is used strictly to load balance traffic among *multiple* hosts in a load-balanced cluster

**Q.** How Do I Configure NLB with Layer 2 Switches?

**A.** If you are connecting NLB hosts to a switch rather than a hub, you need to make sure that the switch does not associate the cluster MAC address with a particular switch port. Knowledge Base article Configuration Options for WLBS Hosts Connected to a Layer 2 Switches (http://go.microsoft.com/fwlink/?LinkId=18367) explains how to configure NLB with Layer 2 switches.

**Q.** How Do I Configure NLB with Layer 3 Switches?

**A.** Layer 3 switches need to be specially configured to work with NLB. A VLAN must be established for the hosts in the cluster, and this VLAN must be configured to operate in Layer 2 mode. All Layer 3 switches may not support this capability, and when they do, the mechanism to setup the Layer-2 VLAN is specific to the particular make and model. Consult the documentation for the switch before attempting to configure such a system.

**Q.** How Do I Remove the Switch as a Single Point-of-Failure?

**A.** Create a subnet that spans two switches and home half of the NLB cluster to each switch. The objective is typically to create a LAN with no single points of failure. To this end you will also need two router uplinks and have one switch uplink to one router. You also need to run a redundant routing protocol such as HSRP for failover of the router links. Finally you will need two cross-over links between the switches (otherwise the cross-over cable is a single point of failure). Each switch has two paths off the network: one via the router it is linked to (which is used by default) and one through the other switch. In this configuration, the loss of a router (or link to a router) causes the affected switch to use the cross link to ship its traffic off the LAN. The loss of a switch cuts the cluster capacity in half.

**Q.** I Have Two Network Adapters on Each Server in My NLB Cluster. How Do I Ensure That All Outbound Traffic Goes Through Non-Load-Balanced Network Adapters?

**A.** Sometimes it is desirable for performance or other reasons to direct all outgoing traffic through a different network adapter that the one that is being load balanced with NLB. This implies that there is more than one network adapter on each host in a cluster: NLB is bound to one network adapter called cluster network interface card, and the other network adapter does not have NLB bound to it. To make sure that the outbound traffic leaves each host through the non-cluster network adapter, do the following:

Set the metric on the cluster network adapter to a higher value than the non-cluster network adapter. For example, if you have two network adapters on each host, set the non-cluster network adapter metric to 1 and cluster network adapter metric to 2. The network adapter with a higher metric means it is more expensive to use than the other one with a lower metric. That will ensure that the outbound traffic will be routed out of the non-cluster network adapter.

If you want to use default gateways on both cluster and non-cluster network adapters, make sure the metric of the default gateway on the cluster network adapter has a higher value than the one on the non-cluster network adapter. If you do not want to route any outgoing traffic out of the cluster network adapter, you should not specify the default gateway for it at all.

**Q.** Can I Have Part of the Cluster Operate in Multicast Mode and the Other in Unicast Mode?

**A.** No, the entire cluster has to be in one mode of operation.

**Q.** Does NLB Support Multiple Virtual IP Addresses?

**A.** Yes, NLB supports multiple, virtual IP addresses. For more details please refer to KB article How to Configure WLBS with Multiple Virtual IP Addresses, (http://go.microsoft.com/fwlink/?LinkId=18368).

**Q.** Is it Possible to Specify Different Port Rules for Different Virtual IP Addresses (VIPs) On the Same Set of Hosts?

**A. Windows 2000:** No, port rules cover all VIPs that are configured. In addition, all of the hosts must have the same VIPs on them, see the KB article How to Configure WLBS with Multiple Virtual IP Addresses, (http://go.microsoft.com/fwlink/?LinkId=18368).

**Windows Server 2003:** *Virtual Clusters* provide per-IP Port Rules capability. Now, it is possible to have different ports rules for different VIPs on the same set of machines.

**Q.** Will NLB Work if Multiple VIPs on the Same Set of Hosts are Added on Different Subnet?

**A.** Yes.

**Q.** Is it Possible to Mix Windows NT 4.0 WLBS, Windows 2000 WLBS and Windows Server 2003 in the Same Cluster?

**A.** Yes, mixing Windows NT 4.0 WLBS, Windows 2000 NLB and Windows Server 2003 is supported. There is no additional work needed and the heartbeat packets from NLB in Windows Server 2003 are backward compatible with WLBS on Windows NT 4.0 and Windows 2000 NLB.

| **Note** |
| --- |
| In mixed mode, you cannot use new features of Windows Server 2003 NLB. For a list of new features of Windows Server 2003 NLB refer to the following document: What's New in Clustering Technologies, (http://go.microsoft.com/fwlink/?LinkId=18369). |

You cannot use Network Load Balancing manager to manage mixed-mode clusters.

**Q.** Is it Possible to Bind NLB to Multiple Interfaces?

**A.** NLB may be bound to multiple interfaces only in Windows Server 2003. The interfaces may not be joined to the same cluster.

**Q.** Can I Have Two NLB Clusters on the Same Subnet?

**A.** Yes. In a switched environment, the clusters will compete for the inbound bandwidth because inbound traffic is flooded to all hosts on the LAN. It is important to keep an eye on the aggregate amount of consumed inbound bandwidth to ensure that the network does not become a bottleneck. Other than that, there is no reason why multiple clusters can't reside on the same subnet.

**Q.** We Need to Span a Cluster Across Buildings. Can We Use NLB to Load-Balance Them?

**A.** Yes, if hosts are part of the same subnet.

**Q.** Does NLB Support Token Ring Networks?

**A.** No. Token Ring networks do not allow multiple hosts to share a common MAC address, which is a fundamental requirement of the NLB algorithm.

# Set up and Configuration

Updated: February 10, 2004

Applies To: Windows Server 2003 with SP1

**Q.** Can NLB Clusters Be Configured and Managed From a Single Point?

**A.** A new tool in Windows Server 2003 called the *Network Load Balancing Manager (NLB Manager)* provides a single point of configuration and management of NLB clusters. Some key features of the NLB Manager:

- Creating new NLB clusters and automatically propagating Cluster Parameters and Port Rules to all hosts in the cluster and propagating Host Parameters to specific hosts in the cluster.
- Adding and removing hosts to and from NLB clusters.
- Configuring NLB to load balance multiple web sites or applications on the same NLB Cluster, including adding all Cluster IP Addresses to TCP/IP and controlling traffic sent to specific applications on specific hosts in the cluster.
- Diagnosing misconfigured clusters.

| **Note** |
| --- |
| You cannot use Network Load Balancing Manager to manage Windows 2000 clusters or mixed clusters, including clusters containing only hosts running Windows 2000 Server operating systems or clusters containing both Windows 2000 and Windows Server 2003 Server operating systems. |

**Q.** Can I Use WMI to Remotely Bind and Configure NLB?

**A.** No.

**Q.** Can I Use WMI to Remotely Add an IP Address to TCP/IP?

**A.** Yes, call the following method:

- Namespace: root\cimv2
- Class name: Win32_NetworkAdapterConfiguration
- Method name: EnableStatic

**Q.** What is the MaskSourceMAC Registry Key Used For?

**A.** To work correctly, every packet directed to the virtual IP address must reach all NLB hosts. Each NLB host then filters those packets. When the cluster network adapter of each NLB host connects to a port on a Layer 2 switch, the switch tries to determine the MAC address of the hosts connected to each of its ports. As a result, the switch can associate a MAC address with a given port. Ethernet switches send frames to a MAC address through the port associated with the destination MAC address. If a switch associates the clusters MAC addresses with one of its ports, NLB cannot correctly load-balance the traffic because the traffic will reach only a single NLB host.

In unicast mode NLB utilizes a technique called *MAC address masking*. NLB substitutes MAC addresses when it sends packets through the switch. The switch maps these substitute MAC address with individual ports, but does not associate the cluster MAC address with any port and therefore sends the traffic to the cluster MAC address to all the ports in the switch. Cluster MAC address masking prevents the switch from learning the association of cluster MAC address with a particular port. If a switch does not have a MAC address associated to a port, it sends the frames to all ports. This is known as *port flooding*. MAC address masking is possible only when the MaskSourceMAC registry key is set to its default value of one. When it is set to 0, NLB does not perform automatic MAC address masking. Therefore, other techniques must be used to prevent a Layer 2 switch from learning the cluster MAC address.

**Q.** Where Can I Learn More About NLB Setup and Configuration Options?

**A.** There are many resources to help you out with setting up and configuring NLB clusters.

First, you should read the Microsoft Windows Server 2003 Deployment Kit (http://go.microsoft.com/fwlink/?LinkId=18370) chapters that explain how to design and deploy NLB clusters: Chapter 10 Designing Network Load Balancing and Chapter 11 Deploying Network Load Balancing of the Planning Server Deployments section.

Once you have familiarized yourself with designing and deployment of NLB clusters, you can use a step-by-step checklist that allows you to set up and configure NLB clusters. The checklist is located in the Windows Server 2003 (http://go.microsoft.com/fwlink/?LinkId=18371) (all versions) online help on your CD, or on the Internet at: http://go.microsoft.com/fwlink/?LinkId=18371.

There are many white papers and helpful documentation at Clustering Services in Windows Server 2003, (http://www.microsoft.com/windowsserver2003/technologies/clustering/default.mspx). There you can find white papers that provide a general overview of Load Balancing, the NLB architecture, configuration information for specific scenarios, troubleshooting and much more.

You should also refer to online Help as often the information you need is located right there.

If you have specific questions that are not answered in the resources listed here, please visit the Clustering Communities page and post your question on one of the NLB or clustering newsgroups. For more information about Microsoft communities, see the Microsoft communities Web site, (http://go.microsoft.com/fwlink/?LinkId=18374).

# Management and Operations

Updated: February 10, 2004

Applies To: Windows Server 2003 with SP1

**Q.** How Can I Keep a Record of NLB Manager Activities?

**A.** You can configure Network Load Balancing Manager to log each Network Load Balancing Manager event. This log can be very useful in troubleshooting problems or errors when using Network Load Balancing Manager. Enable Network Load Balancing Manager logging by clicking **Log Settings** in the Network Load Balancing Manager **Options** menu. Check the **Enable logging** box and specify a name and location for the log file.

The Network Load Balancing Manager log file contains potentially sensitive information about the Network Load Balancing cluster and hosts, so it must be properly secured. By default, the log file inherits the security settings of the directory in which it is created, so you might have to change the explicit permissions on the file to restrict read and write access to those individuals who do not need full control of the file. Be aware that the individual using Network Load Balancing Manager does require full control of the log file.

**Q.** Can I Manage an NLB Cluster Remotely Using WLBS.EXE?

**A.** Yes, but this is not recommended for security reasons. WLBS.EXE can be used to control participation of nodes in the cluster, but it cannot be used to alter the configuration of the cluster. In Windows Server 2003, use NLB Manager to configure and manage NLB clusters.

**Q.** I am Seeing NLBS Event Number ### and am Not Sure What To Do About it. Where Can I Find Detailed Information About NLB Events in the Event Log?

**A.** The document containing detailed descriptions of all NLB events, their causes and possible resolutions can be found at http://www.microsoft.com/technet/support/ee/ee_advanced.aspx.

**Q.** How Do I Deal with Denial of Service (DOS) Attacks on my NLB Cluster?

**A.** NLB utilizes TCP/IP Denial of Service attack protection to protect itself from denial of service attacks. Specifically, NLB is prone to SYN attacks because of the state that it maintains for TCP connection affinity. To protect an NLB cluster from SYN attacks, make sure that TCP/IP SYN attack protection is enabled. See the following KB articles that explain how to enable TCP/IP DOS attack protection: HOW TO: Harden the TCP/IP Stack Against Denial of Service Attacks in Windows 2000, (http://go.microsoft.com/fwlink/?LinkId=18377) and HOW TO: Harden the TCP/IP Stack Against Denial of Service Attacks in Windows Server 2003, (http://go.microsoft.com/fwlink/?LinkId=18376).

NLB can also fail because of heartbeat loss due to insufficient network resources. This may cause partitioning of the cluster, which can cause connectivity problems for clients, as clients may be serviced by multiple NLB hosts. To soften the heartbeat loss criteria in NLB, use the NLB WMI interface to change the AliveMsgTolerance (from 5 to 100; default is 5) and/or the AliveMsgPeriod (from 100 to 10000 in milliseconds; default is 1000). These changes can cause NLB to broadcast heartbeats less often (back-off) and/or allow for more heartbeat loss before logging an event.

| **Note** |
| --- |
| Changing the AliveMsgPeriod requires a re-load of the NLB driver (bind/unbind or reboot); changing AliveMsgTolerance requires only an NLB reload operation. |

**Q.** How Do I Secure My NLB Cluster?

**A.** NLB assumes that the LAN to which it is homed is trusted. Ensuring that only trusted machines are homed to this LAN is the first step to protecting an NLB cluster. As an additional measure, ensure that NLB remote control is disabled on all hosts. If it must be enabled, then it is vital that the firewall or router block traffic to UDP port 1717 and UDP port 2504 except to those clients that need access.

**Q.** How do I configure my cluster to handle load non-uniformly?

**A.** NLB distributes load among hosts within the cluster according to the load's associated port rule. By default, a port rule distributes an equal share of the load to each host. To configure a host to handle more or less than an equal share of the load, edit the port rule to clear the "Equal" load weight check box and enter a load weight number between 1 and 100.

The load weight is a relative weight among converged nodes in the cluster that indicates how much load a host should handle. To determine the percentage load a host will handle, divide that host's load weight by the sum of the load weights from the

other hosts in the cluster for the same port rule. (A port rule with the "Equal" checkbox checked has a load weight of 50.)

For example, consider the case of a two-host cluster. If Host 1's port rule has a load weight of 30 and Host 2's port rule has a load weight of 10, Host 1 will handle 30/(30+10) or 75% of the load. Host 2 will handle 25% of the load.

**Caution for Windows 2000 only:** Modifying the load weight of a port rule on a host causes all current connections handled by that host to reset. This includes connections associated with other port rules, but does not include traffic addressed to the dedicated IP address, if any. This caution does not apply to Windows Server 2003 and later. (Changing any other property of the cluster resets all current connections on that host for all versions of Windows.)

# Support for Sessions

Updated: February 10, 2004

Applies To: Windows Server 2003 with SP1

**Q.** Does NLB Support Sticky Sessions?

**A.** NLB supports limited forms of session stickiness:

- **Single Affinity.** When Single affinity is enabled, the clients port number isn't used and the mapping algorithm uses the clients full IP address to determine load distribution. As a result, all requests from the same client always map to the same host within the cluster. Because there is no time-out value (typical of dispatcher-based implementations), this condition persists until cluster membership changes. However, session stickiness may not be preserved if the cluster membership changes, in particular when a new host is added to the cluster, or a host is re-added after being temporarily out of service.

- **Class C Affinity.** As in the case of Single affinity, client port numbers are not used to calculate load distribution. When Class C affinity is enabled, the mapping algorithm bases load distribution on the Class C portion (the upper 24 bits) of the clients IP address. As with Single affinity, sessions may not be preserved if the cluster membership changes.

- **IPSec and VPN Sessions.** On Windows Server 2003, NLB has specialized support for sticky IPSec and VPN sessions. NLB preserves these sessions even if the cluster membership changes.

NLB cannot track the boundaries of UDP streams, since the logical session boundaries are defined by particular applications. Instead, Network Load Balancing affinity settings are used to assist in preserving client sessions. When a cluster host fails or leaves the cluster, its client connections are always dropped. After a new cluster membership is determined by *convergence* (see How Does NLB cluster convergence work?), clients that previously mapped to the failed host are remapped across the surviving hosts. All other client sessions are unaffected by the failure and continue to receive uninterrupted service from the cluster. In this manner, Network Load Balancing load balancing algorithm minimizes disruption to clients when a failure occurs.

When a new host joins the cluster, it induces convergence, and a new cluster membership is computed. When convergence completes, a minimal portion of the clients will be remapped to the new host. NLB tracks TCP connections on each host, and, after their current TCP connection completes, the next connection from the affected clients will be handled by the new cluster host; UDP streams are immediately handled by the new cluster host. This can potentially break some client sessions that span multiple connections or comprise UDP streams, or application sessions that span TCP sessions. Hence, hosts should be added to the cluster at times that minimize disruption of sessions. To completely avoid this problem, session state must be managed by the server application so that it can be reconstructed or retrieved from any cluster host. For example, session state can be pushed to a backend database server or stored in client cookies.

**Q.** How Does Single Affinity Mode Differ From No Affinity Mode? Which One Should I Use to Load Balance My Application?

**A.** In *Single Affinity* mode, NLB load balances traffic based only on the Source IP Address of the incoming connection. So, *Single Affinity* mode ensures that all TCP connections originating from the same client (IP Address) are sent to the same host in the cluster. This will continue indefinitely until a host is either added or removed from the cluster, at which time the connections originating from that IP address may get mapped to a different host in the cluster.

In *No Affinity* mode, NLB load balances traffic based on Source IP Address and Source Port of the incoming connection request. Therefore, in *No Affinity* mode, multiple connections from the same client may be handled by different hosts in the cluster as long as these connections have different source ports.

Which mode to use really depends on the application being load balanced. If the application makes use of sessions which persist over multiple TCP connections, NLB should be configured in *Single Affinity* mode because you want to make sure that all TCP connections which are part of a single session are mapped to the same host in the cluster.

On the other hand, *No Affinity* allows a better load distribution because it does not require client connections be handled by specific servers. Thus for applications that do not use sessions and for which it is acceptable for multiple incoming connections originating from the same client to be handled by different hosts in the cluster, *No Affinity* would be a better mode of operation.

**Q.** If My Clients Use SSL to Connect to My Front-End Web Servers, Can I Still Use NLB to Cluster These Web Servers?

**A.** Yes. For efficiency reasons, configure the port rule in *Single Affinity* mode. However, note the following side effects:

- Load balancing will not be as precise as in *No Affinity* mode.

- Sessions can break when hosts are either added to or removed from a cluster. Note that an SSL session will be transparently renegotiated by the protocol.

- If all of the sessions come through a client-side proxy, you will not see any load balancing since all of the TCP connections will have the same IP Address and they will all be handled by the same computer in the cluster.

# Application and Protocol Support

Updated: February 10, 2004

Applies To: Windows Server 2003 with SP1

**Q.** Can NLB be Used For Load Balancing Terminal Server Clusters?

**A.** Yes. See Load balancing and terminal servers (http://go.microsoft.com/fwlink/?LinkId=18378), in the Windows Server 2003 online Help.

For detailed information about using Terminal Server Session Directory with load balancing refer to the following white paper: Session Directory and Load Balancing Using Terminal Server, (http://go.microsoft.com/fwlink/?LinkId=18379).

**Q.** Does NLB Support WINS Resolution?

**A.** No, WINS names should not be automatically registered for the IP addresses configured on the NLB interface. WINS registration isn't NLB-aware and as a result, both the dedicated and virtual IP addresses will be registered with the servers name. Note however, that the IP addresses can be mapped statically in WINS.

**Q.** Does NLB Support DNS Resolution?

**A.** NLB does not automatically register the cluster name with DNS. The administrator must directly configure the DNS server. Note however, that the IP addresses can be mapped statically in WINS.

Also note that DHCP should not be used when NLB is bound to any network adapter on a host.

**Q.** Can I Use L2TP/IPSec on a NLB Cluster?

**A.** Yes, in Windows Server 2003 NLB supports both PPTP and L2TP VPN sessions. NLB support for both PPTP and L2TP protocol requires that NLB be configured in single affinity mode. For detailed information about configuring NLB with IPSec see the following Knowledge Base article: How to Configure Network Load Balancing Server Cluster to Work with IPSec, (http://go.microsoft.com/fwlink/?LinkId=18380).

**Q.** How Do I Configure NLB with IPSec?

**A.** Refer to the following Knowledge Base article: How to Configure Network Load Balancing Server Cluster to Work with IPSec, (http://go.microsoft.com/fwlink/?LinkId=18380).

**Q.** Can I Use Kerberos with Applications Load-Balanced by NLB? How?

**A.** Yes.

**Q.** Can I Use NLB with Host Header Names?

**A.** Yes, ensure that all host header names are hosted by every node in the NLB cluster.

**Q.** Can I Use NLB with .NET Remoting?

**A.** .NET Remoting pipelines method invocations from client to server over a single TCP connection, meaning that once a connection is established, it is reused for subsequent method invocations and is closed only after the connection remains idle for a pre-configured amount of time. NLB can load-balance these connections, but load-balancing will likely be coarse because the unit of load-balancing is the TCP connection, not a method invocation Since one client gets pinned to a specific server, load will appear well distributed only if you have many clients connected to the cluster at the same time. Each client will get load-balanced but the connection will stay open for a very long time.

**Q.** When Using .NET Remoting and NLB, Method Invocations From One Client are Against the Same Host and Are Not Load-Balanced. Why?

**A.** See question Can I use NLB with .NET Remoting?

**Q.** I Use NLB to Load-Balance COM+ but Load is Not Being Distributed. Why?

**A.** COM+ uses connection pooling on the client, which results in method invocations that are pipelined over existing TCP connections once established. NLB load-balances TCP connections so COM+ requests are not distributed among hosts. Instead of NLB, use COM+ load-balancing which was introduced to address this issue.

**Q.** Can I Use NLB as a Firewall?

**A.** NLB is not designed to be used as a firewall. Use a certified firewall solution in front of the cluster just as you would if the hosts were not part of a cluster.

**Q.** Can I Load-Balance NetBIOS Traffic?

**A.** Yes, it is possible, though not recommended for File and Print Services. Ensure that both of the following are true:

1. NetBIOS requires that the first IP address in TCP/IP must be used to access shares, so this must be the cluster IP address (this means you can't have a dedicated IP address). See the KB article System Error 53 Has Occurred Using Windows NT Load Balancing Service (http://go.microsoft.com/fwlink/?LinkId=18381) for further discussion.

2. Set the DisableStrictNameChecking registry value using the following instructions:

   - Start Registry Editor (Regedit.exe).
   - Locate and click the following key in the registry:
     HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\LanmanServer\Parameters
   - On the **Edit** menu, click **Add Value**, and then add the following registry value:

     Value name: DisableStrictNameChecking

     Data type: REG_DWORD

     Radix: Decimal

     Value: 1
   - Quit Registry Editor.
   - Open a command window.
   - Run net stop server.
   - Run net start server.

This solution is documented in the KB article Connecting to SMB Share on a Windows 2000-Based Server May Not Work with an Alias Name (http://go.microsoft.com/fwlink/?LinkId=18382).

**For More Information**

This is a preliminary document and may be changed substantially prior to final commercial release of the software described herein. The information contained in this document represents the current view of Microsoft Corporation on the issues discussed as of the date of publication. Because Microsoft must respond to changing market conditions, it should not be interpreted to be a commitment on the part of Microsoft, and Microsoft cannot guarantee the accuracy of any information presented after the date of publication.

# Server Clusters: Frequently Asked Questions for Windows 2000 and Windows Server 2003

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Published: January 1, 2003

# How is this Document Organized?

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** How is this Document Organized?

**A.** The various sections cover different aspects of server clusters from concepts to deployment to operational procedures:

- Introduction to Server clusters
- Availability
- Manageability and deployment
- Scalability
- Server cluster concepts
- Server requirements
- Interconnects
- Storage
- Highly available file servers
- Highly available print servers
- Removing single points of failure
- Active directory and domain controllers
- Security Considerations
- In-the-box HA services
- Geographically dispersed clusters
- Quorum
- Cluster-aware applications
- Miscellaneous topics

# What are Most Frequently Asked Questions?

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** What are Most Frequently Asked Questions?

**A.**

- How do I know if my Server cluster is a supported configuration?
- How many servers can there be in a single cluster?
- How do I benefit from more than two nodes in a cluster?
- Are dynamic disks supported in a cluster?
- Can a cluster disk be extended without rebooting?
- How can I replace a disk that has gone bad in a cluster?
- Why is zoning needed to isolate a Server cluster in a SAN?
- Can a cluster server boot from a SAN?
- Is Kerberos authentication possible for services hosted on a cluster?
- Is IIS cluster-aware?
- Can Server clusters span multiple sites?
- Will Microsoft provide a cluster file system?

# Introduction to Server Clusters

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** What is a Server Cluster?

**A.** A Server cluster is a collection of independent servers that together provide a single, highly available platform for hosting applications

**Q.** What are the benefits of Server clusters?

**A.** There are three primary benefits to server clustering: availability, manageability, and scalability:

| | |
|---|---|
| **Availability:** | Server clusters provide a highly available platform for deploying applications. A Server cluster ensures that applications continue to run in the event of planned downtime due to maintenance or unplanned downtime due to failures. Server clusters protect against hardware failures, failures of the Windows operating system, device drivers or application software. Server clusters allow operating system and application software to be upgraded across the cluster without having to take down the application. |
| **Manageability:** | Server clusters allow administrators to quickly inspect the status of all cluster resources and move workloads around onto different servers within the cluster. This is useful for manual load balancing, and to perform "rolling updates" on the servers without taking important data and applications offline. |
| **Scalability:** | Applications that can be partitioned can be spread across the servers of a cluster allowing additional CPU and memory to be applied to a problem. As the problem size increases, additional servers can be added to the cluster. A partitioned application is one where the data (or function) can be split up into independent units. For example, a customer database could be split into two units, one covering customers with names beginning A thru L and the other for customers with names beginning M thru Z. |

**Q.** What are Server clusters used for?

**A**. Server clusters provide a highly available platform for mission critical, line of business applications. These typically include database servers (such as Microsoft SQL Server), mail and collaboration servers (such as Exchange Server) and infrastructure servers such as file servers and print servers.

**Q.** Is Server cluster the same as Microsoft Cluster Server (MSCS) and/or Wolfpack?

**A.** The code name for the original Server cluster project was Wolfpack. When the product was released as part of Microsoft Windows NT 4.0 Enterprise Edition it was named Microsoft Cluster Server or MSCS. In Microsoft Windows 2000, the official name of the product became Server cluster.

**Q.** How do Server clusters fit into the larger Windows high availability story?

**A.** Server clusters are part of a much larger story for highly available applications running on Microsoft products. Windows has two cluster technologies, server clusters and Network Load Balancing (NLB). Server clusters are used to ensure that *stateful* applications such as a database (e.g., SQL Server) can be kept highly available by *failing over* the application from one server to another in the event of a failure. NLB is used to distribute client requests across a set of identical servers. NLB is particularly useful for ensuring that *stateless* applications such as a web server (e.g., IIS) are highly available and can be *scaled-out* by adding additional servers as the load increases.

In addition, Microsoft Application Center 2000 includes Component Load Balancing (CLB) CLB is a technology used to ensure COM+ applications are highly available and can scale-out.

The Windows platform also uses other technologies to ensure high availability and scalability. For example, Active Directory is made highly available through replication of the directory contents across a set of domain controllers.

**Q.** What is Scale-up verses Scale-out?

**A.** Scale-up is a term used to describe the scalability provided by large symmetric multi-processing (SMP) systems. As the load increases, more processors and more memory can be added to a single server, increasing the processing power and memory available for applications. Windows 2000 Datacenter Server and Windows Server 2003 Datacenter Edition provide the support for scaling up to large computers with many CPUs and large physical memory. In a scale-out environment, Server clusters are

deployed to ensure that the failure of the server does not cause the applications or services to fail. Scale-up is typically done for either hosting large applications that cannot be partitioned, or to consolidate a set of applications into a single server (or small number of servers in the case of a server cluster).

Scale-out is a term used to describe the idea that an application can be scaled by partitioning the workload and spreading it across a set of cooperating servers. If the load increases, additional servers can be added to the set to provide additional processing power and memory.

Server clusters are particularly useful for enhancing the availability of applications that can be scaled out across a set of nodes by allowing the individual pieces or partitions of a scale-out solution to be made highly available via failover.

**Q.** Is Server cluster a standard feature of all Windows operating system products?

**A.** Server clusters are not available in all Windows operating system products. Server clusters are available in:

- Windows NT Server, Enterprise Edition
- Windows 2000 Advanced Server and Datacenter server
- Windows Server 2003 Enterprise Edition and Datacenter Edition
- Windows Server 2003, 64 bit Enterprise Edition and Datacenter Edition

Server clusters are also available as part of the Server Appliance Kit, available to OEMs for building embedded solutions based on the Windows operating system.

**Q.** How do I know if my Server cluster is a supported configuration?

**A.** All server clusters must be qualified to be supported by Microsoft. A qualified configuration has undergone extensive testing using a hardware compatibility test provided by Microsoft. All qualified solutions appear on the Microsoft Hardware Compatibility List (HCL) (http://go.microsoft.com/fwlink/?LinkID=67738). Only cluster solutions listed on the HCL are supported by Microsoft.

The complete cluster solution must be listed on the *Cluster* HCL list. The complete solution includes the servers, the storage adapters, the interconnect type, the storage controllers firmware and driver versions. All of the components must match exactly, including any software, driver or firmware versions for the solution to be qualified.

The HCL contains a set of qualified cluster components. A solution built from qualified components does NOT imply that the solution is qualified.

**The cluster component lists have been a source of confusion in the past and we will be removing the cluster component lists (such as Cluster/RAID) from the HCL for Windows Server 2003.**

**Q.** Where are supported configurations listed?

**A.** All qualified solutions appear on the Microsoft Hardware Compatibility list (HCL) (http://go.microsoft.com/fwlink/?LinkID=67738). Only cluster solutions listed on the HCL are supported by Microsoft.

**Q.** Where can I find more documentation on Server clusters?

**A.** Server clusters are extensively covered in the online help in Windows 2000 and Windows Server 2003. Additional information can be found on the Microsoft web site at:

- http://go.microsoft.com/fwlink/?LinkID=67742
- http://go.microsoft.com/fwlink/?LinkID=67740
- http://go.microsoft.com/fwlink/?LinkID=67741

# Availability

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** Can Server clusters provide zero downtime for applications?

**A.**

- No. Server clusters can dramatically reduce planned and unplanned downtime. However, even with Server clusters, a server could still experience downtime from the following events:

- *Failover time:* If a Server cluster recovers from a server or application failure, or if it is used to move applications from one server to another, the application(s) will be unavailable for a non-zero period of time (typically under a minute).

- *Failures from which Server clusters can not recover:* There are types of failure that Server clusters do not protect against, such as loss of a disk not protected by RAID, loss of power when a UPS is not used, or loss of a site when there is no fast-recovery disaster recovery plan. Most of these can be survived with minimal downtime if precautions are taken in advance.

- *Server maintenance that requires downtime:* Server clusters can keep applications and data online through many types of server maintenance, but not all (for example: installing a new version of an application which has a new on-disk data format that requires reformatting preexisting data).

Microsoft recommends that clusters be used as one element in customers' overall programs to provide high integrity and high availability for their mission-critical server-based data and applications.

**Q.** Which types of applications and services benefit from Server clustering?

**A.** There are three types of server applications that will benefit from Server clusters:

1. "*In the box*" *services provided by the Windows platform:* For example: File shares, print queues, Microsoft Message Queue Server (MSMQ) services, and Component Services (formerly known as Transaction Server) services.

2. *Generic applications:* Server clusters include a point-and-click wizard for setting up any well-behaved server application for basic error detection, automatic recovery, and operator-initiated management (e.g., move from one server to the other). A "well behaved" server application is one which keeps a recoverable state on cluster disk(s), and whose client can gracefully handle a pause in service as the application is automatically re-started.

3. *Cluster-aware applications:* Software vendors test and support their application products on Server clusters.

# Manageability and Deployment

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** Do Server clusters provide a single image view for administration?

**A.** Yes, Server clusters provide administrators with a graphical interface (Cluster Administrator) and a command line tool (Cluster.exe available on Windows 2000 and Windows Server 2003) from which they can monitor and manage all of the resources in a cluster as if it was a single system. The administrator can:

- monitor the status of all servers and applications in the cluster
- setup new applications, file shares, print queues, etc. for high availability
- administer the recovery policies for applications and resources
- take applications offline, bring them back online, and move them from one server to another

The ability to graphically move workload from one server to another with only a momentary pause in service (typically less than a minute), means administrators can easily unload servers for planned maintenance without taking important data and applications offline for long periods of time.

**Q.** Can Server clusters be managed remotely?

**A.** Yes, an authorized cluster administrator can run Cluster Administrator from any Windows NT or Windows 2000 Workstation or Server, any Windows XP machine or any Windows Server 2003 on the network. The cluster.exe command line tool can be run remotely from any Windows 2000 Workstation or Server, any Windows XP machine or any Windows Server 2003 on the network.

**Q.** Can Server clusters be setup and configured remotely?

**A.** Yes, with Windows Server 2003, Cluster administrator and the cluster.exe command line tool can also be used to remotely setup and configure a Server cluster (e.g., create a new cluster, add a new server to an existing cluster or remove servers from a cluster).

**Q**. Is the server cluster software installed by default?

**A.** On Windows NT and Windows 2000, the Server cluster software is not installed by default. On Windows NT you must install the Enterprise Edition CD. With Windows 2000, you must install the Server cluster software using the optional component management tool.

With Windows Server 2003, the Server cluster software is installed by default on Enterprise Edition and Datacenter Edition. The cluster software is NOT configured by default and will not start until the server is either used to create a new cluster or the server is added to an existing cluster. In Windows Server 2003, you must use Cluster Administrator or the Cluster.exe command line tool to configure a cluster.

**Q.** Can a Server cluster be installed and configured using unattended installs?

**A.** Yes, to perform an unattended installation for a Windows 2000 Cluster using an Uttend.txt file, please consult the Windows 2000 Deployment Guide located on the Windows 2000 CD-ROM in the following location: %CDROM%\SUPPORT\TOOLS\DEPLOY.CAB\Unattend.doc

Additional information can be found in article 176507 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkID=67745).

**Q.** Do applications have to be installed separately on all the cluster servers?

**A.** It depends on the application. Each application that can be failed over between servers in a cluster must be available on all servers in the cluster. Historically, application setup has not been cluster-aware and therefore the application must be installed separately on each server.

With more recent versions of some applications, for example SQL Server 2000, the application setup is aware of Server clusters. In the case of Microsoft SQL Server 2000 setup, the appropriate files are copied to all servers and registry settings and other SQL Server configuration is done just once.

**Q.** How can I take advantage of extensibility features of ISA Server?

**A.** A number of third-party vendors offer solutions such as virus detection, content filtering, site categorization, reporting, and administration. Customers and developers also have the ability to create their own extensions to ISA Server. ISA Server includes a comprehensive software development kit for developing tools that build on ISA Server firewall, caching, and management features.

**Q.** Are cluster management operations scriptable?

**A.** Yes, there are a number of options for scripting management operations:

- The Cluster.exe command line tool allows command files to be built that can change the state of cluster resources, move resources around etc.. For more information about the command line, see the online help or type cluster at the command line on a server that has Server clusters installed or has the Windows server admin pack installed.

- In Windows 2000 and Windows Server 2003, there is a scriptable COM interface to the Server cluster APIs. This allows VBScript or any other scripting language supported by Windows to call the cluster APIs. These APIs provide a way to change the state of the cluster as well as return data about the resources or applications in a cluster. For more information about the cluster server APIs, see the Platform SDK, it has comprehensive documentation for the cluster APIs and the COM (automation server) APIs.

- In Windows Server 2003, there is a WMI provider for Server clusters that allows WMI scripts to manage the cluster. For more information about the cluster server WMI schema, see the Platform SDK.

**Q.** Can command line tools be used to manage a cluster?

**A.** Yes, Server clusters have a command line tool cluster.exe that can be used to manage the cluster. With Windows Server 2003, this command line tool can also be used to create new clusters, add servers to existing clusters and remove servers from clusters. Almost all of the functionality provided by Cluster Administrator is available through cluster.exe in Windows Server 2003.

**Q.** Is WMI supported for managing a cluster?

**A.** Yes, in Windows Server 2003, there is a WMI provider that allows a Server cluster to be managed. In addition, all the Server cluster events (such as server up and server down, resource online, offline, failed etc.) are available through WMI events.

**Q.** Does Server clusters support WMI eventing?

**A.** Yes, in Windows Server 2003, all of the Server cluster events (such as server up and server down, resource online, offline, failed etc.) are available through WMI events.

**Q.** Can Group Policy be used on cluster servers?

**A.** You can apply Group Policy to cluster servers. There are a few things to remember. Applications failover from one server to another in a cluster and will typically expect the same policies to be in effect no matter where they are hosted. You should ensure that all cluster servers have the same set of group policies applied to them.

With Windows Server 2003 and Windows 2000 SP3 onwards, virtual servers can be published in active directory. You should NOT apply group policies to a virtual server computer object. The policy will only be applied to the server that is currently hosting the virtual server and all policy settings may be lost if the application fails over.

**Q.** Is Systems Management Server (SMS) supported for deploying applications in a Server cluster?

**A.** No, at this time, SMS is not supported for deploying applications across a cluster.

**Q.** Is Application Center 2000 supported on a Server cluster?

**A.** No, Application Center 2000 provides a set of features that are intended for managing servers hosting web server front-end and middle-tier business logic. Server clusters are typically deployed to ensure high availability of the back-end database engine.

**Q.** Are MOM management packs available for monitoring Server clusters?

**A.** No, at this time, there are no server-aware MOM management packs.

**Q.** How do server clusters help administrators perform rolling upgrades?

**A.** With Server clusters, server administrators no longer have to do all of their maintenance within those rare windows of opportunity when no users are online. Instead, they can simply wait until a convenient off-peak time when one of the servers in

the cluster can be removed for maintenance and the workload distributed across the other cluster servers. By pointing-and-clicking in Cluster Administrator (or using scripts) to move all of the workload onto other servers, one of the servers in the cluster can be upgraded. Once the upgrade is complete and tested, that server can be rebooted where it will automatically re-join the cluster, ready for work. When convenient, the administrator repeats the process to perform maintenance on the other servers in the cluster. This ability to keep applications and data online while performing server maintenance is often referred to as doing "rolling upgrades" to your servers.

Server clusters allows rolling upgrades for a new release and the previous version.

**Q.** What combination of Windows versions supports rolling upgrades?

**A.** Server clusters allow rolling upgrades for a new release and the previous version. The following rolling upgrades are supported:

- Windows NT Enterprise Edition to Windows 2000
- Windows 2000 to Windows Server 2003

**Q.** Can I manage different versions of Server cluster from a single Cluster Administrator tool?

**A.** Yes, the Server cluster tools allow a mixed version cluster to be managed from a single point. During a rolling upgrade, a cluster may contain different versions of the operating system. As an example Windows 2000 and Windows Server 2003 can co-exist in the same cluster. The administration tools provided with Windows Server 2003 allow such a mixed-version cluster to be managed.

**Q.** Are there other manageability benefits with Server clusters?

**A.** Server clusters allow administrators to quickly inspect the status of all cluster resources, and move workload around onto different servers within the cluster. This is useful for manual load balancing, and to perform "rolling updates" on the servers without taking important data and applications offline.

# Scalability (Server Clusters: Frequently Asked Questions for Windows 2000 and Windows Server 2003)

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** Do Server clusters enhance server scalability?

**A.** The primary goal of Server clusters is to provide a highly available platform for applications.

There are some types of applications which can be scaled-out to take advantage of a set of machines. More machines can be added to the set to increase the CPU or memory available to the application. Applications of this type are typically scaled by partitioning the data set. For example, a SQL Server database may be scaled out by partitioning the database into pieces and then using database views to give the client applications the illusion of a single database.

Server clusters do not provide facilities to partition or scale-out an application; however, Server clusters allow such applications to be scaled-out in a highly available environment. Each of the partitions can be failed over independently within the set of machines (or to additional spare nodes) so that in the event of failure, a partition of the application remains available.

**Q.** Do Server clusters provide load balancing of applications?

**A.** Server clusters provide a manual load balancing mechanism. Applications can be moved around the servers of a cluster to distribute the load.

There are no automated tools provided with the operating system to automatically load balance applications and no enhanced failover policies that use load to determine the best placement for an application.

# Server cluster Concepts (Server Clusters: Frequently Asked Questions for Windows 2000 and Windows Server 2003)

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** What hardware do you need to build a Server cluster?

**A.** The most important criteria for Server cluster hardware is that it be included in a validated Cluster configuration on the Microsoft Hardware Compatibility List (HCL), indicating it has passed the Microsoft Cluster Hardware Compatibility Test. All qualified solutions appear on the Microsoft HCL (http://go.microsoft.com/fwlink/?linkid=67738). Only cluster solutions listed on the HCL are supported by Microsoft.

In general, the criteria for building a server cluster include the following:

- **Servers:** Two or more PCI-based machines running one of the operating system releases that support Server clusters (see below). Server clusters can run on all hardware architectures supported by the base Windows operating system, however, you cannot mix 32-bit and 64-bit architectures in the same cluster.

- **Storage:** Each server needs to be attached to a shared, external storage bus(es) that is/are separate from the bus containing the system disk, the startup disk or the pagefile disk. Applications and data are stored on one or more disks attached to this bus. There must be enough storage capacity on the shared cluster bus(es) for all of the applications running in the cluster environment. This shared storage configuration allows applications to failover between servers in the cluster.

  Microsoft recommends hardware Redundant Array of Inexpensive Disks (RAID) for all cluster disks to eliminate disk drives as a potential single point of failure. This means using a RAID storage unit, a host-based RAID adapter that implements RAID across disks, etc.

  SCSI is supported for 2-node cluster configurations only. Fibre channel arbitrated loop is supported for 2-node clusters only. Microsoft recommends using fibre channel switched fabrics for clusters of more than two nodes.

- **Network:** Each server needs at least two network cards. Typically, one is the public network and the other is a private network between the two nodes. A static IP address is needed for each group of applications that move as a unit between nodes. Server clusters can project the identity of multiple servers from a single cluster by using multiple IP addresses and computer names: this is known as a *virtual server*.

**Q.** What is a cluster resource?

**A.** A cluster resource is the lowest level unit of management in a Server cluster. A resource represents a physical object or an instance of running code. For example, a physical disk, an IP address, an MSMQ queue, a COM object all of these things are considered to be resources. From a management perspective, resources can be independently started and stopped and each is monitored to ensure that it is healthy.

Server cluster can monitor any arbitrary resource type. This is possible because Server clusters define a resource plug-in model. Each resource type has an associated resource plug-in or *resource dll* that is used to start, stop and provide health information that is specific to the resource type. For example, starting and stopping SQL Server is different from starting and stopping a physical disk. The resource dll takes care of the differences. Application developers and system administrators can build new resource dlls for their applications that can be registered with the cluster service.

Server clusters provides some generic plug-ins that can be used to make existing applications cluster-aware very quickly, known as *Generic Service* and *Generic Application*. With Windows Server 2003, a *Generic Script* resource plug-in was added that allows the resource dll to be written in any scripting language supported by the Windows operating system.

**Q.** What is a resource dependency?

**A.** A complete application actually consists of multiple pieces or multiple resources, some pieces are code and others are physical resources required by the application. The resources are related in different ways; for example, an application that writes to a disk cannot come online until the disk is online. If the disk fails, then, by definition, the application cannot continue to run since it writes to the disk. Resource dependencies can be defined by the application developer or system administrator

to capture these relationships. Resource dependencies define the order that resources are brought online and control how failures are propagated to the various pieces of the application.

**Q.** What is a resource group?

**A.** A resource group is a collection of one or more resources that are managed and monitored as a single unit. A resource group can be started or stopped. If a resource group is started, each resource in the group is started (taking into account any start order defined by the dependencies between resources in the group). If a resource group is stopped, all of the resources in the group are stopped. Dependencies between resources cannot span a group. In other words, the set of resources within a group is an autonomous unit that can be started and stopped independently from any other group. A group is a single, indivisible unit that is hosted on one server in a Server cluster at any point in time and it is the unit of failover.

**Q.** Can I have dependencies between resources in different groups?

**A.** No, resource dependencies are confined to a single group.

**Q.** What is a virtual server?

**A.** A virtual server is a resource group that contains an IP address resource and a network name resource. When an application is hosted in a virtual server, the application can be accessed by clients using the IP address or network name in that resource group. As the resource group fails over across the cluster, the IP address and network name remain the same, therefore the client becomes unaware of the physical location of the application and will continue to work in the event of a failure of one of the servers in the cluster.

**Q.** How can I take advantage of extensibility features of ISA Server?

**A.** A number of third-party vendors offer solutions such as virus detection, content filtering, site categorization, reporting, and administration. Customers and developers also have the ability to create their own extensions to ISA Server. ISA Server includes a comprehensive software development kit for developing tools that build on ISA Server firewall, caching, and management features.

**Q.** What is failover?

**A.** Server clusters monitor the health of the nodes in the cluster and the resources in the cluster. In the event of a server failure, the cluster software re-starts the failed server's workload on one or more of the remaining servers. If an individual resource or application fails (but the server does not), Server clusters will typically try to re-start the application on the same server; if that fails, it moves the application's resources and re-starts it on the other server. The process of detecting failures and restarting the application on another server in the cluster is known as *failover*.

The cluster administrator can set various recovery policies such as whether or not to re-start an application on the same server, and whether or not to automatically "failback" (re-balance) workloads when a failed server comes back online.

**Q.** Is failover transparent to users?

**A.** Server clusters do not require any special software on client computers, so the user experience during failover depends on the nature of the client side of their client-server application. Client reconnection can be made transparent, because the Server clusters software has restarted the applications, file shares, etc. at exactly the same IP address.

If a client is using "state-less" connections such as a standard browser connection, then the client would be unaware of a failover if it occurred between server requests. If a failure occurs while a client is connected to the failed resource, then the client will receive whatever standard notification is provided by the client side of their application when the server side becomes unavailable. This might be, for example, the standard "Abort, Retry, or Cancel?" prompt you get when using the Windows Explorer to download a file at the time a server or network goes down. In this case, client reconnection is not automatic (the user must choose "Retry"), but the user is fully informed of what is happening and has a simple, well-understood method of re-establishing contact with the server. Of course, in the meantime, the cluster service is busily re-starting the service or application so that, when the user chooses "Retry", it re-appears as if it never went away.

**Q.** What is failback?

**A.** In the event of the failure of a server in a cluster, the applications and resources are failed over to another node in the cluster. When the failed node rejoins the cluster (after reboot for example), that node now is free to be used by applications. A cluster administrator can set policies on resources and resource groups that allow an application to automatically move back to a node if it becomes available, thus automatically taking advantage of a node rejoining the cluster. These policies are known as *failback* policies. You should take care when defining automatic failback policies since depending on the application, automatically moving the application (which was working just fine) may have undesirable consequences on the clients using the applications.

**Q.** When an application restarts after failover, does it restore the application state at the time of failure?

**A.** No, Server clusters provide a fast crash restart mechanism. When an application is failed over and restarted, the application

is restarted from scratch. Any persistent data written out to a database or to files is available to the application, but any in-memory state that the application had before the failover is lost.

**Q.** At what level does failover exist?

**A.** At the resource group level.

**Q.** What is a Quorum Resource and how does it help Server clusters provide high availability?

**A.** Server clusters require a quorum resource to function. The quorum resource, like any other resource, is a resource which can only be owned by one server at a time, and for which servers can negotiate for ownership. Negotiating for the quorum resource allows Server clusters to avoid "split-brain" situations where the servers are active and think the other servers are down. This can happen when, for example, the cluster interconnect is lost and network response time is problematic. The quorum resource is used to store the definitive copy of the cluster configuration so that regardless of any sequence of failures, the cluster configuration will always remain consistent.

**Q.** What is active/active verses active/passive?

**A.** Active/Active and Active/Passive are terms used to describe how applications are deployed in a cluster. Unfortunately, they mean different things to different people and so the terms tend to cause confusion.

From the perspective of a single application or database:

- Active/Active means that the same application or pieces of the same service can be run concurrently on different nodes in the cluster. For example SQL Server 2000 can be configured such that the database is partitioned and each node can be running a single instance of the database. SQL Server provides the notion of views to provide a single image of the entire database.

- Active/Passive means that only one node in the cluster can be hosting the given application. For example, a single file share is active/passive. Any given file share can only be hosted on one node at a time.

From the perspective of a set of instances of an application or service:

- Active/Active means that different instances of the same application can be running concurrently on different cluster nodes. For example, each node in a cluster can be running SQL Server against a different database. A single cluster can support many file shares that are hosted on the nodes in a cluster concurrently.

- Active/Passive means that only one instance of a service can be running anywhere in the cluster. For example, there must only be a single instance of the DHCP service running in the cluster at any point in time.

From the perspective of the cluster:

- Active/Active means that all nodes in the cluster are running applications. These may be multiple instances of the same application or different applications (for example, in a 2-node cluster, WINS may be running on one node and DHCP may be running on the other node).

- Active/Passive means that one of the cluster nodes is spare and not being used to host applications.

Server clusters support all of these different combinations; the terms are really about how specific applications or sets of applications are deployed.

With the advent of more than two servers in a cluster, starting with Windows 2000 Datacenter, the term active/active is confusing because there may be four servers. When there are multiple servers, the set of options available for deployment becomes more flexible, allowing different configurations such as N+I.

**Q.** How do I benefit from more than two nodes in a cluster?

**A.** Failover is the mechanism that instance applications and the individual partitions of a partitioned application typically employ for high availability (the term Pack has been coined to describe a highly available, single instance application or partition).

In a 2-node cluster, defining failover policies is trivial. If one node fails, the only option is to failover to the remaining node. As the size of a cluster increases, different failover policies are possible and each one has different characteristics.

**Failover Pairs**

In a large cluster, failover policies can be defined such that each application is set to failover between two nodes. The simple example below shows two applications App1 and App2 in a 4-node cluster.

**Figure 1: Failover pairs**

Configuration has pros and cons:

| | |
|---|---|
| Pro | Good for clusters that are supporting heavy-weight[1] applications such as databases. This configuration ensures that in the event of failure, two applications will not be hosted on the same node. |
| Pro | Very easy to plan capacity. Each node is sized based on the application that it will need to host (just like a 2-node cluster hosting one application). |
| Pro | Effect of a node failure on availability and performance of the system is very easy to determine. |
| Pro | Get the flexibility of a larger cluster. In the event that a node is taken out for maintenance, the buddy for a given application can be changed dynamically (may end up with standby policy below). |
| Con | In simple configurations such as the one above, only 50% of the capacity of the cluster is in use. |
| Con | Administrator intervention may be required in the event of multiple failures. |

[1] A heavy-weight application is one that consumes a significant number of system resources such as CPU, memory or IO bandwidth.

Failover pairs are supported by server clusters on all versions of Windows by limiting the *possible owner list* for each resource to a given pair of nodes.

**Hot-Standby Server**

To reduce the overhead of failover pairs, the spare node for each pair may be consolidated into a single node, providing a hot standby server that is capable of picking up the work in the event of a failure.

**Figure 2: Standby Server**

Configuration has pros and cons:

| | |
|---|---|
| Pro | Good for clusters that are supporting heavy-weight applications such as databases. This configuration ensures that in the event of a single failure, two applications will not be hosted on the same node. |
| Pro | Very easy to plan capacity. Each node is sized based on the application that it will need to host, the spare is sized to be the maximum of the other nodes. |
| Pro | Effect of a node failure on availability and performance of the system is very easy to determine. |
| Con | Configuration is targeted towards a single point of failure. |
| Con | Does not really handle multiple failures well. This may be an issue during scheduled maintenance where the spare may be in use. |

Server clusters support standby servers today using a combination of the possible owners list and the preferred owners list. The preferred node should be set to the node that the application will run on by default and the possible owners for a given resource should be set to the preferred node and the spare node.

**N+I**

Standby server works well for 4-node clusters in some configurations, however, its ability to handle multiple failures is limited. N+I configurations are an extension of the standby server concept where there are N nodes hosting applications and I nodes spare.

**Figure 3: N+I Spare node configuration**

Configuration has pros and cons:

| | |
|---|---|
| Pro | Good for clusters that are supporting heavy-weight applications such as databases or Exchange. This configuration ensures that in the event of a failure, an application instance will failover to a spare node, not one that is already in use. |
| Pro | Very easy to plan capacity. Each node is sized based on the application that it will need to host. |
| Pro | Effect of a node failure on availability and performance of the system is very easy to determine. |
| Pro | Configuration works well for multiple failures. |
| Con | Does not really handle multiple applications running in the same cluster well. This policy is best suited to applications running on a dedicated cluster. |

Server cluster supports N+I scenarios in the Windows Server 2003 release using a cluster group public property **AntiAffinityClassNames**. This property can contain an arbitrary string of characters. In the event of a failover, if a group being failed over has a non-empty string in the **AntiAffinityClassNames** property, the failover manager will check all other nodes. If there are any nodes in the possible owners list for the resource that are NOT hosting a group with the same value in **AntiAffinityClassNames**, then those nodes are considered a good target for failover. If all nodes in the cluster are hosting groups that contain the same value in the **AntiAffinityClassNames** property, then the preferred node list is used to select a failover target.

**Failover Ring**

Failover rings allow each node in the cluster to run an application instance. In the event of a failure, the application on the failed node is moved to the next node in sequence.

**Figure 4: Failover Ring**

Configuration has pros and cons:

| | |
|---|---|
| Pro | Good for clusters that are supporting several small application instances where the capacity of any node is large enough to support several at the same time. |
| Pro | Effect on performance of a node failure is easy to predict. |
| Pro | Easy to plan capacity for a single failure. |

| | |
|---|---|
| Con | Configuration does not work well for all cases of multiple failures. If one Node 1 fails, Node 2 will host two application instances and Nodes 3 and 4 will host one application instance. If Node 2 then fails, Node 3 will be hosting three application instances and Node 4 will be hosting one instance |
| Con | Not well suited to heavy-weight applications since multiple instances may end up being hosted on the same node even if there are lightly-loaded nodes. |

Failover rings are supported by server clusters on the Windows Server 2003 release. This is done by defining the order of failover for a given group using the preferred owner list. A node order should be chosen and then the preferred node list should be set up with each group starting at a different node.

**Random**

In large clusters or even 4-node clusters that are running several applications, defining specific failover targets or policies for each application instance can be extremely cumbersome and error prone. The best policy in some cases is to allow the target to be chosen at random, with a statistical probability that this will spread the load around the cluster in the event of a failure.

Configuration has pros and cons:

| | |
|---|---|
| Pro | Good for clusters that are supporting several small application instances where the capacity of any node is large enough to support several at the same time. |
| Pro | Does not require an administrator to decide where any given application should failover to. |
| Pro | Provided that there are sufficient applications or the applications are partitioned finely enough, this provides a good mechanism to statistically load balance the applications across the cluster in the event of a failure. |
| Pro | Configuration works well for multiple failures. |
| Pro | Very well tuned to handling multiple applications or many instances of the same application running in the same cluster well. |
| Con | Can be difficult to plan capacity. There is no real guarantee that the load will be balanced across the cluster. |
| Con | Effect on performance of a node failure is not easy to predict. |
| Con | Not well suited to heavy-weight applications since multiple instances may end up being hosted on the same node even if there are lightly-loaded nodes. |

The Windows Server 2003 release of server clusters randomizes the failover target in the event of node failure. Each resource group that has an empty preferred owners list will be failed over to a random node in the cluster in the event that the node currently hosting it fails.

**Customized control**

There are some cases where specific nodes may be preferred for a given application instance.

Configuration has pros and cons:

| | |
|---|---|
| Pro | Administrator has full control over what happens when a failure occurs. |
| Pro | Capacity planning is easy, since failure scenarios are predictable. |
| Con | With many applications running in a cluster, defining a good policy for failures can be extremely complex. |
| Con | Very hard to plan for multiple cascaded failures. |

Server clusters provide full control over the order of failover using the preferred node list feature. The full semantics of the preferred node list can be defined as:

| **Preferred Node List** | **Move group to best possible initiated via administrator** | **Failover due to node or group failure** |
|---|---|---|
| Contains all nodes in cluster | Group is moved to highest node in preferred node list that is up and running in the cluster. | **Group is moved to the next node on the preferred node list.** |
| Contains a subset of the nodes in the cluster | Group is moved to highest node in preferred node list that is up and running in the cluster.<br>If no nodes in the preferred node list are up and running, the group is moved to a random node. | **Group is moved to the next node on the preferred node list.**<br>**If the node that was hosting the group is the last on the list or was not in the preferred node list, the group is moved to a random node.** |
| **Empty** | **Group is moved to a random node.** | **Group is moved to a random node.** |

**Q.** How many resources can be hosted in a cluster?

**A.** The theoretical limit for the number of resources in a cluster is 1,674; however, you should be aware that the cluster service periodically polls the resources to ensure they are alive. As the number of resources increases, the overhead of this polling also increases.

# Server Requirements

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** How many servers can be clustered?

**A.** The number of servers in a Server cluster is dependent on the Windows product and the Windows release. The following table lists the server sizes:

| Windows Operating System | Maximum number of servers |
|---|---|
| Windows NT Enterprise Edition | 2 |
| Windows 2000 Advanced Server | 2 |
| Windows 2000 Datacenter Server | 4 |
| Windows Server 2003 Enterprise Edition | 8 |
| Windows Server 2003 Datacenter Edition | 8 |

**Q.** Is it necessary that the servers in a Server cluster be identical?

**A.** The cluster hardware compatibility test does not require that all the servers in a qualified cluster be identical. As cluster sizes increase and therefore the investment in hardware increases, it is likely that different types of servers will appear in a single cluster.

**The qualification process and the listing process are being improved to allow heterogeneous solutions to be more easily defined and qualified. This is particularly important to OEMs where server families change relatively often and therefore the additional qualification passes required increases dramatically with the current process. The server itself has never been an issue during qualification, it is typically the HBA or other piece of the storage subsystem, and therefore there is no real reason to mandate exact servers in a given qualified solution.**

**Q.** Can 32-bit servers and 64-bit servers be mixed in the same Server cluster?

**A.** No, a single Server cluster must contain all 32-bit servers or all 64-bit servers.

**Q.** Can I use any of my servers to make a Server cluster?

**A.** All qualified solutions appear on the Microsoft Hardware Compatibility list (HCL) (http://go.microsoft.com/fwlink/?linkid=67738). Only cluster solutions listed on the HCL are supported by Microsoft. You can use any servers that are listed as part of a configuration to build a complete solution.

# Interconnects

Updated: May 5, 2006

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** What types of networks are required for cluster interconnects?

**A**. The network interface controllers along with any other components used in certified cluster configurations must have the Windows logo and appear on the Microsoft Hardware Compatibility List. The interconnect itself must support TCP/IP and UDP traffic and must appear as a single, non-routed LAN segment or subnet.

**Q.** Do Server clusters support high-bandwidth, low latency interconnects through WinSock direct?

**A.** The Server cluster code itself does not use WinSock direct path for intra-cluster communication. All communication between cluster nodes is over TCP/IP or UDP. Server clusters can use, but may not take advantage of any high-bandwidth, low latency connection between nodes that looks like a standard NDIS network adapter.

**Q.** How many network adapters should a cluster server have?

**A.** The cluster nodes must be connected by two or more independent networks in order to avoid a single point of failure. The use of two local area networks (LANs) is required. Cluster configurations that have only one network are not supported. At least 2 networks must be configured for cluster communications. Typically, one network is a *private network*, configured for cluster communications only and the other is a *public network*, configured for both client access and cluster communications.

**Q.** Can a cluster support multiple adapters configured as public?

**A.** Yes, however, there are a couple of caveats:

- Each network adapter must be on a different subnet.
- You can create different IP address resources that can be associated with different adapters; however, there is no way to make a resource or application dependent on the two networks so that if one fails, the application will continue to be available. In Server clusters, the dependencies must all be online for the dependent application to be online.

For future versions of the cluster technology, we are working on a feature to allow more flexible dependencies such as: a resource can depend on A OR B for it to be online.

**Q.** Can a cluster support multiple private networks?

**A.** Yes.

**Q.** Why do I see heartbeat packets on the networks marked as client-only?

**A.** In Windows 2000 and beyond, the Server cluster software heartbeats through the public network as well as the private network regardless of the configuration of the public network. This is to ensure that the cluster service can detect failures of the public network adapters and can failover an application if the node currently hosting it cannot communicate with the outside world.

**Q.** How should the different networks be configured?

**A.** The cluster nodes must be connected by two or more independent networks in order to avoid a single point of failure. The use of two local area networks (LANs) is typical. The configuration of a cluster with nodes connected by only one network is not supported.

You should configure the private network as Internal Cluster Communication Only and the public network as All Communications.

**Q.** What type of information is carried over the cluster network?

**A.** The cluster service uses the cluster network for the following intra-cluster traffic:

- Server cluster query/management and control information
- Heartbeats for failure detection
- Intra-cluster communication to ensure tight consistency of cluster configuration

- Cluster join requests when a node reboots or recovers from a failure

**Q.** What types of protocol are supported for applications in a Server cluster?

**A.** Cluster-aware applications must use protocols based on top of TCP/IP. The cluster software only supports the TCP/IP protocols for failover out-of -the-box.

**Q.** Will failover occur if the public network on one server fails?

**A.** Yes, in Windows 2000 and above, additional heartbeats are sent across the public networks to detect public network and/or network adapter failures and to cause applications to failover if the node they are currently hosted on cannot communicate with the other nodes.

**Q.** Is network adapter teaming supported in a Server cluster?

**A.** Yes, however there are caveats. The use of network adapter teaming on all cluster networks concurrently is not supported. At least one of the cluster networks that are enabled for internal communication between cluster nodes must not be teamed. Typically, the un-teamed network is a private interconnect dedicated to this type of communication. The use of network adapter teaming on other cluster networks is acceptable; however, if communication problems occur on a teamed network, Microsoft Product Support Services may require that teaming be disabled. If this action resolves the problem or issue, then you must seek further assistance from the manufacturer of the teaming solution.

**Q.** Is DHCP supported for Server cluster virtual servers?

**A.** No, virtual servers must have static IP addresses.

**Q.** Is DHCP supported for Server cluster nodes?

**A.** Yes, addresses may be assigned to the physical nodes dynamically by DHCP, but manual configuration with static addresses is recommended.

**Q.** Is NetBIOS required to run Server clusters?

**A.** In Windows NT and Windows 2000, NetBIOS is required for Server clusters to function correctly.

In Windows Server 2003, the cluster service does not require NetBIOS. A basic principle of server security is to disable unneeded services. To determine whether to disable NetBIOS, consider the following:

- Some services and applications other than the cluster service use NetBIOS. Review all the ways a clustered server functions before disabling NetBIOS on it.

- With NetBIOS disabled, you will not be able to use the Browse function in Cluster Administrator when opening a connection to a cluster. Cluster Administrator uses NetBIOS to enumerate all clusters in a domain.

- With NetBIOS disabled, Cluster Administrator does not work if a cluster name is specified.

You can control the NetBIOS setting for the cluster through the Cluster IP Address resource property sheet (parameters).

**Q.** Is IPSec supported in a Server cluster?

**A.** Although it is possible to use Internet Protocol Security (IPSec) for applications that can failover in a server cluster, IPSec was not designed for failover situations and we recommend that you do NOT use IPSec for applications in a server cluster.

**Q.** How do Server clusters update router tables when doing IP failover?

**A.** As part of its automatic recovery procedures, the cluster service will issue IETF standard ARP "flush" commands to routers to flush the machine addresses related to IP addresses that are being moved to a different server.

**Q.** How does the Address Resolution Protocol (ARP) cause systems on a LAN to update their tables that translate IP addresses to physical machine (MAC) addresses?

**A.** The ARP specification states that all systems receiving an ARP request must update their physical address mapping for the source of the request. The source IP address and physical network address are contained in the request. As part of the IP address registration process, the Windows TCP/IP driver broadcasts an ARP request on the appropriate LAN several times. This request asks the owner of the specified IP address to respond with its physical network address. By issuing a request for the IP address being registered, Windows can detect IP address conflicts; if a response is received, the address cannot be safely used.

When it issues this request, though, Windows specifies the IP address being registered as the source of the request. Thus, all systems on the network will update their ARP cache entries for the specified address, and the registering system becomes the new owner of the address.

Note that if an address conflict does occur, the responding system can send out another ARP request for the same address, forcing the other systems on the subnet to update their caches again. Windows does this when it detects a conflict with an address that it has successfully registered.

**Q.** Server clusters use ARP broadcasts to re-set MAC addresses, but ARP broadcasts don't pass routers. So what about clients behind the routers?

**A.** If the clients were behind routers, they would be using the router(s) to access the subnet where the cluster servers were located. Accordingly, the clients would use their router (gateway) to pass the packets to the routers through whatever route (OSPF, RIP, etc) is designated. The end result is that their packet is forwarded to a router on the same subnet as the cluster. This router's ARP cache is consistent with the MAC address(es) that have been modified during a failover. Packets thereby get to the correct Virtual server, without the remote clients ever having seen the original ARP broadcast.

# Storage (Server Clusters: Frequently Asked Questions for Windows 2000 and Windows Server 2003)

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

There are many storage questions, these questions are categorized as general questions, questions about deploying Server clusters on a storage area network (SAN) and network attached storage (NAS) questions.

**General Storage Questions**

**Q.** What storage interconnects are supported by Server clusters?

**A.** Cluster Server does not limit the type of storage interconnects supported; however, there are some requirements of the storage subsystem that limit the types from a practical perspective. For example, all of the cluster nodes should be able to access the storage device. This typically impacts the interconnect since only interconnects that allow multiple initiators (i.e. nodes) can be used. The set of interconnects that are currently part of qualified configurations on the HCL include: SCSI (of various flavors), Fibre channel arbitrated loop and fibre channel switched fabrics.

Remember that only clusters where the full configuration appears on the Cluster HCL are supported by Microsoft.

**Q.** How do I configure the nodes and the storage on a SCSI cluster?

**A.** You must make sure that all of the devices on the SCSI bus have different SCSI Ids. By default, SCSI adapters tend to have Id 7. You should make sure that the adapters in each node have different Ids. Likewise, the disks should be given unique SCSI Ids on the bus.

For a SCSI bus to work correctly it must be terminated. There are many ways to terminate the bus, both internally (at the host adapter) and externally (using Y cables). To ensure that the cluster can survive different types of failures (specifically being able to power down one of the nodes), the SCSI bus should be terminated using passive components such as a Y cable. Internal termination, which requires the adapter to be powered up, is not recommended.

| **Note** |
| --- |
| Microsoft only allows 2-node clusters to be built using SCSI storage interconnects. |

**Q.** Does Server clustering support fibre channel arbitrated loop (FC-AL)?

**A.** Yes, Microsoft only allows 2-node clusters to be built using FC-AL storage interconnects. Multiple clusters on a single fibre channel loop are NOT supported.

**Q.** Can multiple clusters be connected to the same storage controller?

**A.** Yes, there is a special device qualification test for storage controllers that ensures they respond correctly if multiple clusters are attached to the same controller. For multiple clusters to be connected to the same controller the storage controller MUST appear on the Multi-cluster device Hardware Compatibility List (HCL) AND each of the individual end-to-end cluster solutions must appear on the Cluster Hardware Compatibility List. For example: EMC Symmetrix 5.0 is on the multi-cluster device HCL list. Multiple clusters (say a Dell PowerEdge cluster and a Compaq Proliant cluster) can be connected to the EMC Symmetrix storage controller as long as Dell PowerEdge + EMC Symmetrix AND Compaq Proliant + EMC Symmetrix as both on the cluster HCL.

**Q.** Will failover occur if the storage cable is pulled from the host bus adapter (HBA)?

**A.** If the storage cable is pulled from the host bus adapter (HBA), there may be a pause before the adapter reacts to losing the connection, however, once the HBA has detected the communication failure, the disk resources within the cluster using the specific HBA will fail. This will trigger a failover to occur and the resource will be brought back on line on another node in the cluster.

If the storage cable is reconnected, the Windows operating system may not rescan for new hardware automatically (this depends on the driver used for the adapter). You may need to manually initiate a rescan for new devices. Once the rescan is done, the node can host any of the physical disk resources. If failback policies are set, any resources that failed over when the cable was removed will failback to the node when the cable is replaced.

| **Note** |
| --- |

An HBA) is the storage interface that is deployed in the server. Typically this is a PCI card that connects the server to the storage fabric.

**Q.** Will Server clusters protect my disks from hardware failures?

**A.** No, Cluster server protects against server failure, operating system or application failure and planned downtime due to maintenance. Microsoft strongly suggests that application and user data is protected against disk failure using redundancy techniques such as mirroring, RAID or replication either in hardware or in software.

**Q.** Do Server clusters support RAID or mirrored disks?

**A.** Yes, Microsoft strongly suggests that application and user data is protected against disk failure using redundancy techniques such as mirroring, RAID or replication either in hardware or in software.

**Q.** Are dynamic disks supported in a cluster?

**A.** Windows server products shipped from Microsoft do not provide support for dynamic disks in a server cluster environment. The Volume Manager for Windows 2000 add-on product from Veritas can be used to add the dynamic disk features to a server cluster. When the Veritas Volume Manager product is installed on a cluster, Veritas should be the first point of support for cluster issues.

**Q.** Can a cluster disk be extended without rebooting?

**A.** Yes, cluster disks can be extended without rebooting if the storage controller supports dynamic expansion of the underlying physical disk. Many new storage controllers virtualize the *Logical Units* (LUNs) presented to the operating system and these controllers allow LUNs to be grown online from the storage controller management console. Microsoft provides a tool called DiskPart that allows volumes or partitions to be grown online to take advantage of the newly created space on the disk without disruption to applications or users using the disk. There are separate versions of DiskPart for Windows 2000 and Windows Server 2003. The Windows 2000 version is available as a free download on the web and the Windows Server 2003 version is shipped on the distribution media.

| **Note** |
| --- |
| An LUN equates to a disk device visible in Disk Administrator. |

**Q.** Can additional disks be added to a cluster without rebooting?

**A.** Yes, you can insert a new disk or create a new LUN and make that visible to the cluster nodes. You should only make the disk visible to one node in the cluster and then create a cluster resource to protect that disk. Once the disk is protected, you can make the LUN visible to other nodes in the cluster. In some cases you may need to do a rescan in device manager to find the new disk. In other cases (especially with fibre channel) the disk may be automatically detected.

**Q.** Can disks be removed from the cluster without rebooting?

**A.** Yes

**Q.** What types of disks can be used for cluster disks?

**A.** Microsoft recommends that all partitions on the cluster disks be formatted with the NTFS file system. This is for two reasons. Firstly, NTFS provides access controls that can be used to secure the data on the disk. Secondly, NTFS can recover from volumes that have been forcibly dismounted; other file systems may become corrupt if they are forcibly dismounted.

Server clusters only support Master Boot Record (MBR) format disks. Cluster disks cannot be GPT format.

**Q.** Can tape devices or other non-disk devices be attached to the same storage bus as the Cluster Disks?

**A.** It depends on the storage interconnect. Server clusters use SCSI reserve and reset to arbitrate for cluster disks. In Windows NT and Windows 2000 cluster server performs an untargeted bus reset. In Windows Server 2003 it is possible to target the reset, however, it may fallback to an untargeted reset. If a tape device receives a reset, this will typically trigger the tape to rewind.

Server cluster does not provide any arbitration mechanism for tape devices that are visible from multiple servers, therefore tape devices are not protected against concurrent access from multiple servers.

Microsoft does NOT support attaching a tape device to the SCSI bus containing the cluster disks in the case of a SCSI cluster or

the loop in and fibre channel arbitrated loop.

Tape devices can be attached to a switched fabric as long as they are not visible through the same adapters as the cluster disks. This can be achieved by either putting the tape drive in a different zone to the cluster disks or by LUN masking techniques.

**Q.** Are software fault tolerant disks (software RAID or mirroring) supported in a Server cluster?

**A.** Windows server products shipped from Microsoft do not provide support for software RAID or mirroring, however, there are 3rd party products that provide this functionality in a clustered environment.

**Q.** Is the Virtual Snapshot Service (VSS) supported in a Server cluster?

**A.** Yes, the Virtual Snapshot Service is new with Windows Server 2003 and provides basic snapshot capabilities that are used by backup applications to create consistent, single point in time backups. The cluster service has a VSS provider that allows the cluster service configuration to be snapshoted and stored as part of the system state by these backup applications.

**Q.** Do Timewarp snapshots work in a Server cluster?

**A.** No, Timewarp is a new feature in Windows Server 2003 that allows persistent snapshot to be created and exposed to clients. TImewarp makes use of features that are not cluster-aware and it is not supported in a cluster at this time.

**Q.** Are hardware snapshots or business recovery volumes supported in a Server cluster?

**A.** Yes, you can use facilities in the latest storage controllers to create snapshots of existing volumes. Note, however, when you create a snapshot of a disk you should NOT expose the snapshot back to the same cluster as the original disk. The cluster service uses the disk signature to uniquely identify a disk. With a snapshot, the disk and the snapshot have the same disk signature.

If you create a hardware snapshot or a business recovery volume of a cluster disk you should expose the snapshot to another server or cluster (typically a dedicated backup server).

**Q.** What other considerations are there when creating clustered disks?

**A.** Modern storage controllers provide a virtual view of the storage itself. A physical RAID set can be carved into multiple logical units that are exposed to the operating system as individual disks or LUNs. If you intend to carve up physical disks in this way and expose them as independent LUNs to the hosts, you should think carefully about the IO characteristics and the failure characteristics remember underneath, there is only a finite bandwidth to each spindle.

Microsoft recommends that you do not create a LUN for use as the quorum disk from the same underlying physical disks that you will be using for applications. The availability of the cluster is directly related to the availability of the quorum disk. If I/Os to the quorum disk take too long, the cluster server will assume that the quorum disk has failed and initiate a failover of the quorum device. At that point, all other cluster related activity is suspended until the quorum device is brought back online.

**Q.** How can I replace a disk that has gone bad in a cluster?

**A.** The answer depends on the Windows release:

- Windows NT Enterprise Edition
    - FTEdit tool along with some manipulate of the registry. This is covered in article 243195 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?linkid=67761).
- Windows 2000
    - DumpCfg.
    - ClusterRecovery Reskit tool provided on Windows Server 2003 Reskit
- Windows Server 2003
    - Automated system recovery.
    - ConfDisk. This is covered in article 280425 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?linkid=67762).

- ClusterRecovery Reskit tool provided on Windows Server 2003 Reskit

# Storage Area Networks (SAN) questions

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** What is a Storage Area Network (SAN)?

**A.** A storage area network (SAN) is defined as a set of interconnected *devices* (e.g. disks and tapes) and *servers* that are connected to a common communication and data transfer infrastructure such as a fibre channel. The common communication and data transfer mechanism for a given deployment is commonly known as the *storage fabric*. The purpose of the SAN is to allow multiple servers access to a pool of storage in which any server can potentially access any storage unit. Clearly in this environment, management plays a large role providing security guarantees (who is authorized to access which devices) and sequencing or serialization guarantees (who can access which devices at what point in time).

**Q.** Why use a SAN?

**A.** Storage area networks provide a broad range of advantages over locally connected devices. They allow compute units to be detached from storage units, thereby allowing flexible deployment and re-purposing of both servers and storage dynamically to suit the current business needs without having to be concerned about buying the right devices for a given server or without re-cabling a datacenter to attach storage to a given server.

**Q.** Can a cluster be connected to a SAN?

**A.** Yes, Microsoft fully supports storage area networks both as part of the base Windows platform and as part of a complete Windows Clustering high availability solution.

**Q.** Can a cluster co-exist on a SAN with other servers?

**A.** One or more Server clusters can be deployed in a single SAN environment along with standalone Windows servers and/or with other non-Windows platforms.

**Q.** What additional SAN configuration is required to put a cluster on a shared SAN?

**A.**

- The cluster disks for each cluster on a SAN MUST be deployed in their own zone. All host bus adapters (HBAs) in a single cluster must be the same type and at the same firmware revision level. Many storage and switch vendors require that ALL HBAs on the same zone, and in some cases the same fabric, are the same type and have the same firmware revision number.

- All storage device drivers and HBA device drivers in a cluster must be at the same software version.

- When adding a new server to a SAN, ensure that the HBA is appropriate for the topology. In some configurations, adding an arbitrated loop HBA to a switched fibre fabric can result in widespread failures of the storage fabric. There have been real-world examples of this causing serious downtime.

| **Note** |
| --- |
| An HBA is the storage interface that is deployed in the server. Typically this is a PCI card that connects the server to the storage fabric. |

**Q.** What is LUN masking or selective presentation?

**A.** LUN masking (also implemented as selective presentations) allows users to express at the controller level a specific relationship between a LUN and a host. Only the hosts that are configured to access the LUN should be able to see it.

**Q.** What is hardware zoning verses software zoning?

**A.** Zoning can be implemented in hardware/firmware on controllers or on software on the hosts. Microsoft recommends that controller based (or hardware) zoning be used since this allows for uniform implementation of access policy that cannot be interrupted or compromised by node disruption or failure of the software component.

**Q.** Why is zoning needed to isolate a Server cluster in a SAN?

**A.** The cluster uses mechanisms to protect access to the disks that can have an adverse effect on other clusters that are in the same zone. By using zoning to separate the cluster traffic from other cluster or non-cluster traffic, there is no chance of interference.

The diagram shows two clusters sharing a single storage controller. Each cluster is in its own zone. The LUNs presented by the storage controller must be allocated to individual clusters using fine-grained security provided by the storage controller itself. LUNs must be setup so that every LUN for a specific cluster is visible and accessible from all nodes of the cluster. A LUN should only be visible to one cluster at a time. The cluster software itself takes care of ensuring that although LUNs are visible to all cluster nodes, only one node in the cluster accesses and mounts the disk at any point in time.

The multi-cluster device test used to qualify storage configurations for the multi-cluster HCL list tests the isolation guarantees when multiple clusters are connected to a single storage controller in this way.

**Q.** Can a cluster server boot from a SAN?

**A.** Yes, however, there is a set of configuration restrictions around how Windows boots from a storage area network. For more information, see article 305547 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?linkid=67837).

Server clusters require that the startup disk, page file disk and system disk be on a different storage bus to the cluster server disks. To boot from a SAN, you must have a separate HBA for the boot, system and pagefile disks than the cluster disks. You MUST ensure that the cluster disks are isolated from the boot, system and pagefile disks by zoning the cluster disks into their own zone.

**Q.** Can I use multiple paths to SAN storage for high availability?

**A.** Microsoft does not provide a generic driver that allows multiple paths to the storage infrastructure for high availability; however, several vendors have built their own proprietary drivers that allow multiple HBAs and SAN fabrics to be used as a highly available storage infrastructure. For a Server cluster that has multi-path drivers to be considered supported, the multipath driver MUST appear as part of the complete cluster solution on the Cluster Hardware Compatibility List (HCL). NOTE: The driver version is VERY important and it MUST match the qualified version on the HCL.

**Q.** Can the startup disk, pagefile disks and the cluster disks be on the same SAN fabric?

**A.** No, in Windows Server 2003, there is a registry key that allows the startup disk, pagefile disks, and cluster disks to be on the same bus. This feature is enabled by a registry key, which helps ensure that it is not accidentally enabled by customers who do not understand the implications of this configuration. It is intended for OEMs to ship qualified and tested configurations and not for a typical end-user or administrator to set up in an ad hoc manner.

In the original release of Windows Server 2003, the registry key is:

**HKLM\SYSTEM\CurrentControlSet\Services\ClusSvc\Parameters\ManageDisksOnSystemBuses 0x01**

In Windows Server 2003 with Service Pack 1 (SP1), the registry key is:

**HKLM\SYSTEM\CurrentControlSet\Services\ClusDisk\Parameters\ManageDisksOnSystemBuses 0x01**

In Windows Server 2003 SP1, the key path was changed to use “Clusdisk” as a subkey instead of “ClusSvc.” This change was made to avoid issues during setup. However, the change is backward compatible, and systems that use the old key locations do not need to be modified.

**Q.** Can serverless backup be performed against cluster disks?

**A.** No, the cluster disk arbitration mechanism uses SCSI reserve and release operations. Once a server arbitrates for a cluster disk, that disk cannot be accessed by any other server on the storage network.

# Network Attached Storage (NAS) questions

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** What is Network Attached Storage (NAS)?

**A.** Network attached storage (NAS) is an alternative way to connect storage to servers that is built using standard network components such as Ethernet or other LAN technologies. The application servers access storage using file system functions such as open file, read file, write file, close file, etc.. These higher-level functions are encapsulated in protocols such as CIFS, NFS or AppleShare and run across standard IP-based connections.

**Q.** Can Server clusters use NAS for the shared storage?

**A.** Yes, providing the applications can store data on file shares and the file shares are accessible to the applications as they failover across the cluster, there is no reason why NAS cannot be used as the storage solution in a cluster.

There is currently no support in Windows to use NAS as the quorum resource.

In Windows Server 2003, we are providing a new quorum resource Majority Node Set that can be used to remove the need for a shared disk for the quorum resource. If you combine NAS storage with Majority Node Set quorum, you can build a failover cluster that does not require shared disks in the traditional sense of SCSI or SAN.

# Highly Available File Servers

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** Can I have an active/active file server?

**A.** The Windows 2000 resource kit contains a tool ClusTool that can be used to migrate file share settings from a single node to a cluster environment.

**Q.** Can FRS be used to replicate clustered file shares?

**A.** No, the file replication service (FRS) provided by Windows cannot be used to replicate a clustered file share. This means that clustered file shares cannot be the source or target for redundant links in a DFS tree. See the online documentation for DFS for more details.

**Q.** What file system types are supported in a cluster?

**A.** All partitions on clustered disks should be formatted with NTFS.

**Q.** Does client-side caching (offline folders) work with Server clusters?

**A.** Yes, in Windows Server 2003, you can select client-side caching (also know as offline folders) for clustered file shares.

**Q.** Is the Encrypting File System (EFS) supported on cluster disks?

**A.** With Windows Server 2003, the encrypting file system (EFS) is supported on clustered file shares. To enable EFS on a clustered file share, you must perform a number of tasks to configure the environment correctly:

- EFS can only be enabled on file shares when the virtual server has Kerberos enabled. By default, Kerberos is not enabled on a virtual server. To enable Kerberos you must check the Enable Kerberos Authentication check box on the network name resource that will be used to connect to the clustered file share. NOTE: Enabling Kerberos on a network name has a number of implications that you should ensure you fully understand before checking the box.

- All cluster node computer accounts, as well as the virtual server computer account, must be trusted for delegation. See online help for how to do this.

- To ensure that the users private keys are available to all nodes in the cluster, you must enable roaming profiles for users who want to store data using EFS. See online help for how to enable roaming profiles.

Once the cluster file shares have been created and the configuration steps above carried out, users data can be stored in encrypted files for added security.

**Q.** How many file shares can be hosted on a cluster?

**A.** The number of file shares in a cluster depends on the number of nodes in the cluster and the failure scenarios that you are trying to protect against. A single server has a limit for the number of file shares it can support so you need to take that into account when planning your cluster.

In a 2-node cluster, if one node fails, the remaining node must pick up all of the file shares. Therefore, to ensure the highest availability, the cluster should host the maximum number of shares that can be hosted by a single node.

| **Note** |
| --- |
| 2-node Server clusters are focused on high availability, not scale-out, therefore you should not expect to hold more shares on a 2-node cluster than a single node. |

In a 4-node cluster, you have other options that may be more appropriate, depending on the failure scenarios that you wish to protect against. For example, if you wish to survive one node failing at any point in time, you can configure the shares so that if one node fails, its work is spread across the remaining three nodes. This means that each node could be loaded to 66% of the maximum number of shares and still be within the maximum limit of a single node in the event of a single failure. In this case, the cluster can host three times the number of shares that a single server can host. If you wish to survive two nodes failing, then a 4-node cluster can hold twice as many shares (since if two nodes fail, the remaining two nodes need to pick up the load from the two failed servers) and so on.

In general, as the number of nodes in a cluster increases, the more options you have and the more you can use server clusters to scale-out a highly available infrastructure.

**Q**. What is the maximum capacity of a cluster disk?

**A.** Server cluster does not impose any restrictions on the size of a volume supported.

**Q.** How many disks can Server cluster support?

**A.** In Windows 2000, each clustered disk had to have a drive letter assigned to it, therefore the maximum number of clustered disks in a single cluster was limited to 23 volumes (26 letters of the alphabet minus A and B [Floppy drives] and C [system/boot drive]).

In Windows Server 2003, there is no longer a requirement for a clustered disk to have a driver letter assigned, therefore the number of disks is limited by the number that can be physically attached and the number supported by the underlying operating system.

| **Note** |
| --- |
| Applications can access disks with no drive letters in one of two ways a) directly using the object name associated with the disk or more likely b) by using mount points to link multiple disks together that can be accessed using a single drive letter. |

**Q.** How can a cluster support more disks than there are drive letters?

**A.** Using file system mount points. For more information about using mount points with clustered disks see the online help for Windows Server 2003.

**Q.** Why can I browse shares owned by different virtual servers?

**A.** File shares are not scoped by the virtual server name that is hosting them. If you use a browsing tool (e.g. the NET VIEW command) you will see all the shares that are currently hosted on the physical node.

# Highly Available Print Servers

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** How do I cluster a printer?

**A.** Printers can be clustered using the Print Spooler cluster resource. The Windows 2000 and the Windows Server 2003 online help both give specific examples and the steps necessary to create a highly available print server.

**Q.** Can I have active/active print servers?

**A.** Yes, it is possible to host multiple print spoolers on a single Server cluster. The spoolers can be failed over independently and can run concurrently on multiple nodes in the cluster.

**Q.** How do I migrate printer settings from a single server to a cluster?

A. Microsoft provides a tool (Print Migrator) as part of the ResKit that can be used to migrate printer settings from one node to another or from one node to a Server cluster.

**Q.** How many printer resources can be hosted on a cluster?

**A.** The number of printers is limited by the number of resources the cluster can support, however, as the number of printers increases, so will the time to failover.

# Removing all Single Points of Failure

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** What other services does the server cluster rely on?

**A.** The cluster service itself relies on being able to authenticate and sign communications traffic between the cluster nodes. It uses the domain infrastructure to authenticate using the cluster service account. In an environment with Server clusters installed, you must ensure that the domain infrastructure is highly available; any disruption to the infrastructure can result in the clusters becoming unavailable.

**Q.** What other services do I need to think about?

**A.** In order for applications to remain highly available in a clustered environment, any services that the application requires external to the cluster must also be highly available. Many of these services have mechanisms such as replication or being made cluster-aware themselves to protect against failures. Examples of services that you should think about include WINS, DNS, DHCP, the domain infrastructure, firewalls, etc.

**Q.** What other single points of failure should I protect against?

**A.** Server clusters are a mechanism that protects applications against hardware, operating system and application failures. There are some types of hardware failure that you should think about:

- Disk failures you should use RAID or mirroring to protect against disk failures
- Hardware failures multiple hot swap fans in the server, redundant power supplies etc.
- Network failures redundant networks that do not have any shared components
- Site failures disaster recovery plans

# Active Directory, DNS and Domain Controllers

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** Is Kerberos authentication possible for services hosted on a cluster?

**A.** Yes, in Windows 2000 SP3 and above and Windows Server 2003, the cluster service publishes a computer object in Active Directory. This provides the infrastructure with sufficient state to allow Kerberos authentication against applications and services hosted in a virtual server.

For more information about Kerberos and how it works, see the TechNet web site (http://go.microsoft.com/fwlink/?linkid=67842).

**Q.** Can cluster servers also be domain controllers?

**A.** Yes, however, there are several caveats that you should fully understand before taking this approach. We recommend that Server cluster nodes are not domain controllers and that you co-locate a domain controller on the same subnet as the Server cluster public.

If you must make the cluster nodes into domain controllers, consider the following important points:

- If one cluster node in a 2-node cluster is a domain controller, all nodes must be domain controllers. It is recommended that you configure at least two of the nodes in a 4-node Datacenter cluster as domain controllers.

- There is overhead that is associated with the running of a domain controller. A domain controller that is idle can use anywhere between 130 to 140 megabytes (MB) of RAM, which includes the running of Windows Clustering. There is also replication traffic if these domain controllers have to replicate with other domain controllers within the domain and across domains. Most corporate deployments of clusters include nodes with gigabytes (GB) of memory so this is not generally an issue.

- If the cluster nodes are the only domain controllers, they each have to be DNS servers as well, and they should point to each other for primary DNS resolution, and to themselves for secondary DNS resolution. You have to address the problem of the ability to not register the private interface in DNS, especially if it is connected by way of a crossover cable (2-node only). For information about how to configure the heartbeat interface refer to article 258750 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkID=46549). However, *before* you can accomplish step 12 in KB article 258750, you must first modify other configuration settings, which are outlined in article 275554 (http://go.microsoft.com/fwlink/?LinkID=67844).

  If the cluster nodes are the only domain controllers, they must each be Global Catalog servers, or you must implement domainlets.

- The first domain controller in the forest takes on all flexible single master operation roles (refer to article 197132 at http://go.microsoft.com/fwlink/?LinkID=67847). You can redistribute these roles to each node. However, if a node fails over, the flexible single master operation roles that the node has taken on are no longer available. You can use Ntdsutil to forcibly take away the roles and assign them to the node that is still running (refer to article 223787 at http://go.microsoft.com/fwlink/?LinkID=67851). Review article 223346 at http://go.microsoft.com/fwlink/?LinkID=19807) for information about placement of flexible, single master operation roles throughout the domain.

- If a domain controller is so busy that the Cluster service is unable to gain access to the Quorum drive as needed, the Cluster service may interpret this as a resource failure and cause the cluster group to fail over to the other node. If the Quorum drive is in another group (although it should not be), and it is configured to affect the group, a failure may move all group resources to the other node, which may not be desirable. For more information regarding Quorum configuration, please refer to the article 280345 listed in the "Reference" section (http://go.microsoft.com/fwlink/?LinkID=67855).

- Clustering other programs such as SQL Server or Exchange Server in a scenario where the nodes are also domain controllers, may not result in optimal performance due to resource constraints. You should thoroughly test this configuration in a lab environment prior to deployment.

- You may want to consider making cluster nodes domain controllers (refer to KB article 171390 at http://go.microsoft.com/fwlink/?LinkID=67857 for more information), but if a domain controller is already local, or there is a reliable high-speed connectivity to a domain controller available, Microsoft does not recommend implementing them on cluster nodes.

| **Note** |
| --- |
| You must promote a cluster node to a domain controller by using the Dcpromo tool *prior* to installing Windows Clustering. |

- You must be extremely careful when demoting a domain controller that is also a cluster node. When a node is demoted from a domain controller, the security settings and the user accounts are radically changed (user accounts are demoted to local accounts for example).

**Q.** Are virtual servers published in active directory?

**A.** Yes, in Windows 2000 SP3 and above and in Windows Server 2003, each virtual server has the option of being published in active directory.

Although the network name server cluster resource publishes a computer object in active directory, that computer object should NOT be used for administration tasks such as applying Group Policy. The ONLY role for the virtual server computer object in Windows 2000 and Windows Server 2003 is to allow Kerberos authentication and delegation and for cluster-aware, active directory-aware services (such as MSMQ) to publish service provider information.

**Q.** Is the cluster configuration stored in active directory?

**A.** No, at this time there is no cluster information other than the computer objects for virtual servers published in Active directory.

**Q.** Do Server clusters make domain controllers highly available?

**A.** No, domain controllers use replication across a set of servers to achieve high availability.

**Q.** How should my DNS server be configured to work with Server clusters?

**A.** The cluster service account needs to be able to publish records. In a secure, DNS backed zone, the DNS administrator can chose to restrict the access rights for users. The cluster service account must be granted permission to create records or alternatively, the records can be pre-created. If the records are pre-created, you should not set the zone to dynamic update.

# Security Considerations (Server Clusters: Frequently Asked Questions for Windows 2000 and Windows Server 2003)

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** How do I update the cluster service account password?

**A.** The cluster service account on ALL nodes in the cluster must match to ensure that the intra-cluster communication can be successfully authenticated. The cluster service itself sends messages between cluster nodes under a variety of conditions and if any of those communications fail, the cluster node will be removed from the cluster (i.e. the cluster service will be stopped). It is not possible to determine when the cluster service will establish communication and therefore there is no clear window that allows the cluster service account to be changed in a reliable way while ensuring that the cluster remains running.

**Windows 2000**

On Windows 2000, the cluster account password can only be reliably changed using the following steps:

1. Stop the cluster service on ALL nodes in the cluster
2. Change the password of the cluster service account at the domain controller
3. Update the service control manager password on ALL cluster nodes
4. Re-start the cluster service on all the cluster nodes

**Windows Server 2003**

The cluster.exe command on Windows Server 2003 has the ability to change the cluster account password dynamically without shutting down the cluster service on any of the nodes. The cluster.exe command changes the domain account password and updates the service control manager account information about all nodes in the cluster.

**Cluster /cluster**:*cluster_name1[,cluster_name2,]***/changepassword***[:new_password[,old_password]]* [**/skipdc**] [**/force**] [/options]

For more information refer to the online help for Windows Server 2003.

**Q.** What other security considerations and best practices do I need to worry about for Server clusters?

**A.** For security best practices, see the online help for Windows Server 2003.

# In-the-box HA Services

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** What highly available operating system services are provided on the Windows release?

**A.** Server clusters following highly available services by default in the Windows operating system:

- IP Address and Network Name: highly available network configuration to allow clients to location independent and failover unaware
- DHCP: Highly available DHCP server
- MSDTC: Highly available distributed transaction coordinator
- IIS: Highly available web server and FTP server*
- File Share: Highly available file share service and DFS
- Message Queue: Highly available MSMQ service
- MSMQ triggers: Highly available MSMQ trigger service (new for Windows Server 2003)
- Print Spooler: Highly available printer service
- WINS: Highly available WINS service

*In Windows Server 2003, IIS is made cluster-aware using the generic script resource and the scripts provided. There is no specific IIS resource type.

**Q.** Are MSMQ triggers supported in a Server cluster?

**A.** Yes, in Windows Server 2003, the MSMQ trigger service can be made highly available using Server clusters.

**Q.** Is IIS cluster-aware?

**A.** Yes, in Windows 2000, IIS web sites and FTP services can be made highly available using the IIS Server Instance resource type. In Windows Server 2003, the IIS Server Instance resource type was replaced with a set of generic scripts provided in the Windows Server 2003 release (see the online help for more information about converting IIS web servers and FTP servers from Windows 2000 to Windows Server 2003).

Although IIS web servers can be made highly available by failover using Server clustering, Microsoft recommends that you use a load balancing cluster such as provided by Network Load Balancing (NLB), another cluster mechanism provided by the Windows operating system to make IIS highly available and to scale-out a web service or web farm.

Depending on the access characteristics, you may choose either Server clusters or Network Load Balancing clusters to provide highly available FTP servers. Server clustering is good for FTP sites with high update rates or where you want to have a single copy of the FTP content. Network Load Balancing is good for mainly read-only FTP Servers.

**Q.** How is the IIS metabase kept consistent across the cluster?

**A.** The Windows operating system comes with a tool (IISSync) that allows the IIS metabase to be kept in sync across the nodes in the cluster. For more details see the online help.

# Geographically Dispersed Clusters

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** Can Server clusters span multiple sites?

**A.** Yes, Server clusters support a single cluster spanning multiple sites. This is known as a geographically dispersed cluster. All qualified geographically dispersed cluster solutions appear on the Microsoft Hardware Compatibility list (HCL) (http://go.microsoft.com/fwlink/?LinkID=67738). Only cluster solutions listed on the HCL are supported by Microsoft.

**Q.** How is a geographically dispersed cluster defined?

**A.** A geographically dispersed cluster is a Server cluster that has the following attributes:

1. Has multiple storage arrays, at least one deployed at each site. This ensures that in the event of failure of any one site, the other site(s) will have local copies of the data that they can use to continue to provide the services and applications.

2. Nodes are connected to storage in such a way that in the event of a failure of either a site or the communication links between sites, the nodes on a given site can access the storage on that site. In other words, in a two-site configuration, the nodes in site A are connected to the storage in site A directly and the nodes in site B are connected to the storage in site B directly. The nodes in site A con continue without accessing the storage on site B and vice-versa.

3. The storage fabric or host-based software provides a way to mirror or replicate data between the sites so that each site has a copy of the data. Different levels of consistency are available.

The following diagram shows a simple two-site cluster configuration.

**Q.** Will geographically dispersed clusters give me disaster tolerance, or disaster recovery?

**A.** The goal of multi-site Server cluster configurations is to ensure that loss of one site in the solution does not cause a loss of the complete application for business continuance and disaster recovery purposes. Sites are typically up to a few hundred miles apart so that they have completely different power, different communications infrastructure providers, and are placed so that natural disasters (e.g., earthquakes) are extremely unlikely to take out more than one site.

Geographically dispersed clusters do not provide disaster tolerance, since, in some cases, manual intervention is required to restart the applications.

**Q.** Can a geographically dispersed cluster use asynchronous replication between sites?

**A.** Yes, however, there are a couple of caveats:

- The quorum data must be synchronously replicated between the sites. To ensure that the Server cluster guarantees of consistency are met, the cluster database must be kept consistent across all nodes. If the quorum disk is replicated across the sites, it MUST be replicated synchronously.

  In Windows Server 2003, a new quorum resource *Majority Node Set* can be used in these configurations as an alternative to replicating the quorum disk.

- If data is replicated asynchronously, in the event of a site failure, the secondary site will be consistent, but out of date. You should check that the applications can handle going back in time and that the client experience makes sense for the business. Applications such as SQL Server can be hosted on asynchronous replication; however, there are a bunch of restrictions and warning that you should be aware of (see the SQL Server high availability documentation for rules around multi-site replication of SQL Server data).

- If data is replicated at the block level, the replication must preserve the order of writes to the secondary site. Failure to ensure this will lead to data corruption.

**Q.** Does Microsoft provide a complete end-to-end geographically dispersed cluster solution?

**A.** No, Microsoft does not provide a software mechanism for replicating application data from one site to another in a geographically dispersed cluster. Microsoft works with hardware and software vendors to provide a complete solution. All qualified geographically dispersed cluster solutions appear on the Microsoft Hardware Compatibility list (HCL) (http://go.microsoft.com/fwlink/?LinkID=67738). Only cluster solutions listed on the HCL are supported by Microsoft.

**Q.** What additional requirements are there on a Server cluster to support multiple sites?

**A.** The Microsoft server clustering software itself is unaware of the extended nature of geographically dispersed clusters. There are no special features in Server cluster in Windows 2000 or Windows Server 2003 that are specific to these kinds of configuration. The network and storage architectures used to build geographically dispersed clusters must preserve the semantics that the server cluster technology expects. Fundamentally, the network and storage architecture of geographically dispersed server clusters must meet the following requirements:

1. The private and public network connections between cluster nodes must appear as a single, non-routed LAN (e.g., using technologies such as VLANs to ensure that all nodes in the cluster appear on the same IP subnets).

2. The network connections must be able to provide a *maximum guaranteed* round trip latency between nodes of no more than 500 milliseconds. The cluster uses heartbeat to detect whether a node is alive or not responding. These heartbeats are sent out on a periodic basis. If a node takes too long to respond to heartbeat packets, the cluster service starts a heavy-weight protocol to figure out which nodes are really still alive and which ones are dead; this is known as a cluster re-group. The heartbeat interval is not a configurable parameter for the cluster service (there are many reasons for this, but the bottom line is that changing this parameter can have a significant impact on the stability of the cluster and the failover time). 500ms round-trip is significantly below any threshold to ensure that artificial re-group operations are not triggered.

3. Windows 2000 requires that a cluster have a single shared disk known as the quorum disk. The storage infrastructure can provide mirroring across the sites to make a set of disks appear to the cluster service like a single disk, however, it must preserve the fundamental semantics that are required by the physical disk resource:

   - Cluster service uses SCSI reserve commands and bus reset to arbitrate for and protect the shared disks. The semantics of these commands must be preserved across the sites even in the face of complete communication failures between sites. If a node on site A reserves a disk, nodes on site B should not be able to access the contents of the disk. These semantics are essential to avoid data corruption of cluster data and application data.

   - The quorum disk must be replicated in real-time, synchronous mode across all sites. The different members of a mirrored quorum disk MUST contain the same data.

In Windows Server 2003, you can use either a mirrored/replicated quorum disk or a new resource *Majority Node Set* for a multi-site cluster.

**Q.** What additional requirements are there on applications?

**A.** As with the Server cluster itself, applications are unaware of the extended nature of geographically dispersed clusters. There is no topology or configuration information provided to applications to make them aware of the different sites.

Typically, no changes are required to ensure that an application runs, as expected, on a geographically dispersed cluster. However, you should check with the application vendors. In some cases different failure timeout periods may be required since disk accesses and failover times may be longer due to the extended distance between clusters and the need to provide mirroring or replication of data between sites.

# Quorum

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** What is the quorum used for?

**A.** Server clusters require a quorum resource to function. The quorum resource, like any other resource, is a resource which can only be owned by one server at a time, and for which servers can negotiate for ownership. Negotiating for the quorum resource allows Server clusters to avoid "split-brain" situations where the servers are active and think the other servers are down. This can happen when, for example, the cluster interconnect is lost and network response time is problematic. The quorum resource is used to store the definitive copy of the cluster configuration so that regardless of any sequence of failures, the cluster configuration will always remain consistent.

**Q.** What options do I have for my quorum resource?

**A.** In Windows 2000, there are two quorum-capable resources:

- **Physical Disk Resource**

  This allows a disk on the shared cluster storage bus to be used as the quorum resource. The cluster code uses SCSI commands to arbitrate for the quorum disk ensuring only one node owns the quorum disk at any point in time. This is the standard quorum resource that Microsoft recommends for all production Windows 2000 clusters.

  | **Note** |
  | --- |
  | Some storage vendors provide their own quorum capable resources for specific hardware solutions (e.g., IBM Shark Storage) or software solutions (such as Veritas Volume Manager). You should use these if they are required for your environment. |

- **Local Quorum**

  This quorum-capable resource allows a single node cluster to be setup without having a second storage bus. This type of cluster is useful for developing cluster-aware software without having to have a multi-node cluster.
  Local Quorum can be used in a production environment if you want to take advantage of the resource health monitoring and local restart facilities provided by Server cluster on a single node.

In Windows Server 2003 we have introduced another quorum capable resource type

**Majority Node Set**

A majority node set is a single quorum resource from a Server cluster perspective; however, all of the quorum data is actually stored on multiple disks across the cluster. The majority node set resource takes care to ensure that the cluster configuration data stored on the majority node set is kept consistent across the different disks.

See *What is Majority Node Set?* for more details.

**Q.** Can other applications share the quorum disk?

**A.** Microsoft recommends that you do NOT use the quorum disk for other applications in the cluster and that the quorum disk is restricted to use by the cluster service itself. If you use the quorum disk for other applications you should be aware of the following:

- The quorum disk health determines the health of the entire cluster. If the quorum disk fails, the cluster service will become unavailable on all cluster nodes. The cluster service checks the health of the quorum disk and arbitrates for exclusive access to the physical drive using standard I/O operations. These operations are queued to the device along with any other I/Os to that device. If the cluster service I/O operations are delayed by extremely heavy traffic, the cluster service will declare the quorum disk as failed and force a regroup to bring the quorum back online somewhere else in the cluster. To protect against malicious applications flooding the quorum disk with I/Os, the quorum disk should be protected. Access to the quorum disk should be restricted to the local administrator group and the cluster service account.

- If the quorum disk fills up, the cluster service may be unable to log required data. In this case, the cluster service will fail, potentially on all cluster nodes. To protect against malicious applications filling up the quorum disk, access should be restricted to the local administrator group and the cluster service account.

- The cluster service itself will always try to bring the quorum disk back online. In doing so, it may violate the failover and failback policies assigned to applications in the same group.

**Q.** Can a NAS device be used as the shared quorum disk?

**A.** No, out-of-the-box, the cluster service supports physical disks on the shared cluster bus or in Windows Server 2003 *Majority Node Set* quorum resources.

**Q.** What is Majority Node Set?

**A.** A majority node set is a single quorum resource from a Server cluster perspective; however, all of the quorum data is actually stored on multiple disks across the cluster. The majority node set resource takes care to ensure that the cluster configuration data stored on the majority node set is kept consistent across the different disks. This allows cluster topologies as follows:

The disks that make up the majority node set could, in principle be local disks physically attached to the nodes themselves or disks on a shared storage fabric. In the majority node set implementation that is provided as part of Server clusters in Windows Server 2003, every node in the cluster uses a directory on its own local system disk to store the quorum data. If the configuration of the cluster changes, that change is reflected across the different disks. The change is only considered to have been committed (i.e. made persistent), if that change is made to:

(<Number of nodes configured in the cluster>/2) + 1

This ensures that a majority of the nodes have an up-to-date copy of the data. The cluster service itself will only start up, and therefore bring resources on line, if a majority of the nodes configured as part of the cluster are up and running the cluster service. If there are fewer nodes, the cluster is said not to have quorum and therefore the cluster service waits (trying to restart) until more nodes try to join. Only when a majority or quorum of nodes, are available, will the cluster service start up the resources be brought online. This way, since the up-to-date configuration is written to a majority of the nodes, regardless of node failures, the cluster will always guarantee that it starts up with the latest and most up-to-date configuration.

# Cluster-Aware Applications

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** What is a Cluster Aware Application?

**A.** A cluster-aware application is an application that calls the cluster APIs to determine the context under which it is running (such as the virtual server name etc.) and can failover between nodes for high availability.

**Can applications that were not written for a cluster be made highly available?**

Yes, Server clusters provide a plug-in environment that allows resource dlls to provide the necessary control and health monitoring functions to make existing applications highly available.

Server clusters provide a set of generic resource types that can be used to make existing applications failover in a cluster. In Windows 2000 there are two generic resource types:

| | |
|---|---|
| **Generic application** | allows any application to be started, stopped and monitored by the cluster service |
| **Generic Service** | allows an existing Windows Service to be started, stopped and monitored. |

These generic services provide very rudimentary health monitoring (for example, is the process that was started still a valid process on the system). It does not check that the application is servicing requests since this requires specific knowledge of the application. The generic resources can be used to make applications failover relatively quickly; however, to provide a more appropriate health check, Microsoft recommends that you build an application-specific resource dll.

In Windows Server 2003, we have provided an additional resource type (**Generic Script**) that allows the start/stop and health monitoring functions to be implemented as scripts rather than using C or C++. This makes the job of building application-specific resource plug-ins much more manageable and easier.

**Q.** How do I build a cluster-aware application?

**A.** Server clusters provides a rich API set that allows applications to recognize and utilize the cluster environment. These APIs are fully documented in the Platform SDK.

**Q.** Should I use the Generic Service or Generic Application resource to make my application highly available?

**A.** The generic services provide very rudimentary health monitoring (for example, is the process that was started still a valid process on the system). It does not check that the application is servicing requests since this requires specific knowledge of the application. The generic resources can be used to make applications failover relatively quickly; however, to provide a more appropriate health check, Microsoft recommends that you build an application-specific resource dll.

**Q.** Does Microsoft validate or logo software products that work with Server clusters?

**A.** Yes, Server clustering is an optional component of the Windows Advanced Server logo program. Applications can be logoed as working on a Server cluster.

**Q.** What Microsoft Applications are cluster-aware?

**A.** The following services shipped as part of the Windows operating system are cluster-aware:

- DHCP Highly available DHCP server
- MSDTC Highly available distributed transaction coordinator
- IIS Highly available web server and FTP server*
- File Share Highly available file share service and DFS
- Message Queue Highly available MSMQ service
- MSMQ triggers Highly available MSMQ trigger service (new for Windows Server 2003)

- Print Spooler Highly available printer service
- WINS Highly available WINS service

The following additional Microsoft Products are cluster-aware:

- SQL Server 6.5, 7.0, 2000 and upwards
- Exchange Server 5.5 and upwards
- Services for Unix 3.0 and upwards

**Q.** Does Exchange 2000 support active/active clusters?

**A.** Yes, there are some caveats to supporting Exchange 2000 in an active/active configuration.

**Q.** Does SQL Server support active/active clusters?

**A.** Yes, SQL Server allows the following:

- Multiple nodes in a cluster hosting different databases. Each database can be failed over independently.
- Multiple nodes in a cluster hosting partitions of a single database using database views to tie the different instances into a single logical database from a client perspective.

**Q.** Where do I find information about writing cluster-aware applications?

**A.** The cluster concepts and APIs are fully documented in the Platform SDK. In addition, there are several examples in the Platform SDK that can be used to demonstrate Server cluster integration.

**Q.** Is Services for Macintosh (SFM) supported in a Server cluster?

**A.** No, Services for Macintosh is not supported in a Server cluster.

**Q.** Is Services for Unix (SFU) supported in a Server cluster?

**A.** Yes, Services for Unix supports highly available NFS shares in SFU 3.0.

# Miscellaneous Topics

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Q.** Can Server clusters and Network Load Balancing be used on the same set of servers?

**A.** No, Microsoft Server clusters (MSCS) and Network Load Balancing (NLB) are not supported on the same set of nodes. Both Server clusters and Network Load Balancing clusters control and configure network adapters. Since they are not aware of each other, configuring one can interfere with the other.

**Q.** Can I use antivirus software with a Server cluster?

**A.** Yes, you should make sure that the vendor has tested their solution in a Server cluster environment. Antivirus software typically layers into the storage stack as a disk driver. This can have an impact on the clusters ability to failover a disk if the driver does not support the required features.

**Q.** Does Microsoft provide a Distributed Lock Manager (DLM)?

**A.** No, at this time, Microsoft has no plans to release a distributed lock manager, however, that may change if there is sufficient customer demand for a DLM service.

| **Note** |
| --- |
| Do not confuse a distributed lock manager with a *cluster file system*. A cluster file system can be built in a number of ways, using a lock manager is one of them. However, just providing a lock manager does not solve the cluster file system problem. |

**Q.** Will Microsoft provide a shared disk cluster file system?

**A.** Microsoft is continually looking at ways to improve the services it provides on the Windows operating system. A shared disk cluster file system is a way to provide a number of attributes in a cluster:

- A single file system namespace visible to all applications on all nodes in the cluster
- High speed access to disks from any node in the cluster

**Q.** How do Server clusters and Fault tolerant servers relate?

**A.** Server clusters address a number of availability issues:

- Hardware failures
- Operating system failures
- Application failures
- Site failures
- Operating system and application upgrades

Fault tolerant servers provide an extremely reliable server platform that addresses hardware failures by providing redundancy at the hardware level. In some cases, fault tolerant servers can be used to address site failures.

In and of themselves, fault tolerant servers do not address issues relating to operating system and application monitoring and failure recovery, nor do they address upgrading the operating system or applications without taking the service down.

In summary, Server clusters are about providing high availability, fault tolerant servers provide high reliability. By combining highly reliable, fault tolerant servers with Server clusters, you get the best of both worlds; a set of reliable servers that can provide high availability in the face of operating system and application failures and upgrades.

**Q.** How do I find Server cluster KB Articles?

**A.** All cluster KB articles can be found at http://go.microsoft.com/fwlink/?LinkID=538

- All Windows NT 4.0 related articles have keyword "MSCS"
- All Windows 2000 articles have keyword "W2000MSCS"

This should allow easy selection of Server cluster related articles.

# Server Clusters : Storage Area Networks - For Windows 2000 and Windows Server 2003

# Introduction (Server Clusters : Storage Area Networks - For Windows 2000 and Windows Server 2003)

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A storage area network (SAN) is defined as a set of interconnected *devices* (e.g. disks and tapes) and *servers* that are connected to a common communication and data transfer infrastructure such as fibre channel. The common communication and data transfer mechanism for a given deployment is commonly known as the *storage fabric*. The purpose of the SAN is to allow multiple servers access to a pool of storage in which any server can potentially access any storage unit. Clearly in this environment, management plays a large role in providing security guarantees (who is authorized to access which devices) and sequencing or serialization guarantees (who can access which devices at what point in time).

SANs evolved to address the increasingly difficult job of managing storage at a time when the storage usage is growing explosively. With devices locally attached to a given server or in the server enclosure itself, performing day-to-day management tasks becomes extremely complex; backing up the data in the datacenter requires complex procedures as the data is distributed amongst the nodes and is accessible only through the server it is attached to. As a given server outgrows its current storage pool, storage specific to that server has to be acquired and attached, even if there are other servers with plenty of storage space available. Other benefits can be gained such as multiple servers can share data (sequentially or in some cases in parallel), backing up devices can be done by transferring data directly from device to device without first transferring it to a backup server.

So why use yet another set of interconnect technologies? A storage area network is a network like any other (for example a LAN infrastructure). A SAN is used to connect many different devices and hosts to provide access to any device from anywhere. Existing storage technologies such as SCSI are tuned to the specific requirements of connecting mass storage devices to host computers. In particular, they are low latency, high bandwidth connections with extremely high data integrity semantics. Network technology, on the other hand, is tuned more to providing application-to-application connectivity in increasingly complex and large-scale environments. Typical network infrastructures have high connectivity, can route data across many independent network segments, potentially over very large distances (consider the internet) and there are many network management and troubleshooting tools.

Storage area networks try to capitalize on the best of the storage technologies and network technologies to provide a low latency, high bandwidth interconnect which can span large distances, has high connectivity and good management infrastructure from the start.

In summary, a SAN environment provides the following benefits:

Centralization of storage into a single pool. This allows storage resources and server resources to grow independently, and allows storage to be dynamically assigned from the pool as and when it is required. Storage on a given server can be increased or decreased as needed without complex reconfiguring or re-cabling of devices.

Common infrastructure for attaching storage allows a single common management model for configuration and deployment.

Storage devices are inherently shared by multiple systems. Ensuring data integrity guarantees and enforcing security policies for access rights to a given device is a core part of the infrastructure.

Data can be transferred directly from device to device without server intervention. For example, data can be moved from a disk to a tape without first being read into the memory of a backup server. This frees-up compute cycles for business logic rather than management related tasks.

Because multiple servers have direct access to storage devices, SAN technology is particularly interesting as a way to build clusters where shared access to a data set is required. Consider a clustered SQL Server environment. At any point in time a SQL Server instance may be hosted on one machine in the cluster and it must have exclusive access to its associated database on a disk from the node on which it is hosted. In the event of a failure or an explicit management operation, the SQL Server instance may *failover* to another node in the cluster. Once failed over, the SQL Server instance must be able to have exclusive access to the database on disk from its new host node.

By deploying multiple clusters onto a single storage area network, all of the benefits of SAN technology described above can be brought to the cluster environment. The rest of this paper describes how clusters can be attached to storage area networks, what the requirements are and what is supported today in Windows 2000.

# Storage Area Network Components

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As previously discussed, the primary technology used in storage area networks today is Fibre Channel. This section provides a basic overview of the components in a fibre channel storage fabric as well as different topologies and configurations open to Windows deployments.

**Fibre Channel Topologies**
Fundamentally, fibre channel defines three configurations:

- Point-to-point
- Fibre Channel Arbitrated Loop (FC-AL)
- Switched Fibre Channel Fabrics (FC-SW).

Although the term fibre channel implies some form of fibre optic technology, the fibre channel specification allows for both fibre optic interconnects as well as copper coaxial cables.

**Point-to-point**
Point-to-point fibre channel is a simple way to connect two (and only two) devices directly together, as shown in Figure 1 below. It is the fibre channel equivalent of direct attached storage (DAS).

**Figure 1: Point to point connection**

From a cluster and storage infrastructure perspective, point-to-point is not a scalable enterprise configuration and we will not consider it again in this document.

**Arbitrated Loops**
A fibre channel arbitrated loop is exactly what it says; it is a set of hosts and devices that are connected into a single loop, as shown in Figure 2 below. It is a cost-effective way to connect up to 126 devices and hosts into a single network.

**Figure 2: Fibre Channel Arbitrated Loop**

Devices on the loop share the media; each device is connected in series to the next device in the loop and so on around the loop. Any packet traveling from one device to another must pass through all intermediate devices. In the example shown, for host A to communicate with device D, all traffic between the devices must flow through the adapters on host B and device C. The devices in the loop do not need to look at the packet; they will simply pass it through. This is all done at the physical layer by the fibre channel interface card itself; it does not require processing on the host or the device. This is very analogous to the way a token-ring topology operates.

When a host or device wishes to communicate with another host or device, it must first arbitrate for the loop. The initiating device does this by sending an arbitration packet around the loop that contains its own loop address (more on addressing later). The arbitration packet travels around the loop and when the initiating device receives its own arbitration packet back, the initiating device is considered to be the loop owner. The initiating device next sends an open request to the destination device which sets up a logical point-to-point connection between the initiating device and target. The initiating device can then send

as much data as required before closing down the connection. All intermediate devices simply pass the data through. There is no limit on the length of time for any given connection and therefore other devices wishing to communicate must wait until the data transfer is completed and the connection is closed before they can arbitrate.

If multiple devices or hosts wish to communicate at the same time, each one sends out an arbitration packet that travels around the loop. If an arbitrating device receives an arbitration packet from a different device before it receives its own packet back, it knows there has been a collision. In this case, the device with the lowest loop address is declared the winner and is considered the loop owner. There is a fairness algorithm built into the standard that prohibits a device from re-arbitrating until all other devices have been given an opportunity, however, this is an optional part of the standard.

**Note**

Not all devices and host bus adapters support loop configurations since it is an optional part of the fibre channel standard. However, for a loop to operate correctly, all devices on the loop MUST have arbitrated loop support1. Figure 3 below shows a schematic of the wiring for a simple arbitrated loop configuration.

**Figure 3: FC-AL wiring schematic**

With larger configurations, wiring a loop directly can be very cumbersome. *Hubs* allow for simpler, centralized wiring of the loop (see section Hubs, Switches, Routers and Bridges). Communication in an arbitrated loop can occur in both directions on the loop depending on the technology used to build the loop, and in some cases communication can occur both ways simultaneously.

Loops can support up to 126 devices, however, as the number of devices on the arbitrated loop increases, so the length of the path and therefore the latency of individual operations increases.

Many loop devices, such as JBODs, have dip switches to set the device address on the loop (known as *hard addressing*). Most, if not all devices, implement hard addresses so it is possible to assign a loop ID to a device, however, just as in a SCSI configuration, different devices must have unique hard IDs. In cases where a device on the loop already has a conflicting address when a new device is added, the new device either picks a different ID or it does not get an ID at all (non-participating).

**Note**

Most of the current FC-AL devices are configured automatically to avoid any address conflicts. However, if a conflict does happen then it can lead to I/O disruptions or failures.

Unlike many bus technologies, the devices on an arbitrated loop do not have to be given fixed addresses either by software configuration or via hardware switches. When the loop initializes, each device on the loop must obtain an Arbitrated Loop Physical Address which is dynamically assigned. This process is initiated when a host or device sends out a LIP; a master is dynamically selected for the loop and the master controls a well defined process where each device is assigned an address.

A LIP is generated by a device or host when the adapter is powered up or when a loop failure is detected (such as loss of carrier). Unfortunately, this means that when new devices are added to a loop or when devices on the loop are power-cycled, all the devices and hosts on the loop can (and probably will) change their physical addresses. This can lead to unstable configurations if the operating system is not fully aware of the changes.

For these reasons, arbitrated loops provide a solution for small numbers of hosts and devices in relatively static configurations.

**Fibre Channel Switched Fabric**

In a switched fibre channel fabric, devices are connected in a many-to-many topology using *fibre channel switches*, as shown in Figure 4 below. When a host or device communicates with another host or device, the source and target setup a point-to-point connection (just like a virtual circuit) between them and communicate directly with each other. The fabric itself routes data from the source to the target. In a fibre channel switched fabric, the media is not shared. Any device can communicate with any other device (assuming it is not busy) and communication occurs at full bus speed (1Gbit/Sec or 2Gbit/sec today depending on

technology) irrespective of other devices and hosts communicating.

**Figure 4: Switched Fibre Channel Fabric**

When a host or device is powered on, it must first login to the fabric. This enables the device to determine the type of fabric (there is a set of characteristics about what the fabric will support) and it causes a host or device to be given a fabric address. A given host or device continues to use the same fabric address while it is logged into the fabric and the fabric address is guaranteed to be unique for that fabric. When a host or device wishes to communicate with another device, it must establish a connection to that device before transmitting data in a way similar to the arbitrated loop. However, unlike the arbitrated loop, the connection open packets and the data packets are sent directly from the source to the target (the switches take care of routing the packets in the fabric).

Fibre channel fabrics can be extended in many different ways such as by federating switches or cascading switches, and therefore, fibre channel switched fabrics provide a much more scalable infrastructure for large configurations. Because device addresses do not change dynamically once a device has logged in to the fabric, switched fabrics provide a much more stable storage area network environment than is possible using an arbitrated loop configuration.

Fibre channel arbitrated loop configurations can be deployed in larger switched SANs. Many of the newer switches from vendors like Brocade incorporate functionality to allow arbitrated loop or point-to-point devices to be connected to any given port. The ports can typically sense whether the device is a loop device or not and adapt the protocols and port semantics accordingly. This allows platforms or specific host adapters or devices which only support arbitrated loop configurations today, to be attached to switched SAN fabrics.

Note that not all switches are created equal. Brocade switches are easy to deploy; Vixel and Gadzoox switches behave more like hubs with respect to addressing.

**Loops verses Fabrics**

Both fibre channel arbitrated loops and switched fabrics have pros and cons. Before deploying either, you need to understand the restrictions and issues as well as the benefits of each technology. The vendor's documentation provides specific features and restrictions; however, the following helps to position the different technologies.

FC-AL

**Pros**

Low cost

Loops are easily expanded and combined with up to 126 hosts and devices

Easy for vendors to develop

**Cons**

Difficult to deploy

Maximum 126 devices

Devices share media thus lower overall bandwidth

Switched Fabric

**Pros**

Easy to deploy

Supports 16 million hosts and devices

Communicate at full wire-speed, no shared media

Switches provide fault isolation and re-routing

**Cons**

Difficult for vendors to develop

Interoperability issues between components from different vendors

Switches can be expensive

**Host Bus Adapters**
A host bus adapter (HBA) is an interface card that resides inside a server or a host computer. It is the functional equivalent of the network adapter in a traditional Ethernet network. All traffic to the storage fabric or loop is done via the HBA.

HBAs, with the exception of older Compaq cards and early Tachyon based cards, support both FC-AL and Fabric (since 1999). However, configuration is not as simple or as automatic as could be supposed. It is difficult to figure out if an HBA configures itself to the appropriate setting. On a Brocade fabric, it is possible to get everything connected, however, some of it might be operating as loop and still appear to work. It is important to verify from the switch side that the hosts are operating in the appropriate mode.

| **Note** |
| --- |
| Be sure to select the correct HBA for the topology that you are using. Although some switches can auto-detect the type of HBA in use, using the wrong HBA in a topology can lead to data loss and can cause many issues to the storage fabric. |

**Hubs, Switches, Routers and Bridges**
Thus far, we have discussed the storage fabric as a generic infrastructure that allows hosts and devices to communication with each other. As you have seen, there are fundamentally different fibre channel topologies and these different topologies use different components to provide the infrastructure.

**Hubs**
Hubs are the simplest form of fibre channel devices and are used to connect devices and hosts into arbitrated loop configurations. Hubs typically have 4, 8, 12 or 16 ports allowing up to 16 devices and hosts to be attached, however, the bandwidth on a hub is shared by all devices on the hub. In addition, hubs are typically half-duplex (newer full duplex hubs are becoming available). In other words, communication between devices or hosts on a hub can only occur in one direction at a time. Because of these performance constraints, hubs are typically used in small and/or low bandwidth configurations.

Figure 5 below shows two hosts and two storage devices connected to the hub with the dark arrows showing the physical loop provided by the hub.

**Figure 5: FC-AL hub configuration**

A typical hub detects empty ports on the hub and does not configure them into the loop. Some hubs provide higher levels of control over how the ports are configured and when devices are inserted into the loop.

**Switches**
A switch is a more complex storage fabric device that provides the full fibre channel bandwidth to each port independently, as shown in Figure 6 below. Typical switches allow ports to be configured in either an arbitrated loop or a switched mode fabric.

When a switch is used in an arbitrated loop configuration, the ports are typically full bandwidth, bi-directional allowing devices and hosts to communicate at full fibre channel speed in both directions. In this mode, ports are configured into a loop, providing performance, arbitrated loop configuration.

Switches are the basic infrastructure used for large, point-to-point, switched fabrics. In this mode, a switch allows any device to communicate directly with any other device at full fibre channel speed (1Gbit/Sec or 2Gbit/sec today).

**Figure 6: Switched fibre configuration**

Switches typically support 16, 32, 64 or even 128 ports today. This allows for complex fabric configurations. In addition, switches can be connected together in a variety of ways to provide larger configurations that consist of multiple switches. Several manufacturers such as Brocade and McData provide a range of switches for different deployment configurations, from very high performance switches that can be connected together to provide a core fabric to edge switches that connect servers and devices with less intensive requirements.

Figure 7 below shows how switches can be interconnected to provide a scalable storage fabric supporting many hundreds of devices and hosts (these configurations are almost certainly deployed in highly available topologies, section Highly Available Solutions deals with high availability).

**Figure 7: Core and edge switches in a SAN fabric**

The core backbone of the SAN fabric is provided by high performance (and typically high port density) switches. The inter-switch bandwidth in the core is typically 8Gbit/sec and above. Large data center class machines and large storage pools can be connected directly to the backbone for maximum performance. Severs and storage with less performance requirements (such as departmental servers) may be connected via large arrays of edge switches (each of which may have 16 to 64 ports).

**Bridges and Routers**

In an ideal world, all devices and hosts would be SAN-aware and all would interoperate in a single, ubiquitous environment. Unfortunately, many hosts and storage components are already deployed using different interconnect technologies. To allow these types of devices to play in a storage fabric environment, a wide variety of *bridge* or *router* devices allow technologies to interoperate. For example, SCSI-to-fibre bridges or routers allow parallel SCSI (typically SCSI-2 and SCSI-3 devices) to be connected to a fibre network, as shown in Figure 8 below. In the future, bridges will allow iSCSI (iSCSI is a device interconnect using IP as the communications mechanism and layering the SCSI protocol on top of IP) devices to connect into a switch SAN fabric.

**Figure 8: SCSI to FibreChannelBridge**

**Storage Components**

Thus far, we have discussed devices being attached to the storage bus as though individual disks are attached. While in some very small, arbitrated loop configurations, this is possible, it is highly unlikely that this configuration will persist. More likely, storage devices such as disk and tape are attached to the storage fabric using a *storage controller* such as an EMC Symmetrix or a Compaq StorageWorks RAID controller. IBM would refer to these types of components as Fibre RAID controllers.

In its most basic form, a storage controller is a box that houses a set of disks and provides a single (potentially redundant and highly available) connection to a SAN fabric. Typically, disks in this type of controller appear as individual devices that map directly to the individual spindles housed in the controller. This is known as a JBOD (just a bunch of disks) configuration. The controller provides no value-add, it is just a concentrator to easily connect multiple devices to a single (or small number for high availability) fabric switch port.

Modern controllers almost always provide some level of redundancy for data. For example, many controllers offer a wide variety of RAID levels such as RAID 1, RAID 5, RAID 0+1 and many other algorithms to ensure data availability in the event of the failure of an individual disk drive. In this case, the hosts do not see devices that correspond directly to the individual spindles; rather the controller presents a virtual view of highly available storage devices to the hosts called *logical devices*.

**Figure 9: Logical devices**

In the example in Figure 9, although there are five physical disk drives in the storage cabinet, only two logical devices are

visible to the hosts and can be addressed through the storage fabric. The controller does not expose the physical disks themselves.

Many controllers today are capable of connecting directly to a switched fabric; however, the disk drives themselves are typically either SCSI, or more common now, are disks that have a built-in FC-AL interface. As you can see in Figure 10 below, the storage infrastructure that the disks connect to is totally independent from the infrastructure presented to the storage fabric.

A controller typically has a small number of ports for connection to the fibre channel fabric (at least two are required for highly available storage controllers). The logical devices themselves are exposed through the controller ports as logical units (LUNs).

**Figure 10: Internal components of a storage controller**

**Highly Available Solutions**

One of the benefits of storage area networks is that the storage can be managed as a centralized pool of resources that can be allocated and re-allocated as required. This powerful paradigm is changing the way data centers and enterprises are built, however, one of the biggest issues to overcome is that of guaranteed availability of data. With all of the data detached from the servers, the infrastructure must be architected to provide highly available access so that the loss of one or more components in the storage fabric does not lead to the servers being unable to access the application data. All areas must be considered including:

No single point of failure of cables or components such as switches, HBAs or storage controllers. Typical highly available storage controller solutions from storage vendors have redundant components and can tolerate many different kinds of failures.

Transparent and dynamic path detection and failover at the host. This typically involves *multi-path* drivers running on the host to present a single storage view to the application across multiple, independent HBAs.

Built-in hot-swap and hot-plug for all components from HBAs to switches and controllers. Many high-end switches and most if not all enterprise class storage controllers allow interface cards, memory, CPU and disk drives to be hot-swapped.

There are many different storage area network designs that have different performance and availability characteristics. Different switch vendors provide different levels of support and different topologies, however, most of the topologies are derived from standard network topology design (after all a SAN is a network, just the interconnect technology is tuned to a given application). Topologies include:

- Multiple independent fabrics
- Federated fabrics
- Core Backbone

**Multiple Independent Fabrics**
In a multiple fabric configuration, each device or host is connected to multiple fabrics, as shown in Figure 11 below. In the event of the failure of one fabric, hosts and devices can communicate using the remaining fabric.

**Figure 11: Multiple independent fabrics**

**Pros**

Resilient to management or user errors. For example, if security is changed or zones are deleted, the configuration on the alternate fabric is untouched and can be re-applied to the broken fabric.

**Cons**

Managing multiple independent fabrics can be costly and error prone. Each fabric should have the same zoning and security information to ensure a consistent view of the fabric regardless of the communication port chosen.

Hosts and devices must have multiple adapters. In the case of a host, multiple adapters are typically treated as different storage buses. Additional *multi-pathing* software such as Compaq SecurePath or EMC PowerPath are required to ensure that the host gets a single view of the devices across the two HBAs.

**Federated Fabrics**
In a federated fabric, multiple switches are connected together, as shown in Figure 12 below. Individual hosts and devices are connected to at least two switches.

**Figure 12: Federated switches for single fabric view**

**Pros**

Management is simplified, the configuration is a highly available, single fabric, and therefore there is only one set of zoning information and one set of security information to manage.

The fabric itself can route around failures such as link failures and switch failures.

**Cons**

Hosts with multiple adapters must run additional *multi-pathing* software such as Compaq SecurePath or EMC PowerPath to ensure that the host gets a single view of the devices where there are multiple paths from the HBAs to the devices.

Management errors are propagated to the entire fabric.

**Core Backbone**
A core backbone configuration is really a way to scale-out a federated fabric environment. Figure 7 shows a backbone configuration. The core of the fabric is built using highly scalable, high performance switches where the inter-switch

connections provide high performance communication (e.g. 8-10GBit/Sec using today's technology). Redundant edge switches can be cascaded from the core infrastructure to provide high numbers of ports for storage and hosts devices.

**Pros**

Highly scalable and available storage area network configuration.

Management is simplified, the configuration is a highly available, single fabric, and therefore there is only one set of zoning information and one set of security information to manage.

The fabric itself can route around failures such as link failures and switch failures.

**Cons**

Hosts with multiple adapters must run additional *multi-pathing* software such as Compaq SecurePath or EMC PowerPath to ensure that the host gets a single view of the devices where there are multiple paths from the HBAs to the devices.

Management errors are propagated to the entire fabric.

[1] Most devices today, except for some McData switches, support FC-AL.

# Management

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As you can see from the previous section, storage area networks are increasingly complex and large configurations are becoming more and more common. While storage area networks certainly provide many benefits over direct attach storage, the big issue is how to manage this complexity.

**Zoning**

A storage fabric can have many devices and hosts attached to it. With all of the data stored in a single, ubiquitous cloud of storage, controlling which hosts have access to what data is extremely important. It is also important that the security mechanism be an end-to-end solution so that badly behaved devices or hosts cannot circumvent security and access unauthorized data.

Zoning is a mechanism, implemented at the switch level, which provides an isolation boundary. A port (either host adapters or storage controller ports) can be configured as part of a zone. Only ports in a given zone can communicate with other ports in that zone. The zoning is configured and access control is implemented by the switches in the fabric, so a host adapter cannot spoof the zones that it is in and gain access to data for which it has not been configured.

**Figure 13: Zoning**

In Figure 13 above, hosts A and B can access data from storage controller S1, however host C cannot as it is not in Zone A. Host C can access data from storage S2.

Many switches today allow overlapping zones. This enables a storage controller to reside in more than one zone, thus enabling the devices in that controller to be shared amongst different servers in different zones, as shown in Figure 14 below. Finer precision access controls are required to protect individual disks against access from unauthorized servers in this environment.

Zoning can be implemented in either hardware or software. Hardware zoning is done by the ASIC in the switch ports themselves. Every packet is checked at line speed to ensure that it is authorized. Software zoning is done by the name server or other fabric access software. When a host tries to open a connection to a device, access controls can be checked at that time.

**Figure 14: Storage controller in multiple zones**

Zoning is an extremely important concept. Not only is it a security feature, but it also limits the traffic flow within a given SAN environment. Traffic (I/O requests and other storage requests) between ports is only routed to those pieces of the fabric that are in the same zone. Typically with modern switches, as new switches are added to an existing fabric, the new switches are automatically updated with the current zoning information.

I/Os (either read/write or such things as device reset or LIP) from hosts or devices in a fabric cannot leak out and affect other zones in the fabric causing noise or cross-talk between zones. As we shall see, this is fundamental to deploying Server clusters on a SAN.

**Fine-grain Security and Access Control**

While zoning provides a high-level security infrastructure in the storage fabric, it does not provide the fine-grain level of access control needed for large storage devices. In a typical environment, a storage controller may have many Gigabytes or Terabytes of storage to be shared amongst a set of servers.

Storage controllers typically provide LUN-level access controls that enable an administrator to restrict access to a given LUN to one or more hosts. By providing this access control at the storage controller, the controller itself can enforce access policies to the data.

LUN masking is a host-based mechanism that hides specific LUNs from applications. Although the host bus adapter and the lower layers of the operating system have access to and could communicate with a set of devices, LUN masking prevents the higher layers from knowing that the device exists and therefore applications cannot use those devices. LUN masking is a policy-driven software security and access control mechanism enforced at the host. For this policy to be successful, the administrator has to trust the drivers and the operating systems to adhere to the policies.

**SAN Management**

SAN management is a huge topic on its own and is outside the scope of this document. Different vendors (both vendors that provide SAN fabric components as well as software vendors that provide storage management tools) provide a wide range of tools for setting up, configuring, monitoring and managing the SAN fabric, as well as the state of devices and hosts on the fabric.

**Virtualized View of Storage**

The previous section touched on virtualization of storage when describing various RAID levels. The logical devices presented by the controller to the storage fabric are some composite of the real physical devices in the storage cabinet. Moving forward, the panacea for storage management is that the devices presented to the storage infrastructure are not tied to any physical storage. In other words, the set of spindles in the cabinet is treated as a pool of storage blocks. Logical devices can be materialized from that storage pool with specific attributes such as must survive a single failure, have xyz performance characteristics etc. The storage controller is then free to store the data associated with the logical devices anywhere (and indeed change the placement at will) as long as the desired characteristics are maintained.

At this point, there are no real physical characteristics associated with a logical disk, any physical notions, such as a disk serial number or identity, are purely software-generated virtualized views. See Figure 15 below.

By taking this route, storage vendors can drive many value-added storage management features down into the storage infrastructure itself without having to have host involvement. We are seeing the first few steps down this path today with the

notion of *snapshots* provided by some storage controllers today.

**Figure 15: Storage virtualization by the controller**

# Deploying Server Clusters in a SAN Environment

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This section covers best practices for MSCS in a SAN environment. Clusters are supported by Microsoft in a SAN environment; however, there are some specific requirements and restrictions placed on the configurations.

| **Note** |
| --- |
| In a SAN environment, the storage fabric provides access to data for a wide range of applications. If the storage fabric stability is compromised, the availability of the entire data center could be at risk, no amount of clustering can protect against an unstable or unavailable storage fabric. |

**Qualified Configurations**

As with all existing cluster configurations, only *complete cluster solutions* that appear on the Microsoft Hardware Compatibility List (HCL) will be supported by Microsoft. Clusters cannot be arbitrarily built up from device-level components (even those components such as RAID controllers, multi-cluster devices etc. that are qualified as cluster components) and put together into a supported configuration.

A single cluster can be qualified and placed on the HCL using fibre channel storage interconnects and switch technology and there are many examples of complete configurations on the HCL today. This, however, does not really constitute a storage area network (SAN) configuration.

Microsoft fully supports multiple clusters and/or servers deployed on a single fibre channel switched fabric and sharing the same storage controllers as long as the configuration adheres to the following rules:

- The storage controller must be on the Cluster/Multi-Cluster Device HCL list if it is shared between clusters.
- The complete configuration for any individual cluster must be on the Cluster HCL list.

Take, for example the following HCL lists:

Cluster/Multi-cluster device HCL list:

Storage Controller St1

Storage Controller St2

Cluster HCL list

2-node advanced server cluster AS1

Server 1: Server Box S1, 256Mb, 700Mhz PIII, HBA H1

Server 2: Server Box S2, 256Mb, 700Mhz PIII, HBA H1

Storage: Storage Controller St1

4-node advanced server cluster AS2

Server 1: Server Box S5, 512Mb, 1.2Ghz PIV, HBA H1

Server 2: Server Box S6, 512Mb, 1.2Ghz PIV, HBA H1

Server 3: Server Box S7, 512Mb, 1.2Ghz PIV, HBA H1

Server 4: Server Box S8, 512Mb, 1.2Ghz PIV, HBA H1

Storage: Storage Controller St1

2-node advanced server cluster AS3

Server 1: Server Box S10, 256Mb, 700Mhz PIII, HBA H2

Server 2: Server Box S11, 256Mb, 700Mhz PIII, HBA H2

Storage: Storage Controller St2

In this case, the 2-node AS1 and the 4-node AS2 configurations can both be placed on the same storage area network and can in fact share the same storage controller St1. It is also possible to have AS3 on the same storage area network as long as it uses storage controller St2 and not St1.

With Windows 2000, the storage area network fabric itself is not on the HCL and is not qualified directly by Microsoft. When building these configurations, you must ensure that the switches and other fabric components are compatible with the HBAs and the storage controllers.

**Arbitrated Loops and Switched Fabrics**
Fibre channel arbitrated loops can be configured to support multiple hosts and multiple storage devices, however, arbitrated loop configurations typically have restrictions due to the nature of the technology. For example, in some cases, a complete storage controller must be assigned to a given server or cluster. Individual devices in the controller cannot be assigned to different servers or clusters. While manufacturers and vendors allow multiple clusters to be hosted on a single arbitrated loop, due to the configuration restrictions and the mechanisms that the cluster service uses to protect disks in a cluster, Microsoft recommends that only one cluster is attached to any single arbitrated loop configuration and that arbitrated loop configurations are limited to small, relatively static cluster configurations.

Fabrics are fully supported by server clusters for both a single cluster and for multiple clusters and independent servers on the same storage fabric. Fabrics provide a much more stable environment where multiple server clusters are deployed using the same storage infrastructure. Nodes (and indeed storage devices) can leave or enter the SAN independently without affecting other parts of the fabric. Highly available fabrics can be built up, and in conjunction with multi-path drivers, can provide a highly available and scalable storage infrastructure.

**Hints, Tips and Don't Dos**
This section describes the dos and don'ts of deploying one or more clusters in a SAN.

**MUST Do**
Each cluster on a SAN MUST be deployed in its own zone. The cluster uses mechanisms to protect access to the disks that can have an adverse effect on other clusters that are in the same zone. By using zoning to separate the cluster traffic from other cluster or non-cluster traffic, there is no chance of interference. Figure 16 shows two clusters sharing a single storage controller. Each cluster is in its own zone. The LUNs presented by the storage controller must be allocated to individual clusters using fine-grained security provided by the storage controller itself. LUNs must be setup as visible to all nodes in the cluster and a given LUN should only be visible to a single cluster.

The multi-cluster device test used to qualify storage configurations for the multi-cluster HCL list tests the isolation guarantees when multiple clusters are connected to a single storage controller in this way.

**Figure 16: Clusters assigned to individual zones**

All HBAs in a single cluster must be the same type and at the same firmware revision level. Many storage and switch vendors require that ALL HBAs on the same zone, and in some cases the same fabric, are the same type and have the same firmware revision number.

All storage device drivers and HBA device drivers in a cluster must be at the same software version.

SCSI bus resets are not used on a fibre channel arbitrated loop; they are interpreted by the HBA and driver software and cause a LIP to be sent. As previously described, this resets all devices on the loop.

When adding a new server to a SAN, ensure that the HBA is appropriate for the topology. In some configurations, adding an arbitrated loop HBA to a switched fibre fabric can result in widespread failures of the storage fabric. There have been real-world examples of this causing serious downtime.

The base Windows 2000 platform will mount any device that it can see when the system boots. The cluster software ensures that access to devices that can be accessed by multiple hosts in the same cluster is controlled and only one host actually mounts the disk at any one time. When first creating a cluster, make sure that only one node can access the disks that are to be managed by the cluster. This can be done either by leaving the other (to be) cluster members powered off, or by using access controls or zoning to stop the other hosts from accessing the disks. Once a single node cluster has been created, the disks marked as cluster-managed will be protected and other hosts can be either booted or the disks made visible to other hosts to be added to the cluster.

**This is no different to any cluster configuration that has disks that are accessible from multiple hosts.**

| **Note** |
| --- |
| In Windows Server 2003 by using the new command mountvol/n you can disable dynamic scanning. It is recommended that dynamic scanning be disabled before the servers are connected to the SAN in a San environment. New Cluster Setup or adding and removing of nodes in a server cluster should be done while dynamic scanning is turned off. It is recommended that dynamic scanning remains turned off as long as the servers are connected to the storage infrastructure. |

**MUST NOT Do**

NEVER allow multiple hosts access to the same storage devices unless they are in the SAME cluster. If multiple hosts that are not in the same cluster can access a given disk, this will lead to data corruption.

NEVER put any non-disk device into the same zone as cluster disk storage devices.

**Other Hints**

Highly available systems such as clustered servers should typically be deployed with multiple HBAs with a highly available storage fabric. In these cases be sure to ALWAYS load the multi-path driver software. If the I/O subsystem in the Windows 2000 platform sees two HBAs, it will assume they are different buses and enumerate all the devices assuming that they are different devices on each bus; where in fact, the host is seeing multiple paths to the same disks. Failure to load the multi-path driver will lead to data corruption. A simple manifestation of this is that the disk signature is re-written. If the Windows platform sees what it thinks are two independent disks with the same signature, it will re-write one of them to ensure that all disks have unique signatures. This is covered in KB article 293778 *Multiple-Path Software May cause Disk Signature to change*.

| **Note** |
| --- |
| Windows Server 2003 will detect the fact that the same volume is being exposed twice. If such a situation arise Windows Server 2003 will not mount the volumes exposed by controller 2 that have were already exposed by the controller 1. |

Many controllers today provide snapshots at the controller level that can be exposed to the cluster as a completely separate LUN. The cluster does not react well to multiple devices having the same signature. If the snapshot is exposed back to the host with the original disk online, the base I/O subsystem will re-write the signature as in the previous example, however, if the snapshot is exposed to another node in the cluster, the cluster software will not recognize it as a different disk. DO NOT expose a hardware snapshot of a clustered disk back to a node in the same cluster. While this is not specifically a SAN issue, the controllers that provide this functionality are typically deployed in a SAN environment.

**Adding and Removing Disks from a Cluster**

In Windows 2000 (SP3 onwards) and Windows Server 2003, adding a disk to the cluster is simple. Simply add the storage (in a SAN this probably means adding the physical drives to a storage controller and then creating a logical unit that is available in the correct zone and with the correct security attributes).

Once the disk is visible to the operating system, you can make the disk a cluster-managed disk by adding a physical disk resource in cluster administrator. The new disk will appear as being capable of being clustered.

| **Note** |
| --- |
| Some controllers use a different cluster resource than physical disk, for those environments; create a resource of the appropriate type. |

Only Basic, MBR format disks that contain at least one NTFS partition can be managed by the cluster. Before adding a disk, it must be formatted.

Remember that the same rules apply when adding disks as in creating a cluster. If multiple nodes can see the disk BEFORE any node in the cluster is managing it, this will lead to data corruption. When adding a new disk, first make the disk visible to only one cluster node and then once it is added as a cluster resource, make the disk visible to the other cluster nodes.

To remove a disk from a cluster, first remove the cluster resource corresponding to that disk. Once it has been removed from the cluster, the disk can be removed (either the drive can be physically removed or the LUN can be deleted or re-purposed)

There are several KB articles on replacing a cluster-managed disk. While disks in a cluster should typically be RAID sets or mirror sets, there are sometimes issues that cause catastrophic failures leading to a disk having to be rebuilt from the ground up. There are also other cases where cluster disks are not redundant and failure of those disks also leads to a disk having to be replaced. The steps outlined in those articles should be used if you need to rebuild a LUN due to failures.

243195 - *Replacing a cluster managed disk in Windows NT 4.0*

280425 - *Recovering from an Event ID 1034 on a Server Cluster*

**Expanding disks**
Now you can expand volumes dynamically without requiring a reboot. Microsoft provided Diskpart tool can be used to expand volumes dynamically. Diskpart tool is available for each Windows 2000 and Windows Server 2003. You can download Windows 2000 version of Diskpart from the www.microsoft.com web site.

**SAN Backup**
Storage area networks provide many opportunities to offload work from the application hosts. Many of the devices in the SAN (either hosts or storage controllers) have CPUs and memory and are capable of executing complex code paths. In addition, any device can communicate with any other device, the SAN provides a peer-to-peer communication mechanism. This leads to such things as SAN-based backups. A storage controller can easily initiate the backup of a disk device to a tape device on the SAN without host intervention. In some cases, hybrid backup solutions are implemented where file system related information is provide by the host, but bulk copying of the data blocks is done directly from storage controller to tape device.

The cluster software uses disk reservations to protect devices that could be accessed by multiple computers simultaneously. The host that currently owns a disk protects it so that no other host can write to it. This is necessary to avoid writes that are in the pipeline when failover occurs from corrupting the disk. When failover occurs, the new owner protects the disk. This means that a cluster disk is always reserved and therefore can only be accessed by the owning host. No other host or device (including the controller that is hosting the disk) can access the disk simultaneously. This means that SAN-based backup solutions where data transfers from disk to tape are initiated by a 3rd party (i.e. initiated by a device other than the owning host) cannot be supported in a cluster environment.

**Booting from a SAN**
Microsoft supports booting from a SAN in limited environments. There are a set of configuration restrictions around how Windows boots from a storage area network, see KB article 305547.

Windows 2000 Server clusters require that the startup disk, page file disk and system disk be on a different storage bus to the cluster server disks. To boot from a SAN, you must have a separate HBA for the boot, system and pagefile disks than the cluster disks. You MUST ensure that the cluster disks are isolated from the boot, system and pagefile disks by zoning the cluster disks into their own zone.

| **Note** |
| --- |
| Windows Server 2003 will allow for startup disk and the cluster server disks hosted on the same bus. However, you would need to use Storport minioprt HBA drivers for this functionality to work. This is NOT supported configuration with in any other combination (for example, SCSI port miniport or Full port drivers). |

# Cluster Service Features in Windows Server 2003

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Windows Server 2003 release has a number of enhancements. The following enhancements are specific to supporting Server clusters in a SAN environment:

**Targeted Reset**
Historically, server clusters use the SCSI reservation mechanism to protect disks against access, guaranteeing that only the host that has the disk online can actually access it. To ensure that devices can be failed over in the event of failures, server clusters implements a challenge/response mechanism that can detect dead or unresponsive server nodes even though they may not have crashed and therefore the storage fabric is unaware that the server is not responding. To do this, the reservations are periodically broken by other nodes in the cluster using SCSI bus reset commands. In a SAN fabric, SCSI reset commands can be very detrimental to the fabric since they are typically not implemented the same way by different vendors and they typically result in a LIP command that takes the fabric sometime to re-settle.

In Windows Server 2003, the server cluster code uses a new mechanism to first try targeted device reset, then LUN reset and if all else fails it will fall-back to a full bus reset. This feature requires the storage mini-port drivers to interpret the new control codes. At this time, several HBA vendors are modifying their mini-port drivers to provide this feature, thus enabling much more stable cluster configurations in a switched fabric environment.

This feature requires no administration to enable it. If the device driver supports the targeted reset functions they will be automatically used.

**Single Storage Bus Configurations**
As described previously, in Windows 2000, only storage devices on a different bus to the system disk will be considered eligible as cluster-managed devices. In a SAN environment, the goal is to centralize all storage into a single fabric accessible through a single port (actually in most cases the host will have multiple HBAs and multi-path drivers to provide a single port view to the cluster software).

In Windows Server 2003 Cluster server has a switch that when enabled, allows any disk on the system, regardless of the bus it is on, to be eligible as a cluster-managed disk. Using this, the system disk, startup disk, pagefile disks and any cluster managed disks can be attached to the same HBA. This feature is enabled by setting the following registry key:

```
HKLM\SYSTEM\CurrentControlSet\Services\ClusSvc\Parameters\ManageDisks
OnSystemBuses   0x01
```

This feature is enabled by a registry key to ensure that it is not accidentally enabled by customers that do not understand the implications of this configuration. It is intended for OEMs to ship qualified and tested configurations and not for a typical end-user or administrator to setup in an ad hoc manner.

A single storage bus configuration MUST have device drivers that support the targeted reset functionality previously defined.

# Related Issues

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Shared disk verses Shared-nothing**

You may see various documents that use terms like shared disk clusters and non-shared disk or shared-nothing clusters. These terms are very misleading and can cause confusion since they depend on the context of the discussion.

When talking about the physical connectivity of devices, shared disk clusters means that multiple computers have direct physical access to any given storage unit (for example, multiple hosts are directly connected to a disk drive on a SCSI bus that the computers are both connected to). Non-shared disk or shared-nothing clusters in this context means that any given disk is only physically connected to one computer. See Figure 17.

**Figure 17: Physical view of cluster topologies**

In the context of file systems or data access from applications, shared disk means that applications running on multiple computers in a cluster can access the same disk directly at the same time. To support this application, the file system must coordinate concurrent access to a single disk from multiple hosts (e.g. a cluster file system). Clearly, shared physical access is required for this configuration. When talking about application or data access, non-shared disk means that only applications running on one computer can access data on any given disk directly. In this case, the physical disk may or may not be connected to multiple computers, but if it is, then only the connection from one computer is in use at any one time. See Figure 18 below.

**Figure 18: Application view of cluster topologies**

**SAN Versus NAS**

There are two industry-wide terms that refer to externally attached storage:

- Storage Area Networks (SAN)
- Network Attached Storage (NAS)

Having two, similar sounding terms leads to some confusion and therefore it is worth discussing the differences between the two different technologies before delving into storage area network details.

Storage area networks (SANs), see Figure 19 below, are typically built-up using storage-specific network technologies. Fibre channel is the current technology leader in this space. Servers connect to storage and access data at the block level. In other words, to the server, a disk drive out on the storage area network is accessed using the same read and write disk block primitives as though it were a locally attached disk. Typically, data and requests are transmitted using a storage-specific protocol (usually based on the SCSI family of protocols). These protocols are tuned for low latency, high bandwidth data transfers required by storage infrastructure.

**Figure 19: Storage Area Network**

While fibre channel is by far the leading technology today, other SAN technologies have been proposed, for example SCSI over Infiniband, iSCSI (which is SCSI protocol running over a standard IP network). All these technologies allow a pool of devices to be accessed from a set of servers, decoupling the compute needs from the storage needs.

In contrast, network attached storage (NAS), see Figure 20 below, is built using standard network components such as Ethernet or other LAN technologies. The application servers access storage using file system functions such as open file, read file, write file, close file, etc.. These higher-level functions are encapsulated in protocols such as CIFS, NFS or AppleShare and run across standard IP-based connections.

**Figure 20: Network Attached Storage**

In a NAS solution, the file servers hide the details of how data is stored on disks and present a high level file system view to application servers. In a NAS environment, the file servers provide file system management functions such as the ability to back up a file server.

As SAN technology prices decrease and the need for highly scalable and highly available storage solutions increases, vendors are turning to hybrid solutions that combine the centralized file server simplicity of NAS with the scalability and availability offered by SAN as shown in Figure 21 below.

**Figure 21: Hybrid NAS and SAN solution**

The following table contrasts the SAN and NAS technologies

**SAN Versus NAS Technologies**

| | **Storage Area Network** | **Network Attached Storage** |
|---|---|---|
| Application Server Access methods | Block-level access | File-level access |
| Communication protocol | SCSI over Fibre Channel iSCSI (SCSI over IP) | CIFS, NFS; AppleShare |
| Network physical technology | Typically storage-specific<br>(e.g. Fibre-channel) but may be high-speed Ethernet | General purpose LAN<br>e.g. Gigabit Ethernet |
| Example Storage Vendors | Compaq StorageWorks SAN family; EMC Symmetrix | Network Appliance NetApp Filers; Maxtor NASxxxx; Compaq TaskSmart N-series |

There are many camps that believe that in the future, various different technologies will win in the storage space and there are those that believe that in the end there will be a single network interconnect that will cover SAN and NAS needs, as well as basic inter-computer networking needs. Over time, the Windows platform and Windows Clustering technologies will support different interconnect technologies as they become important to end-customer deployments.

# Summary (Server Clusters : Storage Area Networks - For Windows 2000 and Windows Server 2003)

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Storage area networks provide a broad range of advantages over locally connected devices. They allow computer units to be detached from storage units, thereby providing flexible deployment and re-purposing of servers and storage to suit current business needs. You do not have to be concerned about buying the right devices for a given server, or with re-cabling a datacenter to attach storage to a specific server.

Microsoft fully supports storage area networks both as part of the base Windows platform, and as part of a complete Windows Clustering, high availability solution. One or more server clusters can be deployed in a single SAN environment, along with standalone Windows servers and/or non-Windows-based platforms.

# Cluster and Application Deployments

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Historically, we have described clusters and applications as being active/active or active/passive, which is a natural result of the fact that the earliest products supported only 2-node clusters. In some cases, however, this has led to confusion because the terms can be interpreted in different ways depending on whether the context is 1) how a given application instance is running, 2) how different instances of an application are running or 3) whether the nodes in the cluster are performing useful work. To fully understand the specific application and cluster deployments, we need to understand the following:

- How many instances of the application are actually up and running?
- How many instances of the same data are in the cluster?
- Do instances of the data move around?
- Do different instances of the same application run on different cluster nodes?
- Can different applications run on different cluster nodes?
- What kind of load does the application put on a server, and how will this load be re-distributed after a failover?

Before describing how an application is deployed, we must first define what an application is. An application, for the purposes of this document, is defined as the running code and data required to provide a *single* service to an end-user or client. Consider a couple of different examples to illustrate the point: A single instance of Microsoft Word running on a workstation is a single application instance. If there are multiple instances of Word running, each instance is considered a different application instance. There are, however, more complex applications. For example, with Microsoft SQL Server, a single database is considered to be a single application instance. Independent databases are considered to be different application instances. A single database, however, can be partitioned into multiple SQL Server instances and tied-together using the SQL Server query engine. In this case, the set of SQL Server instances that are tied together to provide a single database image is considered a single application instance.

Fundamentally, there are five different attributes that together provide a complete view of the deployment and can be used to reason about or characterize the deployment:

- Server load How much of a servers resources are consumed by the applications it supports, and how will this resource utilization be affected by failover?
- Application style Is the application a single monolithic application that runs on a single node or is the complete application split into smaller pieces that can be deployed around the cluster?
- Application deployment How are the pieces of the application spread around the cluster in a given deployment?
- Failover policies How is the application configured to behave after a failover?
- Application implementation How is the application itself implemented?

# Server Load

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When deploying an application, it is always important to consider what demands it will make on a servers resources. With clustering, there is a related issue that also needs to be taken into account: how is the load re-distributed after a failover?

**Server Load The Basics**

Consider one of the simplest cases, an active/active, 2-node file server cluster, with node A and node B each serving a single share. If node A fails, its resources will move to node B, placing an additional load on node B. In fact, if node A and B were each running at only 50% capacity before the failure, node B will be completely saturated (100% of capacity) after the failover is completed, and performance may suffer.

While this situation may not be optimal, it is important to remember that having all of the applications still running, even in a reduced performance scenario, is a 100% improvement over what you would have without the high availability protection that clusters provide. But this does bring up the notion of risk, and what amount of it you are willing to accept in order to protect the performance, and ultimately the availability, of your applications.

We have intentionally chosen the worst case (an active/active, 2-node cluster with each node running a single application that consumes half of the servers resources) for the purpose of clarity. With an additional node, the equation changes: there are more servers to support the workload, but if all three nodes are running at 50% capacity and there are *two* failures, the single remaining server will simply not be able to handle the accumulated load of the applications from both of the failed servers. Of course, the likelihood of two failures is considerably less than that of a single failure, so the risk is mitigated somewhat.

Nevertheless, the load/risk tradeoff must be considered when deploying applications on a cluster. The more nodes in a cluster, the more options you have for distributing the workload. If your requirements dictate that all of your clustered applications must run with no performance degradation, then you may need to consider some form of active/passive configuration. But even in this scenario, you must consider the risks of the various configurations. If you cannot accept even the slightest risk of any reduced performance under any conditions whatsoever, you will need a dedicated passive node for each active node.

If, on the other hand, you are convinced that the risk of multiple failures is small, you have other choices. If you have a 4-node, or 8-node cluster, you may want to consider an N+I configuration. N+I, which is discussed in more detail in section 1.4.3, is a variant of active/passive, where N nodes are active, and I nodes are passive, or reserve nodes. Typically, the value for I is less than the value for N, and an N+I cluster topology can handle I failures before any performance degradation is likely. The risk is that with more than I failures, performance will likely decline, but once again, the likelihood of multiple failures is increasingly remote.

For this reason, N+I clusters are a useful configuration that balances the hardware cost of having 100% passive server capacity against the low level risk of multiple cluster node failures.

**Server Load Some More Realistic Configurations**

The scenarios above were intentionally simplistic, assuming that one application imposed a monolithic load on each server, and thus its resource utilization could not be spread among more than one other server in the event of a failover. That is often not the case in the real world, especially for file and print servers, so we will take a look at some additional scenarios with a 4-node cluster, named ABCD, and having nodes A, B, C, and D.

Typically a single server will support the load of more than one application. If under normal conditions, each server was loaded at 25%, then the ABCD cluster could survive the loss of three members before a likely loss of application availability, which would be nearly a worst-case scenario.

The following series of figures illustrates what would happen with the application load in a 4-node cluster for successive node failures. The shaded, or patterned, areas indicate the capacity demands of the running applications. Further, the example below assumes that the application load on any given server is divisible, and can be redistributed among any of the surviving nodes.

**Figure 1.1: Cluster under normal operating conditions (each node loaded at 25%)**

**Figure 1.2: Cluster after a single node failure. Note redistribution of application load.**

**Figure 1.3: Cluster after two node failures. Each surviving node is now approximately 50% loaded.**

**Figure 1.4: After three node failures, single surviving node is at full capacity.**

If each node were running at 75% capacity, then without sensible failover policies, even a single node failure could result in loss of application availability. Depending on the application(s), however, you can specify that, in the event of a server failure, some percentage of the applications should fail over to node A, node B, node C, and node D. If the applications are spread evenly among the surviving nodes, then this cluster could now survive the loss of a single machine, because one third of the failed servers load (one third of 75% is 25%) is allocated to each of the surviving three machines. The result is three fully loaded servers (each of the nodes running at 75% capacity now have an additional 25%), but all applications are still available.

As a variation on the example that was illustrated previously, the following series of figures will depict what happens to a 4-node cluster, each of which is running at approximately 33% capacity. Further, in this case, the application load is indivisible, and can not be spread among multiple other servers in the event of a failover (perhaps it is a single application or multiple applications that depend on the same resource).

**Figure 2.1: Cluster under normal operating conditions (each node loaded at approximately 33%)**

**Figure 2.2: Cluster after a single node failure. Note redistributed application load.**

**Figure 2.3: Cluster after second node failure. Each surviving node is now running at approximately 66% capacity.**

**Note that in the event of another node failure, this cluster will no longer be capable of supporting all four of these applications.**

**Figure 2.4: After third failure, the single surviving server can only support three of the four applications.**

Another style of failover policy is Failover Pairs, also known as Buddy Pairs. Assuming each of the four servers is loaded at 50% or less, a failover buddy can be associated with each machine. This allows a cluster in this configuration to survive two failures. More details on Failover Pairs can be found in section 1.4.1.

Taking the previous Failover Pair example, we can convert it to an active/passive configuration by loading two servers at 100% capacity, and having two passive backup servers. This active/passive configuration can also survive two failures, but note that under ordinary circumstances, two servers remain unused. Furthermore, performance of these servers at 100% load is not likely to be as good as with the Failover Pair configuration, where each machine is only running at 50% utilization. Between these two examples, note that you have the same number of servers, the same number of applications, and the same survivability (in terms of how many nodes can fail without jeopardizing application availability). However, the Failover Pair configuration clearly comes out ahead of active/passive in terms of both performance and economy.

Still using our ABCD 4-node cluster, consider what happens if we configure it as an N+I cluster (explained in more detail in section 1.4.3) where three nodes are running at 100% capacity, and there is a single standby node. This cluster can only survive a single failure. As before, however, comparing it to the example where each server is running at 75% capacity, you again have the same number of servers, applications, and same survivability, but the performance and economy can suffer when you have passive servers backing up active servers running at 100% load.

**Application Style**

Now it is time to consider some aspects of the applications design, and how that affects the way it is deployed. Applications running in a cluster can be characterized as one of:

- **Single Instance**

  In a single instance application, only one application instance is running in the cluster at any point in time. An example of this is the DHCP service in a server cluster. At any point in time, there is only one instance of the DHCP service running in a cluster. The service is made highly available using the failover support provided with server clusters. Single instance applications typically have state that cannot be partitioned across the nodes. In the case of DHCP, the set of IP addresses that have been leased is relatively small, but potentially highly volatile in a large environment. To avoid the complexities of synchronizing the state around the cluster, the service runs as a single instance application.

**Figure 3: Single instance application**

  In the example above, the cluster has four nodes. The single instance application, by definition, can be running on only one node at a time.

- **Multiple Instance**

  A multiple instance application is one where multiple instances of the same code or different pieces of code that cooperate to provide a single service can be executing around the cluster. Together these instances provide the illusion of

a single service to an end-user or client computer. There are two different types of multiple instance applications that depend on the type of application and data:

- **Cloned Application**. A cloned application is a single logical application that consists of two or more instances of the **same code** running against the **same data** set. Each instance of the application is self-contained, thus enabling a client to make a request to any instance of the application with the guarantee that regardless of the instance, the client will receive the same result. A cloned application is scalable since additional application instances can be deployed to service client requests and the instances can be deployed across different nodes, thus enabling an application to grow beyond the capacity of a single node. By deploying application instances on different nodes, the application is made highly available. In the event that a node hosting application instances fails, there are instances running on other nodes that are still available to service client requests.

  Typically, client requests are load-balanced across the nodes in the cluster to spread the client requests amongst the application instances. Applications that run in this environment do not have long-running in-memory state that spans client requests, since each client request is treated as an independent operation and each request can be load-balanced independently. In addition, the data set must be kept consistent across the entire application. As a result, cloning is a technique typically used for applications that have read-only data or data that is changed infrequently. Web server front-ends, scalable edge-servers such as arrays of firewalls and middle-tier business logic fall into this category.

  While these applications are typically called *stateless applications*[1] they can save client-specific session-oriented state in a persistent store that is available to all instances of the cloned application, however, the client must be given a token or a key that it can present with subsequent requests so that whichever application instance services each request can associate the request with the appropriate client state.

  The Microsoft Windows platform provides Network Load Balancing as the basic infrastructure for building scale-out clusters with the ability to spray client requests across the nodes. Application Center provides a single image view of management for these environments.

**Figure 4: Cloned Application**

  In the example above, the same application App is running on each node. Each instance of the application is accessing the same data set, in this case the dataset A-Z. This example show each instance having access to its own data set (created and kept consistent using some form of staging or replication technique), some applications can share the same data set (where the data is available to the cluster using a file share for example).

**Figure 5: Cloned Application using a file share**

- **Partitioned Applications**. Applications that have long-running in-memory state or have large, frequently updated data sets cannot be easily cloned. These applications are typically called *stateful applications*. The cost of keeping the data consistent across many instances of the application would be prohibitive.

  Fortunately, however, many of these applications have data sets or functionality that can be readily partitioned. For example, a large file server can be partitioned by dividing the files along the directory structure hierarchy or a large customer database can be partitioned along customer number or customer name boundaries (customers from A to L in one database, customers from M to Z in another database, for example). In other cases, the functionality can be partitioned or componentized. Once an application is partitioned, the different partitions can be deployed across a set of nodes in a cluster, thus enabling the complete application to scale beyond the bounds of a single node. In order to present a single application image to the clients, a partitioned application requires an application-dependent decomposition, routing and aggregation mechanism that allows a single client request to be distributed across the set of partitions and the results from the partitions to be combined into a single response back to the client. For example, take a partitioned customer database, a single SQL query to return all of the accounts that have overdue payments requires that the query be sent to every partition of the database. Each partition will contain a subset of customer records that must be combined into a single data set to be retuned to the client. Partitioning an application allows it to scale but does not provide high availability. If a node fails that is hosting a partition of the application, that piece of the data set or that piece of functionality is no longer accessible.

  Partitioning is typically application-specific, since the aggregation mechanism is dependent of the type of application and the type of data returned. SQL Server, Exchange data stores and DFS are all examples of applications and services that can be partitioned for scalability.

**Figure 6: Partitioned Application Data Partitioning**

In the example above, each node is running multiple instances of the same application against different pieces of the complete data set. A single request from a client application can span multiple instances, for example a query to return all the records in the database. This *splitting* of the client across the different application instances and the *aggregation* of the single result passed back to the client can be done either by the applications on the server cooperating amongst themselves (for example the SQLQuery engine) or it can be done by the client (as is the

case with Exchange 2000 data stores).

Applications may also be partitioned along functional lines as well as data sets.

**Figure 7: Partitioned Application - Functional Partitions**

In the above example, each node in the cluster is performing a different function; however, the cluster together provides a single, uniform service. One node is providing a catalog service; one is providing a billing service, etc. The cluster, though, provides a single book buying service to clients.

Computational clusters are built to support explicitly massively parallel applications. In other words, the applications are specifically written to decompose a problem into many (potentially thousands) of sub-operations and execute them in parallel across a set of machines. This type of application is also a partitioned application. Computational clusters typically provide a set of libraries to provide cluster-wide communication and synchronization primitives tailored to the environment (MPI is one such set of libraries). These clusters have been termed *Beowulf* clusters. Microsoft has created the High Performance Computing initiative to provide support for this type of cluster.

**Application Deployments**

Applications can be deployed in different ways across a cluster depending on what style of application is being deployed and the number of applications that are being deployed on the same cluster. They can be characterized as follows:

1. **One, single instance application**

   In this type of deployment, one node of the cluster is executing the application so that it can service user requests, the other nodes are in stand-by, waiting to host the application in the event of failure. This type of deployment is typically suited to 2-node failover clusters and is not typically used for N-node clusters since only 1/N of the total capacity is being used. This is what some people term an active/passive cluster.

2. **Several, single instance applications**

   Several single instance applications can be deployed on the same cluster. Each application is independent from the others. In a failover cluster, each application can failover independently for the others, so in the case of a node hosting multiple applications, if that node fails, the different applications may failover to different nodes in the cluster. This type of deployment is typically used for consolidation scenarios where multiple applications are hosted on a set of nodes and the cluster provides a highly available environment. In this environment, careful capacity planning is required to ensue that in the event of failures, the nodes have sufficient capacity (CPU, memory IO bandwidth etc.) to support the increased load.

3. **A single, multiple instance application**

   In this environment, while the cluster is only supporting one application, various pieces of the application are running on the different nodes. In the case of a cloned application, each node is running the same code against the same data. This is the typical web-front end scenario (all of the nodes in the cluster are identical). In the event of a failure, the capacity is reduced. In a partitioned application, the individual partitions are typically deployed across the nodes in the cluster. If a failure occurs, multiple partitions may be hosted on a single node. Careful planning is required to ensure that, in the event of a failure, the application SLA is achieved. Take a 4-node cluster as an example. If an application is partitioned into four pieces, then in normal running, each node would host a partition. In the event that one node failed, two nodes would

continue to host one partition and the remaining node would end up hosting two partitions, giving the 3rd node twice the load, potentially. If the application were split into 12 partitions, each node would host three partitions in the normal case. In the event of a failure, each partition could be configured to failover to a different node, thereby; the remaining nodes could each host four partitions, spreading the load in the event of a failure. The cost however, is that support for 12 partitions may be more overhead than for four partitions.

4. **Several, multiple instance applications**

   Of course, several multiple instance applications may be deployed on the same cluster (indeed single instance and multiple instances may be deployed on the same cluster). In the case of multiple cloned applications, each node is simply running one instance of each application. In the case of a partitioned application, capacity planning as well as defining failover targets becomes increasingly complex.

**Failover Policies**
Failover is the mechanism that single instance applications and the individual partitions of a partitioned application typically employ for high availability (the term Pack has been coined to describe a highly available, single instance application or partition).

In a 2-node cluster, defining failover policies is trivial. If one node fails, the only option is to failover to the remaining node. As the size of a cluster increases, different failover policies are possible and each one has different characteristics.

**Failover Pairs**
In a large cluster, failover policies can be defined such that each application is set to failover between two nodes. The simple example below shows two applications App1 and App2 in a 4-node cluster.

**Figure 8: Failover pairs**

This configuration has pros and cons:

| | |
|---|---|
| Pro | Good for clusters that are supporting heavy-weight[2] applications, such as databases. This configuration ensures that in the event of failure, two applications will not be hosted on the same node. |
| Pro | Very easy to plan capacity. Each node is sized based on the application that it will need to host (just like a 2-node cluster hosting one application). |
| Pro | Effect of a node failure on availability and performance of the system is very easy to determine. |
| Pro | Get the flexibility of a larger cluster. In the event that a node is taken out for maintenance, the buddy for a given application can be changed dynamically (may end up with standby policy below). |
| Con | In simple configurations, such as the one above, only 50% of the capacity of the cluster is in use.z |
| Con | Administrator intervention may be required in the event of multiple failures. |

Failover pairs are supported by server clusters on all versions of Windows by limiting the *possible owner list* for each resource to a given pair of nodes.

**Hot-Standby Server**

To reduce the overhead of failover pairs, the spare node for each pair may be consolidated into a single node, providing a hot standby server that is capable of picking up the work in the event of a failure.

**Figure 9: Standby Server**

The standby server configuration has pros and cons:

| | |
|---|---|
| Pro | Good for clusters that are supporting heavy-weight applications such as databases. This configuration ensures that in the event of a single failure, two applications will not be hosted on the same node. |
| Pro | Very easy to plan capacity. Each node is sized based on the application that it will need to host, the spare is sized to be the maximum of the other nodes. |
| Pro | Effect of a node failure on availability and performance of the system is very easy to determine. |
| Con | Configuration is targeted towards a single point of failure. |
| Con | Does not really handle multiple failures well. This may be an issue during scheduled maintenance where the spare may be in use. |

Server clusters support standby servers today using a combination of the possible owners list and the preferred owners list. The preferred node should be set to the node that the application will run on by default and the possible owners for a given resource should be set to the preferred node and the spare node.

**N+I**

Standby server works well for 4-node clusters in some configurations, however, its ability to handle multiple failures is limited. N+I configurations are an extension of the standby server concept where there are N nodes hosting applications and I nodes which are spares.

**Figure 10: N+I Spare node configuration**

N+I configurations have the following pros and cons:

| | |
|---|---|
| Pro | Good for clusters that are supporting heavy-weight applications such as databases or Exchange. This configuration ensures that in the event of a failure, an application instance will failover to a spare node, not one that is already in use. |

| | |
|---|---|
| Pro | Very easy to plan capacity. Each node is sized based on the application that it will need to host. |
| Pro | Effect of a node failure on availability and performance of the system is very easy to determine. |
| Pro | Configuration works well for multiple failures. |
| Con | Does not really handle multiple applications running in the same cluster well. This policy is best suited to applications running on a dedicated cluster. |

Server clusters supports N+I scenarios in the Windows Server 2003 release using a cluster group public property **AntiAffinityClassNames**. This property can contain an arbitrary string of characters. In the event of a failover, if a group being failed over has a non-empty string in the **AntiAffinityClassNames** property, the failover manager will check all other nodes. If there are any nodes in the possible owners list for the resource that are NOT hosting a group with the same value in **AntiAffinityClassNames**, then those nodes are considered a good target for failover. If all nodes in the cluster are hosting groups that contain the same value in the **AntiAffinityClassNames** property, then the preferred node list is used to select a failover target.

**Failover Ring**

Failover rings allow each node in the cluster to run an application instance. In the event of a failure, the application on the failed node is moved to the next node in sequence.

**Figure 11: Failover Ring**

This configuration has pros and cons:

| | |
|---|---|
| Pro | Good for clusters that are supporting several small application instances where the capacity of any node is large enough to support several at the same time. |
| Pro | Effect on performance of a node failure is easy to predict. |
| Pro | Easy to plan capacity for a single failure. |
| Con | Configuration does not work well for all cases of multiple failures. If Node 1 fails, Node 2 will host two application instances and Nodes 3 and 4 will host one application instance. If Node 2 then fails, Node 3 will be hosting three application instances and Node 4 will be hosting one instance. |
| Con | Not well suited to heavy-weight applications since multiple instances may end up being hosted on the same node even if there are lightly-loaded nodes. |

Failover rings are supported by server clusters on the Windows Server 2003 release. This is done by defining the order of failover for a given group using the preferred owner list. A node order should be chosen and then the preferred node list should be set up with each group starting at a different node.

**Random**

In large clusters or even 4-node clusters that are running several applications, defining specific failover targets or policies for each application instance can be extremely cumbersome and error prone. The best policy in some cases is to allow the target to be chosen at random, with a statistical probability that this will spread the load around the cluster in the event of a failure.

Random failover policies have pros and cons:

| | |
|---|---|
| Pro | Good for clusters that are supporting several small application instances where the capacity of any node is large enough to support several at the same time. |
| Pro | Does not require an administrator to decide where any given application should failover to. |
| Pro | Provided that there are sufficient applications or the applications are partitioned finely enough, this provides a good mechanism to statistically load-balance the applications across the cluster in the event of a failure. |
| Pro | Configuration works well for multiple failures. |
| Pro | Very well tuned to handling multiple applications or many instances of the same application running in the same cluster well. |
| Con | Can be difficult to plan capacity. There is no real guarantee that the load will be balanced across the cluster. |
| Con | Effect on performance of a node failure is not easy to predict. |
| Con | Not well suited to heavy-weight applications since multiple instances may end up being hosted on the same node even if there are lightly-loaded nodes. |

The Windows Server 2003 release of server clusters randomizes the failover target in the event of node failure. Each resource group that has an empty preferred owners list will be failed over to a random node in the cluster in the event that the node currently hosting it fails.

**Customized control**

There are some cases where specific nodes may be preferred for a given application instance.

A configuration that ties applications to nodes has pros and cons:

| | |
|---|---|
| Pro | Administrator has full control over what happens when a failure occurs. |
| Pro | Capacity planning is easy, since failure scenarios are predictable. |
| Con | With many applications running in a cluster, defining a good policy for failures can be extremely complex. |
| Con | Very hard to plan for multiple, cascaded failures. |

Server clusters provide full control over the order of failover using the preferred node list feature. The full semantics of the preferred node list can be defined as:

| **Preferred Node List** | **Move group to best possible initiated via administrator** | **Failover due to node or group failure** |
|---|---|---|
| Contains all nodes in cluster | Group is moved to highest node in preferred node list that is up and running in the cluster. | **Group is moved to the next node on the preferred node list.** |
| Contains a subset of the nodes in the cluster | Group is moved to highest node in preferred node list that is up and running in the cluster.<br><br>If no nodes in the preferred node list are up and running, the group is moved to a random node. | **Group is moved to the next node on the preferred node list.**<br><br>**If the node that was hosting the group is the last on the list or was not in the preferred node list, the group is moved to a random node.** |
| **Empty** | **Group is moved to a random node.** | **Group is moved to a random node.** |

[1] This is really a misnomer, the applications have state, however, the state does not span individual client requests.

[2] A heavy-weight application is one that consumes a significant number of system resources such as CPU, memory or IO bandwidth.

# Load Balancing

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Load balancing is a term that means many different things. Within a cluster environment, load balancing is typically used in two different ways:

- Spreading client requests across a set of clones In Windows, Network Load Balancing (NLB) provides the capability to spread client TCP/IP requests across a set of nodes (typically Web servers or ISA arrays or terminal server machines). This functionality can also be provided by external network infrastructure such as CISCO local director.

- Optimizing the compute resources across a failover cluster A cluster that supports failover allows application instances to move around the cluster. Historically this has been used to ensure that on failure, the application can be restarted elsewhere. However, using this same mechanism could be used with performance counters and application load metrics to provide a way to balance the load of applications across the nodes in a cluster. This can be done in one of two ways:

    - **Manual load balancing**: Each group in a cluster can be moved around independently of the other cluster groups. By breaking down applications into finely defined groups where it is possible, manual load balancing can be done using the cluster administration tools. If the load on a given node is high relative to the other nodes in the cluster, one or more groups can be manually moved to other cluster nodes.

    - **Dynamic load balancing**: Today, Server clusters do not provide any load balancing mechanism (beyond a randomized failover policy in Windows Server 2003). Dynamic load balancing is an extremely complex issue, while moving an application may at first appear to make sense, the cost of that move can be hard to determine. For example, moving SQL Server may not only incur the cost of having to re-mount the database, but it also loses the in-memory cache and state which may have a significant impact on performance from the client perspective.

Appendix A (Using Clustering with Exchange 2003: An Example)

# Introduction (Using Clustering with Exchange 2003: An Example)

Updated: September 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Microsoft uses its own Exchange 2003 to provide communication within the company. At Microsoft, the Operations and Technology Group (OTG) manages the Exchange servers to keep them highly available and highly reliable.

OTG manages the global messaging environment that supports Microsoft facilities in more than 400 IT locations in 65 countries. Message traffic averages over 6.3 million messages per day, with around 2.5 million messages per day traveling to and from the Internet.

OTG uses server clustering to ensure predictable and trustworthy messaging. A server cluster is a collection of servers that together provide a single, highly available system for hosting applications. To manage the high message traffic, OTG has implemented a clustering solution that makes Exchange servers at Microsoft available (in terms of global overall availability) more than 99.9% of the time (including both planned and unplanned outages).

In the server clusters that support messaging at Microsoft, each node runs Exchange 2003 and Windows Server 2003, Enterprise Edition. Windows Server 2003, Enterprise Edition supports up to eight nodes per cluster. Although OTG uses many server clusters in their operations, only one of the clusters used for internal messaging is described in this document. This unique cluster design has four active nodes, one primary passive node, and two alternate passive nodes. This design uses servers efficiently, and provides a reliable messaging environment that supports approximately 16,000 mailboxes.

| **Note** |
| --- |
| This is the second of two white papers that describe how clustering is used at Microsoft. The first white paper, Using Clustering for a Highly Available Web site: An Example, describes how Microsoft uses Network Load Balancing for its Microsoft.com Web site. You can download this paper at the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=19497). |

**Focus: Server Clusters**

The primary focus of this white paper is how OTG has implemented clustering to manage the Exchange servers that provide messaging for the company. Other details about how the Exchange servers are implemented are only described to the extent that they affect the server cluster.

Although OTG uses many server clusters in their operations, only one of the clusters used for internal messaging is described in this document. Throughout this document, this cluster will be referred to simply as the server cluster or the Exchange server cluster. Exchange server administrators can use this clustering example to assist them in designing their own Exchange servers.

| **Note** |
| --- |
| The information about the Exchange server cluster in this white paper is presented as an example. The actual steps and configuration for computers and devices in your own network will be different. This document shows only the configuration that specifically relate to the objectives that are described later in this document. |

# Topics Discussed in This White Paper

Updated: September 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This paper provides detailed information about the hardware, software, and configuration of the Exchange server cluster, and explains why OTG chose the configuration. It also includes best practices for using server clusters, as well as information about several operational procedures that OTG uses to help make messaging highly reliable and available. The following topics are discussed.

- Reasons for Using Server Clusters
- OTG Objectives
- Server Cluster Overview
- How OTG Configures the Exchange Server Cluster
- How OTG Backs Up the Server Cluster
- How OTG Monitors the Server Cluster
- Best Practices for Server Clusters

# Reasons for Using Server Clusters

Updated: September 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This section discusses specific clustering features that help the Operations and Technology Group (OTG) achieve their objectives.

A server cluster is a collection of servers known as nodes that together provide a single, highly available system for hosting applications. Multiple nodes in a cluster remain in constant communication. A clusters resources and applications are organized into functional units called resource groups. Each resource group is assigned to a node and can only be owned by a single node at any point in time.

There are three primary benefits to using server clusters. Server clusters are highly available, scalable, and easy to manage.

- **Highly available:** Server clusters provide a highly available system for deploying applications. You can use server clusters to protect against failures of hardware, operating systems, device drivers, or applications. If one of the nodes in a cluster is unavailable as a result of failure or maintenance, another node immediately begins providing service (a process known as failover). Server clusters also allow you to upgrade the operating system and application software with minimal downtime.

- **Scalable:** Server clusters provide scalability for important resources and applications. When the overall load of a cluster exceeds its capabilities, you can incrementally add additional nodes to the cluster. In Windows Server 2003, server clusters can include up to eight nodes.

- **Easy to manage:** In a server cluster, you can quickly inspect the status of all cluster resources and move workloads around onto different nodes. Because you can move processing to alternate nodes, you can perform rolling upgrades on the servers. In a rolling upgrade, a server cluster continues to provide service while software is being upgraded on each node until all nodes have been upgraded.

Microsoft has used these cluster features to help achieve its technical and business objectives. These objectives are described in the following section.

# OTG Objectives

Updated: September 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Operations and Technology Group (OTG) at Microsoft has used clustering to achieve the following technical and business objectives for messaging within the company:

- **High availability.** The server cluster discussed in this document provides a messaging solution with a high level of availability to users. OTG strives to make the Exchange servers available 99.99% of the time.

- **Scalability**. In a server cluster, administrators can add additional servers as necessary in a way that is virtually transparent to the users. Because they have implemented clustering to manage the Exchange servers (and for other reasons), OTG has been able to increase the scale limitation of the mail store from 3000 mailboxes (100 MB per mailbox) to 5000 mailboxes (200 MB per mailbox).

- **Manageability**. By using a server cluster, administrators can manage and maintain the Exchange servers through a process that is virtually transparent to users.

- **Consolidation.** Server clusters can help administrators consolidate their resources. Server clusters are helping OTG consolidate their worldwide messaging resources from 75 locations to seven and from 115 servers to 30.

These objectives are similar to those of most businesses who use Exchange 2003. Therefore, the server cluster information presented in this document should be valuable to businesses with similar goals.

# Server Cluster Overview

Updated: September 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This section gives a general overview of server clusters and the Exchange server cluster at Microsoft that supports messaging within the company.

The following terminology is used in this section and throughout the document.

- Active node. The cluster server that currently owns cluster group resources and responds to network requests made to those services.
- Alternative passive node. The cluster server that does not currently own cluster group resources but is available if the active fails over and the primary passive node is unavailable.
- Primary passive node. The cluster server that does not currently own cluster group resources but is available if the active node fails over.
- Virtual server. A collection of services that appear to clients as a physical Windows-based server but are not associated with a specific server. All virtual servers must include a Network Name resource and an IP Address resource.

Server clusters can take two forms: active/passive clusters and active/active clusters. In active/passive clustering, the cluster includes active nodes and passive nodes. The passive nodes are only used if an active node fails. In active/active clusters, all nodes are active. In the event of a failover, the remaining active node takes on the additional processing operations, which causes a reduction in the overall performance of the cluster. Active/passive cluster configurations are generally recommended over active/active configurations because they often increase performance, availability, and scalability.

The Exchange server cluster is based on an active/passive model, with a few alterations that maximize the performance of the hardware. The Operations and Technology Group (OTG) has configured a multinode cluster that consists of four active nodes, one primary passive node, and two alternate passive nodes. The four active nodes provide most of the processing operations for the messaging environment. Like most active/passive configurations, the primary passive node is used only when one of the active nodes fails or to support the process of rolling upgrades. The two alternate passive nodes are only used for messaging if failover occurs and the primary passive node is not available. To take full advantage of the available hardware, the alternate passive nodes are also used to facilitate the backup and upgrade processes. This unique configuration supports a total of 16,000 mailboxes.

The following topics are described in this section:

- Diagram 1. Exchange Server Cluster
- Reasons for Using Alternative Passive Nodes
- Diagram 2. Failover Process of the Server Cluster
- How OTG Configures the Exchange Server Cluster

**Diagram 1 Exchange Server Cluster**

Diagram 1 shows the four active nodes, the primary passive node, and the two alternate passive nodes that make up the Exchange server cluster. All of the nodes are connected to two storage area networks (SANs). The two SANs provide communication between the nodes and the shared storage components, which are two redundant Enterprise Virtual Arrays. For more information about how storage is configured in this cluster, see Storage Components later in this document.

Each node in the cluster has two adapters that support a public network and a private network. This is a best practice that is described later in this document. The private network is reserved exclusively for internal communication between cluster nodes. The public network supports both node-to-node and client-to-cluster communication.

**Reasons for Using Alternative Passive Nodes**

The four active nodes and the primary passive node each have four hyperthreading 1.9-gigahertz (GHz) processors and 4 gigabytes (GB) of RAM. The two alternate passive nodes are less expensive servers with dual 2.4-GHz processors and 2 GB of RAM.

Although it is rare, the alternate passive nodes can be used to support Exchange processing if an active node fails and the primary passive node is unavailable. Instead, the alternate passive nodes serve two main functions. First, the alternate passive nodes are primarily used to facilitate stage 2 of the backup process. Second, these nodes help during scheduled rolling upgrades and/or patch application to the operating system and/or the host.

**Diagram 2 Failover Process of the Server Cluster**

Diagram 2 shows how the primary passive nodes and alternate passive nodes are used during failover. The four active nodes provide the primary processing operations for the messaging environment. The primary passive node is used when one of the active nodes fails. The two alternate passive nodes are used for messaging only if failover occurs and the primary passive node is not available.

# How OTG Configures the Exchange Server Cluster

Updated: September 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This section describes the hardware, software, and server cluster configuration that the Operations and Technology Group (OTG) uses to manage messaging within Microsoft. Because the purpose of this document is to focus on the details of the clustering implementations, only limited information is provided regarding general network hardware configuration, Exchange 2003 configurations, and other configuration settings that are not specifically related to server clusters. However, each server cluster setting is discussed in depth.

- For information about hardware configuration, see Hardware in the Server Cluster.
- For information about the software configuration, see Software in the Server Cluster.
- For information about the server cluster configuration, see Server Cluster Settings.

**Hardware in the Server Cluster**

This section describes the hardware configuration for each of the following components of the server cluster:

- Active and Primary Passive Nodes
- Alternate Passive Nodes
- Network Adapters
- Storage Components

**Active and Primary Passive Nodes**

The four active nodes and the primary passive node in the server cluster all use the same hardware configuration, which is based on the HP ProLiant DL580-G2 processor with the following specification. Each active node supports 4000 mailboxes. Because there are 4 active nodes, this server cluster supports approximately 16,000 mailboxes.

| | |
|---|---|
| **Processors** | HP DL580-G2 Quad - 1.90 GHz, Hyperthreading-enabled |
| **Memory** | 4 GB of Error Correction Coding (ECC) RAM |
| **Controller** | Array controller - Integrated 5i |
| **Hard disk drives** | 2 x 36 GB RAID-1:<br>C$ Windows Server 2003, Enterprise Edition<br>D$ Exchange Application |

**Explanation**

OTG chose this hardware to provide optimized performance during peak usage periods, which are typically experienced on Monday mornings. OTG enabled hyperthreading on these nodes, which has increased performance of the node by 20-25%. (Hyperthreading is a technology that Intel developed that enables multithreaded software applications to execute threads in parallel on a single multicore processor instead of processing threads in a linear fashion). In addition, by increasing the performance, each node can manage more mailboxes.

The hardware for the primary passive node was chosen for the same reasons as the active node hardware. In the event of a failover, the passive node needs to perform exactly like an active node in order to maintain dependable messaging.

| **Note** |
|---|

| |
|---|
| Users who are implementing Exchange 2003 or Windows Server 2003 should refer to the Windows Server Catalog (http://go.microsoft.com/fwlink/?LinkId=4303) before buying hardware to ensure compatibility. The Windows Server Catalog is the online source for customers and partners to find hardware and software that is compatible with the Windows Server 2003 family. |

**Alternate Passive Nodes**

The two alternate nodes in the server cluster have a hardware configuration that is based on the HP ProLiant DL380-G2 dual processor with the following specification.

| | |
|---|---|
| **Processors** | DL380-G2 dual - 2.4 GHz |
| **Memory** | 2 GB RAM |
| **Controller** | Array controller - Integrated 5i |
| **Hard disk drives** | 2 x 36 GB RAID1:<br><br>C$ Windows Server 2003, Enterprise Edition<br><br>D$ Exchange Application |

**Explanation**

As discussed earlier in this paper, OTG chose hardware for the alternate nodes to increase resource efficiency. With this hardware, the alternate passive nodes can be used to facilitate the backup process updates to the system.

For more information about why OTG uses alternative passive nodes, see Reasons for Using Alternative Passive Nodes.

| **Note** |
|---|
| Users who are implementing Exchange 2003 or Windows Server 2003 should refer to the Windows Server Catalog (http://go.microsoft.com/fwlink/?LinkId=4303) before buying hardware. The Windows Server Catalog is the online source for customers and partners to find hardware and software that is compatible with the Windows Server 2003 family. |

**Network Adapters**

Each node in the server cluster has two network adapters installed. OTG has used NC7770 Gigabit Server Adapters that are connected to 100-MB switches.

The following settings appear on the **General** tab that is available when you configure or view the properties of the adapters in Cluster Administrator. You can use Cluster Administrator to configure a cluster and its nodes, resource groups, and resources.

**Adapter 1**

This network adapter enables node-to-node communication. It is connected to the private network that is used exclusively in the cluster. Adapter 2 carries all other communication.

| Configuration setting | Explanation |
|---|---|
| **Name:**<br><br>Internal | OTG has changed the default name for this network connection to clearly identify that it is used for internal communication within the network. |
| **Enabled for cluster use** is checked. | This adapter is available for the cluster to use. |

**Adapter 2**

This network adapter enables both node-to-node (internal) and client-to-cluster (public) communication. Because this network adapter carries both kinds of communication, it can serve as a backup for Adapter 1.

| Configuration setting | Explanation |
|---|---|
| **Name:**<br><br>Internal + Public | OTG has changed the default name for this network connection to clearly identify that it is used for all communication within the network. |

| | |
|---|---|
| **Enabled for cluster use** is checked. | This adapter is available for the cluster to use. |

**Note**

It is important to configure the private network to be the highest priority for internal cluster communication in the Cluster Administrator. It is also important to make sure the public network is first in the TCP/IP binding order.

**Explanation**

OTG uses two networks to ensure network availability for internal cluster communications. Both adapters are configured with static IP addresses. The use of dynamic IP addresses is not recommended in server clusters.

**Note**

The nodes of a cluster must be on the same subnet, but you can use virtual LAN (VLAN) switches on the interconnects between two nodes. (An interconnect is a private network that connects nodes in a cluster). If you use a VLAN, the point-to-point, round-trip latency must be less than 1/2 second and the link between two nodes must appear as a single point-to-point connection from the perspective of the Windows operating system running on the nodes. To avoid single points of failure, use independent VLAN hardware for the different paths between the nodes.

**Storage Components**

This section will discuss the storage design for the Exchange server cluster and the reasons for this configuration.

The following terminology is used in this section and throughout the document.

- Disk group. A group of physical disks. Virtual disks are created across the disk groups.
- Storage group. An Exchange 2003 component that supports five databases (mail stores) using either a single or multiple data device with a common log device.
- Virtual server. A collection of services that appear to clients as a physical Windows-based server, but are not associated with a specific server. All virtual servers must include a Network Name resource and an IP Address resource.
- Storage area network (SAN). A high-speed network that provides a direct connection between servers and storage, including shared storage, clusters, and disaster-recovery devices.

All of the nodes in the cluster are connected to two SANs, which provide communication between the nodes and the two shared storage components.

The shared storage components are two redundant Enterprise Virtual Arrays (HP StorageWorks EVA 5000s). Diagram 1 illustrates the relationship of the nodes and the storage components. Diagram 3 describes the storage configuration for each Exchange virtual server. OTG configured each EVA to support four Exchange virtual servers and a total of 16,000 200-MB mailboxes.

The following table summarizes the storage configuration for each EVA. Each EVA has five disk groups that are characterized by different numbers of hard disks, data types, and Vraid types.

| EVA disk group | Number of 72-GB disks | Data type | Vraid type |
|---|---|---|---|
| DG1 | 48 | Data/SMTP | 1 |
| DG2 | 48 | Data/SMTP | 1 |
| DG3 | 14 | Log/Quorum | 1 |
| DG4 | 28 | Backup | 5 |
| DG5 | 28 | Backup | 5 |

**Explanation**

OTG designed this cluster for optimum performance to support production requirements for peak loads. They also strived to ensure maximum availability by eliminating as many single points of failure within the environment. OTG achieved optimum

performance by scaling the servers to support a realistic number of mailboxes and optimizing the SAN design for peak disk transfers (4K random read/write activity). OTG analyzed I/O requirements for each 200 MB mailbox and determined that each mailbox would generate between 1.0 and 1.2 disk transfers for peak loads (this is specific to the user environment at Microsoft).

With a plan to support 4000 mailboxes for each Exchange virtual server, OTG determined that each host would need to sustain 4800 disk transfers per second and also have the ability to support any unexpected increase in demand.

OTG needed to optimize the SAN design in order to anticipate and account for peak disk transfers while maintaining optimum read and write latencies. They also needed to ensure that Exchange would not encounter any bottlenecks.

After evaluating the performance of the HP StorageWorks EVA 5000s, OTG found that the EVA supported 12,000 transfers in an optimized configuration with acceptable latencies, even under an aggressive 4 KB random I/O load. As a result, OTG implemented two EVA 5000s per cluster. These EVAs support four Exchange virtual servers and a total of 16,000 200-MB mailboxes.

OTG uses HP StorageWorks Secure Path, which is a multipath application, to manage and maintain continuous data access to the storage system. Specifically, they use Secure Path to assist with optimizing disk I/O activity by ensuring disk distribution across fiber channel adapters (FCAs) and SAN controllers on each node. (Fiber channel adapters are expansion cards used to connect the nodes to SANs). Disk distribution has proven to be beneficial in maintaining an optimized environment. It has greatly reduced peak read/write disk latency and has improved online backup to disk.

OTG also uses Secure Path to assist with eliminating single points of failure between nodes and the storage. Secure Path helps maintain I/O even if a node fails. In the event of a node failure, Secure Path detects the failure and moves disks from the failed path to an available path. This process is called failover. Failover keeps the resources available while requiring no downtime. Once the failed nodes are replaced, the disks can be failed back using HPs Secure Path Manager to restore optimized I/O.

**Diagram 3 Storage Configuration for Each Exchange Virtual Server**

Diagram 3 depicts the storage configuration for one of the Exchange virtual servers. OTG configured each EVA to support four Exchange virtual servers and a total of 16,000 200-MB mailboxes. Each Exchange virtual server hosts four storage groups with five databases each. Each database is configured with a 200-MB limit per mailbox. This design specifies a maximum of 200 mailboxes per database, so each Exchange virtual server contains 4,000 mailboxes.

For additional information about the storage configuration for each virtual server, see Appendix A. For more information about Enterprise Virtual Arrays, see Microsoft Exchange 2003 Storage Design for the EVA5000 and other related white papers in the Storage Array Systems White Papers section of the Hewlett-Packard Web site (http://go.microsoft.com/fwlink/?LinkId=19716).

**Software in the Server Cluster**

The nodes in the server cluster have the following software installed.

| Node Type | Software |
|---|---|
| Active node and primary passive node | • Windows Server 2003, Enterprise Edition<br>• Exchange 2003<br>• Microsoft Operations Manager (MOM) Agent<br>• HP StorageWorks Secure Path |
| Alternative passive node | • Windows Server, 2003 Enterprise Edition<br>• Exchange 2003<br>• Microsoft Operations Manager (MOM) Agent<br>• HP StorageWorks Secure Path<br>• Veritas Backup Exec |

OTG has made the following operating system modifications on each node:

- /3-GB switch set in the Boot.ini file.
- /USERVA=3030 parameter set in the Boot.ini file.
- In the registry, SystemPages is set to 0.
- Cluster event log replication is set to 0 in Event Viewer. Because OTG uses Microsoft Operations Manager to manage their clusters, this setting is set to 0 to eliminate event replication across all nodes in the cluster.
- Mount points are used to support the log, SMTP, and backup drives in order to reduce the number of drive letters used.

**Server Cluster Settings**

This section describes how OTG has configured the settings for the Exchange server cluster and the reasons why they chose the settings. It also explains why some settings are specific to OTG and are not recommended for typical customer deployments. This section describes the settings that are configured for the server cluster as a whole, the settings that are specific to each resource group in the cluster, and each of the resource configurations.

The server cluster contains four Exchange virtual servers, four backup virtual servers, and one cluster virtual server. A virtual server is a collection of services that appear to clients as a physical Windows-based server, but are not associated with a specific server. All virtual servers must include a Network Name resource and an IP Address resource.

Each of the virtual servers contains the following specified resources. For server clusters, a resource is a physical or logical entity that is capable of being managed by a cluster, brought online and taken offline, and moved between nodes. A resource can be owned only by a single node at any point in time.

| Virtual Server | Resources |
|---|---|

| | |
|---|---|
| Exchange virtual servers | • Nine Physical Disk resources<br>• One Network Name resource<br>• One IP Address resource<br>• The following Exchange 2003 resources:<br>  • Exchange Message Transfer Agent instance (this resource is only in the first Exchange instance in the cluster)<br>  • Exchange Routing Service instance<br>  • SMTP virtual server instance<br>  • Exchange HTTP virtual server instance<br>  • Exchange IMAP4 virtual server instance<br>  • Exchange POP3 virtual server instance<br>  • Search Service instance<br>  • Exchange System Attendant<br>  • Exchange Information Store |
| Backup virtual servers | • Four Physical Disk resources<br>• Four File Share resources<br>• One IP Address resource<br>• One Network Name resource |
| Cluster virtual server | • One Physical Disk resource<br>• One IP Address resource<br>• One Network Name resource<br>• One Distribution Transaction Coordinator resource<br>• One Majority Node Set resource |

The following sections describe how OTG has configured the settings in Cluster Administrator. You can use Cluster Administrator to configure a cluster and its nodes, resource groups, and resources.

- Cluster Properties
- Exchange Virtual Server Properties
- Backup Virtual Server Properties

- Cluster Virtual Server Properties
- Resource Settings

**Cluster Properties**

This section describes how OTG has configured the server cluster as a whole.

The following settings appear on the **Quorum** tab that is available when you configure or view the cluster properties.

| Configuration setting | Explanation |
|---|---|
| **Quorum resource:**<br><br>Majority Node Set | In a majority node set server cluster, each node maintains its own copy of the cluster configuration data. The Majority Node Set resource, acting as the Quorum Resource, ensures that the cluster configuration data is kept consistent across the different nodes. The majority node set cluster is only meant for use in targeted scenarios like a geographically dispersed cluster, which is a cluster that spans multiple sites.<br><br>OTG has used a majority node set server cluster primarily for validation and testing purposes. Majority node set clusters also reduce the likelihood of a single point of failure in certain hardware devices (such a host bus adapters or fibre switches), which can cause the entire cluster to fail.<br><br>**Important**<br>Do not configure your cluster as a majority node set cluster unless you have a specific need to do so and it is part of a cluster solution offered by your Original Equipment Manufacturer (OEM), Independent Software Vendor (ISV), or Independent Hardware Vendor (IHV). The single quorum device server cluster will still cover the vast majority of your cluster deployment needs. |
| **Reset quorum log at:**<br><br>4096 KB | The maximum size of the quorum log is 4096 KB. This is enough space to hold the cluster configuration information, such as which servers are part of the cluster, what resources are installed in the cluster, and what state those resources are in (for example, online or offline). |

The following settings appear on the **Network Priority** tab that is available when you configure or view the clusters properties.

| Configuration setting | Explanation |
|---|---|
| **Networks used for internal cluster communications:**<br><br>• Internal<br><br>• Internal + Public | The Internal network has the highest priority. The Internal + Public network will only be used if the Internal network becomes unavailable. |

The following settings appear on the **Security** tab that is available when you configure or view the clusters properties.

| Configuration setting | Explanation |
|---|---|
| **Group or user names:**<br><br>• Administrators have full Control<br><br>• Network Service has full Control<br><br>• System has full Control | These groups have permission to alter the configuration of this cluster. |

**Exchange Virtual Server Properties**

This section describes how OTG has configured the Exchange virtual servers in the server cluster.

OTG has configured four Exchange virtual servers, which each host four storage groups. These storage groups contain a total of 20 databases. Each database is configured with a 200-MB limit per mailbox. This design specifies a maximum of 200 mailboxes per database, so each Exchange virtual server can contain a maximum of 4,000 mailboxes.

The following settings appear on the **General** tab that is available when you configure or view properties for the Exchange virtual servers.

| **Configuration setting** | **Explanation** |
|---|---|
| **Preferred owners:**<br>• Active node 1<br>• Primary passive node<br>• Alternate passive node 1<br>• Alternate passive node 2 | The Exchange virtual server will fail over to the indicated nodes in the specified order. If the active node fails, the Exchange virtual server will fail over to the primary passive node. If the primary passive node is unavailable, the Exchange virtual server will fail over to the alternate passive nodes. If none of the nodes are available, this resource group will fail over to a randomly selected node (this also depends on the **possible owner** settings for its resources). |

The following settings appear on the **Failover** tab that is available when you configure or view properties for the Exchange virtual servers.

| **Configuration setting** | **Explanation** |
|---|---|
| **Threshold** set to 10<br>**Period** set to 6 | The Exchange virtual server is allowed to fail 10 times within 6 hours before it is left in a failed state. The 11th time a resource in the resource group fails, the Cluster service fails all other resources in the group and leaves the entire group offline instead of failing over the group. |

The following setting appears on the **Failback** tab that is available when you configure or view properties for the Exchange virtual servers.

| **Configuration setting** | **Explanation** |
|---|---|
| **Prevent Failback** is checked. | The Exchange virtual server will not fail back when a failed node returns to operation. Instead, the Exchange virtual server will continue to run on the alternate node after the failed node comes back online. This requires administrator intervention to move the resource group back to the original, preferred node. OTG prefers this method because the administrator has complete control over when the failback occurs and can coordinate this to give users the least amount of downtime. |

**Backup Virtual Server Properties**

This section describes how OTG has configured the four backup virtual servers in the server cluster. For more information about how the backup process works, see How OTG Backs Up the Server Cluster later in this document.

The following setting appears on the **General** tab that is available when you configure or view the properties for the backup virtual servers.

| **Configuration setting** | **Explanation** |
|---|---|

| | |
|---|---|
| There are no **preferred owners** for this resource group. | OTG has created various scheduled tasks that control the movement of the backup virtual servers between nodes. The scheduled tasks force the backup virtual servers to move between the passive and active nodes, depending on the stage of the backup process that is being completed. The movement of the backup virtual servers between nodes is also determined by the **possible owner** settings of their resources. |

The following settings appear on the **Failover** tab that is available when you configure or view the properties for the backup virtual servers.

| **Configuration setting** | **Explanation** |
|---|---|
| **Threshold** set to 10<br><br>**Period** set to 6 | This resource group is allowed to fail 10 times within 6 hours before it is left in a failed state. The 11th time a resource in the group fails, the Cluster service fails all other resources in the group and leaves the entire group offline instead of failing over the group. |

The following setting appears on the **Failback** tab that is available when you configure or view the properties for the backup virtual servers.

| **Configuration setting** | **Explanation** |
|---|---|
| **Prevent Failback** is checked. | This resource group will not fail back when a failed node returns to operation. Instead, it will continue to run on the alternate node after the failed node comes back online. This requires administrator intervention to move the group back to the original, preferred node. OTG prefers this method because the administrator has complete control over when the failback occurs and can coordinate this to make sure that users experience the least amount of downtime. |

**Cluster Virtual Server Properties**

This section describes how OTG has configured the cluster virtual server in the server cluster. The cluster virtual server is the owner of the cluster quorum resource. The quorum resource maintains the configuration data that is necessary for recovery of the cluster. This data contains details of all of the changes that have been applied to the cluster database.

The following setting appears on the **General** tab that is available when you configure or view properties for the cluster virtual server.

| **Configuration setting** | **Explanation** |
|---|---|
| **Preferred owners:**<br>• Primary passive node | This resource group will first attempt to fail over to the primary passive node because it is best equipped to host the group. If this node is not available, this group will fail over to a randomly selected node (this also depends on the **possible owner** settings of its resources). |

The following settings appear on the **Failover** tab that is available when you configure or view the properties for the cluster virtual server.

| **Configuration setting** | **Explanation** |
|---|---|
| **Threshold** set to 10<br><br>**Period** set to 6 | This resource group is allowed to fail 10 times within 6 hours before it is left in a failed state. The 11th time a resource in the group fails, the Cluster service fails all other resources in the group and leaves the entire group offline instead of failing over the group. |

The following settings appear on the **Failback** tab that is available when you configure or view the properties for the cluster virtual server.

| Configuration setting | Explanation |
| --- | --- |
| **Prevent Failback** is checked. | This resource group will not fail back when a failed node returns to operation. Instead, it will continue to run on the alternate node after the failed node comes back online. This requires administrator intervention to move the group back to the original, preferred node. OTG prefers this method because the administrator has complete control over when the failback occurs and can coordinate this to make sure that users experience the least amount of downtime. |

**Resource Settings**

This section describes how each of the resources used in the server cluster is configured.

All resource settings in the server cluster are the default values with the following exceptions. These exceptions appear on the **Advanced** tab that is available when you configure or view the properties for the resource:

- **Restart** is not enabled for the Exchange Information Store and the Exchange System Attendant resources.
- **Restart** is enabled for all other resources (default) but the **Affect the Group** option is disabled.

For more information regarding why these changes were made, see each specific setting below

For more information about cluster resources, see the information about standard resource types at the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=19502).

For more information about Exchange resources, see Product Documentation for Exchange at the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=116208).

| **Note** |
| --- |
| Each resource of a specific type is configured identically unless otherwise noted. |

**IP Address Resource**

The following settings appear on the **General** tab that is available when you configure or view the IP Address resource properties.

| Configuration setting | Explanation |
| --- | --- |
| All nodes are **possible owners**. | This resource can run on any of the available nodes, which allows failover to occur. During failover, this resource will fail over to a node based on the **preferred owner** settings of the resource group it belongs to. |
| **Run as a separate Resource Monitor** is not checked. | This resource does not run on a separate memory space. |

The following setting appears on the **Dependencies** tab that is available when you configure or view the IP Address resource properties.

| Configuration setting | Explanation |
| --- | --- |
| This resource has no **Resource Dependencies**. | The Cluster service uses the dependencies list when bringing resources online and offline. This resource does not require another resource to operate. |

The following settings appear on the **Advanced** tab that is available when you configure or view the IP Address resource properties.

| Configuration setting | Explanation |
| --- | --- |

| | |
|---|---|
| **Restart** is not enabled.<br><br>The **Affect the group** check box is not selected (with a threshold of 3 and a period of 900 seconds). | This resource restarts after a resource failure.<br><br>The entire resource group will not be failed over when this resource fails. When this resource is in a pending state, the Cluster service will attempt to restart the resource 3 times within 900 seconds before the Cluster service assigns the resource to Offline or Failed status.<br><br>**Important**<br>All resources that restart after a resource failure are not configured to **Affect the group**. This is not a default setting. This allows OTG to track and fix any problems within the cluster. If a resource failure occurs, this setting allows OTG administrators to notify the Microsoft developers of possible bugs in the code.<br><br>This setting also inhibits a cluster resource group from alternating between nodes when a resource fails, which would result in significant instability. This problem can result when a failed disk has default properties that cause a series of bus resets. The resource group then attempts to acquire reservation on a disk that does not exist.<br><br>This configuration is only suitable for users with strong monitoring systems who want to control the location of their groups. |
| **Looks Alive poll interval:**<br>• resource type value | The Cluster service will perform a cursory check the default number of times to determine if a resource is in the Online state. |
| **Is Alive poll interval:**<br>• resource type value | The Cluster service will perform an in-depth check the default number of times to determine if the resource is in the Online state. |
| **Pending timeout** is set at 180 seconds. | This resource has 180 seconds when in a pending state (Online Pending or Offline Pending) to resolve its status, or at least report to the Resource Monitor that it is making progress, before the Cluster service will put the resource in Failed status. |

The following settings appear on the **Parameters** tab that is available when you configure or view the IP Address resource properties.

| Configuration setting | Explanation |
|---|---|
| **Address:**<br><br>XXX.XX.XX.XXX | This parameter specifies the unique IP address. This address is a static IP address that is not already in use on the network. This was obtained by the network administrator. |
| **Subnet mask:**<br><br>XXX.XXX.XXX.XXX | This parameter denotes the subnet mask for the IP address specified. This subnet mask is the same subnet mask as the one for the associated cluster network. This was obtained by the network administrator. |
| **Network**:<br><br>Internal + Public | The mixed communication adapter is being used. For more information, see Network Adapters. |
| **Enable NetBIOS for this address** is checked. | The NetBIOS is enabled for the specified IP address. This allows a dependent network name to be published using NetBIOS. |

**Network Name Resource**

The following settings appear on the **General** tab that is available when you configure or view the Network Name resource properties.

| Configuration setting | Explanation |
|---|---|

| | |
|---|---|
| All nodes are **possible owners**. | This resource can run on any of the available nodes, which allows failover to occur. During failover, this resource will fail over to a node based on the **preferred owner** settings of the resource group it belongs to. |
| **Run as a separate Resource Monitor** is not checked. | This resource does not run on a separate memory space. |

The following setting appears on the **Dependencies** tab that is available when you configure or view the Network Name resource properties.

| Configuration setting | Explanation |
|---|---|
| **Resource Dependencies:**<br>• IP Address Resource | The Cluster service uses the dependencies list when bringing resources online and offline. A dependent resource is one that requires another resource to operate. The network name resource is dependent on the IP Address that you want to correspond to the name. |

The following settings appear on the **Advanced** tab that is available when you configure or view the Network Name resource properties.

| Configuration setting | Explanation |
|---|---|
| **Restart** is not enabled.<br><br>The **Affect the group** check box is not selected (with a threshold of 3 and a period of 900 seconds). | This resource restarts after a resource failure.<br><br>The entire resource group will not be failed over when this resource fails. When this resource is in a pending state, the Cluster service will attempt to restart the resource 3 times within 900 seconds before the Cluster service assigns the resource to Offline or Failed status.<br><br>**Important**<br>All resources that restart after a resource failure are not configured to **Affect the group**. This is not a default setting. This allows OTG to track and fix any problems within the cluster. If a resource failure occurs, this setting allows OTG administrators to notify the Microsoft developers of possible bugs in the code.<br><br>This setting also inhibits a cluster resource group from alternating between nodes when a resource fails, which would result in significant instability. This problem can result when a failed disk has default properties that cause a series of bus resets. The resource group then attempts to acquire reservation on a disk that does not exist.<br><br>This configuration is only suitable for users with strong monitoring systems who want to control the location of their groups. |
| **Looks Alive poll interval:**<br>• resource type value | The Cluster service will perform a cursory check the default number of times to determine if a resource is in the Online state. |
| **Is Alive poll interval:**<br>• resource type value | The Cluster service will perform an in-depth check the default number of times to determine if the resource is in the Online state. |
| **Pending timeout** is set at 180 seconds. | This resource has 180 seconds when in a pending state (Online Pending or Offline Pending) to resolve its status, or at least report to the Resource Monitor that it is making progress, before the Cluster service will put the resource in Failed status. |

The following settings appear on the **Parameters** tab that is available when you configure or view the Network Name resource properties.

| Configuration setting | Explanation | |
|---|---|---|
| **DNS Registration must succeed.** | Exchange virtual server:<br><br>Is not checked. | Domain Name System registration failures are tolerated for this Network Name resource. |
| | Backup virtual server:<br><br>Is not checked. | Domain Name System registration failures are tolerated for this Network Name resource. |
| | Cluster virtual server:<br><br>Is not checked. | Domain Name System registration failures are tolerated for this Network Name resource. |
| **Enable Kerberos Authentication** | Exchange virtual server:<br><br>Is checked. | Clients connecting to the network name represented by this resource can use Kerberos Authentication if they chose to. The System Attendant will not come online unless the Kerberos is enabled in the Network Name for the Exchange virtual server. |
| | Backup virtual server:<br><br>Is not checked. | Clients connecting to the network name represented by this resource can only use NTLM authentication. This is the default configuration. |
| | Cluster virtual server:<br><br>Is not checked. | Clients connecting to the network name represented by this resource can only use NTLM authentication. This is the default configuration. |

**Physical Disk Resource**

The following settings appear on the **General** tab that is available when you configure or view the Physical Disk resource properties.

| Configuration setting | Explanation |
|---|---|
| All nodes are **possible owners**. | This resource can run on any of the available nodes, which allows failover to occur. During failover, this resource will fail over to a node based on the **preferred owner** settings of the resource group it belongs to. |
| **Run as a separate Resource Monitor** is not checked. | This resource does not run on a separate memory space. |

The following settings appear on the **Dependencies** tab that is available when you configure or view the Physical Disk resource properties.

| Configuration setting | Explanation | |
|---|---|---|

| | | |
|---|---|---|
| **Resource Dependencies** | Exchange virtual server:<br><br>Dependencies vary. | The Cluster service uses the dependencies list when bringing resources online and offline. This resource can have varying dependencies based on the following:<br><br>• Mount point disks are dependent on their parent drive.<br><br>• Log drives are dependent on the data drives.<br><br>• Data drives have no dependencies. |
| | Backup virtual server:<br><br>Dependencies vary. | The Cluster service uses the dependencies list when bringing resources online and offline. This resource can have varying dependencies, which enable the transfer of data during backup. |
| | Cluster virtual server:<br><br>Has no dependencies. | The Cluster service uses the dependencies list when bringing resources online and offline. This resource does not require another resource to operate. |

The following settings appear on the **Advanced** tab that is available when you configure or view the Physical Disk resource properties.

| Configuration setting | Explanation |
|---|---|
| **Restart** is not enabled.<br><br>The **Affect the group** check box is not selected (with a threshold of 3 and a period of 900 seconds). | This resource restarts after a resource failure.<br><br>The entire resource group will not be failed over when this resource fails. When this resource is in a pending state, the Cluster service will attempt to restart the resource 3 times within 900 seconds before the Cluster service assigns the resource to Offline or Failed status.<br><br>**Important**<br>All resources that restart after a resource failure are not configured to **Affect the group**. This is not a default setting. This allows OTG to track and fix any problems within the cluster. If a resource failure occurs, this setting allows OTG administrators to notify the Microsoft developers of possible bugs in the code.<br><br>This setting also inhibits a cluster resource group from alternating between nodes when a resource fails, which would result in significant instability. This problem can result when a failed disk has default properties that cause a series of bus resets. The resource group then attempts to acquire reservation on a disk that does not exist.<br><br>This configuration is only suitable for users with strong monitoring systems who want to control the location of their groups. |
| **Looks Alive poll interval:**<br><br>• resource type value | The Cluster service will perform a cursory check the default number of times to determine if a resource is in the Online state. |
| **Is Alive poll interval:**<br><br>• resource type value | The Cluster service will perform an in-depth check the default number of times to determine if the resource is in the Online state. |
| **Pending timeout** is set at 180 seconds. | This resource has 180 seconds when in a pending state (Online Pending or Offline Pending) to resolve its status, or at least report to the Resource Monitor that it is making progress, before the Cluster service will put the resource in Failed status. |

**File Share Resource**

The following settings appear on the **General** tab that is available when you configure or view the File Share resource

properties.

| Configuration setting | Explanation |
|---|---|
| All nodes are **possible owners**. | This resource can run on any of the available nodes, which allows failover to occur. During failover, this resource will fail over to a node based on the **preferred owner** settings of the resource group it belongs to. |
| **Run as a separate Resource Monitor** is not checked. | This resource does not run on a separate memory space. |

The following setting appears on the **Dependencies** tab that is available when you configure or view the File Share resource properties.

| Configuration setting | Explanation |
|---|---|
| **Resource Dependencies** vary. | The Cluster service uses the dependencies list when bringing resources online and offline. This resource can have varying dependencies which enable the transfer of data during backup. |

The following settings appear on the **Advanced** tab that is available when you configure or view the File Share resource properties.

| Configuration setting | Explanation |
|---|---|
| **Restart** is not enabled.<br><br>The **Affect the group** check box is not selected (with a threshold of 3 and a period of 900 seconds). | This resource restarts after a resource failure.<br><br>The entire resource group will not be failed over when this resource fails. When this resource is in a pending state, the Cluster service will attempt to restart the resource 3 times within 900 seconds before the Cluster service assigns the resource to Offline or Failed status.<br><br>**Important**<br>All resources that restart after a resource failure are not configured to **Affect the group**. This is not a default setting. This allows OTG to track and fix any problems within the cluster. If a resource failure occurs, this setting allows OTG administrators to notify the Microsoft developers of possible bugs in the code.<br><br>This setting also inhibits a cluster resource group from alternating between nodes when a resource fails, which would result in significant instability. This problem can result when a failed disk has default properties that cause a series of bus resets. The resource group then attempts to acquire reservation on a disk that does not exist.<br><br>This configuration is only suitable for users with strong monitoring systems who want to control the location of their resource groups. |
| **Looks Alive poll interval:**<br>• resource type value | The Cluster service will perform a cursory check the default number of times to determine if a resource is in the Online state. |
| **Is Alive poll interval:**<br>• resource type value | The Cluster service will perform an in-depth check the default number of times to determine if the resource is in the Online state. |
| **Pending timeout** is set at 180 seconds. | This resource has 180 seconds when in a pending state (Online Pending or Offline Pending) to resolve its status, or at least report to the Resource Monitor that it is making progress, before the Cluster service will put the resource in Failed status. |

The following setting appears on the **Parameters** tab that is available when you configure or view the File Share resource properties.

| Configuration setting | Explanation |
| --- | --- |
| The maximum **User Limit** is allowed. | OTG has not limited the number of simultaneous users. |

**Majority Node Set Resource**

The following settings appear on the **General** tab that is available when you configure or view the Majority Node Set resource properties.

| Configuration setting | Explanation |
| --- | --- |
| All nodes are **possible owners**. | This resource can run on any of the available nodes, which allows failover to occur. During failover, this resource will fail over to a node based on the **preferred owner** settings of the resource group it belongs to. |
| **Run as a separate Resource Monitor** is not checked. | This resource does not run on a separate memory space. |

The following setting appears on the **Dependencies** tab that is available when you configure or view the Majority Node Set resource properties.

| Configuration setting | Explanation |
| --- | --- |
| This resource has no **Resource Dependencies**. | The Cluster service uses the dependencies list when bringing resources online and offline. This resource does not require another resource to operate. |

The following settings appear on the **Advanced** tab that is available when you configure or view the Majority Node Set resource properties.

| Configuration setting | Explanation |
| --- | --- |
| **Restart** is not enabled.<br><br>The **Affect the group** check box is not selected (with a threshold of 3 and a period of 900 seconds). | This resource restarts after a resource failure.<br><br>The entire resource group will not be failed over when this resource fails. When this resource is in a pending state, the Cluster service will attempt to restart the resource 3 times within 900 seconds before the Cluster service assigns the resource to Offline or Failed status.<br><br>**Important**<br>All resources that restart after a resource failure are not configured to **Affect the group**. This is not a default setting. This allows OTG to track and fix any problems within the cluster. If a resource failure occurs, this setting allows OTG administrators to notify the Microsoft developers of possible bugs in the code.<br><br>This setting also inhibits a cluster resource group from alternating between nodes when a resource fails, which would result in significant instability. This problem can result when a failed disk has default properties that cause a series of bus resets. The resource group then attempts to acquire reservation on a disk that does not exist.<br><br>This configuration is only suitable for users with strong monitoring systems who want to control the location of their groups. |
| **Looks Alive poll interval:**<br>• resource type value | The Cluster service will perform a cursory check the default number of times to determine if a resource is in the Online state. |
| **Is Alive poll interval:**<br>• resource type value | The Cluster service will perform an in-depth check the default number of times to determine if the resource is in the Online state. |

| | |
|---|---|
| **Pending timeout** is set at 180 seconds. | This resource has 180 seconds when in a pending state (Online Pending or Offline Pending) to resolve its status, or at least report to the Resource Monitor that it is making progress, before the Cluster service will put the resource in Offline status. |

**Distribution Transaction Coordinator Resource**

The following settings appear on the **General** tab that is available when you configure or view the Distribution Transaction Coordinator resource properties.

| **Note** |
|---|
| OTG has implemented a Distribution Transaction Coordinator resource because Exchange 2003 requires this resource in order to operate. |

| Configuration setting | Explanation |
|---|---|
| All nodes are **possible owners**. | This resource can run on any of the available nodes, which allows failover to occur. During failover, this resource will fail over to a node based on the **preferred owner** settings of the resource group it belongs to. |
| **Run as a separate Resource Monitor** is not checked. | This resource does not run on a separate memory space. |

The following setting appears on the **Dependencies** tab that is available when you configure or view the Distribution Transaction Coordinator resource properties.

| Configuration setting | Explanation |
|---|---|
| **Resource Dependencies:**<br>• Network Name<br>• Quorum Physical Disk | The Cluster service uses the dependencies list when bringing resources online and offline. This resource requires the Network Name resource and the Quorum physical disk resource in order to operate. |

The following settings appear on the **Advanced** tab that is available when you configure or view the Distribution Transaction Coordinator resource properties.

| Configuration setting | Explanation |
|---|---|

| | |
|---|---|
| **Restart** is not enabled.<br><br>The **Affect the group** check box is not selected (with a threshold of 3 and a period of 900 seconds). | This resource restarts after a resource failure.<br><br>The entire resource group will not be failed over when this resource fails. When this resource is in a pending state, the Cluster service will attempt to restart the resource 3 times within 900 seconds before the Cluster service assigns the resource to Offline or Failed status.<br><br>**Important**<br>All resources that restart after a resource failure are not configured to **Affect the group**. This is not a default setting. This allows OTG to track and fix any problems within the cluster. If a resource failure occurs, this setting allows OTG administrators to notify the Microsoft developers of possible bugs in the code.<br><br>This setting also inhibits a cluster resource group from alternating between nodes when a resource fails, which would result in significant instability. This problem can result when a failed disk has default properties that cause a series of bus resets. The resource group then attempts to acquire reservation on a disk that does not exist.<br><br>This configuration is only suitable for users with strong monitoring systems who want to control the location of their groups. |
| **Looks Alive poll interval:**<br><br>resource type value | The Cluster service will perform a cursory check the default number of times to determine if a resource is in the Online state. |
| **Is Alive poll interval:**<br><br>resource type value | The Cluster service will perform an in-depth check the default number of times to determine if the resource is in the Online state. |
| **Pending timeout** is set at 180 seconds. | This resource has 180 seconds when in a pending state (Online Pending or Offline Pending) to resolve its status, or at least report to the Resource Monitor that it is making progress, before the Cluster service will put the resource in Failed status. |

**Exchange Resources**

This section describes how OTG has configured the following Exchange resource properties. The Exchange System Attendant resource and Exchange Information Store resource have different configurations, which are described at the end of this section.

- Exchange Message Transfer Agent instance
- Exchange Routing Service instance
- Exchange SMTP virtual server instance
- Exchange HTTP virtual server instance
- Exchange IMAP4 virtual server instance
- Exchange POP3 virtual server instance
- Search Service instance

**Note**

After the Exchange System Attendant resource is created, the cluster automatically generates all other Exchange resources.

The following settings appear on the **General** tab that is available when you configure or view the various Exchange resource properties.

| Configuration setting | Explanation |
|---|---|

| | |
|---|---|
| All nodes are **possible owners**. | This resource can run on any of the available nodes, which allows failover to occur. During failover, this resource will fail over to a node based on the **preferred owner** settings of the resource group it belongs to. |
| **Run as a separate Resource Monitor** is not checked. | These resources do not run on a separate memory space. |

The following setting appears on the **Dependencies** tab that is available when you configure or view the various Exchange resource properties.

| Configuration setting | Explanation |
|---|---|
| **Resource Dependencies:**<br>• System Attendant | The Cluster service uses the dependencies list when bringing resources online and offline. These resources require the System Attendant resource in order to operate. |

The following settings appear on the **Advanced** tab that is available when you configure or view any of the various Exchange resource properties.

| Configuration setting | Explanation |
|---|---|
| **Restart** is not enabled.<br><br>The **Affect the group** check box is not selected (with a threshold of 3 and a period of 900 seconds). | This resource restarts after a resource failure.<br><br>The entire resource group will not be failed over when this resource fails. When this resource is in a pending state, the Cluster service will attempt to restart the resource 3 times within 900 seconds before the Cluster service assigns the resource to Offline or Failed status.<br><br>**Important**<br>All resources that restart after a resource failure are not configured to **Affect the group**. This is not a default setting. This allows OTG to track and fix any problems within the cluster. If a resource failure occurs, this setting allows OTG administrators to notify the Microsoft developers of possible bugs in the code.<br><br>This setting also inhibits a cluster resource group from alternating between nodes when a resource fails, which would result in significant instability. This problem can result when a failed disk has default properties that cause a series of bus resets. The resource group then attempts to acquire reservation on a disk that does not exist.<br><br>This configuration is only suitable for users with strong monitoring systems who want to control the location of their groups. |
| **Looks Alive poll interval:**<br>• resource type value | The Cluster service will perform a cursory check the default number of times to determine if a resource is in the Online state. |
| **Is Alive poll interval:**<br>• resource type value | The Cluster service will perform an in-depth check the default number of times to determine if the resource is in the Online state. |
| **Pending timeout** is set at 180 seconds. | This resource has 180 seconds when in a pending state (Online Pending or Offline Pending) to resolve its status, or at least report to the Resource Monitor that it is making progress, before the Cluster service will put the resource in Failed status. |

The following settings appear on the **General** tab that is available when you configure or view the Exchange System Attendant resource properties.

| Configuration setting | Explanation |
| --- | --- |
| **Possible Owners:**<br>• Active node 1<br>• Primary passive node<br>• Alternate passive node 1<br>• Alternate passive node 2 | This resource drives the failover path for the Exchange virtual servers because this resource can only run on these specified nodes. If the active node fails, the resource group will fail over to the primary passive node. If the primary passive node is unavailable, the group will fail over to the alternate passive nodes. This ensures that this resource group can only become active on its corresponding active nodes and all passive nodes. |
| **Run as a separate Resource Monitor** is not checked. | This resource does not run on a separate memory space. |

The following setting appears on the **Dependencies** tab that is available when you configure or view the Exchange System Attendant resource properties.

| Configuration setting | Explanation |
| --- | --- |
| **Resource Dependencies:**<br>• 5 physical disks<br>• Network Name | The Cluster service uses the dependencies list when bringing resources online and offline. This System Attendant resource is dependent on five mount drive devices (which are dependent on their parent drives) and the Network name resource. The System Attendant resource requires these resources in order to operate. |

The following settings appear on the **Advanced** tab that is available when you configure or view the Exchange System Attendant resource properties.

| Configuration setting | Explanation |
| --- | --- |
| **Restart** is not enabled. | This resource does not restart after a resource failure. This allows OTG to track and fix any problems within the cluster. If a resource failure occurs, this setting allows OTG administrators to notify the Microsoft developers of possible bugs in the code.<br><br>This setting is specific to OTG as it allows for more precise fault isolation that can then be reported to the server cluster developers. It is not recommended for typical customer deployments. |

| | |
|---|---|
| **Looks Alive poll interval:**<br>• resource type value | The Cluster service will perform a cursory check the default number of times to determine if this resource is in the Online state. |
| **Is Alive poll interval:**<br>• resource type value | The Cluster service will perform an in-depth check the default number of times to determine if this resource is in the Online state. |
| **Pending timeout** is set at 180 seconds. | This resource has 180 seconds when in a pending state (Online Pending or Offline Pending) to resolve its status, or at least report to the Resource Monitor that it is making progress, before the Cluster service will put the resource in Failed status. |

The following settings appear on the **General** tab that is available when you configure or view the Exchange Information Store resource properties.

| Configuration setting | Explanation |
|---|---|
| All nodes are **possible owners**. | This resource can run on any of the available nodes, which allows failover to occur. During failover, this resource will fail over to a node based on the preferred owner settings of the resource group it belongs to. |
| **Run as a separate Resource Monitor** is not checked. | This resource does not run on a separate memory space. |

The following setting appears on the **Dependencies** tab that is available when you configure or view the Exchange Information Store resource properties.

| Configuration setting | Explanation |
|---|---|
| **Resource Dependencies:**<br>System Attendant | The Cluster service uses the dependencies list when bringing resources online and offline. This resource requires the System Attendant resource in order to operate. |

The following settings appear on the **Advanced** tab that is available when you configure or view the Exchange Information Store Resource Properties.

| Configuration setting | Explanation |
|---|---|
| **Restart** is not enabled. | This setting is specific to OTG as it allows for more precise fault isolation that can then be reported to the server cluster developers. It is not recommended for typical customer deployments. |
| **Looks Alive poll interval:**<br>• resource type value | The Cluster service will perform a cursory check the default number of times to determine if this resource is in the Online state. |

| | |
|---|---|
| **Is Alive poll interval:**<br>• resource type value | The Cluster service will perform an in-depth check the default number of times to determine if this resource is in the Online state. |
| **Pending timeout** is set at 180 seconds. | This resource has 180 seconds when in a pending state (Online Pending or Offline Pending) to resolve its status, or at least report to the Resource Monitor that it is making progress, before the Cluster service will put the resource in Failed status. |

# How OTG Backs Up the Server Cluster

Updated: September 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Diagram 4 illustrates the process that the Operations and Technology Group (OTG) uses to back up the mailbox data in the Exchange databases. This backup strategy starts with a defined Service Level Agreement (SLA) that requires OTG to maintain a one-hour backup restore window per database.

Backup is divided into two stages. Stage 1 is a disk-to-disk backup, and stage 2 is a disk-to-tape backup. Stage 1 is a traditional full backup using the Exchange Backup API and is performed daily. The active cluster backs up data to locally mounted backup disks. Each storage group on an active node backs up its individual databases in sequential order, starting with database A and finishing with E. The logs get truncated daily after OTG completes a successful backup.

In Stage 2, the backup disks are failed over to the alternate passive node(s) and then backed up to tape through fibre attached tape devices. This backup can run at any period of the day without impacting server performance.

For more information about how the Exchange data storage is structured, see Storage Components. For additional information about the storage configuration for each virtual server, see Appendix A.

**Diagram 4 Backup Process for the Server Cluster**

# How OTG Monitors the Server Cluster

Updated: September 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This section briefly discusses the tools that the administrators in the Operations and Technology Group (OTG) use to monitor the condition and configuration of the Exchange server cluster. Proactive monitoring has several key components that include managing performance, configuration, and fault tolerance. The primary monitoring tool OTG uses is Microsoft Operations Manager (MOM).

**Microsoft Operations Manager**
OTG relies on Microsoft Operations Manager (MOM) as a proactive tool to monitor the health of its Exchange environment. MOM consolidates event performance and alert data in a centralized database. Cluster administrators can use this data to anticipate and react to server conditions.

MOM includes predefined downloadable solutions called Management Pack modules. Management Pack modules provide immediate monitoring of specific application and environments such as Exchange 2003. The Exchange module includes built-in knowledge of common problems. In addition, documentation is included to begin the steps to resolve issues when MOM identifies problems.

With the Exchange module, OTG can proactively manage and report on Exchange 2003 installations, which helps to avoid outages. For example, the Management Pack Exchange module performs the following tasks to alert OTG of possible critical conditions:

- Monitors vital performance data, which can indicate that the server is running low on resources.
- Collects important warning and error events from Exchange 2003 servers and alerts operators to problems.
- Monitors disk capacity and alerts operators when disk capacity is running low.
- Provides knowledge about which Exchange files are on the affected drives.
- Monitors the Exchange services that are expected to be running on a specific server.
- Monitors whether an Exchange database can actually be reached by a MAPI client logon, which verifies both the Exchange database and the Active Directory functionality.
- Monitors high queue lengths that are caused when e-mail cannot be sent to a destination server.
- Monitors and alerts operators to a high number of simultaneous connections, which can indicate a denial-of-service attack.
- Monitors configuration errors or resource shortages affecting service levels.

In addition, OTG uses MOM to monitor backup and restore of all Exchange servers from a central console.

**Other Monitoring Tools**
OTG uses a variety of other tools besides MOM to monitor and report the overall performance of servers and Exchange 2003.

- **HP Storage Management Appliance (SMA)**. The SMA is a centralized, appliance-based monitoring and management server for the storage area network (SAN) fabric. The SMA performs management functions without involving the host servers and allows data transfers to proceed independently between servers and storage devices whether the appliance is operating or not. OTG primarily uses the SMA to remotely manage regional and local SANs.
- **HP Open SAN Manager**. This tool provides a Web-based aggregation and entry point (or portal) for all SMA software applications. With this tool, administrators can organize, visualize, configure, and monitor storage from a single navigation point on the SAN. It also provides a centralized launch site for a variety of external management applications (that is, fabric management).

- **Command View EVA (HSV Element Manager)**. This is a graphical storage monitoring and configuration tool for the HP StorageWorks Enterprise Virtual Array (EVA). Administrators can use it to remotely manage HP SANs.

- **HP StorageWorks Secure Path**. Secure Path is multipath software that manages and maintains continuous data access to HP storage systems to ensure that no single point of failure occurs from server to storage. Secure Path is host-resident software that monitors the data paths between server and storage to increase availability of information.

- **Secure Path Manager 4.0x**. This tool provides simplified management of secure paths through a Web-based GUI that can integrate with the Storage Management Appliance. This tool can host and store views of preferred and available paths.

# Best Practices for Server Clusters

Updated: September 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This section describes best practices for deploying a server cluster.

**Planning Your Cluster**
Before designing your cluster, analyze how your messaging system is used and design your cluster in a way that will accommodate peak usage periods. For example, the entire configuration of the server cluster that is discussed in this document (hardware, software and cluster configuration) is designed to meet the requirements for peak usage. At Microsoft, Monday mornings are the busiest time for e-mail, as employees attempt to catch up from the weekend. Every server cluster configuration should accommodate the peak usage periods.

**Planning the Hardware for Your Cluster**

- Use identical network adapters in all cluster nodes. Each adapter should be the same make, model, and firmware version.
- Reserve one network exclusively for internal communication between cluster nodes. This is the private network. Use other networks for communication with clients. These are public networks. Having two networks ensures that the network will be available for internal cluster communications.
- Do not use teaming network adapters on the private network. Teaming network adapters, which are network adapters that are grouped on multiple ports to a single physical network segment, are used to provide fault tolerance.
- Create a standard naming system for your resources, nodes, disks, IP Addresses, and backup sets. This will increase clarity for anyone working with the cluster.

**Configuring the Network Adapters**

- Use static IP addresses for all nodes on the private network.
- Use static IP addresses for all nodes on all public networks. We do not recommend using dynamic configuration with Dynamic Host Configuration Protocol (DHCP). Failure to renew a lease of an IP Address could disrupt cluster operation.
- Do not configure DNS servers, WINS servers, or a default gateway on the private network adapters.
- Configure WINS or DNS servers on the public network adapters. If network name resources will be deployed on the public network, then the DNS servers should support dynamic updates.
- In Cluster Administrator, set the network connection order for each node to be:
    - Private network highest priority
    - Public network(s)
    - Remote access connections lowest priority
- Change the default name for each network connection to clearly identify the use of each network. For example, you might change the name of the private network connection from Local Area Connection (x) to Private Cluster Network.
- Isolate the internal network from public network communication. Only nodes that are part of the cluster should be connected to the private subnet. Where there are several clusters, using the same subnet for the private network for all of the clusters is reasonable.

**Configuring the Cluster Service**

- Set the private network role to Internal cluster communications only. Verify that the role for each public network is set to All communications, which is the default value. These settings are available in Cluster Administrator.

- In Cluster Administrator, configure the private network to be the highest priority for internal cluster communication. In addition, make sure the Public network is first in the TCP/IP Binding Order.

**More Information**

- For more server cluster best practices, see Best Practices for Configuring and Operating Server Clusters at the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=19500).

- For more information about best practices for Enterprise Virtual Arrays, see EVA Best Practices - Cost, Performance, and Availability and other related white papers in the Storage Array Systems White Papers section of the Hewlett-Packard Web site (http://go.microsoft.com/fwlink/?LinkId=19716).

# Summary (Using Clustering with Exchange 2003: An Example)

Updated: September 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Operation and Technology Group (OTG) at Microsoft uses Windows Server 2003 server cluster technology in a typical way, with a few changes that maximize the performance of the hardware. Because OTG selected these configurations (both server and storage) for deployment at Microsoft, they might not meet your specific deployment needs. IT professionals should use the Microsoft implementation as an example when configuring their own Exchange server cluster. As always, careful analysis, planning, testing, and piloting should precede any Exchange deployment and cluster design decisions. Ensure that you apply all applicable best practices and recommendations when making your own design decisions. In addition, ensure that you have properly characterized your environment before server configuration choices are made and hardware is purchased. When properly used and implemented, server cluster technology can create more reliable and available messaging

# Appendix A (Using Clustering with Exchange 2003: An Example)

Updated: September 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The following table shows the disk drives, data types, disk groups, Enterprise Virtual Arrays, sizes, Vraid types, and Logical Unit Numbers (LUNs) that correspond to each Exchange virtual server in the Exchange server cluster that is described in this document.

The server cluster contains four Exchange virtual servers (EVS), four backup virtual servers, and one cluster virtual server (CVS). The Exchange virtual servers include all of the resources that are required to form an Exchange server.

| Host name | Disk drive letters | Data type | Disk group | EVA | Size/ GB | RAID type | LUN |
|---|---|---|---|---|---|---|---|
| EVS1 | E:\Exchsrvr (Mount point) | SMTP | DG1 | EVA-1 | 50 | 1 | 1 |
| | E$ | SG1-Data | DG1 | EVA-1 | 350 | 1 | 2 |

# Microsoft Windows Server 2003 TCP/IP Implementation Details

Updated: July 6, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Published: June 1, 2003 | Updated: June 13, 2006

Microsoft Corporation

This article describes the implementation of the TCP/IP protocol stack in the Microsoft Windows Server 2003 family and is a supplement to the Windows Server 2003 Help and Support Center and Technical Reference documentation. This article contains an overview of TCP/IP in Windows Server 2003 features and capabilities, a discussion of protocol architecture, and detailed discussions of the core components, network application interfaces, and critical client components and services. The intended audience for this article is network engineers and support professionals who are already familiar with TCP/IP. Except where noted, the TCP/IP implementation for Windows XP is the same as that for Windows Server 2003.

**In This White Paper**

Introduction (Microsoft Windows Server 2003 TCP/IP Implementation Details)

Capabilities and Functionality

Architectural Model

The NDIS Interface and Below

Core Protocol Stack Components and the TDI Interface

Network Application Interfaces

Critical Client Services and Stack Components

Appendix B: NetBIOS over TCP/IP Configuration Parameters

Appendix C: Windows Sockets and DNS Registry Parameters

Appendix D: Tuning TCP/IP Response to Attack

Appendix E: Format of the Daytime Service Response String

Summary - Microsoft Windows Server 2003 TCP/IP Implementation Details

# Introduction (Microsoft Windows Server 2003 TCP/IP Implementation Details)

Updated: July 6, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Microsoft has adopted TCP/IP as the strategic enterprise network transport for its platforms. In the early 1990s, Microsoft started an ambitious project to create a TCP/IP stack and services that would greatly improve the scalability of Microsoft networking. With the release of the Microsoft Windows NT 3.5 operating system, Microsoft introduced a completely rewritten TCP/IP stack. This new stack was designed to incorporate many of the advances in performance and ease of administration that were developed over the past decade. The stack was a high-performance implementation of the industry-standard TCP/IP protocol. It has evolved with each version of Windows based on the Windows NT code base to include new features and services that enhance performance, security, and reliability.

The goals in designing the TCP/IP stack were to make it:

- Standards-compliant and interoperable
- Portable
- Scalable and fast
- Versatile
- Self-tuning and easy to administer

In this article, the Windows Server 2003 TCP/IP protocol suite is examined from the bottom up. Throughout the article, network traces are used to illustrate key concepts. These traces were gathered and formatted using Microsoft Network Monitor 2.0, a software-based protocol tracing and analysis tool included in the Microsoft Systems Management Server product. Windows 2000 Server and Windows Server 2003 include a limited functionality version of Network Monitor. The primary difference between this version and the Systems Management Server version is that the limited version can only capture frames that would normally be seen by the computer that it is installed on, rather than all frames that pass over the network (which requires the network interface card to be in promiscuous mode). It also does not support connecting to remote Network Monitor Agents.

# Capabilities and Functionality

Updated: July 6, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Overview**
Windows Server 2003 TCP/IP was designed to make it easy to integrate Microsoft systems into large-scale corporate, government, and public networks, and to provide the ability to operate over those networks in a secure manner. The Windows Server 2003 TCP/IP protocol is installed by default and, unlike previous versions of Windows, cannot be uninstalled. However, you can reset the TCP/IP configuration to a default state with the **netsh interface ip reset** command.

**Support for Standard Features**
Windows Server 2003 TCP/IP supports the following standard features:

- Ability to bind to multiple network adapters with different media types
- Logical and physical multihoming
- Internal IP routing capability
- Internet Group Management Protocol (IGMP) version 3 (IP multicasting)
- Duplicate IP address detection
- Multiple default gateways
- Dead gateway detection
- Automatic Path Maximum Transmission Unit (PMTU) discovery
- Internet Protocol security (IPsec)
- Quality of Service (QoS)
- ATM Services
- Virtual Private Networks (VPNs) with the Point-to-Point Tunneling Protocol (PPTP) and the Layer Two Tunneling Protocol with IPsec (L2TP/IPsec)

**Performance Enhancements**
In addition, Windows Server 2003 TCP/IP has the following performance enhancements:

- Protocol stack tuning, including increased default window sizes and new algorithms for high-delay and high-loss links, which increases throughput
- TCP-scalable window sizes (described in RFC 1323)
- Selective acknowledgments (SACK) (described in RFC 2018)
- TCP fast retransmit and fast recovery (described in RFC 2581)
- Round Trip Time (RTT) and Retransmission Timeout (RTO) calculation improvements
- Improved performance for management of large numbers of connections
- Hardware task offload mechanisms including checksum offload and large send offload (LSO)

**Services Available**

The Windows Server 2003 operating system provides the following TCP/IP-related services:

- Dynamic Host Configuration Protocol (DHCP) client and server and DHCP Relay Agent (with the Routing and Remote Access service)
- In the absence of a DHCP server, Automatic Private IP Addressing (APIPA) is used
- Windows Internet Name Service (WINS), a NetBIOS name client and server
- Domain Name System (DNS) client and server, including support for DNS dynamic updates
- Dial-up support using the Point-to-Point Protocol (client and server) and Serial Line Internet Protocol (client only)
- PPTP and L2TP/IPsec, used for remote access and site-to-site VPN connections
- TCP/IP network printing (client only with the Lpr.exe and Lpq.exe tools)
- SNMP agent
- NetBIOS interface
- Network Location Service
- Windows Sockets version 2 (Winsock2) interface
- Remote Procedure Call (RPC) support
- Network Dynamic Data Exchange (NetDDE)
- Computer browsing (My Network Places) across IP routers
- Reliable multicast with the Pragmatic General Multicast (PGM) protocol
- Basic TCP/IP connectivity utilities, including: finger, ftp, rcp, rexec, rsh, telnet, and tftp
- Server and client software for simple network protocols, including: Character Generator, Daytime, Discard, Echo, and Quote of the Day
- Routing Information Protocol (RIP) listener (for Windows XP Professional) and RIP and Open Shortest Path First (OSPF) (with the Routing and Remote Access service)
- Network Address Translator (NAT) capabilities using either the Internet Connection Sharing (ICS) or the NAT/Basic Firewall routing protocol component of the Routing and Remote Access service
- Stateful firewalling capabilities using either the Internet Connection Firewall (for Windows Server 2003 with no service packs installed), Windows Firewall (for Windows Server 2003 Service Pack 1), or the NAT/Basic Firewall routing protocol component of the Routing and Remote Access service
- Multicast forwarding and IGMP router and proxy capabilities with the Routing and Remote Access service
- TCP/IP management and diagnostic tools, including: arp, ipconfig, nbtstat, netsh, netstat, ping, pathping, route, nslookup, and tracert

**New Features for Windows Server 2003 TCP/IP**

The features and improvements of TCP/IP that are new for Windows Server 2003 include the following:

- Windows Server 2003, Windows XP with Service Pack 1, and Windows XP with Service Pack 2 now include a production-quality IPv6 protocol stack. For more information about IPv6, see Windows Server 2003 Help and Support Center or the Microsoft Windows IPv6 Web site (http://go.microsoft.com/fwlink/?LinkID=17074).
- Auto-negotiation of RFC 1323 options (window scaling and TCP timestamps).
- Default support of network interface cards providing large send offload (LSO) and checksum offload.
- IGMP version 3.
- Reliable multicast with PGM.
- Alternate configuration.
- Automatic determination of the interface-related and default route metrics.

The table below lists features and the operating system versions that they are present in as a reference. Features are described in more detail throughout this article.

**Table 1. Feature Comparison Table for Windows TCP/IP Versions**

| Product | Windows 98 | Windows 98 SE | Windows NT 4.0 SP5 | Windows 2000 | Windows Server 2003 |
|---|---|---|---|---|---|
| **Dead gateway detection** | Y | Y | Y | Y | Y |
| **Fast retransmit/recovery** | Y | Y | Y | Y | Y |
| **APIPA** | Y | Y | N | Y | Y |
| **Selective ACK (SACK)** | Y | Y | N | Y | Y |
| **Jumbo frame support** | Y | Y | Y | Y | Y |
| **Large windows** | D | D | N | D | D |
| **DNS dynamic update** | N | N | N | Y | Y |
| **Media sense** | N | N | N | Y | Y |
| **Wake on LAN** | N | N | N | Y | Y |
| **IP forwarding** | N | D | D | D | D |
| **NAT** | N | D | N | D | D |
| **Kerberos v5** | N | N | N | Y | Y |
| **IPsec** | N | N | N | Y | Y |
| **PPTP** | Y | Y | Y | Y | Y |
| **L2TP/IPsec** | N | N | N | Y | Y |
| **IP Helper API** | Y | Y | Y | Y | Y |
| **Winsock2 API** | Y | Y | Y | Y | Y |
| **GQoS API** | Y | Y | N | Y | Y |
| **IP Filtering API** | N | N | N | Y | Y |

| | | | | | |
|---|---|---|---|---|---|
| **Firewall hook** | N | N | N | Y | Y |
| **Packet scheduler** | N | N | N | D | D |
| **Network location** | N | N | N | N | Y |
| **ISSLOW** | Y | Y | N | Y | Y |
| **Personal firewall** | N | N | N | N | D |
| **Block source routing** | N | Y | Y | Y | Y |
| **ICMP Router Discovery** | Y | Y | D | D | D |
| **IPsec offload** | N | N | N | Y | Y |
| **IGMP v3** | N | N | N | N | Y |
| **Reliable multicast (PGM)** | N | N | N | N | Y |
| **Alternate configuration** | N | N | N | N | Y |
| **Auto-determination of routing metrics** | N | N | N | N | Y |
| **Checksum offload** | N | N | N | N | Y |
| **Large send offload** | N | N | N | N | Y |

N=No, Y=Yes, and D=Disabled by Default

**Internet RFCs Supported by Windows Server 2003 TCP/IP**

Requests for Comments (RFCs) are a constantly evolving series of reports, proposals for protocols, and protocol standards used by the Internet community. You can obtain RFCs from the Engineering Task Force Web site (http://go.microsoft.com/fwlink/?LinkID=29138).

**Table 2. RFCs supported by Windows Server 2003 TCP/IP**

| RFC | Title |
|---|---|
| **768** | User Datagram Protocol (UDP) |
| **783** | Trivial File Transfer Protocol (TFTP) |
| **791** | Internet Protocol (IP) |
| **792** | Internet Control Message Protocol (ICMP) |
| **793** | Transmission Control Protocol (TCP) |

| **3208** | PGM Reliable Transport Protocol Specification |
| **3376** | Internet Group Management Protocol, Version 3 |

**New Features for TCP/IP in Windows Server 2003 Service Pack 1**
The features and improvements of TCP/IP that are new for Windows Server 2003 Service Pack 1 include the following:

- Windows Firewall
- The Netstat –b option
- Netsh commands for Windows Sockets
- SYN attack protection is enabled by default
- SYN attack notification IP Helper APIs
- Registry parameter for ICMP host routes
- Smart TCP port allocation
- Registry value for multiple ARP replies

**Windows Firewall**
Windows Firewall replaces the Internet Connection Firewall provided with Windows Server 2003 with no service packs installed. Windows Firewall is a stateful firewall that drops unsolicited incoming traffic that does not correspond to either traffic sent in response to a request of the computer (solicited traffic) or unsolicited traffic that has been specified as allowed (excepted traffic). Windows Firewall provides a level of protection from malicious users and programs that rely on unsolicited incoming traffic to attack computers.

For more information about Windows Firewall in Windows Server 2003 Service Pack 1, see the Microsoft Windows Server 2003 Windows Firewall TechCenter (http://go.microsoft.com/fwlink/?linkid=67902).

**The Netstat –b option**

The Netstat tool displays a variety of information about active TCP connections, ports on which the computer is listening, Ethernet statistics, the IP route table, and IPv4 and IPv6 statistics. In Windows Server 2003 Service Pack 1, the Netstat tool supports a new **–b** option that displays the set of components that are listening on each open TCP and UDP port.

With Windows Server 2003 with no service packs installed, you can use the **–o** option to display the set of ports being listened on and the corresponding process ID (PID). You can then lookup the PID in the display of the **tasklist /svc** command to discover the name of the process that owns the port. However, in some cases, there are multiple services within a single process and it is not possible to determine which service within the process owned the port.

With the **–b** option, Netstat displays the TCP or UDP port, the file names corresponding to the components of the service that owns the port, and the PID. From the file names and PID, you can determine which of the services in the display of the **tasklist /svc** command owns the port.

**Netsh Commands for Windows Sockets**

There are now Windows Sockets (Winsock) Netsh commands to view the set of installed Winsock Layered Service Providers (LSPs) (the **netsh winsock show catalog** command) and to reset the Winsock LSP catalog to a default configuration (the **netsh winsock reset catalog** command). The **netsh winsock reset catalog** command is useful for restoring the Winsock LSP catalog when it has been corrupted by programs or services that install LSPs. However, you must reinstall the programs or services that use LSPs.

**SYN Attack Protection is Enabled by Default**

A TCP Synchronize (SYN) attack is a denial-of-service attack that exploits the retransmission and time-out behavior of the Synchronize-Acknowledgement (SYN-ACK) segment during the TCP three-way handshake to create a large number of half-open TCP connections. Depending on the TCP/IP protocol implementation, a large number of half-open TCP connections could do any of the following:

- Use all available memory.
- Use all possible entries in the TCP Transmission Control Block (TCB), an internal table used to track TCP connections. Once the half-open connections use all the entries, further connection attempts are responded to with a TCP connection reset.
- Use all available half-open connections. Once all the half-open connections are used, further connection attempts are responded to with a TCP connection reset.

To create a large number of TCP half-open connections, attackers send a large number of SYN segments, each from a spoofed IP address and TCP port number. Each spoofed IP address and TCP port number are for a process that does not respond to the SYN-ACKs being sent by the attacked host. SYN attacks are typically used to render Internet servers inoperative.

To mitigate the impact on a host experiencing a SYN attack, TCP/IP minimizes the amount of resources devoted to incomplete TCP connections and reduces the amount of time before abandoning the half-open connection. When a SYN attack is detected, TCP/IP in Windows Server 2003 and Windows XP lowers the number of retransmissions of the SYN-ACK segment and does not allocate memory or table entry resources for the connection until the TCP three-way handshake has been completed.

You can control SYN attack protection through the SynAttackProtect registry entry at HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\Tcpip\Parameters (type REG_DWORD). You set SynAttackProtect to 0 to disable SYN attack protection and to 1 to enable it.

For TCP/IP in Windows XP (all versions) and Windows Server 2003 with no service packs installed, SynAttackProtect is set to 0 by default. For TCP/IP in Windows Server 2003 Service Pack 1, SynAttackProtect is set to 1 by default.

**SYN Attack Notification IP Helper APIs**

To allow an application to notify network administrators that a SYN attack is taking place, the IP Helper API supports new SYN attack notification APIs named NotifySecurityHealthChange and CancelSecurityHealthChangeNotify. For information about these new APIs, see the Microsoft Developer Network (MSDN) (http://go.microsoft.com/fwlink/?linkid=67904).

**Registry Parameter for ICMP Host Routes**

TCP/IP for Windows Server 2003 SP1 supports a new registry parameter that restricts the number of host routes that can be added to the local IP route table by receiving ICMP Redirect messages. The new registry parameter is HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\ MaxICMPHostRoutes (REG_DWORD type). MaxICMPHostRoutes has a default value of 1000. You should not change this value unless the computer needs to be able to add a large number of host routes by receiving ICMP Redirect messages. The update to Windows Server 2003 SP1 available from article 898060 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?linkid=69231) changes the default

value of MaxICMPHostRoutes to 10000.

**Smart TCP Port Allocation**
When a TCP peer initiates a TCP connection termination and the connection termination completes, the TCP connection enters the TIME WAIT state. Once the TIME WAIT state is reached, TCP must wait twice the maximum segment lifetime (MSL) before a connection with the same set of socket addresses can be created. The set of socket addresses consist of the combination of the source and destination IP addresses and source and destination TCP ports. The MSL is the maximum amount of time a TCP segment can exist in an internetwork, and its recommended value is 120 seconds. This delay prevents a new connection's TCP segments that are using the same set of socket addresses from being confused with duplicated TCP segments of the old connection.

The TCP port for a connection in the TIME WAIT state is considered an available port and can be assigned for use by an application. This can lead to the following situation:

- An application requests any available TCP port.
- TCP/IP assigns a TCP port to use for the application socket.
- The application attempts to open a socket with a specific destination IP address.
- The application establishes a TCP connection and sends data.
- The application terminates the TCP connection.
- TCP/IP places the application's TCP connection in the TIME WAIT state until twice the MSL has passed.
- The same application requests another available TCP port.
- TCP/IP assigns a TCP port to use for the application socket. Because the port for the connection in the TIME WAIT state is considered open, it can be chosen as the next port to assign to the requesting application.
- Assuming that TCP/IP assigns the same TCP port number, the application attempts to open a socket with the same destination IP address.
- Because the connection is using the same set of socket addresses as the connection in the TIME WAIT state, TCP/IP indicates an error to the application.

You can mitigate this situation by setting the TcpTimedWaitDelay registry entry at HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\Tcpip\Parameters (REG_DWORD type) to a lower value. The value of TcpTimedWaitDelay determines the length of time that a connection stays in the TIME-WAIT state. However, lowering the value of TcpTimedWaitDelay is contrary to the original design of TCP and the MSL.

To prevent an application from creating a connection with the same set of socket addresses of a connection that is in a TIME WAIT state, TCP/IP in Windows Server 2003 Service Pack 1 has implemented a smart TCP port allocation algorithm. When an application requests any available TCP port, TCP/IP first attempts to find an available port that does not correspond to a connection in the TIME WAIT state. If a port cannot be found, then it picks any available port.

This new behavior makes it much more unlikely that an application will be assigned a TCP port that is in the TIME-WAIT state when connecting to the same destination. You no longer need to modify the TcpTimedWaitDelay registry entry.

**Registry Value for Multiple ARP Replies**
TCP/IP for Windows Server 2003 SP1 supports a new registry value that determines which MAC address is stored in the ARP cache when multiple ARP Reply messages are received. If there are multiple computers that are using the same IP address on a subnet, when a node sends an ARP Request frame for the IP address, it will receive multiple ARP replies. The new registry value HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters\StrictARPUpdate (REG_DWORD type) allows you to specify whether TCP/IP in Windows Server 2003 SP1 will store the MAC address of the last ARP reply received (StrictARPUpdate=0 [default]) or the MAC address of the first ARP reply received (StrictARPUpdate=1).

# Architectural Model

Updated: July 6, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Overview**

The Windows TCP/IP suite contains *core protocol elements*, *services*, and the *interfaces* between them. The Transport Driver Interface (TDI) and the Network Device Interface Specification (NDIS) are public, and their specifications are available from Microsoft.[1] In addition, there are a number of higher-level interfaces available to user-mode applications. The most commonly used are Windows Sockets, remote procedure call (RPC), and NetBIOS.

**Figure 1. The Windows Server 2003 TCP/IP architectural model**

| **Note** |
| --- |
| Figure 1 does not show the IPsec components. For more information, see How IPSec Works (http://go.microsoft.com/fwlink/?linkid=67907). |

**Sending and Receiving IP Packets**

When the source sends an IP packet, the following components analyze or change the packet in the following order:

1. Routing and Remote Access service IP packet filters
2. IPsec

When a router running Windows Server 2003 forwards an IP packet, the following components analyze or change the packet in the following order:

1. Internet Connection Sharing of the Network Connections folder or the NAT/Basic Firewall component of the Routing and Remote Access service
2. Routing and Remote Access service IP packet filters

3. IPsec

When an IP packet is received for forwarding, the following components analyze or change the packet in the following order:

1. IPsec
2. Routing and Remote Access service IP packet filters
3. Internet Connection Sharing of the Network Connections folder or the NAT/Basic Firewall component of the Routing and Remote Access service

When an IP packet is received that is destined for the local host, the following components analyze or change the packet in the following order:

1. IPsec
2. Routing and Remote Access service IP packet filters
3. Internet Connection Firewall (for Windows Server 2003 with no service packs installed), Windows Firewall (for Windows Server 2003 with Service Pack 1), or the NAT/Basic Firewall component of the Routing and Remote Access service
4. TCP/IP filters

This discussion only includes components that are provided with Windows Server 2003. This does not include any Windows Sockets layered service providers or NDIS intermediate miniport drivers.

**Plug and Play**
Windows Server 2003 includes support for Plug and Play. Plug and Play has the following capabilities and features:

- Automatic and dynamic recognition of installed hardware. This includes initial system installation, recognition of static hardware changes that may occur between boots, and response to run-time hardware events, such as dock or undock, and insertion or removal of cards.
- Streamlined hardware configuration in response to automatic and dynamic recognition of hardware, including dynamic hardware activation, resource arbitration, device driver loading, drive mounting, and so on.
- Support for particular buses and other hardware standards that facilitate automatic and dynamic recognition of hardware and streamlined hardware configuration, including Plug and Play ISA, PCI, PCMCIA, PC Card/CardBus, USB, and IEEE 1394. This includes promulgation of standards and advice about how hardware should behave.
- An orderly Plug and Play framework in which driver writers can operate. This includes infrastructure, such as device information (INF) interfaces, APIs, kernel-mode notifications, executive interfaces, and so on.
- Mechanisms that allow user-mode code and applications to learn of changes in the hardware environment so that they can take appropriate actions.

Plug and Play operation does not require Plug and Play hardware. To the degree possible, the first two bullets above apply to legacy hardware, as well as Plug and Play hardware. In some cases, orderly enumeration of legacy devices is not possible because the detection methods are destructive or inordinately time-consuming.

The primary impact that Plug and Play support has on protocol stacks is that network interfaces can come and go at any time. Windows Server 2003 TCP/IP and related components have been adapted to support Plug and Play.

# The NDIS Interface and Below

Updated: July 6, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Microsoft networking protocols use the Network Device Interface Specification (NDIS) to communicate with network card drivers. Much of the OSI model link layer functionality is implemented in the protocol stack. This makes development of network card drivers much simpler.

**Network Driver Interface Specification (3.1 through 5.1)**
NDIS 3.1 supports basic services that allow a protocol module to send raw packets over a network device and allow that same module to be notified of incoming packets received by a network device.

NDIS 4.0 added the following new features to NDIS 3.1:

- Out-of-band data support.
- WirelessWAN Media Extension.
- High-speed packet send and receive (a significant performance win).
- Fast IrDA Media Extension.
- Media Sense (required for the Designed for Windows logo in PC 97 and later Hardware Design Guide). The Windows Server 2003 TCP/IP stack utilizes media sense information, which is described in the "Automatic Client Configuration" section of this article.
- All local packet filter (prevents Network Monitor from monopolizing the CPU).
- Numerous new NDIS system functions (required for miniport binary compatibility across Windows 98, Windows Millennium Edition, Windows NT 4.0, Windows 2000, Windows XP, and Windows Server 2003).

NDIS 5.0 includes all functionality defined in NDIS 4.0, plus the following extensions:

- NDIS power options (required for Network Power Options and Network Wake-up).
- Plug and Play.
- Support for Windows Management Instrumentation (WMI), which provides Web-based Enterprise Management (WBEM)–compatible instrumentation of NDIS miniports and their associated adapters.
- Support for a single INF format across Windows operating systems. The INF format is based on the Windows 98 INF format.
- Deserialized miniport for improved performance.
- Task offload mechanisms, such as TCP and UDP checksum and Fast Packet Forwarding.
- TCP segmentation offload, also known as large-send offload (LSO).
- Broadcast Media Extension (needed for Broadcast Services for Windows).
- Connection-oriented NDIS (required to support Asynchronous Transfer Mode [ATM], Asymmetric Digital Subscriber Line [ADSL], and Windows Driver Model–Connection Streaming Architecture [WDM-CSA]).
- Support for Quality of Service (QoS).

- Intermediate Driver Support (required for Broadcast PC, Virtual LANs, Packet Scheduling for QoS, and NDIS support of IEEE 1394 network devices).

| **Note** |
| --- |
| You can disable a network interface card's use of task offload capabilities on the **Advanced** tab of the properties of the network interface card driver in Control Panel-Network or Device Manager. |

NDIS 5.1 enhancements for Windows Server 2003 include:

- **Plug and Play and Power Event Notification** – Enables network interface card miniport drivers to be notified of power or Plug and Play events. This results in cleaner system operation during these events.

- **Support for Send Cancellation** – Allows network protocols to avoid having to wait lengthy amounts of time for network packet send requests to complete.

- **Increased Statistics Capacity (64-bit statistic counters)** – This enhancement enables accurate network statistic displays, even on today's high-speed network media.

- **Performance Enhancements** – Several enhancements were made to speed up critical network data paths and avoid unnecessary packet copies.

- **Wake on LAN Change** – A change was made to Wake on LAN to allow you to limit wake up packets to just magic packets (instead of protocol registered packet patterns). This is now configurable from the properties of a network interface card driver.

- **Miscellaneous Changes** – Several additional changes have been made to support common needs or requests from driver developers or to improve driver integrity.

Remote NDIS is also included as part of the Windows Server 2003 family. Remote NDIS enables the support of USB-attached network devices without the installation of third party drivers. Microsoft supplies the drivers required to communicate with the network devices. This results in easier installation and a lessened chance of system failure because of a poorly built or tested driver.

For more information about NDIS 5.1 and Remote NDIS, see the Windows DDK (http://go.microsoft.com/fwlink/?linkid=38448) and the following Web pages:

- http://go.microsoft.com/fwlink/?linkid=67945

- http://go.microsoft.com/fwlink/?linkid=67946

NDIS can power down network adapters when the system requests a power level change. Either the user or the system can initiate this request. For example, the user may want to put the computer in sleep mode, or the system may request a power level change based on keyboard or mouse inactivity. In addition, disconnecting the network cable can initiate a power-down request if the network interface card supports this functionality. In this case, the system waits a configurable time period before powering down the network interface card because the disconnect could be the result of temporary wiring changes on the network, rather than the disconnection of a cable from the network device itself.

NDIS power management policy is *no network activity*–based. This means that all overlying network components must agree to the request before the network interface card can be powered down. If there are any active sessions or open files over the network, the power-down request can be refused by any or all of the components involved.

The computer can also be awakened from a lower power state, based on network events. A wakeup signal can be caused by:

- Detection of a change in the network link state (for example, cable reconnect)

- Receipt of a network wakeup frame

- Receipt of a Magic Packet.

At driver initialization, NDIS queries the capabilities of the miniport to determine if it supports such things as Magic Packet, pattern match, or link change wakeups, and to determine the lowest required power state for each wakeup method. The network protocols then query the miniport capabilities. At run time, the protocol sets the wakeup policy, using object identifiers (OIDs), such as **Enable Wakeup**, **Set Packet Pattern**, and **Remove Packet Pattern**.

Currently, TCP/IP is the only Microsoft protocol stack that supports network power management. It registers the following packet patterns at miniport initialization:

- Directed IP packet
- ARP broadcast for the station’s IP address
- NetBIOS over TCP/IP broadcast for the station's assigned computer name

NDIS-compliant drivers are available for a wide variety of network adapters from many vendors. The NDIS interface allows multiple protocol drivers of different types to bind to a single network adapter driver and allows a single protocol to bind to multiple network adapter drivers. The NDIS specification describes the multiplexing mechanism used to accomplish this. Bindings can be viewed or changed as advanced settings from the Network Connections folder.

Windows Server 2003 TCP/IP provides support for the following media types:

- Ethernet (using Ethernet II or IEEE 802.3 Sub-Network Access Protocol [SNAP] encapsulation)
- Fiber Distributed Data Interchange (FDDI)
- Token Ring (IEEE 802.5)
- IEEE 802.11 Wireless LAN
- ATM (using LAN emulation [LANE] and Classical IP [CLIP] over ATM)
- Attached Resource Computing Network (ARCnet)
- Dedicated wide area network (WAN) links such as Dataphone Digital Service (DDS) and T-carrier (Fractional T1, T1, T3, E1, and E3)
- Dial-up or permanent circuit-switched WAN services such as analog phone, Integrated Services Digital Network (ISDN), and Digital Subscriber Line (xDSL)
- Packet-switched WAN services such as X.25, Frame Relay, and ATM

**Link Layer Functionality**

Link layer functionality is divided between the network interface card/driver combination and the low-level protocol stack driver. The network card/driver combination filters are based on the destination media access control (MAC) address of each frame.

Normally, the hardware filters out all incoming frames except those containing one of the following destination addresses:

- The address of the adapter
- The all ones broadcast address (0xFF-FF-FF-FF-FF-FF)
- Multicast addresses that a protocol driver on this host has registered interest in, using the **NDISRequest()** function

Because this first filtering decision is made by the hardware, the network interface card discards any frames that do not meet the filter criteria without incurring any CPU processing. All frames (including broadcasts) that pass the hardware filter and Frame Check Sequence (FCS) validation are then passed up to the network interface card driver through a hardware interrupt.[2] The network interface card driver is software that runs on the computer, so any frames that make it this far require some CPU time to process. The network interface card driver brings the frame into system memory from the interface card. Then the frame is indicated (passed up) to the appropriate bound transport driver(s). The NDIS 5.1 specification provides more detail on this process.

Frames are passed up to all bound transport drivers in the order that they are bound.

As a packet traverses a network or series of networks, the source MAC address is always that of the network interface card that placed it on the media, and the destination MAC address is that of the network interface card that is intended to pull it off the media. This means that, in a routed network, the source and destination MAC address changes with each hop through a network-layer device (router or Layer 3 switch).

**Maximum Transmission Unit (MTU)**

Each media type has a maximum frame size that cannot be exceeded. The link layer is responsible for discovering this MTU and reporting it to the protocols above. NDIS drivers may be queried for the local MTU by the protocol stack. Knowledge of the MTU for an interface is used by upper layer protocols, such as TCP, that optimize packet sizes for each media automatically. For details, see the discussion of TCP path Maximum Transmission Unit (PMTU) discovery in the "Transmission Control Protocol (TCP)" section of this article.

If a network interface card driver—such as an ATM driver—uses LAN emulation mode, it may report that it has an MTU that is higher than what is expected for that media type. For example, it may emulate Ethernet but report an MTU of 9180 bytes. Windows Server 2003 TCP/IP accepts and uses the MTU size reported by the adapter, even when it exceeds the normal MTU for a given media type.

Sometimes the MTU reported to the protocol stack may be less than what would be expected for a given media type. For instance, use of the 802.1p standard for QoS over Ethernet often reduces the MTU reported by 4 bytes due to larger link-layer headers (this is hardware dependent).

# Core Protocol Stack Components and the TDI Interface

Updated: July 6, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The core protocol stack components are those shown between the NDIS and TDI interfaces in Figure 1. They are implemented in the Windows Server 2003 Tcpip.sys driver. The TCP/IP stack is accessible through the TDI interface and the NDIS interface. The Winsock2 interface also provides some support for direct access to the protocol stack.

**Address Resolution Protocol (ARP)**
ARP performs IP address-to-MAC address resolution for outgoing packets. As each outgoing IP datagram is encapsulated in a frame, source and destination MAC addresses must be added. Determining the destination MAC address for each frame is the responsibility of ARP.

ARP compares the next-hop IP address on every outbound IP datagram to the ARP cache for the network interface card over which the frame will be sent. If there is a matching entry, the MAC address is retrieved from the cache. If not, ARP broadcasts an ARP Request frame on the local subnet, requesting that the owner of the IP address in question reply with its MAC address. If the packet is going through a router, the next-hop address is that of a neighboring router and ARP resolves the MAC address for that next-hop router, rather than the final destination host. When an ARP reply is received, the ARP cache is updated with the new information, and it is used to address the packet at the link layer.

**ARP Cache**
You can use the ARP utility to view, add, or delete entries in the ARP cache. Examples are shown below. Entries added manually are static and are not automatically removed from the cache, whereas dynamic entries are removed from the cache (see the "ARP Cache Aging" section for more information).

The **arp** command can be used to view the ARP cache, as shown here:

```
C:\>arp -a

Interface: 157.60.137.88 --- 0x10003
  Internet Address      Physical Address      Type
  157.60.136.1          00-0a-42-b0-54-0a     dynamic
  157.60.137.0          00-b0-d0-e9-41-43     dynamic

Interface: 10.0.0.3 --- 0x10004
  Internet Address      Physical Address      Type
  10.0.0.1              08-00-2b-c4-25-b6     dynamic
```

The computer in this example is *multihomed*—has more than one network interface card—so there is a separate ARP cache for each interface.

In the following example, the command **arp –s** is used to add a static entry to the ARP cache used by the second interface for the host whose IP address is 10.0.0.32 and whose network interface card address is 00-60-8C-0E-6C-6A:

```
C:\>arp -s 10.0.0.32 00-60-8c-0e-6c-6a 10.0.0.3

C:\>arp -a

Interface: 157.60.137.88 --- 0x10003
  Internet Address      Physical Address      Type
  157.60.136.1          00-0a-42-b0-54-0a     dynamic
  157.60.137.0          00-b0-d0-e9-41-43     dynamic

Interface: 10.0.0.3 --- 0x10004
  Internet Address      Physical Address      Type
  10.0.0.1              08-00-2b-c4-25-b6     dynamic
  10.0.0.32             00-60-8c-0e-6c-6a     static
```

**ARP Cache Aging**
Windows Server 2003 adjusts the size of the ARP cache automatically to meet the needs of the system. If an entry is not used by any outgoing datagram for two minutes, the entry is removed from the ARP cache. Entries that are being referenced are removed from the ARP cache after ten minutes. Entries added manually are not removed from the cache automatically. The registry parameter *ArpCacheLife*, described in Appendix A, allows more administrative control over aging.

Use the command **arp –d** to delete entries from the cache, as shown below:

```
C:\>arp -d 10.0.0.32

C:\>arp -a

Interface: 157.60.137.88 --- 0x10003
  Internet Address      Physical Address      Type
  157.60.136.1          00-0a-42-b0-54-0a     dynamic
  157.60.137.0          00-b0-d0-e9-41-43     dynamic

Interface: 10.0.0.3 --- 0x10004
  Internet Address      Physical Address      Type
  10.0.0.1              08-00-2b-c4-25-b6     dynamic
```

ARP queues only one outbound IP datagram for a specified destination address while that IP address is being resolved to a MAC address. If a UDP-based application sends multiple IP datagrams to a single destination address without any pauses between them, some of the datagrams may be dropped if there is no ARP cache entry already present. An application can compensate for this by calling the Iphlpapi.dll routine **SendArp()** to establish an ARP cache entry, before sending the stream of packets. See article 193059 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?linkid=67951) or MSDN (http://go.microsoft.com/fwlink/?linkid=67904) for IP Helper API details.

**Internet Protocol (IP)**

IP is the mailroom of the TCP/IP stack, where packet sorting and delivery take place. At this layer, each incoming or outgoing packet is referred to as a *datagram*. Each IP datagram bears the source IP address of the sender and the destination IP address of the intended recipient. Unlike MAC addresses, the IP addresses in a datagram remain the same throughout a packet's journey across an internetwork, unless you are using source routing. IP layer functions are described below.

**Routing**

Routing is a primary function of IP. Datagrams are handed to IP from UDP and TCP above, and from the network interface card(s) below. Each datagram is labeled with a source and destination IP address. IP examines the destination address on each datagram, compares it to a locally maintained route table, and decides what action to take. There are three possibilities for each datagram:

- It can be passed up to a protocol layer above IP on the local host.
- It can be forwarded using one of the locally attached network interface cards.
- It can be discarded.

The route table maintains four different types of routes:

1. Host route (a route to a single, specific destination IP address)
2. Subnet route (a route to a subnet)
3. Network route (a route to an entire network)
4. Default route (used when there is no other match)

To determine the single route to use to forward an IP datagram, IP uses the following process:

1. For each route in the route table, IP performs a bit-wise logical AND between the destination IP address and the netmask. IP compares the result with the network destination for a match. If they match, IP marks the route as one that matches the destination IP address.
2. From the list of matching routes, IP determines the route that has the most bits in the netmask. This is the route that matches the most bits to the destination IP address and is therefore the most specific route for the IP datagram. This is known as finding the longest or closest matching route.
3. If multiple closest matching routes are found, IP uses the route with the lowest metric. If multiple closest matching routes with the lowest metric are found, IP can choose to use any of those routes. For Windows Server 2003, IP uses the route corresponding to the adapter that is the highest in the binding order. You can view and modify the binding order from

the **Adapters and Bindings** tab in the **Advanced Settings** dialog box for the Network Connections folder.

You can use the **route print** command to view the route table from the command prompt, as shown here:

```
C:\>route print
IPv4 Route Table
===========================================================================
Interface List

Default Gateway:      157.60.136.1
===========================================================================
Persistent Routes:
None
```

If the IPv6 protocol is installed, the display of the **route print** command also lists IPv6 routes.

The route table above is for a computer with the IP address of 157.60.137.88, the subnet mask of 255.255.252.0, and the default gateway of 157.60.136.1. It contains the following entries:

- The first entry, to destination 0.0.0.0, is the default route.
- The second entry is for the subnet 157.60.136.0, on which this computer resides.
- The third entry, to destination 157.60.137.88, is a host route for the local host. It specifies the loopback address, which makes sense because a datagram bound for the local host should be looped back internally.
- The fourth entry is for the all-subnets-directed broadcast address corresponding to the original Class B network ID 157.60.0.0.
- The fifth entry is for the loopback network, 127.0.0.0.
- The sixth entry is for IP multicasting, which is discussed later in this article.
- The final entry is for the limited broadcast (all ones) address.

The *Default Gateway* is the currently active default gateway. This is useful to know when multiple default gateways are configured.

On this host, if a packet is sent to 157.60.138.49, the closest matching route is the local subnet route (157.60.136.0 with the mask of 255.255.252.0). The packet is sent via the local interface that is assigned the IP address 157.60.137.88. If a packet is sent to 10.200.1.1, the closest matching route is the default route. In this case, the packet is forwarded to the default gateway at 157.60.136.1.

The route table is maintained automatically in most cases. When a host initializes, entries for the local network(s), loopback, multicast, and configured default gateway are added. More routes may appear in the table as the IP layer learns of them. For instance, the default gateway for a host may advise it of a better route to a specific address using ICMP redirect, which is explained later in this article. Routes also may be added manually using the **route** command, or by a routing protocol. The **-p** (persistent) switch can be used with the route command to specify permanent routes. Persistent routes are stored in the registry under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters \PersistentRoutes.

Windows Server 2003 TCP/IP introduces a new **Automatic metric** configuration option for interface-based and default gateway routing metrics. If selected for the interface, automatic metric configuration determines the metric for the routes associated with the interface configuration, such as subnet routes and host routes, based on the speed (bit rate) of the interface. The higher the speed, the lower the metric. For example, routes associated with 10 Mbps Ethernet interfaces have a metric of 30 and routes associated with 100 Mbps Ethernet interfaces have a metric of 20. If selected for the default gateway, automatic metric configuration determines the metric for the default route assigned to the interface, which is also based on the speed of the interface. Automatic metric configuration for both interface metrics and default routes are enabled by default and can be modified from the advanced configuration properties of the TCP/IP protocol for a connection in Network Connections. For more information, see article 299540 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?linkid=67955).

DHCP servers can also provide a base metric and a list of default gateways. If a DHCP server provides a base of 100, and a list of three default gateways, the gateways will be configured with metrics of 100, 101, and 102 respectively. A DHCP-provided base metric does not apply to statically configured default gateways.

By default, Windows-based systems do not behave as routers and do not forward IP datagrams between interfaces. However, the Routing and Remote Access service is included in Windows Server 2003 and can be enabled and configured to provide dynamic IP routing services using RIP and OSPF. Windows XP Professional includes support for silent RIP.

When running multiple logical subnets on the same physical network, the following command can be used to have IP treat all subnets as local (all destinations are on the local link):

**route add 0.0.0.0 MASK 0.0.0.0** <*my local ip address*>

Thus, packets destined for non-local subnets are transmitted directly onto the local media instead of being sent to a router. In essence, the local interface card can be designated as the default gateway. This can be useful where several class C networks are used on one physical network with no router to the outside world, or in a proxy-ARP environment.

**Duplicate IP Address Detection**

Duplicate address detection is an important feature. When the stack is first initialized or when a new IP address is added, gratuitous ARP requests are broadcast for the IP addresses of the local host. The number of ARP requests to send is controlled by the *ArpRetryCount* registry parameter described in Appendix A, which defaults to 3. If another host replies to any of these ARP requests, the IP address is already in use. When this happens for an interface with a single manually-configured address, the Windows-based computer still boots; however, the interface containing the offending address is disabled, a system log entry is generated, and an error message is displayed. If the host that is defending the address is also a Windows-based computer, a system log entry is generated, and an error message is displayed on that computer. In order to update the ARP caches on other computers, the offending computer re-broadcasts another ARP request, spoofing the MAC address of the defending computer, to restore the proper values in the ARP caches of the other computers.

A computer using a duplicate IP address can be started when it is not attached to the network, in which case no conflict would be detected. However, if it is then plugged into the network, the first time that it sends an ARP request for another IP address, any computer running a version of Windows with the Windows NT codebase with a conflicting address detects the conflict. The computer detecting the conflict displays an error message and logs a detailed event in the system log. A sample event log entry is shown below:

The system detected an address conflict for IP address 10.199.40.123 with the system having network hardware address 00:DD:01:0F:7A:B5. Network operations on this system may be disrupted as a result.

DHCP-enabled clients inform the DHCP server with a DHCPDecline message when an IP address conflict is detected and, instead of disabling the TCP/IP protocol, they request a new address from the DHCP server and request that the server mark the conflicting address as bad.

**Multihoming**

When a computer is configured with more than one IP address, it is referred to as a multihomed system. Multihoming is supported in three different ways:

- **Multiple IP addresses per network interface card**
    - To add addresses for an interface, obtain properties of the **Internet Protocol (TCP/IP)** protocol in Network Connection, and then click **Advanced**. In the **Advanced Settings** dialog box, click **Add** on the **IP Settings** tab to add IP addresses.
    - NetBIOS over TCP/IP (NetBT) binds to only one IP address per interface card. When a NetBIOS name registration is sent out, only one IP address is registered per interface. This registration occurs over the IP address that is

listed first on the **IP Settings** tab.

- **Multiple network interface cards per physical network.** There are no restrictions, other than hardware limitations on the number of network interface cards.

- **Multiple networks and media types.** There are no restrictions, other than hardware and media support. See the "The NDIS Interface and Below" section for supported media types.

When an IP datagram is sent from a multihomed host, it is passed to the interface with the best apparent route to the destination. Accordingly, the datagram may contain the source IP address of one interface in the multihomed host, yet be placed on the media by a different interface. The source MAC address on the frame is that of the interface that actually transmitted the frame to the media, and the source IP address is the one that the sending application sourced it from, not necessarily one of the IP addresses assigned to the sending interface.

When a computer is multihomed with network interface cards attached to disjoint networks (networks that are separate from and unaware of each other, such as a private network using private addressing and the Internet), routing problems may arise. It is often necessary to set up static routes to the private networks in this situation.

When configuring a computer to be multihomed on two disjoint networks, the best practice is to configure the default gateway on the interface connected to the largest and least-known network, in which the default route summarizes the most destinations. Then, either add static routes or use a routing protocol to provide connectivity to the hosts on the smaller or better-known network. Avoid configuring a different default gateway on each side; this can result in unpredictable behavior and loss of connectivity. For more information, see Default Gateway Behavior for Windows TCP/IP (http://go.microsoft.com/fwlink/?linkid=47705).

| **Note** |
| --- |
| There can only be one active default gateway for a computer at any moment in time. |

More details on name registration, resolution, and choice of network interface card on outbound datagrams with multihomed computers are provided in the "Transmission Control Protocol (TCP)," "NetBIOS over TCP/IP," and "Windows Sockets" sections of this article.

**Classless Inter-Domain Routing (CIDR)**

CIDR, described in RFCs 1518 and 1519, removes the concept of address classes from the IP address assignment and management process. In place of predefined, well-known boundaries, CIDR allocates addresses defined by a network prefix, which makes more efficient use of available space. The network prefix defines the portion of the address that is fixed. For example, an assignment from an ISP to a corporate client might be expressed as 157.60.1.128/25. In this prefix, the first 25 bits are fixed and the last 7 bits can be used for address assignment. This would result in a 128-address block for local use, with the upper 25 bits being the network identifier part of the address. A legacy, class-full prefix would be expressed as *w*.0.0.0/8, *w.x*.0.0/16, or *w.x.y*.0/24. As these are reclaimed, they will be reallocated using classless CIDR techniques.

Given the installed base of classful systems, the initial implementation of CIDR was to summarize portions of the Class C address space. This process was called *supernetting*. Supernetting can be used to consolidate several network IDs into one prefix. For example, the network IDs 131.107.4.0, 131.107.5.0, 131.107.6.0, and 131.107.7.0 can be summarized with the network ID 131.107.4.0 with a subnet mask of 255.255.252.0 (131.107.4.0/22). For example:

```
NET     131.107.4.0   (1100 0111.1100 0111.0000 0100.0000 0000)
NET     131.107.5.0   (1100 0111.1100 0111.0000 0101.0000 0000)
NET     131.107.6.0   (1100 0111.1100 0111.0000 0110.0000 0000)
NET     131.107.7.0   (1100 0111.1100 0111.0000 0111.0000 0000)
MASK  255.255.252.0   (1111 1111.1111 1111.1111 1100.0000 0000)
```

All four of the network IDs share the same high-order 22 bits (bolded).

When routing decisions are made, only the bits covered by the subnet mask are used, thus making all these addresses appear to be part of the same network for routing purposes. Any routers in use must also support CIDR and may require special configuration.

Windows Server 2003 TCP/IP includes support for the all-0's and all-1's subnets as described in RFC 1878.

**IP Multicasting**

IP multicasting is used to provide efficient multicast services to clients that may not be located on the same network segment. Windows Sockets applications can join a multicast group to participate in a wide-area conference, for instance.

Windows Server 2003 TCP/IP is level 2-compliant with RFC 1112 (send and receive). IGMP is the protocol used to track multicast membership on a subnet, which is described later in this article.

**IP over ATM**
Windows Server 2003 includes support for IP over ATM. RFC 1577 (and successors) define the basic operation of an IP over ATM network known as Classical IP over ATM (CLIP), which defines a Logical IP Subnet (LIS). A LIS is a set of IP hosts that can communicate directly with each other. Two hosts belonging to different LISs can communicate only through an IP router that is a member of both subnets. Windows Server 2003 also includes support for ATM LAN Emulation (LANE), which supports broadcasting.

**ATM Address Resolution**
Because an ATM network is non-broadcast, ARP broadcasts (as used by Ethernet or Token Ring) are not a suitable solution. Instead, a dedicated ARP server is used to provide IP-to-ATM address resolution.

One of the stations in a LIS is designated as an ARP server, and the ARP server software is loaded on it. Stations that use the services of the ARP server are referred to as *ARP clients*. All IP stations within a LIS are ARP clients. Each ARP client is configured with the ATM address of the ARP server. When an ARP client starts up, it makes an ATM connection to the ARP server, and sends a packet to the server that contains the client's IP and ATM addresses. The ARP server builds a table of IP-address-to-ATM-address mappings. When a client has an IP packet to be sent to another client (whose IP address is known but whose ATM address is unknown), it first queries the ARP server for the ATM address of the desired client. When it receives a reply that contains the desired ATM address, the client establishes a direct ATM connection to the target client and sends IP packets for that client on this connection.

The clients close any ATM connection, including the connection to the server, if the connections are inactive. All clients refresh their IP and ATM address information with the server periodically (the default is 15 minutes). The server purges an entry that is not refreshed after 20 minutes (by default). The ATM ARP client and ARP server both support a number of adjustable registry parameters, which are listed in Appendix A.

**Internet Control Message Protocol (ICMP)**
ICMP is a maintenance protocol specified in RFC 792 and is normally considered part of the Internet layer. ICMP messages are encapsulated within IP datagrams, so that they can be routed throughout an internetwork. Windows Server 2003 TCP/IP uses ICMP to:

- Report delivery problems encountered by routers or destination hosts.
- Build and maintain route tables.
- Perform router discovery.
- Assist in Path Maximum Transmission Unit (PMTU) discovery.
- Diagnose reachability problems (the ping, tracert, and pathping tools).
- Adjust flow control to prevent link or router saturation.

**ICMP Router Discovery**
Windows Server 2003 TCP/IP can perform router discovery as specified in RFC 1256. Router discovery provides an improved method of configuring and detecting default gateways. Instead of using manually- or DHCP-configured default gateways, hosts can dynamically discover routers on their subnet. If the primary router fails or the network administrators change router preferences, hosts can automatically switch to a backup router.

When a host that supports router discovery initializes, it joins the all-systems IP multicast group (224.0.0.1), and then listens for the router advertisements that routers send to that group. Hosts can also send router-solicitation messages to the all-routers IP multicast address (224.0.0.2) when an interface initializes to avoid any delay in being configured. Windows Server 2003 TCP/IP sends a maximum of three solicitations at intervals of approximately 600 milliseconds.

The use of router discovery is controlled by the *PerformRouterDiscovery* and *SolicitationAddressBCast* registry parameters, and it defaults to DHCP controlled in Windows Server 2003. Setting *SolicitationAddressBCast* to 1 causes router solicitations to be broadcast, instead of multicast, as described in RFC 1256.

**Maintaining Route Tables**
When a Windows-based computer is initialized, the route table normally contains only a few entries. One of those entries specifies a default gateway. Datagrams that have a destination IP address with no better match in the route table are sent to

the default gateway. However, because routers share information about network topology, the default gateway may know a better route to a given address. When this is the case, then upon receiving a datagram that could take the better path, the router forwards the datagram normally. It then advises the sender of the better route, using an *ICMP Redirect* message. These messages typically specify redirection for a specific destination address. When a Windows-based computer receives an ICMP redirect, a validity check is performed to be sure that it came from the first-hop gateway in the current route, and that the gateway is on a directly connected network. If so, a host route with a 10-minute lifetime is added to the route table for that destination IP address. If the ICMP redirect did not come from the first-hop gateway in the current route, or if that gateway is not on a directly connected network, the ICMP redirect is ignored.

In Windows Server 2003 Service Pack 1, the new MaxICMPHostRoutes registry value defines the maximum number of host routes that can be added through the receipt of ICMP Redirect messages. For more information, see Appendix A.

**Path Maximum Transmission Unit (PMTU) Discovery**
TCP employs Path Maximum Transmission Unit (PMTU) discovery, as described in the "Transmission Control Protocol (TCP)" section of this article. The mechanism relies on ICMP Destination Unreachable messages.

**Use of ICMP to Diagnose Problems**
The ping command-line utility is used to send ICMP echo requests to an IP address and wait for ICMP echo responses. Ping reports on the number of responses received and the time interval between sending the request and receiving the response. There are many different options that can be used with the ping utility.

Tracert is a route-tracing utility that can be very useful. Tracert works by sending ICMP echo requests to an IP address, while incrementing the Time to Live (TTL) field in the IP header, starting at 1, and analyzing the ICMP errors that are returned. Each succeeding echo request should get one hop further into the network before the TTL field reaches 0 and the router attempting to forward it returns an ICMP Time Exceeded-TTL Exceeded in Transit error message. Tracert prints out an ordered list of the routers in the path that returned these error messages, including the name and the IP address the nearside interface of each router. If the **-d** (do not do a DNS reverse query on each IP address) switch is used, only the IP address is reported. The example below illustrates using tracert to find the route from a computer dialed in over Point-to-Point Protocol (PPP) to an Internet service provider in Seattle to www.whitehouse.gov.

```
C:\>tracert www.whitehouse.gov
Tracing route to www.whitehouse.gov [128.102.252.1]
over a maximum of 30 hops:
1  300 ms  281 ms  280 ms roto.seanet.com [199.181.164.100]
2  300 ms  301 ms  310 ms sl-stk-1-S12-T1.sprintlink.net [144.228.192.65]
3  300 ms  311 ms  320 ms sl-stk-5-F0/0.sprintlink.net [144.228.40.5]
4  380 ms  311 ms  340 ms icm-fix-w-H2/0-T3.icp.net [144.228.10.22]
5  310 ms  301 ms  320 ms arc-nas-gw.arc.nasa.gov [192.203.230.3]
6  300 ms  321 ms  320 ms n254-ed-cisco7010.arc.nasa.gov [128.102.64.254]
7  360 ms  361 ms  371 ms www.whitehouse.gov [128.102.252.1]
```

Pathping is a command-line utility that combines the functionality of ping and tracert as well as introducing some new features. Along with the tracing functionality of tracert, pathping will ping each hop along the route multiple times and display delay and packet loss information per hop, which can help you determine if there is a high-loss link or router in the path.

**Internet Protocol Security (IPsec)**
Windows Server 2003 includes support for Internet Protocol security (IPsec). IPsec features and implementation details are very complex and are described in detail in a series of RFCs, Internet drafts, and in other Microsoft technical papers. For more information, see the Windows Server 2003 IPsec Web page (http://go.microsoft.com/fwlink/?linkid=63067).

IPsec uses cryptography-based security to provide data integrity, data origin authentication, replay protection, data confidentiality (encryption), and limited traffic-flow confidentiality. Because IPsec is provided at the IP layer, its services are available to the upper-layer protocols in the stack and, transparently, to existing applications.

IPsec enables a system to select security protocols, decide which algorithm(s) to use for the service(s), and establish and maintain cryptographic keys for each security relationship. IPsec can protect paths between hosts, between security gateways, or between hosts and security gateways. The services available and required for traffic are configured using IPsec policy. IPsec policy may be configured locally on a computer or can be assigned through Group Policy mechanisms using the Active Directory directory service. When using Active Directory, hosts detect policy assignment at startup, retrieve the policy, and then periodically check for policy updates. The IPsec policy specifies how computers trust each other. IPsec can use certificates, Kerberos, or preshared keys as authentication methods. The easiest trust to use is the Windows Server 2003 domain trust based on Kerberos.

Each IP datagram processed at the IP layer is compared to a set of filters that are provided by the security policy, which is maintained by an administrator for a computer that belongs to a domain. IP can do one of three things with any datagram:

- Apply IPsec protections to it.
- Allow it to pass unmodified.
- Discard it.

An IPsec policy contains one or more rules, each of which contain a filter, a filter action, authentication methods, a tunnel setting, and a connection type. For example, two stand-alone computers can be configured to use IPsec between them and activate the secure server policy. If the two computers are not members of the same or a trusted domain, trust must be configured using a certificate or preshared key in a secure server mode by:

- Setting up a filter that specifies all traffic between the two hosts
- Choosing an authentication method
- Selecting a negotiation policy (secure server in this case, indicating that all traffic matching the filter(s) must use IPsec)
- Specifying a connection type (LAN, dial-up, or all)

Once the policy has been put in place, traffic that matches the filters uses the services provided by IPsec. When a host directs IP traffic to another host (including something as simple as ping traffic), a Security Association (SA) is established through an Internet Key Exchange (IKE) negotiation using UDP port 500, and then the traffic begins to flow. The following network trace illustrates setting up a TCP connection between two such IPsec-enabled hosts. The only parts of the IP datagram that are unencrypted and visible to Network Monitor after the SA is established are the MAC and IP headers:

```
Source IP      Dest IP       Prot  Description
192.168.10.47  10.197.14.91  UDP   Src Port: ISAKMP, (500); Dst Port: ISAKMP (500);

Length = 128 (0x80)
10.197.14.91   192.168.10.47 UDP   Src Port: ISAKMP, (500); Dst Port: ISAKMP (500);
Length = 128 (0x80)
192.168.10.47  10.197.14.91  UDP   Src Port: ISAKMP, (500); Dst Port: ISAKMP (500);
Length = 76 (0x4C)
10.197.14.91   192.168.10.47 UDP   Src Port: ISAKMP, (500); Dst Port: ISAKMP (500);
Length = 76 (0x4C)
192.168.10.47  10.197.14.91  UDP   Src Port: ISAKMP, (500); Dst Port: ISAKMP (500);
Length = 212 (0xD4)
10.197.14.91   192.168.10.47 UDP   Src Port: ISAKMP, (500); Dst Port: ISAKMP (500);
Length = 172 (0xAC)
192.168.10.47  10.197.14.91  UDP   Src Port: ISAKMP, (500); Dst Port: ISAKMP (500);
Length = 84 (0x54)
10.197.14.91   192.168.10.47 UDP   Src Port: ISAKMP, (500); Dst Port: ISAKMP (500);
Length = 92 (0x5C)
192.168.10.47  10.197.14.91  IP    ID = 0xC906; Proto = 0x32; Len: 96
10.197.14.91   192.168.10.47 IP    ID = 0xA202; Proto = 0x32; Len: 96
192.168.10.47  10.197.14.91  IP    ID = 0xCA06; Proto = 0x32; Len: 88
```

Opening one of the IP datagrams sent after the SA is established reveals very little of what is actually in the datagram (a TCP SYN, or connection request). The only clear parts of the packet are the Ethernet and IP headers. Even the TCP header is encrypted and cannot be parsed by Network Monitor if ESP is used.

```

```

Using a secure server policy also restricts all other types of traffic from reaching destinations that do not understand IPsec or are not part of the same trusted group. A secure initiator policy provides settings that apply best to servers; traffic security is attempted, but if the client does not understand IPsec, the negotiation falls back to sending clear text packets.

When IPsec is used to encrypt data, network performance generally drops, due to the processing overhead of encryption. One possible method for reducing the impact of this overhead is to offload the processing to a hardware device. Because NDIS 5.1 supports task offloading, it is feasible to include encryption hardware on network adapters. Network adapters supporting IPsec hardware offload are available from several vendors.

IPsec promises to be popular for protecting both public network traffic and internal corporate or government traffic that requires confidentiality. One common deployment is to apply *secure server* IPsec policies only to specific servers that are used to store and/or serve confidential information.

**Internet Group Management Protocol (IGMP)**

Windows Server 2003 TCP/IP provides level 2 (full) support for IP multicasting and IGMP versions 1 through 3, as described in RFCs 1112, 2236, and 3376. The introduction to RFC 1112 provides a good overall summary of IP multicasting. The text reads:

"IP multicasting is the transmission of an IP datagram to a *host group*—a set of zero or more hosts identified by a single IP destination address. A multicast datagram is delivered to all members of its destination host group with the same 'best-effort' reliability as regular unicast IP datagrams; that is, the datagram is not guaranteed to arrive intact to all members of the destination group or in the same order relative to other datagrams.

"The membership of a host group is dynamic; that is, hosts may join and leave groups at any time. There is no restriction on the location or number of members in a host group. A host may be a member of more than one group at a time. A host need not be a member of a group to send datagrams to it.

"A host group may be permanent or transient. A permanent group has a well-known, administratively assigned IP address. It is the address—not the membership of the group—that is permanent; at any time a permanent group may have any number of members, even zero. Those IP multicast addresses that are not reserved for permanent groups are available for dynamic assignment to transient groups that exist only as long as they have members.

"Internetwork forwarding of IP multicast datagrams is handled by multicast routers that may be co-resident with, or separate from, Internet gateways. A host transmits an IP multicast datagram as a local network multicast that reaches all immediately-neighboring members of the destination host group. If the datagram has an IP time-to-live greater than 1, the multicast router(s) attached to the local network take responsibility for forwarding it towards all other networks that have members of the destination group. On those other member networks that are reachable within the IP time-to-live, an attached multicast router completes delivery by transmitting the datagram as a local multicast."

**IP/ARP Extensions for IP Multicasting**

To support IP multicasting, an additional route is defined on the host. The route (added by default) specifies that if a datagram is being sent to a multicast host group, it should be sent to the IP address of the host group through the local network interface card, and not forwarded to the default gateway. The following route (which you can discover using the **route print** command) illustrates this:

```
Network Address  Netmask    Gateway Address  Interface     Metric
224.0.0.0        240.0.0.0  157.60.137.88    157.60.137.88     20
```

IP multicast addresses are easily identified, as they are from the class D range, 224.0.0.0 to 239.255.255.255 (224.0.0.0/4). These IP addresses all have 1110 as their high-order bits.

To send a packet to a host group, using the local interface, the IP address must be resolved to a media access control address. As stated in RFC 1112:

"An IP host group address is mapped to an Ethernet multicast address by placing the low-order 23 bits of the IP address into the low-order 23 bits of the Ethernet multicast address 01-00-5E-00-00-00 (hexadecimal). Because there are 28 significant bits in an IP host group address, more than one host group address may map to the same Ethernet multicast address."

For example, a datagram addressed to the multicast address 225.0.0.5 would be sent to the (Ethernet) MAC address 01-00-5E-00-00-05. This MAC address is formed by the junction of 01-00-5E and the 23 low-order bits of 225.0.0.5 (00-00-05).

Because more than one host group address can map to the same Ethernet multicast address, the interface may indicate hand-up multicasts for a host group for which no local applications have a registered interest. These extra multicasts are discarded by the TCP/IP protocol.

**Multicast Extensions to Windows Sockets**
Internet Protocol multicasting is currently supported only on AF_INET sockets of type SOCK_DGRAM and SOCK_RAW. By default, IP multicast datagrams are sent with a Time to Live (TTL) of 1. Applications can use the setsockopt() function to specify a TTL. By convention, multicast routers use TTL thresholds to determine how far to forward datagrams. These TTL thresholds are defined as follows:

- Multicast datagrams with initial TTL 0 are restricted to the same host.
- Multicast datagrams with initial TTL 1 are restricted to the same subnet.
- Multicast datagrams with initial TTL 32 are restricted to the same site.
- Multicast datagrams with initial TTL 64 are restricted to the same region.
- Multicast datagrams with initial TTL 128 are restricted to the same continent.
- Multicast datagrams with initial TTL 255 are unrestricted in scope.

**Use of Multicast and IGMP by Windows Components**
Some Windows Server 2003 components use IP multicast traffic. For example, router discovery uses multicasts, by default. WINS servers use multicasting when attempting to locate replication partners. The Windows Server 2003 Routing and Remote Access service supports multicast forwarding and the configuration of interfaces to operate in IGMP router or IGMP proxy mode.

**Transmission Control Protocol (TCP)**
TCP provides a connection-based, reliable byte-stream service to applications. Microsoft networking relies upon TCP for logon, file and print sharing, replication of information between domain controllers, transfer of browse lists, and other common functions. It can only be used for one-to-one communications.

TCP uses a checksum on both the TCP header and payload of each segment to reduce the chance that network corruption will go undetected. NDIS 5.1 provides support for task offloading, and Windows Server 2003 TCP/IP takes advantage of this by allowing the network interface card to perform the TCP checksum calculations if the network interface card driver offers support for this function. Offloading the checksum calculations to hardware can result in performance improvements in very high-throughput environments.

Windows Server 2003 TCP/IP has also been strengthened against a variety of attacks that were published over the past couple of years and has been subject to an internal security review intended to reduce susceptibility to future attacks. For instance, the initial sequence number (ISN) algorithm has been modified so that ISNs increase in random increments, using an RC4-based random number generator initialized with a 2048-bit random key upon system startup.

**TCP Receive Window Size Calculation and Window Scaling (RFC 1323)**
The TCP receive window size is the amount of receive data (in bytes) that can be buffered at one time on a connection. The sending host can send only that amount of data before waiting for an acknowledgment and window update from the receiving host. The Windows Server 2003 TCP/IP stack was designed to tune itself in most environments and uses larger default window sizes than earlier versions. Instead of using a hard-coded default receive window size, TCP adjusts to even increments of the maximum segment size (MSS) negotiated during connection setup. Matching the receive window to even increments of the MSS increases the percentage of full-sized TCP segments used during bulk data transmission.

The default advertised TCP receive-window size in Windows Server 2003 depends on the following, in order of precedence:

1. The SO_RCVBUF WinSock option for the connection.
2. The per-interface *TcpWindowSize* registry parameter.
3. The global *TcpWindowSize* registry parameter.

4. Autodetermination based on the NDIS-reported bit rate of the media The stack also tunes itself based on the media speed:

    - Below 1 Mbps: 8 KB
    - 1 Mbps – 100 Mbps: 17 KB
    - Greater than 100 Mbps: 64 KB

For 10 and 100 Mbps Ethernet, the window is normally set to 17,520 bytes (17 KB rounded up to twelve 1460-byte segments.) There are two methods for setting the receive window size to specific values:

- The *TcpWindowSize* registry parameter (see Appendix A)
- The setsockopt() Windows Sockets function (on a per-socket basis)

To improve performance on high-bandwidth, high-delay networks, Windows Server 2003 TCP/IP supports scalable windows support as described in RFC 1323. This RFC details a method for supporting scalable windows by allowing TCP to negotiate a scaling factor for the window size at connection establishment. This allows for an actual receive window of up to 1 gigabyte (GB). Section 2.2 of RFC 1323 provides a good description:

"The three-byte Window Scale option may be sent in a SYN segment by a TCP. It has two purposes: 1. indicate that the TCP is prepared to do both send and receive window scaling, and 2. communicate a scale factor to be applied to its receive window. Thus, a TCP that is prepared to scale windows should send the option, even if its own scale factor is 1. The scale factor is limited to a power of two and encoded logarithmically, so it may be implemented by binary shift operations.

"This option is an offer, not a promise; both sides must send Window Scale options in their SYN segments to enable window scaling in either direction. If window scaling is enabled, then the TCP that sent this option will right-shift its true receive-window values by 'shift.cnt' bits for transmission in SEG.WND. The value *shift.cnt* may be zero (offering to scale, while applying a scale factor of 1 to the receive window).

"This option may be sent in an initial <SYN> segment (in other words, a segment with the SYN bit on and the ACK bit off). It may also be sent in a <SYN,ACK> segment, but only if a Window Scale option was received in the initial <SYN> segment. A Window Scale option in a segment without a SYN bit should be ignored.

"The Window field in a SYN (in other words, a <SYN> or <SYN,ACK>) segment itself is never scaled."

When you read network traces of a connection that was established by two computers that support scalable windows, keep in mind that the window sizes advertised in the TCP headers must be scaled by the negotiated scale factor. The scale factor can be observed in the connection establishment (three-way handshake) packets, as illustrated in the following Network Monitor capture:

```

****************************************************************
```

The computer sending the packet above is offering the Window Scale option, with a scaling factor of 5. If the target computer responds, accepting the Window Scale option in the SYN-ACK, then it is understood that any TCP window advertised by this computer needs to be left-shifted 5 bits from this point onward (the SYN itself is not scaled). For example, if the computer advertised a 32 KB window in its first send of data, this value would need to be left-shifted (shifting in 0's from the right) 5 bits as shown below:

```
32 KB = 0x7fff =    111 1111 1111 1111
Left-shift 5 bits = 1111 1111 1111 1110 0000 = 0xfffe0 (1,048,544 bytes)
```

As a check, left-shifting a number 5 bits is equivalent to multiplying it by $2^5$, or 32. Performing the calculation in decimal, we get 32767 * 32 = 1,048,544.

The scale factor is not necessarily symmetrical, so it may be different for each direction of data flow.

TCP window scaling is negotiated on-demand in Windows Server 2003, based on the value set for the SO_RCVBUF WinSock option when a connection is initiated. Additionally, the Window Scale option is used by default on a connection if the received SYN segment for a connection initiated by a TCP peer contains the Window Scale option. You can modify this default behavior with the *Tcp1323Opts* registry parameter (see Appendix A).

**Delayed Acknowledgments**

As specified in RFC 1122, TCP uses delayed acknowledgments (ACKs) to reduce the number of packets sent on the media. The Windows Server 2003 TCP/IP stack takes a common approach to implementing delayed ACKs. As data is received by TCP on a connection, it only sends an acknowledgment back if one of the following conditions is met:

- No ACK was sent for the previous segment received.
- A segment is received, but no other segment arrives within 200 milliseconds for that connection.

In summary, normally an ACK is sent for every other TCP segment received on a connection, unless the delayed ACK timer (200 milliseconds) expires. The delayed ACK timer can be adjusted through the *TcpDelAckTicks* registry parameter.

**TCP Selective Acknowledgment (RFC 2018)**

Windows Server 2003 TCP/IP includes support for an important performance feature known as Selective Acknowledgement (SACK). SACK is especially important for connections using large TCP window sizes. Prior to SACK, a receiver could only acknowledge the latest sequence number of contiguous data that had been received, or the left edge of the receive window. When SACK is enabled, the receiver continues to use the ACK number to acknowledge the left edge of the receive window, but it can also acknowledge other non-contiguous blocks of received data individually. SACK uses two different TCP header options:

- The Sack-Permitted option is used to indicate that the sender can receive and interpret the SACK option. This option is sent in TCP segments in which the SYN flag is set.
- The SACK option is used to convey extended acknowledgment information from the receiver to the sender over an established TCP connection. Within the SACK option are up to four pairs of TCP sequence numbers acknowledging up to four non-continuous blocks. Each TCP sequence pair contains the left edge (the sequence number of the first byte in the block) and the right edge (the sequence number of the byte immediately following the last byte in the block) of the block being acknowledged.

When SACK is enabled (the default), a packet or series of packets can be dropped, and the receiver can inform the sender of

exactly which data has been received, and where the holes in the data are. The sender can then selectively retransmit the missing data without needing to retransmit blocks of data that have already been received successfully. SACK is controlled by the *SackOpts* registry parameter and is enabled by default. The Network Monitor capture below illustrates a host acknowledging all data up to sequence number 54857340, plus the data from sequence number 54858789-54861684.

```

**TCP Timestamps (RFC 1323)**

Windows Server 2003 TCP/IP supports TCP time stamps, as described in RFC 1323. Like SACK, time stamps are important for connections using large window sizes. Time stamps were conceived to assist TCP in accurately measuring round-trip time (RTT) to adjust retransmission time-outs.

The Timestamps option carries two four-byte time stamp fields. The time-stamp value field (TSval) contains the current value of the time-stamp clock of the TCP sending the option. The Timestamp Echo Reply field (TSecr) is only valid if the ACK bit is set in the TCP header; if it is valid, it echoes a timestamp value that was sent by the remote TCP peer in the TSval field of a Timestamps option. When TSecr is not valid, its value must be zero. The TSecr value will generally be from the most recent Timestamp option that was received; however, there are exceptions that are explained below.

A TCP peer may send the Timestamps option (TSopt) in an initial SYN segment (i.e., segment containing a SYN bit and no ACK bit), and may send a TSopt in other segments only if it received a TSopt in the initial SYN segment for the connection.

The Timestamps option field can be viewed in a Network Monitor capture by expanding the TCP options field, as shown below:

```
TCP: Timestamps Option
TCP: Option Type = Timestamps
TCP: Option Length = 10 (0xA)
TCP: Timestamp = 2525186 (0x268802)
TCP: Reply Timestamp = 1823192 (0x1BD1D8)
```

By default, the Timestamp option is only used on a connection if the received SYN segment for a connection initiated by a TCP peer contains the Timestamp option. This default behavior can be modified with the *Tcp1323Opts* registry parameter (see Appendix A).

**Path Maximum Transmission Unit (PMTU) Discovery**

PMTU discovery is described in RFC 1191. When a connection is established, the two hosts involved exchange their TCP maximum segment size (MSS) values. The smaller of the two MSS values is used for the connection. Historically, the MSS for a host has been the MTU at the link layer minus 40 bytes for the IP and TCP headers. However, support for additional TCP options, such as time stamps, has increased the typical TCP+IP header to 52 or more bytes. Figure 2 shows the difference between MTU and MSS.

**Figure 2. MTU versus MSS**

When TCP segments are destined to a non-local network, the Don't Fragment (DF) flag is set in the IP header. Any link along the path can have an MTU that differs from that of the two hosts. If a link has an MTU that is too small for the IP datagram being routed, the router attempts to fragment the datagram. However, the Don't Fragment bit is set in the IP header. At this point, the router should inform the sending host that the datagram couldn't be forwarded further without fragmentation. This is done with an ICMP Destination Unreachable-Fragmentation Needed and DF Set message. Most routers also specify the MTU for the next hop by putting the value for it in the low-order 16 bits of the ICMP header field that is unused in RFC 792. See RFC 1191, section 4, for the format of this message. Upon receiving this ICMP error message, TCP adjusts its MSS for the connection to the specified MTU minus the TCP and IP header size so that any further packets sent on the connection are no larger than the maximum size that can traverse the path without fragmentation.

| **Note** |
| --- |
| The minimum MTU permitted is 88 bytes, and Windows Server 2003 TCP/IP enforces this limit. |

Some noncompliant routers may silently drop IP datagrams that cannot be fragmented or may not correctly report their next-hop MTU. If this occurs, it may be necessary to make a configuration change to the PMTU detection algorithm. There are two registry changes that can be made to Windows Server 2003 TCP/IP stack to work around these problematic devices:

- *EnablePMTUBHDetect*—Adjusts the PMTU discovery algorithm to attempt to detect PMTU black hole routers. PMTU black hole detection is disabled by default.

- *EnablePMTUDiscovery*—Completely enables or disables the PMTU discovery mechanism. When PMTU discovery is disabled, an MSS of 536 bytes is used for all non-local destination addresses. PMTU discovery is enabled by default (this is the recommended setting).

These registry entries are described in more detail in Appendix A.

The PMTU between two hosts can be discovered manually using the **ping** tool with the **-f** (don't fragment) switch, as follows:

**ping -f -n** <*number of pings*> **-l** <*size*> <*destination ip address*>

As shown in the example below, the *size* parameter can be varied until the MTU is found. The *size* parameter used by ping is the size of the data buffer to send, not including headers. The ICMP header consumes 8 bytes, and the IP header is normally 20 bytes. In the case below (Ethernet), the link layer MTU is the maximum-sized ping buffer plus 28, or 1500 bytes:

```
C:\>ping -f -n 1 -l 1472 10.99.99.10
Pinging 10.99.99.10 with 1472 bytes of data:
Reply from 10.99.99.10: bytes=1472 time<10ms TTL=128
Ping statistics for 10.99.99.10:
Packets: Sent = 1, Received = 1, Lost = 0 (0% loss),
Approximate round trip times in milli-seconds:
Minimum = 0ms, Maximum =  0ms, Average =  0ms

C:\>ping -f -n 1 -l 1473 10.99.99.10
Pinging 10.99.99.10 with 1473 bytes of data:
Packet needs to be fragmented but DF set.
Ping statistics for 10.99.99.10:
Packets: Sent = 1, Received = 0, Lost = 1 (100% loss),
Approximate round trip times in milliseconds:
Minimum = 0ms, Maximum =  0ms, Average =  0ms
```

In the example shown above, the IP layer returned an ICMP error message that ping interpreted. If the router had been a PMTU black hole router, ping would simply not be answered once its size exceeded the MTU that the router could handle. Ping can be used in this manner to detect such a router.

A sample ICMP Destination Unreachable-Fragmentation Needed and DF Set message is shown here:

```
*****************************************************************
Src Addr        Dst Addr      Protocol  Description
10.99.99.10     10.99.99.9    ICMP      Destination Unreachable:
```

```
                                        10.99.99.10   See frame 3
+ FRAME: Base frame properties
+ ETHERNET: ETYPE = 0x0800 : Protocol = IP:  DOD Internet Protocol
+ IP: ID = 0x4401; Proto = ICMP; Len: 56
ICMP: Destination Unreachable: 10.99.99.10   See frame 3
ICMP: Packet Type = Destination Unreachable
ICMP: Unreachable Code = Fragmentation Needed, DF Flag Set
ICMP: Checksum = 0xA05B
ICMP: Next Hop MTU = 576 (0x240)
ICMP: Data: Number of data bytes remaining = 28 (0x001C)
ICMP: Description of original IP frame
```

This error was generated by using **ping -f –n 1 -l 1000** on an Ethernet-based host to send a large datagram across a router interface that only supports an MTU of 576 bytes. When the router tried to place the large frame onto the network with the smaller MTU, it found that fragmentation was not allowed. Therefore, it returned the error message indicating that the largest datagram that could be forwarded is 576 bytes.

**Dead Gateway Detection**

Dead gateway detection is used to allow TCP to detect failure of the default gateway and to adjust the IP route table to use another default gateway. Windows Server 2003 TCP/IP uses the triggered reselection method described in RFC 816, with slight modifications based upon customer experience and feedback.

When a TCP connection routed through the default gateway attempts to send a TCP packet to the destination a number of times (equal to one-half of the registry value *TcpMaxDataRetransmissions*) without receiving a response, the algorithm changes the Route Cache Entry (RCE) for that remote IP address to use the next default gateway in the list as its next-hop address. When 25 percent of the TCP connections have moved to the next default gateway, the algorithm advises IP to change the computer's default gateway to the one that the connections are now using.

For example, assume that there are currently TCP connections to 11 different IP addresses that are being routed through the default gateway. Now assume that the default gateway fails, that there is a second default gateway configured, and that the value for *TcpMaxDataRetransmissions* is at the default of 5.

When the first TCP connection tries to send data, it does not receive any acknowledgments. After the third retransmission, the RCE for that remote IP address is switched to the next default gateway in the list. At this point, any TCP connections to that one remote IP address have switched over, but the remaining connections still try to use the original default gateway.

When the second TCP connection tries to send data, the same thing happens. Now, two of the 11 RCEs point to the new gateway.

When the third TCP connection tries to send data, after the third retransmission, three of 11 RCEs have been switched to the second default gateway. Because, at this point, over 25 percent of the RCEs have been moved, the default gateway for the whole computer is moved to the new one.

That default gateway remains the primary one for the computer until it experiences problems (causing the dead gateway algorithm to try the next one in the list again) or until the computer is restarted.

When the search reaches the last default gateway, it returns to the beginning of the list.

**TCP Retransmission Behavior**

TCP starts a retransmission timer when each outbound segment is handed down to IP. If no acknowledgment has been received for the data in a given segment before the timer expires, the segment is retransmitted. For new connection requests, the retransmission timer is initialized to 3 seconds (controllable using the *TcpInitialRtt* per-adapter registry parameter), and the request (SYN) is resent up to the value specified in *TcpMaxConnectRetransmissions* (the default for Windows Server 2003 is 2 times). On existing connections, the number of retransmissions is controlled by the *TcpMaxDataRetransmissions* registry parameter (5 by default). The retransmission time-out is adjusted on the fly to match the characteristics of the connection, using Smoothed Round Trip Time (SRTT) calculations as described in Van Jacobson's article named "Congestion Avoidance and Control." The timer for a given segment is doubled after each retransmission of that segment. Using this algorithm, TCP tunes itself to the normal delay of a connection. TCP connections over high-delay links take much longer to time-out than those over low-delay links.[3]

The following Network Monitor capture shows the retransmission algorithm for two hosts that are connected over Ethernet on the same subnet. An FTP file transfer was in progress when the receiving host was disconnected from the network. Because the SRTT for this connection was very small, the first retransmission was sent after about one-half second. The timer was then doubled for each of the retransmissions that followed. After the fifth retransmission, the timer was once again doubled. If no acknowledgment was received before it expired, the connection was aborted.

```

There are some circumstances under which TCP retransmits data prior to the time that the retransmission timer expires. The most common of these occurs due to a feature known as *fast retransmit*. When a receiver that supports fast retransmit receives data with a sequence number beyond the current expected one, it assumes that some data was dropped. To help make the sender aware of this event, the receiver immediately sends an ACK, with the ACK number set to the sequence number that it was expecting. It continues to do this for each additional TCP segment that arrives containing data subsequent to the missing data in the incoming stream. When the sender starts to receive a stream of ACKs that are acknowledging the same sequence number and that sequence number is earlier than the current sequence number being sent, it can infer that a segment (or more) must have been dropped. Senders that support the fast retransmit algorithm immediately resend the segment that the receiver is expecting to fill in the gap in the data, without waiting for the retransmission timer to expire for that segment. This optimization greatly improves performance in a busy network environment.

With fast retransmit, the sender retransmits the TCP segments to fill in the gap in the data before their retransmission timers expire. Because the retransmission timers did not expire for the missing TCP segments, the sender can more quickly send additional segments to the receiver. This is known as *fast recovery*. Fast retransmit and fast recovery are described in RFC 2581.

By default, Windows Server 2003 resends a segment if it receives three ACKs for the same sequence number and that sequence number lags the current one. This is controllable with the *TcpMaxDupAcks* registry parameter. See also the "TCP Selective Acknowledgment (RFC 2018)" section in this article.

**TCP Keep-Alive Messages**

A TCP keep-alive packet is simply an ACK with the sequence number set to one less than the current sequence number for the connection. A host receiving one of these ACKs responds with an ACK for the current sequence number. Keep-alives can be used to verify that the computer at the remote end of a connection is still available. TCP keep-alives can be sent once every *KeepAliveTime* (defaults to 7,200,000 milliseconds or two hours) if no other data or higher-level keep-alives have been carried over the TCP connection. If there is no response to a keep-alive, it is repeated once every *KeepAliveInterval* seconds. *KeepAliveInterval* defaults to 1 second. NetBT connections, such as those used by other Microsoft networking components, send NetBIOS keep-alives more frequently, so normally no TCP keep-alives are sent on a NetBIOS connection. TCP keep-alives are disabled by default, but Windows Sockets applications can use the **setsockopt()** function to enable them.

**Slow Start Algorithm and Congestion Avoidance**

When a connection is established, TCP starts slowly at first to assess the bandwidth of the connection, and to avoid overflowing the receiving host or any other devices or links in the path. The send window is set to two TCP segments, and if that is acknowledged, it is incremented to three segments.[4] If those are acknowledged, it is incremented again, and so on until the amount of data being sent per burst reaches the size of the receive window on the remote host. At that point, the slow start algorithm is no longer in use, and flow control is governed by the receive window. However, congestion could still occur on a connection at any time during transmission. If this happens (evidenced by the need to retransmit), a congestion-avoidance algorithm is used to reduce the send window size temporarily and to grow it back towards the receive window size. Slow start and congestion avoidance are described in RFC 2581.

**Silly Window Syndrome (SWS)**

Silly Window Syndrome is described in RFC 1122 as follows:

"In brief, SWS is caused by the receiver advancing the right window edge whenever it has any new buffer space available to receive data and by the sender using any incremental window, no matter how small, to send more data [TCP:5]. The result can be a stable pattern of sending tiny data segments, even though both sender and receiver have a large total buffer space for the connection."

Windows Server 2003 TCP/IP implements SWS avoidance, as specified in RFC 1122, by not sending more data until there is a sufficient window size advertised by the receiving end to send a full TCP segment. It also implements SWS avoidance on the receive end of a connection by not opening the receive window in increments of less than a TCP segment.

**Nagle Algorithm**
Windows Server 2003 TCP/IP implements the Nagle algorithm described in RFC 896. The purpose of this algorithm is to reduce the number of very small segments sent, especially on high-delay (remote) links. The Nagle algorithm allows only one small segment to be outstanding at a time without acknowledgment. If more small segments are generated while awaiting the ACK for the first one, these segments are coalesced into one larger segment. Any full-sized segment is always transmitted immediately, on the assumption that there is a sufficient receive window available. The Nagle algorithm is effective in reducing the number of packets sent by interactive applications, such as Telnet, especially over slow links.

The Nagle algorithm can be observed in the following Network Monitor capture. The trace was captured by using PPP to dial up an Internet service provider. A Telnet (character-mode) session was established, and then the **Y** key was held down on the computer. At all times, one segment was sent, and further **Y** characters were held by the stack until an acknowledgment was received for the previous segment. In this example, three to four **Y** characters were buffered each time and sent together in one segment. The Nagle algorithm resulted in a huge savings in the number of packets sent—the number of packets was reduced by a factor of about three.

```

data
```

Windows Sockets applications can disable the Nagle algorithm for their connections by setting the TCP_NODELAY socket option. However, this practice should be avoided unless it is absolutely necessary because it increases network utilization. Some network applications may not perform well if their design does not take into account the effects of transmitting large numbers of small packets and the Nagle algorithm. The Nagle algorithm is not applied to loopback TCP connections for performance reasons. Windows Server 2003 NetBT disables Nagling for NetBIOS over TCP connections as well as direct-hosted redirector/server connections, which can improve performance for applications issuing numerous small file manipulation commands. An example is an application that uses file locking/unlocking frequently.

**TCP TIME-WAIT Delay**
When a TCP connection is closed, the socket-pair is placed into a state known as TIME-WAIT. This is done so that a new connection does not use the same protocol, source IP address, destination IP address, source port, and destination port until enough time has passed to ensure that any segments that may have been misrouted or delayed are not delivered unexpectedly. RFC 793 specifies the length of time that the socket-pair should not be reused as two maximum segment lifetimes (2 MSL), or four minutes. This is the default setting for Windows Server 2003 TCP/IP. However, with this default setting, some network applications that perform many outbound connections in a short time may use up all available ports before the ports can be recycled.

Windows Server 2003 TCP/IP offers two methods of controlling this behavior. First, the *TcpTimedWaitDelay* registry parameter can be used to alter this value. Windows Server 2003 TCP/IP allows it to be set as low as 30 seconds, which should not cause problems in most environments. Second, the number of user-accessible ephemeral ports that can be used to source outbound connections is configurable using the *MaxUserPort* registry parameter. By default, when an application requests any socket from the system to use for an outbound call, a port between the values of 1024 and 5000 is supplied. The *MaxUserPort*

parameter can be used to set the value of the uppermost port that the administrator chooses to allow for outbound connections. For instance, setting this value to 10,000 (decimal) would make approximately 9000 user ports available for outbound connections. For more details on this concept, see RFC 793. See also the *MaxFreeTcbs* and *MaxHashTableSize* registry parameters in Appendix A.

TCP/IP for Windows Server 2003 Service Pack 1 has implemented a smart TCP port allocation algorithm. When an application requests any available TCP port, TCP/IP first attempts to find an available port that does not correspond to a connection in the TIME WAIT state. If a port cannot be found, then it picks any available port. For more information, see "Smart TCP Port Allocation" in this article.

**TCP Connections to and from Multihomed Computers**

When TCP connections are made to a multihomed host, both the WINS client and the Domain Name Resolver (DNR) attempt to determine whether any of the destination IP addresses provided by the name server are on the same subnet as any of the interfaces in the local computer. If so, these addresses are sorted to the top of the list so that the application can try them prior to trying addresses that are not on the same subnet. If none of the addresses is on a common subnet with the local computer, behavior is different depending upon the name space. The *PrioritizeRecordData* TCP/IP registry parameter can be used to prevent the DNR component from sorting local subnet addresses to the top of the list.

In the WINS name space, the client is responsible for randomizing or load balancing between the provided addresses. The WINS server always returns the list of addresses in the same order, and the WINS client randomly picks one of them for each connection.

In the DNS name space, the DNS server is usually configured to provide the addresses in a round robin fashion. The DNR does not attempt to further randomize the addresses. In some situations, it is desirable to connect to a specific interface on a multihomed computer. The best way to accomplish this is to provide the interface with its own DNS entry. For example, a computer named *raincity* could have one DNS entry listing both IP addresses (actually two separate records in the DNS with the same name), and also records in the DNS for raincity1 and raincity2, each associated with just one of the IP addresses assigned to the computer.

When TCP connections are made from a multihomed host, things get a bit more complicated. If the connection is a Winsock connection using the DNS name space, once the target IP address for the connection is known, TCP attempts to connect from the best source IP address available. Again, the route table is used to make this determination. If there is an interface in the local computer that is on the same subnet as the target IP address, its IP address is used as the source in the connection request. If there is no best source IP address to use, the system chooses one randomly.

If the connection is a NetBIOS-based connection using the redirector, little routing information is available at the application level. The NetBIOS interface supports connections over various protocols and has no knowledge of IP. Instead, the redirector places calls on all of the transports that are bound to it. If there are two interfaces in the computer and one protocol installed, there are two transports available to the redirector. Calls are placed on both, and NetBT submits connection requests to the stack, using an IP address from each interface. It is possible that both calls succeed. If so, the redirector cancels one of them. The choice of which one to cancel depends upon the redirector *ObeyBindingOrder* registry value[5]. If this is set to 0 (the default value), the primary transport (determined by binding order) is the preferred one, and the redirector waits for the primary transport to time out before accepting the connection on the secondary transport. If this value is set to 1, the binding order is ignored, and the redirector accepts the first connection that succeeds and cancels the other(s).

**Throughput Considerations**

TCP was designed to provide optimum performance over varying link conditions, and Windows Server 2003 TCP/IP contains improvements such as those supporting RFC 1323. Actual throughput for a link depends on a number of variables, but the most important factors are:

- Link speed (bits-per-second that can be transmitted)
- Propagation delay
- Window size (amount of unacknowledged data that may be outstanding on a TCP connection)
- Link reliability
- Network and intermediate device congestion
- Path MTU

TCP throughput calculation is discussed in detail in Chapters 20–24 of *TCP/IP Illustrated*, by W. Richard Stevens[6]. Some key considerations are listed below:

- The capacity of a pipe is bandwidth multiplied by round-trip time. This is known as the *bandwidth-delay product*. If the link is reliable, for best performance the window size should be greater than or equal to the capacity of the pipe so that the sending stack can fill it. The largest window size that can be specified, due to its 16-bit field in the TCP header, is 65535, but larger windows can be negotiated by using window scaling as described earlier in this article. See *TcpWindowSize* in Appendix A.

- Throughput can never exceed window size divided by round-trip time.

- If the link is unreliable or badly congested and packets are being dropped, using a larger window size may not improve throughput. Along with scaling windows support, Windows Server 2003 TCP/IP supports Selective Acknowledgments (SACK; described in RFC 2018) to improve performance in environments that are experiencing packet loss. It also includes support for timestamps (described in RFC 1323) for improved RTT estimation.

- Propagation delay is dependent upon the speed of light, latencies in transmission equipment, and so on.

- Transmission delay depends on the speed of the media.

- For a specified path, propagation delay is fixed, but transmission delay depends upon the packet size.

- At low speeds, transmission delay is the limiting factor. At high speeds, propagation delay may become the limiting factor.

To summarize, Windows Server 2003 TCP/IP can adapt to most network conditions and can dynamically provide the best throughput and reliability possible on a per-connection basis. Attempts at manual tuning are often counter-productive unless a qualified network engineer first performs a careful study of data flow.

**User Datagram Protocol (UDP)**
UDP provides a connectionless, unreliable transport service. It is often used for communications that use broadcast or multicast IP datagrams. Since delivery of UDP datagrams is not guaranteed, applications using UDP must supply their own mechanisms for reliability, if needed. Microsoft networking components use UDP for logon, browsing, and name resolution. UDP can also be used to carry IP multicast streams.

**UDP and Name Resolution**
UDP is used for NetBIOS name resolution by unicast to a NetBIOS name server or subnet broadcasts, and for DNS host name to IP address resolution. NetBIOS name resolution is accomplished over UDP port 137. DNS queries use UDP port 53. Because UDP itself does not guarantee delivery of datagrams, both of these services use their own retransmission schemes if they receive no answer to queries. Broadcast UDP datagrams are not usually forwarded over IP routers, so NetBIOS name resolution in a routed environment requires a name server of some type, or the use of static database files.

**Mailslots over UDP**
Many NetBIOS applications use *mailslot* messaging. A second-class mailslot is a simple mechanism for sending a message from one NetBIOS name to another over UDP. Mailslot messages can be broadcast on a subnet or directed to the remote host. To direct a mailslot message to another host, there must be some method of NetBIOS name resolution available. Microsoft provides WINS for this purpose.

**NetBIOS over TCP/IP (NetBT)**
The Windows Server 2003 implementation of NetBIOS over TCP/IP is referred to as *NetBT*. NetBT uses the following TCP and UDP ports:

- UDP port 137 (name services)

- UDP port 138 (datagram services)

- TCP port 139 (session services)

NetBIOS over TCP/IP is specified by RFC 1001 and RFC 1002. The Netbt.sys driver is a kernel-mode component that supports

the Transport Driver Interface (TDI) interface. Services such as Workstation (redirector) and Server (file server) use the TDI interface directly, but traditional NetBIOS applications have their calls mapped to TDI calls by the Netbios.sys driver. Using TDI to make calls to NetBT is a more difficult programming task, but can provide higher performance and freedom from historical NetBIOS limitations. NetBIOS concepts are discussed further in the "Network Application Interfaces" section of this article.

**Transport Driver Interface (TDI)**
Microsoft developed the Transport Driver Interface (TDI) to provide greater flexibility and functionality than is provided by existing interfaces, such as NetBIOS and Windows Sockets. All Windows transport providers expose TDI. The TDI specification describes the set of primitive functions by which transport drivers and TDI clients communicate and the call mechanisms used for accessing them. Currently, TDI is kernel-mode only.

The Windows Server 2003 redirector and server both use TDI directly, rather than going through the NetBIOS mapping layer. By doing so, they are not subject to many of the restrictions imposed by NetBIOS, such as the legacy 254-session limit.

**TDI Features**
TDI may be the most difficult to use of all Windows network APIs. It is a simple conduit, so the programmer must determine the format and meaning of messages.

TDI includes the following features:

- Most Windows Server 2003 transports support TDI
- An open naming and addressing scheme
- Message and stream-mode data transfer
- Asynchronous operation
- Support for unsolicited indication of events
- Extensibility—clients can submit private requests to a transport driver that understands them.
- Support for limited use of standard kernel-mode I/O functions to send and receive data
- 32-bit addressing and values
- Support for Access Control Lists (ACLs, used for security) on TDI address objects

More information about TDI is available from the Windows DDK.

**Security Considerations**
Network security is a serious consideration for administrators with computers exposed to public networks. The Microsoft TCP/IP stack has been strengthened against many attacks and in its default state handles most of the common attacks. Some additional protection against popular Denial of Service attacks can be added by setting the value of the *SynAttackProtect* parameter in the registry. This key allows the administrator to choose several levels of protection against SYN attacks.

Here are general guidelines that can lower your exposure to attack:

- Disable unnecessary or optional services (for instance, the Client for Microsoft Networks and the File and Printer Sharing for Microsoft Networks components on the network connections of an IIS server).
- Enable TCP/IP filtering and restrict access to only the ports that are necessary for the server to function. See article 150543 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?linkid=67962) for a list of ports that Windows services use.
- Disable NetBIOS over TCP/IP on network connections where it is not needed.
- Configure static IP addresses and parameters for network adapters connected to the Internet.
- Configure registry parameters for maximum protection (see Appendix D).

Consult the Microsoft Security Web site (http://go.microsoft.com/fwlink/?linkID=7420) regularly for security bulletins.

# Network Application Interfaces

Updated: July 6, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

There are a number of ways that network applications can communicate using the TCP/IP protocol stack. Some of them, such as named pipes, go through the network redirector, which is part of the Workstation service. Many older applications were written to the NetBIOS interface, which is supported by NetBIOS over TCP/IP.

The Windows Sockets interface is the most popular API for writing Windows network applications today. A quick overview of the Windows Sockets Interface and the NetBIOS Interface is presented here.

**Windows Sockets**
Windows Sockets specifies a programming interface that was originally based on the familiar socket interface from the University of California at Berkeley. It includes a set of extensions designed to take advantage of the message-driven nature of Microsoft Windows. Version 1.1 of the specification was released in January 1993, and version 2.2.0 was published in May of 1996. Windows Server 2003 supports version 2.2, commonly referred to as Winsock2.

**Applications**
There are many Windows Sockets applications available. A number of the utilities that ship with Windows Server 2003 are based on Windows Sockets, including the FTP and DHCP clients and servers, Telnet client, and so on. There are also higher-level programming interfaces that rely on Winsock, such as the Windows Internet API (WinInet) used by Internet Explorer.

**Name and Address Resolution**
Traditionally, Windows Sockets applications use the **gethostbyname()** function to resolve a host name to an IP address and the **gethostbyaddr()** function to resolve an IP address to a host name. The **gethostbyname()** and **gethostbyaddr()** functions are specific to IPv4. To accommodate the use of either IPv4 or IPv6, these functions have been deprecated in RFC 2553 and replaced by the new functions **getaddrinfo()** and **getnameinfo()**. Both **getaddrinfo()** and **getnameinfo()** are independent of whether IPv4, IPv6, or both are installed on the computer.

To allow applications to run over both IPv4 and IPv6, application developers must modify their applications to use **getaddrinfo()** and **getnameinfo()** and make other modifications. For more information about modifying applications to run over both IPv4 and IPv6, see the IPv6 Guide for Windows Sockets Applications (http://go.microsoft.com/fwlink/?linkID=68008).

The **gethostbyname()** or **getaddrinfo()** functions use the following (default) name look-up sequence:

1. Check the local host name for a matching name.
2. Check the Hosts file for a matching name entry.
3. If a DNS server is configured, query it.
4. If no match is found, attempt NetBIOS name-resolution.

The **gethostbyaddr()** or **getnameinfo()** functions use the following (default) address look-up sequence:

1. Check the Hosts file for a matching address entry.
2. If a DNS server is configured, query it.
3. Send a NetBIOS Adapter Status Request to the IP address being queried. If it responds with a list of NetBIOS names registered for the adapter, parse it for the computer name.

**Support for IP Multicasting**
Winsock2 provides support for IP multicasting. Multicasting is described in the Windows Sockets 2.0 specification and in the IGMP section of this article. IP multicasting is currently supported only on AF_INET and AF_INET6 sockets of the types SOCK_DGRAM and SOCK_RAW.

Winsock2 and Windows Server 2003 also support IP multicasting on SOCK_RDM sockets, which provide reliable multicast delivery using the Pragmatic General Multicast (PGM) protocol. Installing the Reliable Multicast Protocol through Network

Connections enables PGM and reliable multicast support. The Reliable Multicast Protocol installs a driver, Rmcast.sys, which communicates directly with the TCP/IP protocol to provide its own transport layer. Windows XP does not include the Reliable Multicast Protocol. PGM is described in RFC 3208.

**Backlog Parameter**
Windows Sockets server applications generally create a socket, and then use the **listen()** function on it to listen for connection requests. One of the parameters passed when calling **listen()** is the backlog of connection requests that the application would like Windows Sockets to queue for it. This value controls the number of unaccepted connections that can be queued. Once an application *accepts* a connection, it is moved out of the connection request backlog and no longer counts. The Windows Sockets 1.1 specification indicates that the maximum allowable value for a backlog is 5; however, Windows NT 4.0, Windows 2000 Server, and Windows Server 2003 accept a backlog of 200. Windows XP Professional accepts a backlog of 5.

**Push Bit Interpretation**
By default, Windows Server 2003 TCP/IP completes a **recv()** call when one of the following conditions is met:

- Data arrives with the PUSH bit set
- The user **recv** buffer is full
- 0.5 seconds have elapsed since any data has arrived

If a client application is run on a computer with a TCP/IP implementation that does not set the push bit on send operations, response delays may result. It is best to correct this on the client; however, a configuration parameter (*IgnorePushBitOnReceives*) was added to Afd.sys to force it to treat all arriving packets as though the push bit were set.

**ConnectEx/TransmitPackets and TCP/IP**
The following two functions are Microsoft-specific extensions to the Windows Sockets 2 specification:

- The Windows Sockets **ConnectEx()** function establishes a connection to another socket application and optionally sends the block of data after the connection is established.
- The Windows Sockets **TransmitPackets()** function transmits in memory and/or file data over a connected socket (either datagram or stream). The operating system's cache manager is used to retrieve file data and locks memory for the minimum necessary time required to transmit it. This provides high performance and efficiency for file and memory data transfer over sockets.

**Windows Sockets Direct Path for System Area Networks**
The Windows Server 2003 family contains substantial performance improvements to Windows Sockets Direct (WSDP) for System Area Networks (SANs). WSD enables Windows Sockets applications written for SOCK_STREAM to obtain the performance benefits of SANs without having to make application modifications. The fundamental component of this technology is the WinSock switch that emulates TCP/IP semantics over native SAN service providers. For the Windows 2000 Server family, WSD support was only available for Windows 2000 Advanced Server and Windows 2000 Datacenter Server. WSD support is included for all members of the Windows Server 2003 family.

**NetBIOS over TCP/IP**
NetBIOS defines a software interface and a naming convention, not a protocol. Early versions of Microsoft networking products provided only the NetBIOS Extended User Interface (NetBEUI) protocol with a NetBIOS application-programming interface. NetBEUI is a small, fast protocol with no networking layer; thus, it is not routable and is not suitable for internetworks. NetBEUI relies on multicasts for name resolution and location of services. NetBIOS over TCP/IP provides the NetBIOS programming interface over the TCP/IP protocol, extending the reach of NetBIOS client and server programs to the WAN, and providing interoperability with various other operating systems.

The Workstation, Server, Browser, Messenger, and NetLogon services are all (direct) NetBT clients. They use TDI (described earlier in this article) to communicate with NetBT. Windows Server 2003 also includes a NetBIOS emulator. The emulator takes standard NetBIOS requests from NetBIOS applications and translates them to equivalent TDI primitives.

Windows Server 2003 still uses NetBIOS over TCP/IP to communicate with prior versions of Windows NT and other clients, such as Windows 98. However, the Windows Server 2003 redirector and server components also support *direct hosting* to communicate with other computers capable of direct hosting. Direct hosting uses DNS for name resolution. No NetBIOS name resolution (WINS or broadcast) is used, and the protocol is simpler. Direct hosting uses TCP port 445, instead of the NetBIOS TCP port 139.

By default, both NetBIOS and direct hosting are enabled, and both are tried in parallel when a new connection is established. The first to succeed in connecting is used for any attempt. NetBIOS support can be disabled to force all traffic to use direct hosting.

**To disable NetBIOS support**

1. On the **Start** menu, point to **Control Panel**, and then double-click **Network Connections**. Right-click **Local Area Connection** (or the name of your LAN connection) and then click **Properties**.
2. Select **Internet Protocol (TCP/IP)** in the list of components, and click **Properties**.
3. Click **Advanced**.
4. On the **WINS** tab, select **Disable NetBIOS over TCP/IP**.

Applications and services that depend on NetBIOS no longer function after this is done, so it is important that you verify that any clients and applications no longer need NetBIOS support before you disable it. For example, computers that cannot direct host will be unable to browse, locate, or create file and print share connections to a Windows Server 2003 computer with NetBIOS disabled.

**NetBIOS Names**

The NetBIOS namespace is flat, meaning that all names within the name space must be unique. NetBIOS names are 16 characters in length. Resources are identified by NetBIOS names, which are registered dynamically when computers boot, services or applications start, or users log on. Names can be registered as unique (one owner) or as group (multiple owner) names. A NetBIOS Name Query is used to locate a resource by resolving the name to an IP address.

Microsoft networking components, such as Workstation and Server services, allow the first 15 characters of a NetBIOS name to be specified by the user or administrator, but reserve the sixteenth character of the NetBIOS name to indicate a resource type (0x00-0xFF). Many popular third-party software packages also use this character to identify and register their specific services. Table 3 lists some example NetBIOS names used by Microsoft components.

**Table 3. Examples of NetBIOS names used by Windows components**

| Unique name | Service |
|---|---|
| *computer_name* **[00h]** | Workstation service |
| *computer_name* **[03h]** | Messenger service |
| *computer_name* **[1Fh]** | NetDDE service |
| *computer_name* **[20h]** | Server service |

To see which names a computer has registered over NetBT, type the following from a command prompt:

nbtstat -n

Windows Server 2003 allows you to re-register names with the WINS server after a computer has already been started. To do this, type the following from a command prompt:

nbtstat –RR

**NetBIOS Name Registration and Resolution**
Windows TCP/IP systems use several methods to locate NetBIOS resources:

- NetBIOS name cache
- NetBIOS name server
- Broadcast NetBIOS Name Query Request messages
- Static Lmhosts file
- Local host name (optional, depends on *EnableDns* registry parameter)
- Static Hosts file (optional, depends on *EnableDns* registry parameter)
- DNS servers (optional, depends on *EnableDns* registry parameter)

NetBIOS name resolution order depends upon the node type and system configuration. The following node types are supported:

- *B-node* uses broadcasts for name registration and resolution.
- *P-node* uses a NetBIOS name server (such as WINS) for name registration and resolution.
- *M-node* uses broadcasts for name registration. For name resolution, it tries broadcasts first, but switches to p-node if it receives no answer.
- *H-node* uses a NetBIOS name server for both registration and resolution. However, if no name server can be located, it switches to b-node. It continues to poll for a name server and switches back to p-node when one becomes available.
- *Microsoft-enhanced* uses the local Lmhosts file or WINS proxies plus Windows Sockets gethostbyname() calls (using standard DNS and/or local Hosts files) in addition to standard node types.

Microsoft ships a NetBIOS name server known as the Windows Internet Name Service (WINS). Most WINS clients are set up as H-nodes; that is, they first attempt to register and resolve names using WINS, and if that fails, they try local subnet broadcasts. Using a WINS server to locate resources is generally preferable to broadcasting for two reasons:

- Routers do not usually forward broadcasts.
- All computers on a subnet process broadcasts.

**NetBIOS Name Registration and Resolution for Multihomed Computers**
As previously described, NetBT binds to only one IP address per physical network interface. From the NetBT viewpoint, a computer is multihomed only if it has more than one network interface card installed. When a name registration packet is sent from a multihomed machine, it is flagged as a multihomed name registration so that it does not conflict with the same name being registered by another interface in the same computer.

If a multihomed machine receives a broadcast name query, all NetBT-interface bindings receiving the query respond with their addresses, and by default the client chooses the first response and connects to the address supplied by it. This behavior can be controlled by the *RandomAdapter* registry parameter described in Appendix B.

When a directed name query is sent to a WINS server, the WINS server responds with a list of all IP addresses that were registered with WINS by the multihomed computer.

Choosing the best IP address to connect to on a multihomed computer is a client function. Currently, the following algorithm is employed, in the order listed:

1. If one of the IP addresses in the name query response list is on the same logical subnet as the calling binding of NetBT on the local computer, that address is selected. If more than one of the addresses meets the criteria, one is picked at random

from those that match.

2. If one of the IP addresses in the list is on the same (classless) network as the calling binding of NetBT on the local computer, that address is selected. If more than one of the addresses meets the criteria, one is picked at random from those that match.

3. If one of the IP addresses in the list is on the same logical subnet as any binding of NetBT on the local computer, that address is selected. If more than one of the addresses meets the criteria, one is picked at random from those.

4. If none of the IP addresses in the list is on the same subnet as any binding of NetBT on the local computer, an address is selected at random from the list.

This algorithm provides a reasonably good way of balancing connections to a server across multiple network adapters, and still favoring direct (same subnet) connections when they are available. When a list of IP addresses is returned, they are sorted into the best order, and NetBT attempts to ping each of the addresses in the list until one responds. NetBT then attempts a connection to that address. If no addresses respond, a connection attempt is made to the first address in the list anyway. This is tried in case there is a firewall or other device filtering ICMP traffic. Windows Server 2003 supports per interface NetBT name caching, and the **nbtstat -c** command displays the name cache on a per-interface basis.

**NetBT Internet/DNS Enhancements and the SMB Device**

It has always been possible to connect from one Windows-based computer to another using NetBT over the Internet. To do so, some means of name resolution had to be provided. Two common methods were to use the Lmhosts file or a WINS server. Several enhancements were introduced in Windows NT 4.0 and carried forward in Windows Server 2003 to eliminate these special configuration needs.

It is possible to connect to a NetBIOS over TCP/IP resource in the following ways:

- Use the command **net use ***ip address******share_name*. This eliminates the need for NetBIOS name resolution configuration.

- Use the command **net use ***FQDN******share_name*. This allows the use of a DNS to connect to a computer using its fully qualified domain name (FQDN).

Examples of using new functionality to map a drive to ftp.microsoft.com are shown here. The IP address listed here is subject to change.

- **net use f: \\ftp.microsoft.com\data**

- **net use \\131.107.232.1\data**

- **net view \\131.107.232.1**

- **dir \\ftp.microsoft.com\bussys\winnt**

In addition, various applications, such as the Event Viewer **Select Computer** option on the **Log** menu, allow you to enter an FQDN or IP address directly. In Windows Server 2003, it is also possible to use direct hosting to establish redirector or server connections between computers running Windows Server 2003 without the use of the NetBIOS namespace or mapping layer at all. By default, Windows attempts to make connections using both methods so that it can support connections to lower-level computers. However, in Windows XP and Windows Server 2003–only environments, you can disable NetBIOS completely for each network connection in Network Connections.

The interface in Windows Server 2003 that makes NetBIOS-less operation possible is termed the *Server Message Block (SMB) device*. It appears to the redirector and server as another interface, much as an individual network adapter/protocol stack combination does. At the TCP/IP stack however, the SMB device is bound to ADDR_ANY, and it uses the DNS namespace natively, like a Windows Sockets application. Calls placed on the SMB device will result in a standard DNS lookup to resolve the (DNS) name to an IP address, followed by a single outbound connection request (even on a multihomed computer) using the best source IP address and interface as determined by the route table. Additionally, there is no NetBIOS session setup on top of the TCP connection, as there is with traditional NetBIOS over TCP/IP. By default, the redirector places calls on both the NetBIOS device(s) and the SMB device, and the file server receives calls on both. The file server SMB device listens on TCP port 445

instead of the traditional NetBIOS over TCP port 139.

**NetBIOS over TCP Sessions**
NetBIOS sessions are established between two names. For example, when a Windows XP Professional-based workstation makes a file-sharing connection to a server using NetBIOS over TCP/IP, the following sequence of events takes place:

1. The NetBIOS name for the server is resolved to an IP address.

2. The next-hop address for the IP address of the server is resolved to a MAC address.

3. A TCP connection is established from the workstation to the server, using port 139.

4. The workstation sends a NetBIOS Session Request to the server name over the TCP connection. If the server is listening on that name, it responds affirmatively, and a session is established.

When the NetBIOS session has been established, the workstation and server negotiate which level of the SMB protocol to use. Microsoft networking uses only one NetBIOS session between two names at any time. Any additional file or print sharing connections are multiplexed over the same NetBIOS session using identifiers within the SMB header.

NetBIOS keep-alives are used on each connection to verify that both the server and workstation are still able to maintain their session. Therefore, if a workstation is shut down ungracefully, the server eventually cleans up the connection and associated resources, and vice versa. NetBIOS keep-alives are controlled by the *SessionKeepAlive* registry parameter and default to once per hour.

If Lmhosts files are used and an entry is misspelled, it is possible to attempt to connect to a server using the correct IP address but an incorrect name. In this case, a TCP connection is still established to the server. However, the server rejects the NetBIOS session request (using the wrong name), because there is no listen posted on that name. An Error 51, "Remote computer not listening," is returned.

**NetBIOS Datagram Services**
Datagrams are sent from one NetBIOS name to another over UDP port 138. The datagram service provides the ability to send a message to a unique name or to a group name. Group names may resolve to a list of IP addresses or a broadcast. For example, the command **net send /d:***mydomain* **test** sends a datagram containing the text "test" to the group name *mydomain*[03]. The *mydomain*[03] name resolves to an IP subnet broadcast, so the datagram is sent with the following characteristics:

- Destination MAC address: broadcast (0xFF-FF-FF-FF-FF-FF).

- Source MAC address: The MAC address of the sending interface.

- Destination IP address: The local subnet broadcast address.

- Source IP address: The IP address of the local computer.

- Destination name: *mydomain*[03] (the messenger service on the remote computers).

- Source name: *username*[03] (the messenger service on the local computer).

All hosts on the subnet pick up the datagram and process it, at least to the UDP protocol. On hosts that are running a NetBIOS datagram service, UDP hands the datagram to NetBT on port 138. NetBT checks the destination name to see if any application has posted a datagram receive on it and if so, passes the datagram up. If no receive is posted, the datagram is discarded.

If support for NetBIOS is disabled in Windows Server 2003 (as described earlier in this section), NetBIOS datagram services are not available.

# Critical Client Services and Stack Components

Updated: July 6, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The focus of this article is on core TCP/IP stack components, not on the many available services that use it. However, the stack itself relies upon a few services for configuration information and name and address resolution. A few of these critical client services are discussed here.

**Automatic Client Configuration and Media Sense**

One of the most important client services is the Dynamic Host Configuration Protocol (DHCP) client. The DHCP client has an expanded role in Windows Server 2003. Its primary new feature is the ability to automatically configure an IP address and subnet mask when the client is started on a small private network without a DHCP server available to assign addresses (such as a home network). Another new feature is support for *Media Sense*, which can improve the roaming experience for portable device users.

If the TCP/IP is configured to dynamically obtain TCP/IP protocol configuration information from a DHCP server (instead of being manually configured with an IP address and other parameters), the DHCP client service is engaged each time the computer is restarted. The DHCP client service now uses a two-step process to configure the client with an IP address and other configuration information.

When the client is installed, it attempts to locate a DHCP server and obtain a configuration from it. Many TCP/IP networks use DHCP servers that are administratively configured to allocate TCP/IP configuration information to clients on the network. If this attempt to locate a DHCP server fails, the Windows Server 2003 DHCP client uses one of the following:

1. If Automatic Private IP Addressing (APIPA) is selected, TCP/IP automatically selects an IP address from the IANA-reserved class B network 169.254.0.0 with the subnet mask 255.255.0.0[8]. The DHCP client tests (using a gratuitous ARP) to make sure that the IP address that it has chosen is not already in use. If it is in use, it selects another IP address (it does this for up to 10 addresses). Once the DHCP client has selected an address that is verifiably not in use, it configures the interface with this address. APIPA allows single subnet home office or small office networks to use TCP/IP without static configuration or the administration of a DHCP server. Note that APIPA does not configure a default gateway. Therefore, only local subnet traffic is possible.

2. If an alternate configuration is selected, TCP/IP is configured with the alternate configuration settings. Alternate configuration is useful when a computer is used on more than one network, at least one of the networks does not have a DHCP server, and an APIPA configuration is not wanted. For example, if you have a laptop computer that you use both at the office and at home, it is useful to configure TCP/IP for an alternate configuration. At the office, the laptop uses a DHCP-allocated TCP/IP configuration. At home, where there is no DHCP server present, the laptop automatically uses the alternate configuration, which provides easy access to home network devices and the Internet and allows seamless operation on both networks, without the manual reconfiguration of TCP/IP settings.

You can select whether to use APIPA or an alternate configuration from the **Alternate Configuration** tab from the properties of the TCP/IP protocol in the Network Connections folder.

Once configured for either APIPA or an alternate configuration, TCP/IP continues to check for a DHCP server in the background every 5 minutes. If a DHCP server is found, the APIPA or alternate configuration information is abandoned, and the configuration offered by the DHCP server is used instead.

If the DHCP client has previously obtained a lease from a DHCP server, the following modified sequence of events occurs:

1. If the client's lease is still valid (not expired) at boot time, the client tries to renew its lease with the DHCP server. If the client fails to locate a DHCP server during the renewal attempt, it tries to ping the default gateway that is listed in the lease. If pinging the default gateway succeeds, the DHCP client assumes that it is still located on the same network where it obtained its current lease and continues to use the lease. By default, the client attempts to renew its lease in the background when half of its assigned lease time has expired.

2. If the attempt to ping the default gateway fails, the client assumes that it has been moved to a network that has no DHCP services currently available (such as a home network), and autoconfigures itself as described above. Once autoconfigured, it continues to try to locate a DHCP server every 5 minutes, in the background.

*Media Sense* support was added in NDIS 5.0. It provides a mechanism for the network interface card to notify the protocol stack of media connect and media disconnect events. Windows Server 2003 TCP/IP utilizes these notifications to assist in automatic configuration. For instance, in Windows NT 4.0, when a portable computer was located and DHCP was configured on an Ethernet subnet, and then moved to another subnet without rebooting, the protocol stack received no indication of the move. This meant that the configuration parameters became stale, and not relevant to the new network. Additionally, if the computer was shut off, carried home and rebooted, the protocol stack was not aware that the network interface card was no longer connected to a network, and again stale configuration parameters remained. This could be problematic, as subnet routes, default gateways, and so on, could conflict with dial-up parameters.

Media Sense support allows the protocol stack to react to events and invalidate stale parameters. For instance, if a computer running Windows Server 2003 is unplugged from the network (assuming the network interface card supports Media Sense), after a damping period implemented in the stack (currently 3 seconds), TCP/IP will invalidate the parameters associated with the network which has been disconnected. The IP address(es) will no longer allow sends, and any routes associated with the interface are invalidated. You can make the network connection status when connected visible on the taskbar by selecting a connection, right-clicking it, clicking **Properties**, and then selecting the **Show icon in taskbar when connected** check box. The network connection icon will also appear automatically with a red "X" when the adapter is having a connectivity problem.

If an application is bound to a socket that is using an invalidated address, it should handle the event and recover in a graceful way, such as attempting to use another IP address on the system or notifying the user of the disconnect.

**DNS Dynamic Update Client**

Windows Server 2003 includes support for DNS dynamic updates as described in RFC 2136. Every time there is an address event (new address or renewal), the DHCP client sends option 81 and its fully qualified name to the DHCP server, and requests the DHCP server to register a DNS pointer (PTR) resource record (RR) on its behalf. The DHCP client handles the dynamic update of the address (A) RR on its own. This is done because only the client knows which IP addresses on the host map to that name. The DHCP server may not be able to properly do the A RR registration because it has incomplete knowledge. However, the DHCP server can be configured to instruct the client to allow the server to register both records with the DNS. Registry parameters associated with the DNS dynamic update client are documented in Appendix C.

The Windows Server 2003 DHCP server handles option 81 requests as specified in the Internet draft titled "The DHCP Client FQDN Option" (draft-ietf-dhc-fqdn-option-0x.txt). If a Windows Server 2003 DHCP client obtains an IP address configuration from a down-level DHCP server that does not handle option 81, it registers a PTR RR on its own. The Windows Server 2003 DNS server is capable of handling dynamic updates.

Statically configured (non-DHCP) clients register both the A and PTR RRs with the DNS server themselves.

**DNS Resolver Cache Service**

Windows Server 2003 includes a caching DNS resolver service, which is enabled by default. For troubleshooting purposes, this service can be viewed, stopped, and started like any other Windows service. The caching resolver reduces DNS network traffic and speeds name resolution by providing a local cache for DNS queries. Name query responses are cached for the TTL specified in the response (not to exceed the value specified in the *MaxCacheEntryTtlLimit* parameter), and future queries are answered from the cache, when possible. One interesting feature of the DNS Resolver Cache Service is that it supports negative caching. For example, if a query is made to a DNS server for a given host name and the response is negative, succeeding queries for the same name are answered (negatively) from the cache for *NegativeCacheTime* seconds (the default is 300). Another example of negative caching is that if all DNS servers are queried and none are available, for *NetFailureCacheTime* seconds (the default is 30) all succeeding name queries fail instantly, instead of timing out. This feature can save time for services that query the DNS during the boot process, especially when the client is booted from the network.

The DNS Resolver Cache Service has a number of other adjustable registry parameters, which are documented in Appendix C.

# Appendix A: TCP/IP Configuration Parameters

Updated: July 6, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The TCP/IP protocol suite implementation for Windows Server 2003 obtains all of its configuration data from the registry. This information is written to the registry by the Setup program. Some of this information is also supplied by the Dynamic Host Configuration Protocol (DHCP) client service, if it is enabled. This appendix defines all of the registry parameters used to configure the protocol driver, Tcpip.sys, which implements the standard TCP/IP network protocols.

The implementation of the protocol suite should perform properly and efficiently in most environments using only the configuration information gathered by Setup and DHCP. Optimal default values for all other configurable aspects of the protocols for most cases have been encoded into the drivers. Some customer installations may require changes to certain default values. To handle these cases, optional registry parameters can be created to modify the default behavior of some parts of the protocol drivers.

| **Note** |
| --- |
| The Windows TCP/IP implementation is largely self-tuning. Adjusting registry parameters may adversely affect system performance. |

All of the TCP/IP parameters are registry values located under the registry key

HKEY_LOCAL_MACHINE

\SYSTEM

\CurrentControlSet

\Services:

\Tcpip

\Parameters

Adapter-specific values are listed under subkeys for each adapter identified by the adapter's globally unique identifier (GUID).

To determine the GUID value for an adapter corresponding to a LAN connection in the Network Connections folder, do the following:

1. Open the Network Connections folder and note the name of the LAN connection, such as "Local Area Connection."

2. Click **Start**, click **Run**, type **regedit.exe**, and then click **OK**.

3. Use the tree view (the left pane) of the Registry Editor tool to open the following key:
   HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Network\{4D36E972-E325-11CE-BFC1-08002BE10318}

4. Under this key are one or more keys for the globally unique identifiers (GUIDs) corresponding to the installed LAN connections. Each of these GUID keys has a Connection subkey. Open each of the *GUID*\Connection keys and look for the Name setting in the contents pane whose value matches the name of your LAN connection from step 1.

5. When you have found the *GUID*\Connection key that contains the Name setting that matches the name of your LAN connection, write down or otherwise note the GUID value.

Depending on whether the system or adapter is DHCP-configured or static override values are specified, parameters may have both DHCP and statically configured values. If any of these parameters are changed using the registry editor, a restart of the system is generally required for the change to take effect. A restart is usually not required if values are changed using the Network Connections folder.

**Parameters Configurable Using the Registry Editor**

The following parameters receive default values during the installation of the TCP/IP components. To modify any of these values, use the Registry Editor (**Regedit.exe**). A few of the parameters are visible in the registry by default, but most must be

created to modify the default behavior of the TCP/IP protocol driver. Parameters configurable from the user interface are listed separately.

**AllowUserRawAccess**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**Valid Range:** 0, 1 (False, True)

**Default:** 0 (False)

**Description:** This parameter controls access to raw sockets. If true, non-administrative users have access to raw sockets. By default, only administrators have access to raw sockets. For more information about raw sockets, see Windows Sockets 2 (http://go.microsoft.com/fwlink/?LinkID=31786).

**ArpAlwaysSourceRoute**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1, or not present (false, true, or not present)

**Default:** not present

**Description:** By default, the stack transmits ARP queries without source routing first and retries with source routing enabled if no reply is received. Setting this parameter to 0 causes all IP broadcasts to be sent without source routing. Setting this parameter to 1 forces TCP/IP to transmit all ARP queries with source routing enabled on Token Ring networks.

**ArpCacheLife**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Number of seconds

**Valid Range:** 0–0xFFFFFFFF

**Default:** In absence of an *ArpCacheLife* parameter, the defaults for ARP cache time-outs are a two-minute time-out on unused entries and a ten-minute time-out on used entries.

**Description:** See *ArpCacheMinReferencedLife*

**ArpCacheMinReferencedLife**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Number of seconds

**Valid Range:** 0–0xFFFFFFFF

**Default:** 600 seconds (10 minutes)

**Description:** *ArpCacheMinReferencedLife* controls the minimum time until a referenced ARP cache entry expires. This parameter can be used in combination with the *ArpCacheLife* parameter, as follows:

- If *ArpCacheLife* is greater than or equal to *ArpCacheMinReferencedLife*, referenced and unreferenced ARP cache entries expire in *ArpCacheLife* seconds.

- If *ArpCacheLife* is less than *ArpCacheMinReferencedLife*, unreferenced entries expire in *ArpCacheLife* seconds, and referenced entries expire in *ArpCacheMinReferencedLife* seconds.

Entries in the ARP cache are referenced each time that an outbound packet is sent to the IP address in the entry.

**ArpRetryCount**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Number

**Valid Range:** 0–3

**Default:** 3

**Description:** This parameter controls the number of times that the computer sends a gratuitous ARP for its own IP address(es) while initializing. Gratuitous ARPs are sent to ensure that the IP address is not already in use on the locally attached subnet. The value controls the actual number of ARPs sent, not the number of retries.

**ArpTRSingleRoute**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** Setting this parameter to 1 causes ARP broadcasts that are source-routed (Token Ring) to be sent as single-route broadcasts, instead of all-routes broadcasts.

**ArpUseEtherSNAP**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** Setting this parameter to 1 forces TCP/IP to transmit Ethernet packets using IEEE 802.3 SNAP encoding. By default, the stack transmits packets in Ethernet II format, also known as Ethernet DIX format. It always receives both formats.

**DatabasePath**
**Key:** Tcpip\Parameters

**Value Type:** REG_EXPAND_SZ—Character string

**ValidRange:** A valid file path

**Default:** %*SystemRoot*%\system32\drivers\etc

**Description:** This parameter specifies the path to the standard Internet database files (Hosts, Lmhosts, Network, Protocols, Services). It is used by the Windows Sockets interface.

**DefaultTTL**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Number of seconds/hops

**ValidRange:** 0–0xff (0–255 decimal)

**Default:** 128

**Description:** Specifies the default time-to-live (TTL) value set in the header of outgoing IP packets. The TTL determines the maximum amount of time that an IP packet may live in the network without reaching its destination. It is effectively a limit on the number of links on which an IP packet is allowed to travel before being discarded.

**DisableDHCPMediaSense**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** This parameter can be used to control DHCP Media Sense behavior. If set to 1, the DHCP client ignores Media Sense events from the interface. By default, Media Sense events trigger the DHCP client to take an action, such as attempting to obtain a lease (when a connect event occurs), or invalidating the interface and routes (when a disconnect event occurs).

**DisableIPSourceRouting**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**Valid Range:** 0, 1, 2

0 - forward all packets

1 - do not forward Source Routed packets

2 - drop all incoming Source Routed packets

**Default:** 1 (for Windows Server 2003 with no service packs installed), 2 (for Windows Server 2003 with Service Pack 1)

**Description:** IP source routing is a mechanism allowing the sender to determine the IP route that a datagram should take through the network. The Ping and Tracert tools have options to specify source routing.

**DisableMediaSenseEventLog**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** This parameter can be used to disable logging of DHCP Media Sense events. By default, Media Sense events (connection/disconnection from the network) are logged in the event log for troubleshooting purposes.

**DisableTaskOffload**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** This parameter instructs the TCP/IP stack to disable offloading of tasks to the network interface card for troubleshooting and test purposes.

**DisableUserTOSSetting**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1 (true)

**Description:** This parameter can be used to allow programs to manipulate the Type Of Service (TOS) bits in the header of outgoing IP packets. In Windows Server 2003, this defaults to **True**. In general, individual applications should not be allowed to manipulate TOS bits.

**DontAddDefaultGateway**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0

**Description:** When you make a remote access connection that uses TCP/IP, a new default route is added to the route table with a metric lower than all other existing default routes. You can disable the automatic adding of this new default route by setting this registry parameter to 1. You can also disable this behavior from the properties of the TCP/IP protocol for a remote access connection in Network Connections. After doing so, you may need to configure static routes for destinations that are reachable across the remote access connection.

**EnableAddrMaskReply**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** This parameter controls whether the computer responds to an ICMP address mask request.

**EnableBcastArpReply**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1 (true)

**Description:** This parameter controls whether the computer responds to an ARP request when the source Ethernet address in the ARP is not unicast. Network Load Balancing Service (NLBS) will not work properly if this value is set to 0.

**EnableDeadGWDetect**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1 (true)

**Description:** When this parameter is set to 1, TCP is allowed to perform dead gateway detection. With this feature enabled, TCP informs IP to change to a backup default gateway if a number of connections are experiencing difficulty. Backup default gateways are configured as advanced TCP/IP settings from the Network Connections folder. See the "Dead Gateway Detection" section in this article for details.

**EnableICMPRedirects**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD--BOOLEAN

**Valid Range:** 0, 1 (False, True)

**Default:** 1 (True)

**Recommendation:** 0 (False)

**Description:** This parameter controls whether Windows Server 2003 TCP/IP will update its route table in response to ICMP Redirect messages that are sent to it by network devices such as a routers.

**EnableFastRouteLookup**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** Fast route look-up is enabled if this flag is set. This can make route lookups faster at the expense of non-paged pool memory. This flag is used only if the computer runs Windows Server 2003 and falls into the medium or large class (in other words, contains at least 64 MB of memory). This parameter is created by the Routing and Remote Access service.

**EnableMulticastForwarding**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** The routing service uses this parameter to control whether or not IP multicasts are forwarded. This parameter is

created by the Routing and Remote Access service.

**EnablePMTUBHDetect**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** Setting this parameter to 1 (true) causes TCP to try to detect PMTU black hole routers while doing Path MTU Discovery. A PMTU black hole router does not return ICMP Destination Unreachable messages when it needs to fragment an IP datagram with the Don't Fragment bit set. TCP depends on receiving these messages to perform Path MTU Discovery. With this feature enabled, TCP tries to send segments without the Don't Fragment bit set if several retransmissions of a segment go unacknowledged[91]. If the segment is acknowledged as a result, the MSS is decreased and the Don't Fragment bit is set in future packets on the connection. Enabling PMTU black hole detection increases the maximum number of retransmissions that are performed for a given segment.

**EnablePMTUDiscovery**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1 (true)

**Description:** When this parameter is set to 1 (true) TCP attempts to discover the Maximum Transmission Unit (MTU), or largest packet size, over the path to a remote host. By discovering the Path MTU (PMTU) and limiting TCP segments to this size, TCP can eliminate fragmentation at routers along the path that connect networks with different MTUs. Fragmentation adversely affects TCP throughput and network congestion. Setting this parameter to 0 (not recommended) causes an MTU of 576 bytes to be used for all connections that are not to destinations on a locally attached subnet.

**FFPControlFlags**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1 (true)

**Description:** If this parameter is set to 1, Fast Forwarding Path (FFP) is enabled. If it is set to 0, TCP/IP instructs all FFP-capable adapters not to do any fast forwarding on this computer. FFP-capable network adapters can receive routing information from the stack and forward subsequent packets in hardware without passing them up to the stack. FFP parameters are located in the TCP/IP registry key, but are actually placed there by the Routing and Remote Access service.

**FFPFastForwardingCacheSize**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Number of bytes

**Valid Range:** 0–0xFFFFFFFF

**Default:** 100,000 bytes

**Description:** This is the maximum amount of memory that a driver that supports fast forwarding path (FFP) can allocate for its fast-forwarding cache if it uses system memory for its cache. If the device has its own memory for fast-forwarding cache, this value is ignored.

**GlobalMaxTcpWindowSize**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Number of bytes

**Valid Range:** 0–0x3FFFFFFF (1073741823 decimal; however, values greater than 64 KB can only be achieved when connecting to other systems that support RFC 1323 window scaling, which is discussed in the TCP section of this article.)

**Default:** This parameter does not exist by default.

**Description:** The *TcpWindowSize* parameter can be used to set the receive window on a per-interface basis. This parameter can be used to set a global limit for the TCP window size on a system-wide basis.

**IPAutoconfigurationAddress**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_SZ—String

**ValidRange:** A valid IP address

**Default:** None

**Description:** The DHCP client stores the IP address chosen using APIPA autoconfiguration here. This value should not be altered.

**IPAutoconfigurationEnabled**
**Key:** Tcpip\Parameters, Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1 (true)

**Description:** This parameter enables or disables IP autoconfiguration using APIPA. See the "Automatic Client Configuration and Media Sense" section of this article for details. This parameter can be set globally or per interface. If a per-interface value is present, it overrides the global value for that interface.

**IPAutoconfigurationMask**
**Key:** Tcpip\Parameters, Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_SZ—String

**ValidRange:** A valid IP subnet mask

**Default:** 255.255.0.0

**Description:** This parameter controls the subnet mask assigned to the client using APIPA autoconfiguration. See the "Automatic Client Configuration and Media Sense" section of this article for details. This parameter can be set globally or per interface. If a per-interface value is present, it overrides the global value for that interface.

**IPAutoconfigurationSeed**
**Key:** Tcpip\Parameters, Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—Number

**Valid Range:** 0–0xFFFF

**Default:** 0

**Description:** This parameter is used internally by the DHCP client and should not be modified.

**IPAutoconfigurationSubnet**
**Key:** Tcpip\Parameters, Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_SZ—String

**ValidRange:** A valid IP subnet

**Default:** 169.254.0.0

**Description:** This parameter controls the initial network ID used by APIPA autoconfiguration to pick an IP address for the client. See the "Automatic Client Configuration and Media Sense" section of this article for details. This parameter can be set globally or per interface. If a per-interface value is present, it overrides the global value for that interface.

**IGMPLevel**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Number

**Valid Range:** 0,1,2

**Default:** 2

**Description:** This parameter determines to what extent the system supports IP multicasting and participates in the Internet Group Management Protocol. At level 0, the system provides no multicast support. At level 1, the system can send IP multicast packets but cannot receive them. At level 2, the system can send IP multicast packets and fully participate in IGMP to receive multicast packets.

**IPEnableRouter**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** Setting this parameter to 1 (true) causes the system to forward IP packets that have a destination address that is not assigned to it.

**IPEnableRouterBackup**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** Setup writes the previous value of *IPEnableRouter* to this key. It should not be adjusted manually.

**KeepAliveInterval**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—time in milliseconds

**Valid Range:** 1–0xFFFFFFFF

**Default:** 1000 (one second)

**Description:** This parameter determines the interval between TCP keep-alive retransmissions until a response is received. Once a response is received, the delay until the next keep-alive transmission is again controlled by the value of *KeepAliveTime*. The connection is aborted after the number of retransmissions specified by *TcpMaxDataRetransmissions* have gone unanswered.

**KeepAliveTime**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—time in milliseconds

**Valid Range:** 1–0xFFFFFFFF

**Default:** 7,200,000 (two hours)

**Description:** The parameter controls how often TCP attempts to verify that an idle connection is still intact by sending a keep-alive packet. If the remote system is still reachable and functioning, it acknowledges the keep-alive transmission. Keep-alive packets are not sent by default. This feature may be enabled on a connection by an application.

**MaxForwardBufferMemory**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number of bytes

**ValidRange:** *network MTU*–0xFFFFFFFF

**Default:** 2097152 decimal (2 MB)

**Description:** This parameter limits the total amount of memory that IP can allocate to store packet data in the router packet queue. This value must be greater than or equal to the value of the *ForwardBufferMemory* parameter. See the description of *ForwardBufferMemory* for more details.

**MaxForwardPending**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—number of packets

**Valid Range:** 1–0xFFFFFFFF

**Default:** 0x1388 (5000 decimal)

**Description:** This parameter limits the number of packets that the IP forwarding engine can submit for transmission to a specific network interface at any time. Additional packets are queued in IP until outstanding transmissions on the interface complete. Most network adapters transmit packets very quickly, so the default value is sufficient. A single remote access interface, however, may multiplex many slow serial lines. Configuring a larger value for this type of interface may improve its performance. The appropriate value depends on the number of outgoing lines and their load characteristics.

**MaxFreeTcbs**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number

**Valid Range:** 0–0xFFFFFFFF

**Default:** The following default values are used (note that *small* is defined as a computer with less than 19 MB of RAM, *medium* is 19–63 MB of RAM, and *large* is 64 MB or more of RAM. Although this code still exists, nearly all computers are *large* now).

For Windows Server 2003:

- Small system—500
- Medium system—1000
- Large system—2000

For Windows XP:

- Small system—250
- Medium system—500
- Large system—1000

**Description:** This parameter controls the number of cached (pre-allocated) Transport Control Blocks (TCBs) that are available. A TCB is a data structure that is maintained for each TCP connection.

**MaxHashTableSize**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number (must be a power of 2)

**ValidRange:** 0x40–0x10000 (64-65536 decimal)

**Default:** 512

**Description:** This value should be set to a power of 2 (for example, 512, 1024, 2048, and so on.) If this value is not a power of 2, the system configures the hash table to the next power of 2 value (for example, a setting of 513 is rounded up to 1024.) This value controls how fast the system can find a TCB and should be increased if *MaxFreeTcbs* is increased from the default.

**MaxICMPHostRoutes**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number

**ValidRange:** 0–0x7FFFFFFE

**Default:** 0x3E8 (1000 in decimal) or 0x2710 (10000 in decimal) with the update to Windows Server 2003 SP1, which is available in article 898060 from the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkID=67906).

**Description:** This value restricts the number of host routes that can be added to the local IP route table by receiving ICMP Redirect messages. You should not change this value unless the computer needs to be able to add a large number of host routes by receiving ICMP Redirect messages.

**MaxNormLookupMemory**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number

**ValidRange:** Any **DWORD** (0xFFFFFFFF means no limit on memory.)

**Default:** The following default values are used (Small is defined as a computer with less than 19 MB of RAM, Medium is 19–63 MB of RAM, and Large is 64 MB or more of RAM. Although this code still exists, nearly all computers are Large now).

For Windows Server 2003:

- Small system—150,000 bytes, which accommodates 1000 routes
- Medium system—1,500,000 bytes, which accommodates 10,000 routes
- Large system—5,000,000 bytes, which accommodates 40,000 routes

For Windows XP:

- 150,000 bytes, which accommodates 1000 routes

**Description:** This parameter controls the maximum amount of memory that the system allows for the route table data and the routes themselves. It is designed to prevent memory exhaustion on the computer caused by adding large numbers of routes.

**MaxNumForwardPackets**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number

**Valid Range:** 1–0xFFFFFFFF

**Default:** 0xFFFFFFFF

**Description:** This parameter limits the total number of IP packet headers that can be allocated for the router packet queue. This value must be greater than or equal to the value of the *NumForwardPackets* parameter. See the description of *NumForwardPackets* for more details.

**MaxUserPort**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—maximum port number

**ValidRange:** 5000–65534 (decimal)

**Default:** 0x1388 (5000 decimal)

**Description:** This parameter controls the maximum port number used when an application requests any available user port from the system. Normally, short-lived ports are allocated in the range from 1024 through 5000. Setting this parameter to a value outside of the valid range causes the nearest valid value to be used (5000 or 65534).

**MTU**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—number

**ValidRange:** 88–*the MTU of the underlying network*

**Default:** 0xFFFFFFFF

**Description:** This parameter overrides the default Maximum Transmission Unit (MTU) for a network interface. The MTU is the maximum IP packet size, in bytes, that can be transmitted over the underlying network. For values larger than the default for the underlying network, the network default MTU is used. For values smaller than 88, the MTU of 88 is used.

| **Note** |
| --- |
| Windows Server 2003 TCP/IP uses PMTU detection by default and queries the network interface card driver to find out what local MTU is supported. Altering the MTU parameter is generally not necessary and may result in reduced performance. See the "Path Maximum Transmission Unit (PMTU) Discovery" section of this article for more details. |

**NumForwardPackets**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number

**ValidRange:** 1—*some reasonable value smaller than 0xFFFFFFFF*

**Default:** 0x32 (50 decimal)

**Description:** This parameter determines the number of IP packet headers that are allocated for the router packet queue. When all headers are in use, the system attempts to allocate more, up to the value configured for *MaxNumForwardPackets*. This value should be at least as large as the *ForwardBufferMemory* value divided by the maximum IP data size of the networks that are connected to the router. It should be no larger than the *ForwardBufferMemory* value divided by 256 because at least 256 bytes of forward buffer memory is used for each packet. The optimal number of forward packets for a given *ForwardBufferMemory* size depends on the type of traffic that is carried on the network and is somewhere between these two values. This parameter is ignored and no headers are allocated if routing is not enabled.

**NumTcbTablePartitions**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number of TCB table partitions

**Valid Range:** 1–0xFFFF

**Default:** 4

**Description:** This parameter controls the number of TCB table partitions. The TCB table can be portioned to improve scalability on multi-processor systems by reducing contention on the TCB table. This value should not be modified without a careful performance study. A suggested maximum value is (number of CPUs)(2.

**PerformRouterDiscovery**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD

**Valid Range:** 0, 1, 2

0 (disabled)

1 (enabled)

2 (enable only if DHCP sends the Perform Router Discovery option)

**Default:** 2, DHCP-controlled but off by default.

**Description:** This parameter controls whether Windows Server 2003 TCP/IP attempts to perform router discovery per RFC 1256 on a per-interface basis. See also *SolicitationAddressBcast*.

**PerformRouterDiscoveryBackup**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** none

**Description:** This parameter is used internally to keep a back-up copy of the *PerformRouterDiscovery* value. It should not be modified.

**PPTPTcpMaxDataRetransmissions**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number of times to retransmit a PPTP packet

**Valid Range:** 0–0xFF

**Default:** 5

**Description:** This parameter controls the number of times that a PPTP packet is retransmitted if it is not acknowledged. This parameter was added to allow retransmission of PPTP traffic to be configured separately from regular TCP traffic.

**ReservedPorts**
**Key:** Tcpip\Parameters

**Value Type:** REG_MULTI_SZ

**ValidRange:** *xxxx-yyyy* The string uses the format *xxxx-yyyy*. (port range)

**Default:** NA

**Description:** Allows ports to be reserved so that they are not used as part of the 1024 or greater range. This is useful for applications that want a specific port range.

**SackOpts**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1 (true)

**Description:** This parameter controls whether or not Selective Acknowledgment (SACK) support, as specified in RFC 2018, is enabled. SACK is described in more detail in the "Transmission Control Protocol (TCP)" section of this article.

**SolicitationAddressBcast**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** This parameter can be used to configure Windows to send router discovery messages as broadcasts instead of multicasts, as described in RFC 1256. By default, if router discovery is enabled, router discovery solicitations are sent to the all-routers multicast group (224.0.0.2). See also *PerformRouterDiscovery*.

**StrictARPUpdate**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD

**Valid Range:** 0-1

**Default:** 0

**Description:** Specifies whether TCP/IP in Windows Server 2003 SP1 will store in the ARP cache the MAC address of the last ARP reply received (StrictARPUpdate=0) or the MAC address of the first ARP reply received (StrictARPUpdate=1). With StrictARPUpdate set to 1, TCP/IP will not update the MAC address of an existing ARP cache entry if it receives additional unsolicited ARP replies.

**SynAttackProtect**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD

**Valid Range:** 0, 1

0 (no SYN attack protection)

1 (reduced retransmission retries and delayed RCE [route cache entry] creation if the *TcpMaxHalfOpen* and *TcpMaxHalfOpenRetried* settings are satisfied and a delayed indication to Winsock is made.)

| **Note** |
| --- |
| When the system finds itself under attack the following options on any socket can no longer be enabled: scalable windows (RFC 1323) and per adapter configured TCP parameters (Initial RTT, window size). This is because when protection is functioning the route cache entry is not queried before the SYN-ACK is sent and the Winsock options are not available at this stage of the connection. |

**Default:** 1 - enabled for Windows Server 2003 Service Pack 1, 0 -disabled for Windows Server 2003 with no service packs installed

**Recommendation:** 1

**Description:** SYN attack protection involves reducing the amount of retransmissions for the SYN-ACKS, which will reduce the time for which resources have to remain allocated. The allocation of route cache entry resources is delayed until a connection is made and the connection indication to AFD is delayed until the three-way handshake is completed. Note that the actions taken by the protection mechanism only occur if *TcpMaxHalfOpen* and *TcpMaxHalfOpenRetried* settings are exceeded.

**Tcp1323Opts**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number (flags)

**Valid Range:** 0, 1, 2, 3

0 (disable RFC 1323 options)

1 (window scaling enabled only)

2 (timestamps enabled only)

3 (both options enabled)

**Default:** No value. The default behavior is as follows: do not use the Timestamp and Window Scale options when initiating TCP connections but use them if the TCP peer that is initiating communication includes them in the SYN segment.

**Description:** This parameter controls the use of RFC 1323 Timestamp and Window Scale TCP options. Explicit settings for timestamps and window scaling are manipulated with flag bits. Bit 0 controls window scaling, and bit 1 controls timestamps.

**TcpAckFrequency**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—number

**Valid Range:** 0–255

**Default:** 2

**Description:** Specifies the number of ACKs that will be outstanding before the delayed ACK timer is ignored. Microsoft does not recommend changing this value from the default without careful study of the environment.

**TcpDelAckTicks**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—number

**Valid Range:** 2–6

**Default:** 2

**Description:** Specifies the number of 100-millisecond intervals to use for the delayed-ACK timer on a per-interface basis. By default, the delayed-ACK timer is 200 milliseconds. If you set this value to 0 or 1, the delayed-ACK time is 200 milliseconds. Microsoft does not recommend changing this value from the default without careful study of the environment.

**TcpInitialRTT**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—number

**Valid Range:** 0–0xFFFF

**Default:** 3

**Description:** This parameter controls the initial time-out in seconds used for a TCP connection request and initial data retransmission on a per-interface basis. Use caution when tuning with this parameter because exponential backoff is used. Setting this value to larger than 3 results in much longer time-outs to nonexistent addresses.

**TcpMaxConnectResponseRetransmissions**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number

**Valid Range:** 0–255

**Default:** 2

**Description:** This parameter controls the number of times that a SYN-ACK is retransmitted in response to a connection request if the SYN is not acknowledged. If this value is greater than or equal to 2, the stack employs SYN attack protection internally. If this value is less than 2, the stack does not read the registry values at all for SYN attack protection. See also *SynAttackProtect*, *TCPMaxPortsExhausted*, *TCPMaxHalfOpen*, and *TCPMaxHalfOpenRetried*.

**TcpMaxConnectRetransmissions**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number

**ValidRange:** 0–255 (decimal)

**Default:** 2

**Description:** This parameter determines the number of times that TCP retransmits a connect request (a SYN segment) before aborting the attempt. The retransmission time-out is doubled with each successive retransmission in a given connect attempt. The initial time-out is controlled by the *TcpInitialRtt* registry value.

**TcpMaxDataRetransmissions**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number

**Valid Range:** 0–0xFFFFFFFF

**Default:** 5

**Description:** This parameter controls the number of times that TCP retransmits an individual data segment (not connection request segments) before aborting the connection. The retransmission time-out is doubled with each successive retransmission on a connection. It is reset when responses resume. The Retransmission Timeout (RTO) value is dynamically adjusted, using the historical measured round-trip time (Smoothed Round Trip Time) on each connection. The starting RTO on a new connection is controlled by the *TcpInitialRtt* registry value.

**TcpMaxDupAcks**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number

**Valid Range:** 1–3

**Default:** 2

**Description:** This parameter determines the number of duplicate ACKs that must be received for the same sequence number of sent data before fast retransmit is triggered to resend the segment that has been dropped in transit. This mechanism is described in more detail in the “Transmission Control Protocol (TCP)” section of this article.

**TcpMaxSendFree**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number

**Valid Range:** 0–0xFFFF

**Default:** 5000

**Description:** This parameter controls the size limit of the TCP header table. On machines with large amounts of RAM increasing this setting can improve responsiveness during a SYN attack.

**TcpNumConnections**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number

**Valid Range:** 0–0xFFFFFE

**Default:** 0xFFFFFE

**Description:** This parameter limits the maximum number of connections that TCP can have open simultaneously.

**TcpTimedWaitDelay**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—time in seconds

**ValidRange:** 30-300 (decimal)

**Default:** 0xF0 (120 decimal)

**Description:** This parameter determines the length of time that a connection stays in the TIME_WAIT state when being closed. While a connection is in the TIME_WAIT state, the socket pair cannot be reused. This is also known as the 2MSL state because the value should be twice the maximum segment lifetime on the network. See RFC 793 for further details.

**TcpUseRFC1122UrgentPointer**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** This parameter determines whether TCP uses the RFC 1122 or RFC 793 specification for urgent data (used by BSD-derived systems). There are two ways to interpret the value of the Urgent Pointer field in the TCP header: RFC 793 defines the value as indicating the first byte of normal data, RFC 1122 defines the value as indicating the last byte of urgent data. These two interpretations are not interoperable. Windows Server 2003 TCP/IP defaults to the RFC 793 interpretation (BSD mode).

**TcpWindowSize**
**Key:** Tcpip\Parameters, Tcpip\Parameters\Interface*interfaceGUID*

**Value Type:** REG_DWORD—number of bytes

**ValidRange:** 0–0x3FFFFFFF (1073741823 decimal). In practice the TCP/IP stack will round the number set to the nearest multiple of maximum segment size (MSS). Values greater than 64 KB can be achieved only when connecting to other systems that support RFC 1323 Window Scaling, which is discussed in the "Transmission Control Protocol (TCP)" section of this article.

**Default:** The smaller of the following values:

- 0xFFFF
- *GlobalMaxTcpWindowSize* (another registry parameter)
- The larger of four times the MSS
- 16384 rounded up to an even multiple of the MSS

The stack also tunes itself based on the media speed:

- Below 1 Mbps: 8 KB
- 1 Mbps – 100 Mbps: 17 KB
- Greater than 100 Mbps: 64 KB

The default can start at 17520 for Ethernet, but may shrink slightly when the connection is established to another computer that supports extended TCP header options, such as Selective Acknowledgements (SACK) and TCP Timestamps, because these options increase the size of the TCP header beyond the usual 20 bytes, leaving slightly less room for data.

**Description:** This parameter determines the maximum TCP receive window size offered. The receive window specifies the number of bytes that a sender can transmit without receiving an acknowledgment. In general, larger receive windows improve performance over high-delay, high-bandwidth networks. For greatest efficiency, the receive window should be an even multiple of the TCP Maximum Segment Size (MSS). This parameter is both a per-interface parameter and a global parameter, depending upon where the registry key is located. If there is a value for a specific interface, that value overrides the system-wide value. See also *GobalMaxTcpWindowSize*.

**TrFunctionalMcastAddress**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1 (true)

**Description:** This parameter determines whether IP multicasts are sent using the Token Ring functional address of 0xC0-00-00-04-00-00 (=1) or the MAC-level broadcast address of 0xFF-FF-FF-FF-FF-FF (=0). For more information, see RFC 1469.

**TypeOfInterface**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD

**Valid Range:** 0, 1, 2, 3

**Default:** 0 (allow multicast and unicast)

**Description:** This parameter determines whether the interface gets routes plumbed for unicast, multicast, or both traffic types, and whether those traffic types can be forwarded. If it is set to 0, both unicast and multicast traffic are allowed. If it is set to 1, unicast traffic is disabled. If it is set to 2, multicast traffic is disabled. If it set to 3, both unicast and multicast traffic are disabled. Since this parameter affects forwarding and routes, it may still be possible for a local application to send multicasts out over an interface, if there are no other interfaces in the computer that are enabled for multicast, and a default route exists.

**UseZeroBroadcast**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** If this parameter is set to 1 (true), IP will use the all 0s address for the limited broadcast address (0.0.0.0) instead of the all 1s address (255.255.255.255). Most systems use the all 1s broadcasts, but some systems derived from BSD implementations use the all 0s broadcasts. Systems that use different broadcasts do not interoperate well on the same network.

**Parameters Configurable from the User Interface**
The following parameters are created and modified automatically by configuring TCP/IP properties from Network Connections. There should be no need to configure them directly in the registry.

**DefaultGateway**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_MULTI_SZ—list of dotted decimal IP addresses

**ValidRange:** Any set of valid IP addresses

**Default:** None

**Description:** This parameter specifies the list of gateways to be used to route packets that are not destined for a subnet that the computer is directly connected to, and for which a more specific route does not exist. This parameter, if it has a valid value, overrides the *DhcpDefaultGateway* parameter. There is only one active default gateway for the computer at any time, so adding multiple addresses is only done for redundancy. See the "Dead Gateway Detection" section in this article for details.

**Domain**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_SZ—character string

**ValidRange:** Any valid DNS domain name

**Default:** None

**Description:** This parameter specifies the DNS domain name of the interface. In Windows Server 2003, this and NameServer are per-interface parameters, rather than system-wide parameters. This parameter overrides the *DhcpDomain* parameter (filled in by the DHCP client), if it exists.

**EnableDhcp**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** If this parameter is set to 1 (true), the DHCP client service attempts to use DHCP to configure the first IP interface on this adapter.

**EnableSecurityFilters**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** If this parameter is set to 1 (true), IP security filters are enabled. See *TcpAllowedPorts*, *UdpAllowedPorts*, and *RawIPAllowedPorts*. To configure these values, on the **Start** menu, point to **Settings**, then click **Network Connections**, right-click **Local Area Connection**, and then click **Properties**. Select **Internet Protocol (TCP/IP)**, and click **Properties**, then click **Advanced**. Click the **Options** tab, select **TCP/IP filtering**, and click **Properties**.

**Hostname**
**Key:** Tcpip\Parameters

**Value Type:** REG_SZ—character string

**ValidRange:** Any valid DNS hostname

**Default:** The computer name of the system

**Description:** This parameter specifies the DNS host name of the system, which is returned by the **hostname** command.

**IPAddress**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_MULTI_SZ—list of dotted-decimal IP addresses

**ValidRange:** Any set of valid IP addresses

**Default:** None

**Description:** This parameter specifies the IP addresses of the IP interfaces to be bound to the adapter. If the first address in the list is 0.0.0.0, the primary interface on the adapter is configured from DHCP. A system with more than one IP interface for an

adapter is *logically multihomed*. There must be a valid subnet mask value in the *SubnetMask* parameter for each IP address that is specified in this parameter. To add parameters with **Regedit.exe**, select this key and type the list of IP addresses, pressing **Enter** after each one. Then modify the *SubnetMask* value, and type a corresponding list of subnet masks.

**NameServer**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_SZ—a space delimited list of dotted decimal IP addresses

**ValidRange:** Any set of valid IP address

**Default:** None (blank)

**Description:** This parameter specifies the DNS name servers that Windows Sockets queries to resolve names. In Windows Server 2003, this and the *DomainName* are per-interface settings.

**RawIpAllowedProtocols**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_MULTI_SZ—list of IP protocol numbers

**ValidRange:** Any set of valid IP protocol numbers

**Default:** None

**Description:** This parameter specifies the list of IP protocol numbers for which incoming datagrams are accepted on an IP interface when security filtering is enabled (*EnableSecurityFilters* = 1). The parameter controls the acceptance of IP datagrams by the raw IP transport, which is used to provide raw sockets. It does not control IP datagrams that are passed to other transports (for example, TCP). An empty list indicates that no values are acceptable. A single value of 0 indicates that all values are acceptable. The behavior of a list containing the value 0 mixed with other, nonzero values is undefined. If this parameter is missing from an interface, all values are acceptable. This parameter applies to all IP interfaces that are configured on a specific adapter.

**SearchList**
**Key:** Tcpip\Parameters

**Value Type:** REG_SZ—space delimited list of DNS domain name suffixes

**Valid Range:** 1-50

**Default:** None

**Description:** This parameter specifies a list of domain name suffixes to append to a name to be resolved through DNS if resolution of the unadorned name fails. By default, only the value of the *Domain* parameter is appended. This parameter is used by the Windows Sockets interface. See also the *AllowUnqualifiedQuery* parameter.

**SubnetMask**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_MULTI_SZ—list of dotted decimal subnet masks

**ValidRange:** Any set of valid subnet masks.

**Default:** None

**Description:** This parameter specifies the subnet masks to be used with the IP interfaces bound to the adapter. If the first mask in the list is 0.0.0.0, the primary interface on the adapter is configured using DHCP. There must be a valid subnet mask value in this parameter for each IP address specified in the *IPAddress* parameter.

**TcpAllowedPorts**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_MULTI_SZ—list of TCP port numbers

**ValidRange:** Any set of valid TCP port numbers

**Default:** None

**Description:** This parameter specifies the list of TCP port numbers for which incoming SYNs are accepted on an IP interface

when security filtering is enabled (*EnableSecurityFilters* = 1). An empty list indicates that no values are acceptable. A single value of 0 indicates that all values are acceptable. The behavior of a list containing the value 0 mixed with other, nonzero values is undefined. If this parameter is missing from an interface, all values are acceptable. This parameter applies to all IP interfaces configured on a specified adapter.

**UdpAllowedPorts**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_MULTI_SZ—list of UDP port numbers

**ValidRange:** Any set of valid UDP port numbers

**Default:** None

**Description:** This parameter specifies the list of UDP port numbers for which incoming datagrams are accepted on an IP interface when security filtering is enabled (*EnableSecurityFilters* = 1). An empty list indicates that no values are acceptable. A single value of 0 indicates that all values are acceptable. The behavior of a list containing the value 0 mixed with other, nonzero values is undefined. If this parameter is missing from an interface, all values are acceptable. This parameter applies to all IP interfaces configured on a specified adapter.

**Parameters Configurable Using the Route Command**
The **route** command can store persistent IP routes as values under the Tcpip\Parameters\PersistentRoutes registry key. Each route is stored in the value name string as a comma-delimited list of the form:

destination,subnet mask,gateway,metric

For example, the command:

route add 10.99.100.0 MASK 255.255.255.0 10.99.99.1 METRIC 1 /p

produces the registry value:

10.99.100.0,255.255.255.0,10.99.99.1,1

The value type is a REG_SZ. There is no value data (empty string). Addition and deletion of these values can be accomplished using the route command. There should be no need to configure them directly.

**Non-Configurable Parameters**
The following parameters are created and used internally by the TCP/IP components. They should never be modified using the Registry Editor. They are listed here for reference only.

**DhcpDefaultGateway**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_MULTI_SZ—list of dotted decimal IP addresses

**ValidRange:** Any set of valid IP addresses

**Default:** None

**Description:** This parameter specifies the list of default gateways to be used to route packets that are not destined for a subnet to which the computer is directly connected and for which a more specific route does not exist. This parameter is written by the DHCP client service, if enabled. This parameter is overridden by a valid *DefaultGateway* parameter value. Although this parameter is set on a per-interface basis, there is always only one default gateway active for the computer. Additional entries are treated as alternatives if the first one is down.

**DhcpIPAddress**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_SZ—dotted decimal IP address

**ValidRange:** Any valid IP address

**Default:** None

**Description:** This parameter specifies the DHCP-configured IP address for the interface. If the *IPAddress* parameter contains a first value other than 0.0.0.0, that value overrides this parameter.

**DhcpDomain**

**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_SZ—Character string

**ValidRange:** Any valid DNS domain name

**Default:** None (provided by DHCP server)

**Description:** This parameter specifies the DNS domain name of the interface. In Windows Server 2003, this and NameServer are now per-interface parameters, rather than system-wide parameters. If the *Domain* key exists, it overrides the *DhcpDomain* value.

**DhcpNameServer**
**Key:** Tcpip\Parameters

**Value Type:** REG_SZ—A space delimited list of dotted decimal IP addresses

**ValidRange:** Any set of valid IP address

**Default:** None

**Description:** This parameter specifies the DNS name servers to be queried by Windows Sockets to resolve names. It is written by the DHCP client service, if enabled. If the *NameServer* parameter has a valid value, it overrides this parameter.

**DhcpServer**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_SZ—dotted decimal IP address

**ValidRange:** Any valid IP address

**Default:** None

**Description:** This parameter specifies the IP address of the DHCP server that granted the lease on the IP address in the *DhcpIPAddress* parameter.

**DhcpSubnetMask**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_SZ—dotted decimal IP subnet mask

**ValidRange:** Any subnet mask that is valid for the configured IP address

**Default:** None

**Description:** This parameter specifies the DHCP-configured subnet mask for the address specified in the *DhcpIPAddress* parameter.

**DhcpSubnetMaskOpt**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_SZ—dotted decimal IP subnet mask

**ValidRange:** Any subnet mask that is valid for the configured IP address

**Default:** None

**Description:** This parameter is filled in by the DHCP client service and is used to build the *DhcpSubnetMask* parameter, which the stack actually uses. Validity checks are performed before the value is inserted into the *DhcpSubnetMask* parameter.

**Lease**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—time in seconds

**Valid Range:** 1–0xFFFFFFFF

**Default:** None

**Description:** The DHCP client service uses this parameter to store the time, in seconds, for which the lease on the IP address for this adapter is valid.

**LeaseObtainedTime**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—absolute time, in seconds, since midnight of 1/1/70

**Valid Range:** 1–0xFFFFFFFF

**Default:** None

**Description:** The DHCP client service uses this parameter to store the time at which the lease on the IP address for this adapter was obtained.

**LeaseTerminatesTime**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—absolute time, in seconds, since midnight of 1/1/70

**Valid Range:** 1–0xFFFFFFFF

**Default:** None

**Description:** The DHCP client service uses this parameter to store the time at which the lease on the IP address for this adapter expires.

**LLInterface**
**Key:** Tcpip\Parameters\Adapters*interfaceGUID*

**Value Type:** REG_SZ—Windows Server 2003 device name

**ValidRange:** A legal Windows Server 2003 device name

**Default:** Empty string (blank)

**Description:** This parameter is used to direct IP to bind to a different link-layer protocol than the built-in ARP module. The value of the parameter is the name of the Windows Server 2003 device to which IP should bind. This parameter is used in conjunction with the RAS component, for example. It is only present when ARP modules other than LAN bind to IP.

**NTEContextList**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_MULTI_SZ—number

**Valid Range:** 0–0xFFFF

**Default:** none

**Description:** This parameter identifies the context of the IP address associated with an interface. Each IP address associated with an interface has its own context number. The values are used internally to identify an IP address and should not be altered.

**T1**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—absolute time, in seconds, since midnight of 1/1/70

**Valid Range:** 1–0xFFFFFFFF

**Default:** None

**Description:** The DHCP client service uses this parameter to store the time at which the service first tries to renew the lease on the IP address for the adapter by contacting the server that granted the lease.

**T2**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—absolute time, in seconds, since midnight of 1/1/70

**Valid Range:** 1–0xFFFFFFFF

**Default:** None

**Description:** The DHCP client service uses this parameter to store the time at which the service tries to renew the lease on the

IP address for the adapter by broadcasting a renewal request. Time T2 should only be reached if the service is unable to renew the lease with the original server for some reason.

# Appendix B: NetBIOS over TCP/IP Configuration Parameters

Updated: July 6, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

All of the NetBIOS over TCP/IP (NetBT) parameters are registry values located under one of two different subkeys of **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services**:

- NetBT\Parameters
- NetBT\Adapters\Interfaces*interface*, in which *interface* refers to the subkey for a network interface to which NetBT is bound

Values under the latter key(s) are specific to each interface. If the system is configured using DHCP, a change in parameters takes effect if you issue the command **ipconfig /renew** from a command prompt. Otherwise, you must reboot the system for a change in any of these parameters to take effect.

**Parameters Configurable Using the Registry Editor**

The following parameters are installed with default values by Control Panel-Network Connections during the installation of the TCP/IP components. They may be modified using the Registry Editor (Regedit.exe). A few of the parameters are visible in the registry by default, but most must be created in order to modify the default behavior of the NetBT driver.

**BacklogIncrement**

**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—number

**ValidRange:** 3–0x14 (1–20 decimal)

**Default:** 3

**Description:** This parameter was added in response to Internet SYN-ATTACK issues. When a connection attempt is made to the NetBIOS TCP port (139), if the number of free connection blocks is below 2, a *BackLogIncrement* number of new connection blocks are created by the system. Each connection block consumes 78 bytes of memory. A limit on the total number of connection blocks allowed can be set using the *MaxConnBackLog* parameter. One connection block is required for each NetBT connection.

**BcastNameQueryCount**

**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—number

**Valid Range:** 1–0xFFFF

**Default:** 3

**Description:** This value determines the number of times NetBT broadcasts a query for a specific name without receiving a response.

**BcastQueryTimeout**

**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—time in milliseconds

**Valid Range:** 100–0xFFFFFFFF

**Default:** 0x2ee (750 decimal)

**Description:** This value determines the time interval between successive broadcast name queries for the same name.

**BroadcastAddress**

**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—4-byte, little-endian encoded IP address

**Valid Range:** 0–0xFFFFFFFF

**Default:** The 1s-broadcast address for each network

**Description:** This parameter can be used to force NetBT to use a specific address for all broadcast name-related packets. By default, NetBT uses the 1s-broadcast address appropriate for each net (that is, for a network of 10.101.0.0 with a subnet mask of 255.255.0.0, the subnet broadcast address would be 10.101.255.255). This parameter would be set, for example, if the network uses the 0s-broadcast address (set using the *UseZeroBroadcast* TCP/IP parameter). The appropriate subnet broadcast address would then be 10.101.0.0 in the example above. This parameter would then be set to 0x0b650000. This parameter is global and is used on all subnets to which NetBT is bound.

**CachePerAdapterEnabled**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1 (true)

**Description:** This value determines whether NetBIOS remote name caching is done on a per-adapter basis. Nbtstat -c has been enhanced to show the per-adapter name cache.

**CacheTimeout**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—time, in milliseconds

**Valid Range:** 0xEA60–0xFFFFFFFF

**Default:** 0x927c0 (600000 milliseconds = 10 minutes)

**Description:** This value determines the time interval that names are cached in the remote name table. The **nbtstat –c** command can be used to view the remaining time for each name in the cache.

**ConnectOnRequestedInterfaceOnly**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** This value can be used to allow NetBT connections on the requested adapter only. When the redirector on a multihomed computer calls another *computername*, it places calls on all NetBT transports (protocol/adapter combinations) to which it is bound. Each transport independently attempts to reach the target name. Setting this parameter limits each transport to connecting to other computers that are reachable via its own adapter, preventing crossover traffic. For more details, see the "NetBIOS Name Registration and Resolution for Multihomed Computers" section of this article.

It no longer works no wonder it doesn't make sense.

**EnableDns**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1 (true)

**Description:** If this value is set to 1 (true), NetBT queries the DNS server for names that cannot be resolved by WINS, broadcast, or the Lmhosts file.

**EnableProxyRegCheck**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** If this parameter is set to 1 (true), the proxy name server sends a negative response to a broadcast name registration if the name is already registered with WINS or is in the proxy's local name cache with a different IP address. This feature prevents a system from changing its IP address as long as WINS has a mapping for the name. For this reason, it is disabled by default.

**InitialRefreshT.O.**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—time, in milliseconds

**Valid Range:** 960000–0xFFFFFFF

**Default:** 960000 (16 minutes)

**Description:** This parameter specifies the initial refresh time-out used by NetBT during name registration. NetBT tries to contact the WINS servers at one-eighth of this time interval when it is first registering names. When it receives a successful registration response, that response contains the new refresh interval to use.

**LmhostsTimeout**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—time in milliseconds

**Valid Range:** 1000–0xFFFFFFFF

**Default:** 6000 (6 seconds)

**Description:** This parameter specifies the time-out value for Lmhosts and DNS name queries submitted by NetBT. The actual time-out could be as much as twice the value.

**MaxConnBackLog**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—number

**ValidRange:** 2–0x9c40 (1-40,000 decimal)

**Default:** 1000

**Description:** This value determines the maximum number of connection blocks that NetBT allocates. See the *BackLogIncrement* parameter for more details.

**MaxPreloadEntries**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—number

**ValidRange:** 0x3E8–0x7D0 (1000–2000 decimal)

**Default:** 1000 decimal

**Description:** This value determines the maximum number of entries that are preloaded from the Lmhosts file. Entries to preload into the cache are flagged in the Lmhosts file with the #PRE tag.

**MaxDgramBuffering**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—number of bytes

**Valid Range:** 0x20000–0xFFFFFFFF

**Default:** 0x20000 (128K)

**Description:** This parameter specifies the maximum amount of memory that NetBT dynamically allocates for all outstanding datagram sends. Once this limit is reached, further sends fail due to insufficient resources.

**MinimumRefreshSleepTime**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—number

**Valid Range:** 21600000-4294967295

**Default:** 21600000 ms (6 hours)

**Description:** This parameter is used to reset the TTL on the WakeupTimer if ½ of the TTL is less than 6 hours when the machine is put into sleep or hiberate mode.

**MinimumFreeLowerConnections**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—number

**Valid Range:** 20-500

**Default:** 50

**Description:** This parameter is used allocate the number of free handles that the system has upon boot to accept incoming connections. These handles are allocated in addition to the number of active connections that are being serviced. Once the machine is in a steady state the number of free handles increases to ½ the value of the used handles. The number of free handles is never less than 50 unless specified in the registry.

**NameServerPort**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—UDP port number

**Valid Range:** 0–0xFFFF

**Default:** 0x89

**Description:** This parameter determines the destination port number to which NetBT sends name service-related packets, such as name queries and name registrations, to WINS. The Microsoft WINS Server listens on port 0x89 (138 decimal). NetBIOS name servers from other vendors may listen on different ports.

**NameSrvQueryCount**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—number

**Valid Range:** 0–0xFFFF

**Default:** 3

**Description:** This value determines the number of times that NetBT sends a query to a WINS server for a specified name without receiving a response.

**NameSrvQueryTimeout**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—time in milliseconds

**Valid Range:** 100–0xFFFFFFFF

**Default:** 1500 (1.5 seconds)

**Description:** This value determines the time interval between successive name queries to WINS for a specified name.

**NodeType**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—number

**ValidRange:** 1, 2, 4, 8 (b-node, p-node, m-node, h-node)

**Default:** 1 or 8 based on the WINS server configuration

**Description:** This parameter determines what methods NetBT uses to register and resolve names. A b-node system uses broadcasts. A p-node system uses only point-to-point name queries to a name server (WINS). An m-node system broadcasts

first, and then queries the name server. An h-node system queries the name server first, and then broadcasts. Resolution through Lmhosts and DNS, if enabled, follows these methods. If this key is present, it overrides the DhcpNodeType key. If neither key is present, the system defaults to b-node if there are no WINS servers configured for the client. The system defaults to h-node if there is at least one WINS server configured.

**NoNameReleaseOnDemand**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** This parameter determines whether the computer releases its NetBIOS name when it receives a name-release request from the network. It was added to allow the administrator to protect the machine against malicious name-release attacks.

**RandomAdapter**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** This parameter applies to a multihomed host only. If it is set to 1 (true), NetBT randomly chooses the IP address to put in a name-query response from all of its bound interfaces. Usually, the response contains the address of the interface to which the query arrived. This feature would be used for load balancing by a server with two interfaces on the same network.

**RefreshOpCode**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—number

**Valid Range:** 8, 9

**Default:** 8

**Description:** This parameter forces NetBT to use a specific opcode field in name-refresh packets. The specification for the NetBT protocol is somewhat ambiguous in this area. Although the default of 8 that is used by Microsoft implementations appears to be the intended value, some other implementations, such as those by Ungermann-Bass, use the value 9. Two implementations must use the same opcode field to interoperate.

**ScopeId**
**Key:** Netbt\Parameters

**Value Type:** REG_SZ—character string

**ValidRange:** Any valid DNS domain name consisting of two dot-separated parts or an asterisk (*).

**Default:** None

**Description:** This parameter specifies the NetBIOS name scope for the node. This value must not begin with a period. If this parameter contains a valid value, it overrides the DHCP parameter of the same name. A blank value (empty string) is ignored. Setting this parameter to the value "*" indicates a null scope and overrides the DHCP parameter.

**SessionKeepAlive**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—time in milliseconds

**Valid Range:** 60,000–0xFFFFFFFF

**Default:** 3,600,000 (1 hour)

**Description:** This value determines the time interval between keep-alive transmissions on a session. Setting the value to 0xFFFFFFF disables keep-alives.

**SingleResponse**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** This parameter applies to a multihomed host only. If this parameter is set to 1 (true), NetBT supplies only the IP address from one of its bound interfaces in name-query responses. By default, the addresses of all bound interfaces are included.

**Size/Small/Medium/Large**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD

**ValidRange:** 1, 2, 3 (small, medium, large)

**Default:** 1 (small)

**Description:** This value determines the size of the name tables that are used to store local and remote names. In general, a setting of 1 (small) is adequate. If the system is acting as a proxy name server, the value is automatically set to 3 (large) to increase the size of the name cache hash table. Hash table buckets are sized as follows:

- Small: 16
- Medium: 128
- Large: 256

**SMBDeviceEnabled**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1 (true)

**Description:** Windows Server 2003 supports a new network transport known as the SMB Device, which is enabled by default. This parameter can be used to disable the SMB device for troubleshooting purposes. See the "NetBT Internet/DNS Enhancements and the SMB Device" section of this article for more details.

**TryAllNameServers**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** This parameter controls whether the client continues to query additional name servers from the list of configured servers when a NetBIOS session setup request to one of the IP addresses fails. If this parameter is enabled, attempts are made to query all the WINS servers in the list and connect to all the IP addresses supplied before failing the request to the user.

**TryAllIPAddrs**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1 (true)

**Description:** When a WINS server returns a list of IP addresses in response to a name query, they are sorted into a preference

order based on whether any of them are on the same subnet as an interface belonging to the client. This parameter controls whether the client pings the IP addresses in the list and attempts to connect to the first one that responds, or whether it tries to connect to the first IP address in the (sorted) list and fails if that connection attempt fails. By default, the client pings each address in the list and attempts to connect to the first one that answers the ping.

**UseDnsOnlyForNameResolutions**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** This parameter is used to disable all NetBIOS name queries. NetBIOS name registrations and refreshes are still used, and NetBIOS sessions are still allowed. To completely disable NetBIOS on an interface, see the *NetbiosOptions* parameter.

**WinsDownTimeout**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—time in milliseconds

**Valid Range:** 1000–0xFFFFFFFF

**Default:** 15,000 (15 seconds)

**Description:** This parameter determines the amount of time that NetBT waits before trying to use WINS again after it fails to contact any WINS server. This feature primarily allows computers that are temporarily disconnected from the network, such as laptops, to proceed through boot processing without waiting to time out each WINS name registration or query individually.

**Parameters Configurable from the Connections UI**
The following parameters can be set using the Control Panel-Network Connections. There should be no need to configure them directly.

**EnableLmhosts**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1 (true)

**Description:** If this value is set to 1 (true), NetBT searches the Lmhosts file, if it exists, for names that cannot be resolved by WINS or broadcast. By default, there is no Lmhosts file database directory (specified by Tcpip\Parameters\DatabasePath), so no action is taken. This value is written by the Advanced TCP/IP Configuration dialog box.

**EnableProxy**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** If this value is set to 1 (true), the system acts as a proxy name server for the networks to which NetBT is bound. A proxy name server answers broadcast queries for names that it has resolved through WINS. A proxy name server allows a network of b-node implementations to connect to servers on other subnets that are registered with WINS.

**NameServerList**
**Key:** Netbt\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_MULTI_SZ—space separated, dotted decimal IP address (that is, 10.101.1.200)

**ValidRange:** any list of valid WINS server IP addresses.

**Default:** blank (no address)

**Description:** This parameter specifies the IP addresses of the list of WINS servers configured for the computer. If this

parameter contains a valid value, it overrides the DHCP parameter of the same name. This parameter replaces the Windows NT 4.0 parameters *NameServer* and *NameServerBackup*, which are no longer used.

**NetbiosOptions**
**Key:** Netbt\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—number

**Valid Range:** 1, 2

**Default:** 1

**Description:** This parameter controls whether NetBIOS is enabled on a per-interface basis. On the **Start** menu, point to **Settings**, and click **Network Connections**. Right-click **Local Area Connection**, and click **Properties**. Select **Internet Protocol (TCP\IP)**, and click **Properties**, then click **Advanced**. Click the **WINS** tab. The NetBIOS options are **Enable NetBIOS over TCP\IP**, **Disable NetBIOS over TCP\IP**, or **Use NetBIOS setting from the DHCP server**, the default. When enabled, the value is 1. When disabled, the value is set to 2. If this key does not exist, the *DHCPNetbiosOptions* key is read. If this key does exist, *DHCPNetbiosOptions* is ignored.

**Non-Configurable Parameters**
The following parameters are created and used internally by the NetBT components. They should never be modified using the Registry Edit or it can cause the component to become unstable. They are listed here for reference only.

**DHCPNameServerList**
**Key:** Netbt\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_MULTI_SZ—space separated, dotted decimal IP address (that is, 10.101.1.200)

**ValidRange:** any list of valid WINS server IP addresses.

**Default:** blank (no address)

**Description:** This parameter specifies the IP addresses of the list of WINS servers, as provided by the DHCP service. This parameter replaces the Windows NT 4.0 parameters *DHCPNameServer* and *DHCPNameServerBackup*, which are no longer used. See also *NameServerList*, which overrides this parameter if it is present.

**DHCPNetbiosOptions**
**Key:** Netbt\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD—number

**Valid Range:** 1, 2

**Default:** 1

**Description:** This parameter is written by the DHCP client service. See the *NetbiosOptions* parameter for a description.

**DhcpNodeType**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—number

**Valid Range:** 1–8

**Default:** 1

**Description:** This parameter specifies the NetBT node type. It is written by the DHCP client service, if enabled. A valid NodeType value overrides this parameter. See the entry for *NodeType* for a complete description.

**DhcpScopeId**
**Key:** Netbt\Parameters

**Value Type:** REG_SZ—character string

**ValidRange:** a dot-separated name string such as microsoft.com

**Default:** none

**Description:** This parameter specifies the NetBIOS name scope for the node. It is written by the DHCP client service, if enabled. This value must not begin with a period. See the entry for *ScopeId* for more information.

**NbProvider**
**Key:** Netbt\Parameters

**Value Type:** REG_SZ—character string

**ValidRange:** _tcp

**Default:** _tcp

**Description:** This parameter is used internally by the RPC component. The default value should not be changed.

**TransportBindName**
**Key:** Netbt\Parameters

**Value Type:** REG_SZ—character string

**Valid Range:** N/A

**Default:** \Device\

**Description:** This parameter is used internally during product development. The default value should not be changed.

# Appendix C: Windows Sockets and DNS Registry Parameters

Updated: July 21, 2011

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**AFD Registry Parameters**
Afd.sys is the kernel-mode driver that is used to support Windows Sockets applications. When there are three default values, the default is calculated based on the amount of memory detected in the system:

- The first value is the default for smaller computers (less than 19 MB).
- The second value is the default for medium computers (<32 MB on Windows XP Professional, <64 MB on Windows Server 2003).
- The third value is the default for large computers (>32 MB on Windows XP Professional, >64 MB on Windows Server 2003).

For example, if the default is given as 0/2/10, a system containing 12.5 to 20 MB of RAM would default to 2.

The following values can be set under:

HKEY_LOCAL_MACHINE

\SYSTEM

\CurrentControlSet

\Services

\Afd

\Parameters

**DefaultReceiveWindow**
**Value Type:** REG_DWORD

**Default:** 4096/8192/8192

**Description:** The number of receive bytes that AFD buffers on a connection before imposing flow control. For some applications, a larger value here gives slightly better performance at the expense of increased resource utilization. Applications can modify this value on a per-socket basis with the SO_RCVBUF socket option.

**DefaultSendWindow**
**Value Type:** REG_DWORD

**Default:** 4096/8192/8192

**Description:** This is similar to *DefaultReceiveWindow*, but for the send side of connections.

**DisableAddressSharing**
**Value Type:** REG_DWORD

**Default:** 0

**Range:** 0, 1

**Description:** This parameter is used to prevent address sharing (SO_REUSEADDR) between processes so that if a process opens a socket, no other process can steal data from it. A similar effect can be achieved if an application uses the new socket option SO_EXCLUSIVEADDRUSE. This setting allows administrators to secure older applications that are not aware of this option.

**FastCopyReceiveThreshold**
**Value Type:** REG_DWORD

**Default:** 1024

**Description:** When an application posts a receive with a buffer that is smaller than the current packet being buffered by Winsock, AFD can either make an additional copy of the packet and then copy data to the application buffers directly (which is a two-stage copy because application buffers cannot be accessed directly under the lock), or it can lock and map application buffers and copy data once. This value represents a compromise between extra code execution for data copying, and extra code execution in the I/O subsystem and memory manager. The default value was found, by testing, to be the best overall value for performance. Changing this value is not generally recommended.

**FastSendDatagramThreshold**
**Value Type:** REG_DWORD

**Default:** 1024

**Description:** Datagrams smaller than the value of this parameter go through the fast I/O path or are buffered on send. Larger ones are held until the datagram is actually sent. The default value was found by testing to be the best overall value for performance. Fast I/O means copying data and bypassing the I/O subsystem, instead of mapping memory and going through the I/O subsystem. This is advantageous for small amounts of data. Changing this value is not generally recommended.

**IgnorePushBitOnReceives**
**Value Type:** REG_DWORD—Boolean

ValidRange: 0, 1 (false, true)

**Default:** 0 (false)

**Description:** Normally, Windows Server 2003 completes a Windows Sockets **Receive** when one of the following occurs:

- Data arrives with the push bit set.
- The user **recv** buffer is full.
- 0.5 seconds have elapsed since any data arrived.

Setting this parameter to a 1 causes Afd.sys to treat all incoming packets as though the push bit was set. This should only be done when necessary to work around client TCP/IP implementations that are not properly pushing data.

**LargeBufferSize**
**Value Type:** REG_DWORD

**Default:** PAGE_SIZE (4096 bytes on i386, 8192 bytes on Alpha)

**Description:** The size, in bytes, of large buffers used by AFD. Smaller values use less memory and larger values can improve performance.

**LargeBufferListDepth**
**Value Type:** REG_DWORD

**Default:** 0/2/10

**Description:** Depth of large buffer look-aside list.

**MaxFastTransmit**
**Value Type:** REG_DWORD

**Valid Range:** 0–0xffffffff

**Default:** 64 KB

**Description:** This parameter controls the maximum amount of data that is transferred in a **TransmitFile** request on the fast path. Fast I/O is essentially copying data and bypassing the I/O subsystem, instead of mapping memory and going through the I/O subsystem. This is advantageous for small amounts of data. Changing this value is not generally recommended.

**MaxFastCopyTransmit**
**Value Type:** REG_DWORD

**Valid Range:** 0–0xFFFFFFFF

**Default:** 128

**Description:** This parameter controls the maximum size of data that uses copy instead of cached memory on the fast-path. Fast I/O is essentially copying data and bypassing the I/O subsystem, instead of mapping memory and going through the I/O subsystem. This is advantageous for small amounts of data. Changing this value is not generally recommended.

**MediumBufferSize**
**Value Type:** REG_DWORD

**Default:** 1504

**Description:** The size, in bytes, of medium buffers used by AFD.

**MediumBufferListDepth**
**Value Type:** REG_DWORD

**Default:** 4/8/24

**Description:** Depth of medium buffer look-aside list.

**OverheadChargeGranularity**
**Value Type:** REG_DWORD

**Default:** 1 page

**ValidRange:** A power of 2

**Description:** This parameter determines in what increments overhead is actually charged. The default is one page, and the intention is to properly charge and contain attacker type applications that try to run the system out of memory.

**PriorityBoost**
**Value Type:** REG_DWORD

**Default:** 2

**Valid Range:** 0–16

**Description:** The priority boost that AFD gives to a thread when it completes I/O for that thread. If a multithreaded application experiences starvation of some threads, the problem may be remedied by reducing this value.

**SmallBufferListDepth**
**Value Type:** REG_DWORD

**Default:** 8/16/32

**Description:** Depth of the small buffer look-aside list.

**SmallBufferSize**
**Value Type:** REG_DWORD

**Default:** 128

**Description:** The size in bytes of small buffers used by AFD.

**StandardAddressLength**
**Value Type:** REG_DWORD

**Default:** 22

**Description:** The length of TDI addresses that are typically used for the computer. When using an alternate transport protocol, such as TP4, which uses very long addresses, increasing this value results in a slight performance improvement.

**TransmitIoLength**
**Value Type:** REG_DWORD

**Default:** PAGE_SIZE/PAGE_SIZE*2/65536

**Description:** The default size for I/O (reads and sends) performed by TransmitFile(). For Windows XP Professional, the default I/O size is exactly one page.

**TransmitWorker**

**Value Type:** REG_DWORD

**Default:** 0x10

**Valid Range:** 0x10, 0x20

**Description:** This parameter controls how Afd.sys uses system threads. Setting it to 0x10 causes AFD to use system threads to perform IO that results from a long (more than 2 *SendPacketLength* worth of data) TransmitFile request. Setting it to 0x20 causes AFD to use kernel-mode APC for IO and to execute everything in the context of the same thread. This is new in Windows Server 2003 and can improve performance by reducing the number of context switches in long TransmitFile requests.

#### Dynamic Update Registration Parameters

These parameters control behavior of the dynamic update DNS registration client. If a parameter is not present, the default value listed is used.

##### DNSQueryTimeouts

**Key:** Tcpip\Parameters

**Value Type:** REG_MULTI_SZ—list of timeouts terminated by a zero

**ValidRange:** valid list of numbers

**Default:** 1 2 2 4 8 0 (format note: after entering each number hit return and terminate the list with zero)

**Description:** This parameter can be used to change the DNS query timeouts that the DNS client uses. In a controlled non-Internet or low-delay environment this could be used to decrease the time to failure of the query.

##### DefaultRegistrationTTL

**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—seconds

**Default:** 0x4B0 (1200 decimal, or 20 minutes)

**Valid Range:** 0–0xFFFFFFFF

**Description:** This parameter can be used to control the TTL value sent dynamically with DNS registrations.

##### EnableAdapterDomainNameRegistration

**Key:** Tcpip\Parameters\Interfaces*interface*

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** This parameter can be used to enable DNS dynamic update registration of a specific adapter's domain name information. This setting is useful when registrations of the adapter address(es) under the adapter's domain name are needed. When this key is set to true and *DisableDynamicUpdate* is false, the given adapter's address(es) is registered under the specific adapter's domain name and under the system's primary domain name.

##### DisableDynamicUpdate

**Key:** Tcpip\Parameters, Tcpip\Parameters\Interfaces*interface*

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false; dynamic update-enabled)

**Description:** This parameter can be used to completely disable DNS dynamic update registration. This parameter is both a per-interface parameter and a global parameter, depending upon where the registry key is located. If the value at the Tcpip\Parameters level is set to 1, dynamic update is disabled for the entire system. If the value at the Tcpip\Parameters level is set to 0, dynamic updates can be disabled on a per-adapter basis.

##### DisableReplaceAddressesInConflicts

**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** This parameter is used to turn off the address registration conflict rule that the last writer wins. By default, a computer does not replace any current records on the DNS server that do not appear to have been owned by it at one time.

**DisableReverseAddressRegistrations**
**Key:** Tcpip\Parameters\Interfaces*interface*

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false; registration of PTR records enabled)

**Description:** This parameter can be used to turn off DNS dynamic update reverse address (PTR) record registration. If the DHCP server that configures this computer is running Windows Server 2003, then it is capable of registering the PTR record with the DNS dynamic update protocol. However, if the DHCP server is not capable of performing DNS dynamic update PTR registrations and you do not want to register PTR records with the DNS dynamic update protocol, set this parameter to 1.

**UpdateSecurityLevel**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—flags

**Default:** 0

**Valid Range:** 0,0x00000010, 0x00000020, 0x00000100

**Description:** This parameter can be used to control the security that is used for DNS dynamic updates. It defaults to 0, to try nonsecure update, and if refused, to send Windows Server 2003 secure dynamic updates. Valid values are listed below:

- **0x00000000**—default, nonsecure updates
- **0x00000010**—security OFF
- **0x00000100**—secure ONLY ON

**DNS Caching Resolver Service Registry Parameters**
Windows Server 2003 includes a DNS caching resolver service. This service performs the function of caching DNR answers so that the DNS server does not need to be repeatedly queried for the same information. The service can be stopped using the Service Control Manager MMC snap-in. Registry parameters for this service are located under the **\System\CurrentControlSet\Services\Dnscache\Parameters** key.

**AdapterTimeoutCacheTime**
**Value Type:** REG_DWORD—seconds

**Valid Range:** 0–0xFFFFFFFF

**Default:** 300 (5 minutes)

**Description:** The amount of time that a particular adapter on a multihomed machine is disabled when a DNS query attempt fails (times out) for all of the given adapter's DNS servers. For instance, if you have two adapters and the DNS servers on one of the networks are unreachable, mark the adapter as unusable for this time period. (A Plug and Play event or cache time-out forces the resolver to retry this interface and mark it as disabled, if needed.)

**DefaultRegistrationRefreshInterval**
**Value Type:** REG_DWORD—time in seconds

**Default:** 0x15180 (86400 decimal, or 24 hours)

Range: 0–0xFFFFFFFF

**Description:** This parameter can be used to control the dynamic update DNS registration refresh interval.

**MaxCacheEntryTtlLimit**
**Value Type:** REG_DWORD—time in seconds

**Default:** 0x15180 (86400 decimal)

**ValidRange:** 0–0xFFFFFFFF (suggested value less than one day, to prevent very stale records)

**Description:** This parameter can be used to control the maximum cache entry time-to-live (TTL) value. It overrides any value that may have been set on a specific record that is larger.

**MaxSOACacheEntryTtlLimit**
**Value Type:** REG_DWORD—time, in seconds

**Valid Range:** 0–0xFFFFFFFF

**Default:** 120 (2 minutes)

**Description:** The maximum number of seconds that the resolver cache caches any SOA records. This value overrides any TTL value greater than itself for a specific SOA record that is returned from a DNS query. SOA records are essential for dynamic updates; therefore, they are not cached for long, to ensure that the most up-to-date record data is available for the DNS start of authority.

**NegativeCacheTime**
**Value Type:** REG_DWORD—time, in seconds

**Default:** 0x12c (300 decimal, or 5 minutes)

**ValidRange:** 0–0xFFFFFFFF (the suggested value is less one day, to prevent very stale records)

**Description:** This parameter can be used to control the cache time for negative records.

**NegativeSOACacheTime**
**Value Type:** REG_DWORD—time, in seconds

**Default:** 0x78 (120 decimal, or 2 minutes)

**ValidRange:** 0–0xFFFFFFFF (the suggested value is less than five minutes)

**Description:** This parameter can be used to control the cache time for negative Start of Authority (SOA) records. DNS registrations that fail are retried at five and ten minutes, so if this value is set to five minutes or more, retries are answered negatively from cache, instead of from the server, which could be available.

**NetFailureErrorPopupLimit**
**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Description:** This parameter enables the UI popup to indicate that the DNS resolver was unable to query (reach) the configured DNS servers for a repeated number of query attempts.

**NetFailureCacheTime**
**Value Type:** REG_DWORD—time, in seconds

**Default:** 0x1e (30 decimal)

**ValidRange:** 0–0xFFFFFFFF (suggested value is less than five minutes)

**Description:** This parameter is used to control the general network failure cache time. It prevents the resolver from querying for a period of time when it has been detected that a time-out error is occurring for queries against all known DNS servers. This avoids slowness (caused by time-outs) when the network does not respond.

**Name Resolution Parameters**
The following list of parameters is used by the Domain Name Resolver service.

**AllowUnqualifiedQuery**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0

**Description:** This parameter controls whether or not the Domain Name Resolver queries the Domain Name Server(s) with the host name, followed by a dot (.) only (an unqualified query). For example, if your computer is in mydomain.com and you ping *target*, by default the DNS is queried for *target.mydomain.com* only. When this parameter is set to 1, *target* is also queried.

**DisjointNameSpace**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1

**Description:** This parameter instructs the DNR to treat each interface as a disjoint name space. On a multihomed computer, a query to the DNS server(s) that is/are configured for one interface may result in a name error. This parameter is used to instruct the resolver to try the query against the possible DNS servers that are configured for other interfaces before returning results.

**PrioritizeRecordData**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1

**Description:** This parameter controls whether or not the Domain Name Resolver sorts the addresses that are returned in response to a query for a multihomed host. By default, the DNR sorts addresses that are on the same subnet as one of the interfaces in the querying computer to the top of the list. This is done to give preference to a common-subnet (non-routed) IP address, when possible.

**QueryIpMatching**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1

**Description:** This parameter controls whether or not the IP address of the DNS server queried is matched to the IP address of the server that sent the DNS response. This can be used as a primitive security feature to ensure that the resolver is not being fooled by a random query response from some computer other than the intended DNS server.

**UseDomainNameDevolution**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—binary

**ValidRange:** 0, 1 (false, true)

**Default:** 1 (true)

**Description:** This parameter can be used to disable domain name *devolution* for unqualified DNS queries. Devolution describes the process of attempting to locate a host in the DNS by first appending the domain suffix of the client to the host name, and then querying for the full string. If that query fails, one label is removed at a time, and the query is resubmitted. For example, if a user or application on the computer *mycomputer.support.microsoft.com* attempts to reach a host named *target*, the DNR by default tries *target.support.microsoft.com*, and *target.microsoft.com*, and possibly *target*, depending on the value of the *AllowUnqualifiedQuery* parameter.

# Appendix D: Tuning TCP/IP Response to Attack

Updated: July 6, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**TCP/IP Security Settings**
In addition to the settings that are listed above, the following keys can be altered to assist the system to deal more effectively with an attack. It is important to note that these recommendations by no means makes the system impervious to attack and only focuses on tuning the TCP/IP stack's response to an attack. The setting of these keys does not address any of the many other components on the system, which could be used to attack the system. As with any change to the registry, the administrator needs to fully understand how these changes affect the default function of the system and whether they are appropriate in their environment.

**SynAttackProtect**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD

**Valid Range:** 0, 1

0 (no SYN attack protection)

1 (reduced retransmission retries and delayed RCE [route cache entry] creation if the *TcpMaxHalfOpen* and *TcpMaxHalfOpenRetried* settings are satisfied and a delayed indication to Winsock is made.)

| **Note** |
| --- |
| When the system finds itself under attack the following options on any socket can no longer be enabled: scalable windows (RFC 1323) and per adapter configured TCP parameters (Initial RTT, window size). This is because when protection is functioning the route cache entry is not queried before the SYN-ACK is sent and the Winsock options are not available at this stage of the connection. |

**Default:** 1 - enabled for Windows Server 2003 Service Pack 1, 0 - disabled for Windows Server 2003 with no service packs installed

**Recommendation:** 1

**Description:** SYN attack protection involves reducing the amount of retransmissions for the SYN-ACKS, which will reduce the time for which resources have to remain allocated. The allocation of route cache entry resources is delayed until a connection is made and the connection indication to AFD is delayed until the three-way handshake is completed. Note that the actions taken by the protection mechanism only occur if *TcpMaxHalfOpen* and *TcpMaxHalfOpenRetried* settings are exceeded.

**TcpMaxHalfOpen**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number

**Valid Range:** 100–0xFFFF

**Default:** 100 (Windows Server 2003, Standard Edition), 500 (Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition)

**Description:** This parameter controls the number of connections in the SYN-RCVD state allowed before SYN-ATTACK protection begins to operate. If SynAttackProtect is set to 1, ensure that this value is lower than the AFD listen backlog on the port that you want to protect (see backlog parameters in Appendix C for more information). See the *SynAttackProtect* parameter for more details.

**TcpMaxHalfOpenRetried**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—number

**Valid Range:** 80–0xFFFF

**Default:** 80 (Windows Server 2003, Standard Edition), 400 (Windows Server 2003, Enterprise Edition; Windows Server 2003,

Datacenter Edition)

**Description:** This parameter controls the number of connections in the SYN-RCVD state for which there has been at least one retransmission of the SYN sent, before SYN-ATTACK attack protection begins to operate. See the *SynAttackProtect* parameter for more details.

**EnablePMTUDiscovery**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1 (true)

**Recommendation:** 1

**Description:** When this parameter is set to 1 (true) TCP attempts to discover the Maximum Transmission Unit (MTU or largest packet size) over the path to a remote host. By discovering the Path MTU and limiting TCP segments to this size, TCP can eliminate fragmentation at routers along the path that connect networks with different MTUs. Fragmentation adversely affects TCP throughput and network congestion. Setting this parameter to 0 causes an MTU of 576 bytes to be used for all connections that are not to hosts on the local subnet.

**NoNameReleaseOnDemand**
**Key:** Netbt\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 0 (false)

**Recommendation:** 1

**Description:** This parameter determines whether the computer releases its NetBIOS name when it receives a name-release request from the network. It was added to allow the administrator to protect the machine against malicious name-release attacks.

**EnableDeadGWDetect**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—Boolean

**ValidRange:** 0, 1 (false, true)

**Default:** 1 (true)

**Recommendation:** 0

**Description:** When this parameter is set to 1, TCP is allowed to perform dead-gateway detection. With this feature enabled, TCP may ask IP to change to a backup gateway if a number of connections are experiencing difficulty. Backup gateways may be defined in the advanced properties of the TCP/IP protocol. See the "Dead Gateway Detection" section in this article for details.

**KeepAliveTime**
**Key:** Tcpip\Parameters

**Value Type:** REG_DWORD—time in milliseconds

**Valid Range:** 1–0xFFFFFFFF

**Default:** 7,200,000 (two hours)

**Recommendation:** 300,000

**Description:** The parameter controls how often TCP attempts to verify that an idle connection is still intact by sending a keep-alive packet. If the remote system is still reachable and functioning, it acknowledges the keep-alive transmission. Keep-alive packets are not sent by default. This feature may be enabled on a connection by an application.

**PerformRouterDiscovery**
**Key:** Tcpip\Parameters\Interfaces*interfaceGUID*

**Value Type:** REG_DWORD

**Valid Range:** 0, 1, 2

0 (disabled)

1 (enabled)

2 (enable only if DHCP sends the router discover option)

**Default:** 2, DHCP-controlled but off by default.

**Recommendation:** 0

**Description:** This parameter controls whether Windows Server 2003 attempts to perform router discovery per RFC 1256 on a per-interface basis. See also *SolicitationAddressBcast*.

# Appendix E: Format of the Daytime Service Response String

Updated: July 6, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

RFC 867 does not specify the format of the response sent by the daytime service. For Windows 2000 and Windows Server 2003, the daytime service sends an ASCII text string containing the current system time and date formatted in a single line as follows:

*TimeString DateString*

with a single ASCII space character separating the time (*TimeString*) and date (*DateString*) components. Each of these components is formatted according to the default format for the selected locale of the computer. For example, the default format for “English (United States)” is:

*TimeString* = h:mm:ss tt

*DateString* = m/dd/yyyy

in which tt is either "AM" or "PM".

Here is example output for the English (United States) locale:

10:23:16 AM 4/11/2003

The default formats for the date and time for any locale may be viewed or configured from Control Panel-Regional Options (for Windows 2000) or Control Panel-Regional and Language Options (for Windows Server 2003).

There is no ability to change the format of the daytime service ASCII text string.

# Summary - Microsoft Windows Server 2003 TCP/IP Implementation Details

Updated: July 6, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The TCP/IP stack in Windows Server 2003 has extensive support for standard features, performance enhancements, and services. Windows Server 2003 TCP/IP consists of the following core protocols: Address Resolution Protocol (ARP), Internet Protocol (IP), Internet Protocol security (IPsec), Internet Group Management Protocol (IGMP), Transmission Control Protocol (TCP), User Datagram Protocol (UDP), and NetBIOS over TCP/IP (NetBT). Windows TCP/IP applications typically use the Windows Sockets or NetBIOS APIs. Windows Server 2003 TCP/IP includes support for automatic client configuration, media sense, and DNS dynamic update and client-side caching.

**For More Information**
For the latest information about Windows Server 2003, see the Windows Server 2003 Web site at (http://go.microsoft.com/fwlink/?LinkID=17075).

For more information about IPv6, see the Microsoft Windows IPv6 Web site (http://go.microsoft.com/fwlink/?LinkID=68045).

1. Specifications and programming information are included in the Microsoft Windows Driver Development Kits (DDKs) (http://go.microsoft.com/fwlink/?LinkID=38448).

2. Most network interface cards have the ability to be placed into a mode in which the network interface card does not perform any address filtering on frames that appear on the media. Instead, it passes every frame upwards that passes the cyclic redundancy check (CRC). This feature is used by some protocol analysis software, such as Microsoft Network Monitor.

3. Adding [1] to the registry parameter TcpMaxDataRetransmissions or TcpMaxConnectRetransmissions approximately doubles the total retransmission time-out period. If it is necessary to configure longer time-outs, these parameters should be increased very gradually.

4. Instead of sending one TCP segment when starting out, Windows NT/Windows Server 2003 TCP starts with two. This avoids the need to wait for the delayed ACK timer to expire on the first send to the target computer, which improves performance for some applications.

5. See the Microsoft Knowledge Base for redirector registry parameters.

6. Stevens, Richard. TCP/IP Illustrated, Volume 1: The Protocols. Reading, MA: Addison-Wesley Publishing Co., 1993.

7. IP autoconfiguration can be disabled using the IPAutoconfigurationEnabled registry key. The subnet and subnet mask used can be controlled using the IPAutoconfigurationSubnet and IPAutoconfigurationMask registry keys. These keys are described in Appendix A.

# An Overview of Windows Clustering Technologies: Server Clusters and Network Load Balancing

Updated: January 1, 2003

# Introduction (An Overview of Windows Clustering Technologies: Server Clusters and Network Load Balancing)

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Microsoft listened to customers and worked steadily to improve the underlying technology architecture of the Windows operating system.

**Microsoft Cluster Technologies**
While Windows 2000 represents a dramatic improvement over its predecessors in terms of total uptime (availability), reduced system failure (reliability) and ability to add resources and computers to improve performance (scalability), Windows Server 2003 takes the availability, reliability and scalability of the Windows operating system to the next level by enhancing existing features and providing new options.

**Three Part Clustering Strategy**
Microsoft clustering technologies are the key to improving availability, reliability and scalability. With Windows 2000 and Windows Server 2003, Microsoft uses a three-part clustering strategy that includes:

- **Server cluster** provides failover support for applications and services that require high availability, scalability and reliability. With clustering, organizations can make applications and data available on multiple servers linked together in a cluster configuration. Back-end applications and services, such as those provided by database servers, are ideal candidates for Server cluster.

- **Network Load Balancing** provides failover support for IP-based applications and services that require high scalability and availability. With Network Load Balancing (NLB), organizations can build groups of clustered computers to support load balancing of Transmission Control Protocol (TCP), User Datagram Protocol (UDP) and Generic Routing Encapsulation (GRE) traffic requests. Web-tier and front-end services are ideal candidates for NLB.

- **Component Load Balancing**, which is a feature of Microsoft Application Center 2000, provides dynamic load balancing of middle-tier application components that use COM+. With Component Load Balancing (CLB), COM+ components can be load balanced over multiple nodes to dramatically enhance the availability and scalability of software applications.

**Protection Against Failure**
Microsoft cluster technologies guard against three specific types of failure:

- **Application/service failure** affects application software and essential services.

- **System/hardware failure** affects hardware components (for example, CPUs, drives, memory, network adapters, power supplies, etc.).

- **Site failure** could be caused by natural disaster, power outages or connectivity outages.

**Clustering TechnologiesPurposes and Requirements**
Each technology has a specific purpose and is designed to meet different requirements.

- **Server cluster** is designed to maintain data integrity and provide failover support.

- **Network Load Balancing** is designed to address bottlenecks caused by front-end Web services.

- **Component Load Balancing** is designed to address the unique scalability and availability needs of middle-tier applications.

Organizations can use Microsoft cluster technologies to increase overall availability, while minimizing single points of failure and reducing costs by using industry-standard hardware and software.

**E-Commerce Scenario**
The clustering technologies outlined above can be (and typically are) combined to architect a comprehensive service offering. The most common scenario where all three solutions are combined is an e-commerce site where front-end Web servers use NLB, middle-tier application servers use CLB, and back-end database servers use Server cluster.

These technologies alone are not enough to ensure the highest levels of availability. To ensure the highest availability for line-of-business applications and mission-critical services, organizations must take an end-to-end service approach to operations and availability. This means treating the entire service offering as a whole and designing, implementing, and operating the service solution following industry-standard best practices, such as those used by Microsoft Enterprise Services.

**Topics Covered**
The main topics covered in the rest of this article include:

- Cluster Architecture Essentials
- Server cluster Architecture
- Network Load Balancing Architecture
- Component Load Balancing Architecture

# Cluster Architecture Essentials

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This section introduces the concept of clustering and its benefits and limitations. It then goes on to discuss cluster organization, infrastructure scaling, cluster operating modes and how clustering is used on multiple, geographically dispersed sites.

**The Concept of a Cluster**
The concept of a cluster involves taking two or more computers and organizing them to work together to provide higher availability, reliability and scalability than can be obtained by using a single system. When failure occurs in a cluster, resources can be redirected and the workload can be redistributed. Typically, the end user experiences a limited failure, and may only have to refresh the browser or reconnect to an application to begin working again.

**Cluster Benefits and Limitations**
A Server cluster provides high availability by making application software and data available on several servers linked together in a cluster configuration. If one server stops functioning, a process called failover automatically shifts the workload of the failed server to another server in the cluster. The failover process is designed to ensure continuous availability of critical applications and data.

While clusters can be designed to handle failure, they are not fault tolerant with regard to user data. The cluster by itself does not guard against loss of a user's work. Typically, the recovery of lost work is handled by the application software; the application software must be designed to recover the user's work, or it must be designed in such a way that the user session state can be maintained in the event of failure.

**Solving Three Typical Problems**
Clusters can be used to solve three typical problems in a data center environment:

- **Need for High Availability**. High availability refers to the ability to provide end user access to a service for a high percentage of scheduled time while attempting to reduce unscheduled outages. A solution is highly available if it meets the organization's scheduled uptime goals. Availability goals are achieved by reducing unplanned downtime and then working to improve total hours of service operation.

- **Need for High Reliability**. High reliability refers to the ability to reduce the frequency of system failure, while attempting to provide fault tolerance in case of failure. A solution is highly reliable if it minimizes the number of single points of failure and reduces the risk that failure of a single component/system will result in the outage of the entire service offering. Reliability goals are achieved using redundant, fault tolerant hardware components, application software and systems.

- **Need for High Scalability**. High scalability refers to the ability to add resources and computers while attempting to improve performance. A solution is highly scalable if it can be scaled up and out. Individual systems in a service offering can be scaled up by adding more resources (for example, CPUs, memory, disks, etc.). The service can be scaled out by adding additional computers.

A well-designed service solution uses redundant systems and components so that the failure of an individual server does not affect the availability of the entire service.

**Limitations**
While a well-designed solution can guard against application failure, system failure and site failure, cluster technologies do have limitations. Cluster technologies depend on compatible applications and services to operate properly. The software must respond appropriately when failure occurs. Cluster technology cannot protect against failures caused by viruses, software corruption or human error. To protect against these types of problems, organizations need solid data protection and recovery plans.

**Cluster Organization**
Clusters are organized in loosely coupled groups that are often referred to as farms or packs. In most cases, as shown below on Figure 1, front-end and middle-tier services are organized as farms using clones, while back-end and critical support services such as component routing are organized as packs.

**IT Staff Considerations**

As IT staff architect clustered solutions, they need to look carefully at the cluster organization they plan to use. The goal should be to organize servers according to the way the servers will be used and the applications they will be running. Typically, Web servers, application servers and database servers are all organized differently.

**Figure 1: Clusters are organized and farms or packs**

**Cluster Farm**

A farm is a group of servers that run similar services, but do not typically share data. They are called a farm because they handle whatever requests are passed out to them using identical copies of data that is stored locally. Because they use identical copies of data (rather than sharing data), members of a farm operate autonomously and are also referred to as *clones*.

Front-end Web servers running Internet Information Services (IIS) and using NLB are an example of a farm. With a Web farm, identical data is replicated to all servers in the farm, and each server can handle any request that comes to it using local copies of the data. Because the servers are identical and the data is replicated to all the servers in the Web farm, the servers are also referred to as *clones*.

ExampleA Load Balanced Web Farm

In a load balanced Web farm with ten servers, you could have:

- Clone 1Web server using local data
- Clone 2Web server using local data
- Clone 3Web server using local data
- Clone 4Web server using local data
- Clone 5Web server using local data
- Clone 6Web server using local data
- Clone 7Web server using local data
- Clone 8Web server using local data
- Clone 9Web server using local data

- Clone 10Web server using local data

**Cluster Pack**
A pack is a group of servers that operate together and share partitioned data. They are called a pack because they work together to manage and maintain services. Because members of a pack share access to partitioned data, they have unique operations modes and usually access the shared data on disk drives to which all members of the pack are connected.

Example - A 4-node SQL Server Cluster Pack

An example of a pack is a database Server cluster running SQL Server 2000 and a server cluster with partitioned database views. Members of the pack share access to the data and have a unique chunk of data or logic that they handle, rather than handling all data requests.

In a 4-node SQL Server cluster:

- Database Server 1 may handle accounts that begin with A-F.
- Database Server 2 may handle accounts that begin with G-M.
- Database Server 3 may handle accounts that begin with N-S.
- Database Server 4 may handle accounts that begin with T-Z.

Combining Techniques A Large-Scale E-Commerce Site

Servers in a tier can be organized using a combination of the above techniques as well. An example of this combination is a large-scale e-commerce site that has middle-tier application servers running Application Center 2000 and CLB.

To configure CLB, two clusters are recommended:

- The Component Routing Cluster handles the message routing between the front-end Web servers and the application servers.
- The Application Server cluster activates and runs the components installed on the application servers.

While the Component Routing Cluster could be configured on the Web tier without needing additional servers, a large e-commerce site may want the high availability benefits of a separate cluster. In this case, the routing would take place on separate servers that are clustered using Server cluster. The application servers would then be clustered using CLB.

**Infrastructure Scaling**
With proper architecture, the servers in a particular tier can be scaled out or up as necessary to meet growing performance and throughput needs. Figure 2 below, provides an overview of the scalability of Windows clustering technologies.

**IT Staff Considerations**
As IT staff look at scalability requirements, they must always address the real business needs of the organization. The goal should be to select the right edition of the Windows operating system to meet the current and future needs of the project.

The number of servers needed depends on the anticipated server load, and the size and types of requests the servers will handle. Processors and memory should be sized appropriately for the applications and services the servers will be running, as well as the number of simultaneous user connections.

**Figure 2: Windows cluster technologies can be scaled to meet business requirements**

**Scaling by Adding Servers**

When looking to scale out by adding servers to the cluster, the clustering technology and the server operating system used are both important. As Table 1 below shows, the key difference in the outward scaling capabilities of Advanced Server and Datacenter Server is the number of nodes that can be used with Server cluster.

- Under Windows 2000, the maximum number of Server cluster nodes is four.
- Under Windows Server 2003, the maximum number of Server cluster nodes is eight.

**Table 1 Cluster Nodes Supported by Operating System and Technology.**

| Operating System | Edition | Network Load Balancing | Component Load Balancing | Server cluster |
|---|---|---|---|---|
| **Windows 2000** | | | | |
| | Advanced Server | 32 | 8 | 2 |
| | Datacenter Server | 32 | 8 | 4 |
| **Windows Server 2003** | | | | |
| | Enterprise Edition | 32 | 8 | 8 |
| | Datacenter Edition | 32 | 8 | 8 |

**Scaling by Adding CPUs and RAM**

When looking to scale up by adding CPUs and RAM, the edition of the server operating system used is extremely important.

In terms of both processor and memory capacity, Datacenter Server is much more expandable.

- Windows 2000 Advanced Server supports up to eight processors and eight gigabytes (GB) of RAM.
- Windows 2000 Datacenter Server supports up to 32 processors and 64 GB of RAM.
- Windows Server 2003 Enterprise Edition supports up to eight processors and 32 GB of RAM.
- Windows Server 2003 Datacenter Edition supports up to 32 processors and 64 GB of RAM.

Thus, organizations typically scale up from Advanced Server or Enterprise Edition to Datacenter Server or Datacenter Edition as their needs change over time.

**Cluster Operating Modes**
With NLB and CLB, cluster nodes usually are identical clones of each other. Because of this, all members of the cluster can actively handle requests, and they can do so independent of each other. When members of a cluster share access to data, however, they have unique operating requirements, as is the case with Server cluster.

**IT Staff Considerations**
As IT staff considers the impact of operating modes in their cluster architecture, they need to look carefully at the business requirements and the expected server loads.

With NLB and CLB, all servers are active and the architecture is scaled out by adding additional servers, which typically are configured identically to the existing NLB or CLB nodes.

With Server cluster, nodes can be either active or passive, and the configuration of nodes depends on the operating mode (active or passive), as well as how failover is configured. A server that is designated to handle failover must be sized to handle the workload of the failed and the current workload (if any). Additionally, both average and peak workloads must be considered. Severs need additional capacity to handle peak loads.

**Server cluster Nodes**
Server cluster nodes can be either active or passive.

- **Active Node**. When a node is active, it is actively handling requests.

- **Passive Node**. When a node is passive, it is idle, on standby waiting for another node to fail.

Multi-node clusters can be configured using different combinations of active and passive nodes.

**Architecting Multi-node Clusters**
When architecting multi-node clusters, the decision as to whether nodes are configured as active or passive is extremely important. To understand why, consider the following:

- **If an active node fails and there is a passive node available**, applications and services running on the failed node can be transferred to the passive node. Since the passive node has no current workload, the server should be able to assume the workload of the failed server without any problems (providing all servers have the same hardware configuration).

- **If all severs in a cluster are active and a node fails**, the applications and services running on the failed node can be transferred to another active node. Since the server is already active, the server will have to handle the processing load of both systems. The server must be sized to handle multiple workloads or it may fail as well.

**In a multi-node configuration where there is one passive node for each active node**, the servers could be configured so that under average workload they use about 50% of CPU and memory resources.

In the 4-node configuration depicted on Figure 3 below, where failover goes from one active node to a specific passive node, this could mean two active nodes (A1 and A2) and two passive nodes (P1 and P2)each with four processors and 4GB of RAM. In this example, node A1 fails over to node P1 and node A2 fails over to node P2 with the extra capacity used to handle peak workloads.

**Figure 3: Examples of Active/Passive and Active/Active configurations**

In a multi-node configuration where there are more active nodes than passive nodes, the servers can be configured so that under average workload they use a proportional percentage of CPU and memory resources.

In the 4-node configuration illustrated on Figure 3 above, where nodes A, B, C, and D are configured as active and failover could go to between nodes A and B or nodes C and D, this could mean configuring servers so that they use about 25% of CPU and memory resources under average workload. In this example, node A could fail over to B (and vice versa) or node C could fail over to D (and vice versa).

Because the servers in this example would need to handle two workloads in case of a node failure, the CPU and memory configuration would at least be doubled, so instead of using four processors and four GB of RAM, the servers may use eight processors and eight GB of RAM.

**Shared-Nothing Database Configuration**

When Server cluster has multiple active nodes, data must be shared between applications running on the clustered servers. In most cases, this is handled with a shared-nothing database configuration.

In a shared-nothing database configuration, the application is partitioned to access private database sections. This means that a particular node is configured with a specific view into the database that allows it to handle specific types of requests, such as account names that started with the letters A-F, and that it is the only node that can update the related section of the database. This eliminates the possibility of corruption from simultaneous writes by multiple nodes.

| **Note** |
| --- |
| Both Microsoft Exchange 2000 and Microsoft SQL Server 2000 support multiple active nodes and shared-nothing database configurations. |

**Multiple Sites and Geographically Dispersed Clusters**

Most organizations build disaster recovery and increased availability into their infrastructure using multiple physical sites. Multi-site architecture can be designed in many ways. In most cases, the architecture has a primary site and one or more remote sites. Figure 4 below shows an example of a primary site and a remote site for an e-commerce operation.

The architecture at the remote site mirrors that of the primary site. The level of integration for multiple sites and the level at which components are mirrored between sites, depends on the service-level agreement and the business requirements.

**Full Implementation Design**

With a full implementation, the complete infrastructure of the primary site could be recreated at remote sites. This allows for a remote site to operate independently, or to handle the full load of the primary site if necessary. In this case, the design should incorporate real-time replication and synchronization for databases and applications.

Real-time replication ensures a consistent state for data and application services between sites. If real-time updates are not possible, databases and applications should be replicated and synchronized as rapidly as possible.

**Figure 4: Multiple site architecture**

**Partial Implementation Design**

With a partial implementation only essential components are installed at remote sites to:

- Handle overflow in peak periods.
- Maintain uptime on a limited basis in case the primary site fails.
- Provide limited services as needed.

**Replicating static content on Web sites and read-only data from databases**. This partial implementation technique would allow remote sites to handle requests for static content and other types of data that is infrequently changed. Users could browse sites, access account information, product catalogs, and other services. If they needed to access dynamic content or modify information (add, change, delete, etc.), the sites geographical load balancers could redirect users to the primary site.

**Implement all layers of the infrastructure, but with fewer redundancies in the architecture**, or **implement only core components, relying on the primary site to provide the full array of features**. With either of these partial implementation techniques, the design may need to incorporate near real-time replication and synchronization for databases and applications. This ensures a consistent state for data and application services.

**Geographically Dispersed Clusters**

A full or partial design could also use geographically dispersed clusters running Server cluster. Geographically dispersed clusters use virtual LANs to connect storage area networks (SANs) over long distances.

- A VLAN connection with latency of 500 milliseconds or less ensures that cluster consistency can be maintained.
- If the VLAN latency is over 500 milliseconds, the cluster consistency cannot be easily maintained.

Geographically dispersed clusters are also referred to as stretched clusters and are available in Windows 2000 and Windows Server 2003.

**Majority Node Clustering**
Windows Server 2003 offers many improvements in the area of geographically dispersed clusters, including a new type of quorum resource called a majority node set. Majority node clustering changes the way the cluster quorum resource is used. This allows cluster servers to be geographically separated while maintaining consistency in the event of node failure.

With a standard cluster configuration, as illustrated on Figure 5 below, the quorum resource writes information about all cluster database changes to the recovery logs; this ensures that the cluster configuration and state data can be recovered. The quorum resource resides on the shared disk drives and can be used to verify whether other nodes in the cluster are functioning.

**Figure 5: Comparing local and geographically dispersed clusters**

With a majority node cluster configuration in Windows Server 2003, the quorum resource is configured as a majority node set resource. This new type of quorum resource allows the quorum data, which includes cluster configuration changes and state information, to be stored on the system disk of each node in the cluster. Because the data is localized, even though the cluster itself is geographically dispersed, the cluster can be maintained in a consistent state.

As the name implies, the majority of nodes must be available for this cluster configuration to operate normally. Should the cluster state become inconsistent, IT staff can force the quorum to get a consistent state. An algorithm also runs on the cluster nodes to help ensure the cluster state.

# Server cluster Architecture

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This section discusses Server cluster and how to configure it for failover support for applications and services. Resource groups, cluster storage devices, network configuration and storage area networks are also discussed.

**Server cluster**
Server cluster is used to provide failover support for applications and services. A Server cluster can consist of up to eight nodes. Each node is attached to one or more cluster storage devices. Cluster storage devices allow different servers to share the same data, and by reading this data provide failover for resources.

**Connecting Storage Devices**
The preferred technique for connecting storage devices is fibre channel.

- When using three or more nodes, fibre channel is the only technique that should be used.
- When using 2-node clustering with Advanced Server, SCSI or fibre channel can be used to connect to the storage devices.

**Configuring Server clusters**
Server clusters can be setup using many different configurations. Servers can be either active or passive, and different servers can be configured to take over the failed resources of another server. Failover can take several minutes, depending on the configuration and the application being used, but is designed to be transparent to the end-user.

**Server cluster and Failover**
When a node is active, it makes its resources available. Clients access these resources through dedicated virtual servers.

Server cluster uses the concept of virtual servers to specify groups of resources that failover together. When a server fails, the group of resources configured on that server for clustering fails over to another server. The server that handles the failover should be configured for the extra capacity needed to handle the additional workload. When the failed server comes back online, Server cluster can be configured to allow failback to the original server, or to allow the current server to continue to process requests.

**Figure 6: Multi-node clusters with all nodes active**

Figure 6 above shows a configuration where all nodes in a database cluster are active and each node has a separate resource group. With a partitioned view of the database, each resource group could handle different types of requests. The types of requests handled could be based on one or more factors, such as the name of an account or geographic location. In the event of a failure, each node is configured to fail over to the next node in turn.

**Resource Groups**
Resources that are related or dependent on each other are associated through resource groups. Only applications that need high availability should be part of a resource group. Other applications can run on a server cluster, but don't need to be a part

of a resource group. Before adding an application to a resource group, IT staff must determine if the application can work within the cluster environment.

**Cluster-Aware Applications**. Applications that can work within the cluster environment and support cluster events are called cluster-aware. Cluster-aware applications can register with the Server cluster to receive status and notification information.

**Cluster-Unaware Applications**. Applications that do not support cluster events are called cluster-unaware. Some cluster-unaware applications can be assigned to resource groups and can be failed over.

Applications that meet the following criteria can be assigned to resource groups.

- IP-based protocols are used for cluster communications. The application must use an IP-based protocol for their network communications. Applications cannot use NetBEUI, IPX, AppleTalk or other protocols to communicate.
- Nodes in the cluster access application data through shared storage devices. If the application is not able to store its data in a configurable location, the application data will not be available on failover.
- Client applications experience a temporary loss of network connectivity when failover occurs. If client applications cannot retry and recover from this, they will cease to function normally.

#### New Features for Resources and Resource Types

Windows Server 2003 adds new features for resources and resource types. A new resource type allows applications to be made cluster-aware using VBScript and JScript. Additionally, Windows Management Instrumentation (WMI) can be used for cluster management and event notification.

#### Architecting Resource Groups

When architecting resource groups, IT staff should list all server-based applications and services that will run in the cluster environment, regardless of whether they will need high availability. Afterward, divide the list into three sections:

- Those that need to be highly available
- Those that are not part of the cluster and on which clustered resources do not depend
- Those that are running on the cluster servers that do not support failover and on which the cluster may depend.

**Applications and services that need to be highly available should be placed into resource groups**. Other applications should be tracked, and their interactions with clustered applications and services should be clearly understood. Failure of an application or service that is not part of a resource group should not impact the core functions of the solution being offered. If it does, the application or service may need to be clustered.

| **Note** |
| --- |
| In the case of dependent services that do not support clustering, IT staff may want to provide backup planning in case these services fail, or may want to attempt to make the services cluster-aware using VBScript and JScript. Remember that only Windows Server 2003 supports this feature. |

**Focus on selecting the right hardware to meet the needs of the service offering**. A cluster model should be chosen to adequately support resource failover and the availability requirements. Based on the model chosen, excess capacity should be added to ensure that storage, processor and memory are available in the event a resource fails, and failover to a server substantially increases the workload.

**With a clustered SQL Server configuration, IT staff should consider using high-end CPUs, fast hard drives and additional memory**. SQL Server 2000 and standard services together use over 100 megabytes (MB) of memory as a baseline. User connections consume about 24 kilobytes (KB) each. While the minimum memory for query execution is one MB of RAM, the average query may require two to four MB of RAM. Other SQL Server processes use memory as well.

#### Optimizing Cluster Storage Devices

Cluster storage devices should be optimized based on performance and availability needs. While the Windows Datacenter Hardware Compatibility List provides a detailed list of acceptable Redundant Array of Independent Disks (RAID) configurations for clusters, Table 2 below provides an overview of common RAID configurations. The table entries are organized from the highest RAID level to the lowest.

**Table 2 RAID Configurations**

| RAID Level | RAID Type | RAID Description | Advantages & Disadvantages |
|---|---|---|---|
| 5+1 | Disk striping with parity + mirroring | Six or more volumes, each on a separate drive, are configured identically as a mirrored stripe set with parity error checking. | Provides very high level of fault tolerance but has a lot of overhead. |
| 5 | Disk striping with parity | Three or more volumes, each on a separate drive, are configured as a stripe set with parity error checking. In the case of failure, data can be recovered. | Fault tolerance with less overhead than mirroring. Better read performance than disk mirroring. |
| 1 | Disk mirroring | Two volumes on two drives are configured identically. Data is written to both drives. If one drive fails, there is no data loss because the other drive contains the data. (Does not include disk striping.) | Redundancy. Better write performance than disk striping with parity. |
| 0+1 | Disk striping with mirroring | Two or more volumes, each on a separate drive, are striped and mirrored. Data is written sequentially to drives that are identically configured. | Redundancy with good read/write performance. |
| 0 | Disk striping | Two or more volumes, each on a separate drive, are configured as a stripe set. Data is broken into blocks, called stripes, and then written sequentially to all drives in the stripe set. | Speed/Performance without data protection. |

**Optimizing Network Configuration**

The network configuration of the cluster can also be optimized. All nodes in a cluster must be a part of the same domain and can be configured as domain controllers or member servers. Ideally, multi-node clusters will have at least two nodes that act as domain controllers and provide failover for critical domain services. If this is not the case, the availability of cluster resources may be tied to the availability of the controllers in the domain.

**Private and Public Network Addresses**

Typically nodes in a cluster are configured with both private and public network addresses.

- Private network addresses are used for node-to-node communications.
- Public network addresses are used for client-to-cluster communications.

Some clusters may not need public network addresses and instead may be configured to use two private networks. In this case, the first private network is for node-to-node communications and the second private network is for communicating with other servers that are a part of the service offering.

**Storage Area Networks**

Increasingly, clustered servers and storage devices are connected over SANs. SANs use high-performance interconnections between secure servers and storage devices to deliver higher bandwidth and lower latency than comparable traditional networks. Windows 2000 Datacenter Server and Windows Server 2003 Datacenter Edition implement a feature called Winsock Direct that allows direct communication over a SAN using SAN providers.

**SAN providers have user-mode access to hardware transports**. When communicating directly at the hardware level, the individual transport endpoints can be mapped directly into the address space of application processes running in user mode. This allows applications to pass messaging requests directly to the SAN hardware interface, which eliminates unnecessary system calls and data copying.

**SANs typically use two transfer modes**. One mode is for small transfers, which primarily consist of transfer control information. For large transfers, SANs can use a bulk mode whereby data is transferred directly between the local system and the remote system by the SAN hardware interface without CPU involvement on the local or remote system. All bulk transfers are pre-arranged through an exchange of transfer control messages.

**Other SAN Benefits**

In addition to improved communication modes, SANs have other benefits.

- They allow IT staff to consolidate storage needs, using several highly reliable storage devices instead of many.

- They also allow IT staff to share storage with non-Windows operating systems, allowing for heterogeneous operating environments.

# Network Load Balancing Architecture

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This section discusses Network Load Balancing and its role in providing failover support for IP-based applications and services that require high scalability and availability.

**Network Load Balancing**
Network Load Balancing provides failover support for IP-based applications and services that require high scalability and availability. NLB allows IT staff to incrementally scale-out up to 32 servers as demand increases. NLB is ideally suited to improving the availability of Web servers, media servers, terminal servers and e-commerce sites. Load balancing these services ensures there is no single point of failure and that there is no performance bottleneck.

Many of the concepts that apply to Server cluster also apply to NLB. NLB nodes work together to provide availability for critical IP-based resources, which can include: TCP, UDP and GRE traffic requests.

| **Note** |
| --- |
| Support for GRE traffic is supported in Windows Server 2003 and not in Windows 2000. |

**Failover and Failback Using a Virtual IP Address**
As shown on Figure 7 below, NLB uses a virtual IP address. Client requests are directed to this virtual IP address which allows for transparent failover and failback. When a load balanced resource fails on one server, the remaining servers in the group take over the workload of the failed server. When the failed server comes back online, the server can automatically rejoin the cluster group and NLB starts to automatically distribute the load to the server. Failover takes less than 10 seconds in most cases.

**Figure 7: Network load balancing overview**

**No Clustered Storage Devices**
NLB does not use clustered storage devices. Each server runs a copy of the IP-based application or service that is being load balanced, and the data necessary for the application or service to run is stored on local drives.

**Directing Traffic to a Specific Server**
Although NLB is normally used to distribute the workload for an application or service, NLB can also be used to direct a specific type of traffic to a particular server. For example, IT staff may want to load balance HTTP and FTP traffic to a group of servers, but may also want a single server to handle media services traffic. In this latter case, NLB allows traffic to flow to a designated server and only reroutes traffic to another server in case of failure.

**No Hardware Changes Required**
NLB runs as a network driver and requires no hardware changes to install and run. Its operations are transparent to the IP networking stack. Because NLB is IP-based, IP networking must be installed on all load-balanced computers.

**NLB Network Adapters**
To provide high performance throughput and responsiveness, NLB normally uses two network adapters.

- Cluster adapterhandles network traffic for the cluster.
- Dedicated adapterhandles client-to-cluster network traffic, and other traffic originating outside the cluster network.

NLB uses unicast or multicast broadcasts to direct incoming traffic to all servers in the cluster. The NLB driver on each host acts as a filter between the cluster adapter and the TCP/IP stack, allowing only traffic bound for the designated host to be received. NLB only controls the flow of TCP, UDP and GRE traffic on specified ports. It does not control the flow of TCP, UDP and GRE traffic on non-specified ports, and it does not control the flow of other incoming IP traffic. All traffic that is not controlled is passed through without modification to the IP stack.

**Using a Single NLB Network Adapter**
NLB can work with a single network adapter. When it does so, there are limitations.

**Unicast mode**. With a single adapter in unicast mode, node-to-node communications are not possible, meaning nodes within the cluster cannot communicate with each other. Servers can, however, communicate with servers outside the cluster subnet.

**Multicast mode**. With a single adapter in multicast mode, node-to-node communications are possible, as are communications with servers outside the cluster subnet. However, the configuration is not optimal for handling moderate-to-heavy traffic from outside the cluster subnet to specific cluster hosts.

For handling node-to-node communications and moderate to heavy traffic, two adapters should be used.

**Optimizing NLB Servers**
As with Server cluster, servers that use NLB can benefit from optimization. Servers should be optimized for their role, the types of applications they will run and the anticipated local storage they will use.

While IT staff may want to build redundancy into the local hard drives on NLB servers, this adds to the expense of the server without significant availability gains in most instances. Because of this, NLB servers often have drives that do not use RAID and do not provide fault tolerance; the idea being that if a drive causes a server failure, other servers in the NLB cluster can quickly take over the workload of the failed server.

**Synchronizing Data**
If it seems odd to not use RAID, keep in mind that servers using NLB are organized as clones with identical copies of data on each server. Because many different servers have the same data, maintaining the data with RAID sets is not as important as it is with server clusters. A key consideration IT staff does have to make when using NLB, however, is data synchronization. The state of the data on each server must be maintained so that the clones are updated whenever changes are made. This need to synchronize data periodically is an overhead that needs to be considered when designing the server architecture.

# Component Load Balancing Architecture

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This section discusses CLB and its key structures. Also discussed are routing servers, designing and optimizing CLB clusters, and storage and memory requirements.

**Component Load Balancing**
Unlike Server cluster and NLB, which are built into the Advanced Server and Datacenter Server editions of the Windows operating system, CLB is a feature of Microsoft Application Center 2000. It is designed to provide high availability and scalability for transactional components. CLB is scalable up to eight servers and is ideally suited to building distributed solutions.

CLB makes use of the COM+ Services supplied as part of the Windows 2000 and Windows Server 2003 operating systems. COM+ Services provide:

- Enterprise functionality for transactions
- Object management
- Security
- Events
- Queuing

COM+ components use the Component Object Model (COM) and COM+ Services to specify their configuration and attributes. Groups of COM+ components that work together to handle common functions are referred to as COM+ applications.

**CLBKey Structures**
Figure 8 below provides an overview of CLB. CLB uses several key structures:

- **CLB Software** handles the load balancing and is responsible for determining the order in which cluster members activate components.
- The **router** handles message-routing between the front-end Web servers and the application servers. It can be implemented through component routing lists stored on front-end Web servers, or a component routing cluster configured on separate servers.
- **Application server clusters** activate and run COM+ components. The application Server cluster is managed by Application Center 2000.

**Figure 8: Component load balancing**

**Routing List**
The routing list, made available to the router, is used to track the response time of each application server from the Web servers. If the routing list is stored on individual Web servers, each server has its own routing list and uses this list to periodically check the response times of the application servers. If the routing list is stored on a separate routing cluster, the

routing cluster servers handle this task.

The goal of tracking the response time is to determine which application server has the fastest response time from a given Web server. The response times are tracked as an in-memory table, and are used in round robin fashion to determine which application server should be passed an incoming request. The application server with the fastest response time (and theoretically, the least busy and most able to handle a request) is given the next request. The next request goes to the application server with the next fastest time, and so on.

**Designing CLB Clusters**
The architecture of CLB clusters should be designed to meet the availability requirements of the service offering. With small-to-moderate sized implementations, the front-end Web servers can host the routing list for the application Server cluster. With larger implementations, dedicated routing clusters are desirable to ensure that high availability requirements can be met.

**Optimizing CLB Servers**
As with NLB, servers in CLB clusters should be optimized for their role, the types of applications they will run and the anticipated local storage they will use.

**High Speed Connections**
Routing servers maintain routing lists in memory and need high-speed connections to the network.

**Storage and Memory Requirements**
Whether configured separately or as part of the front-end, CLB does not require a lot of storage, but a limited amount of additional RAM may be required. Application servers on the other hand, typically need a lot of RAM, fast CPUs and limited redundancy in the drive array configuration. If redundant drive arrays are used, a basic configuration, such as RAID 1 or RAID 5, may be all that is needed to maintain the level of availability required.

# Summary (An Overview of Windows Clustering Technologies: Server Clusters and Network Load Balancing)

Updated: January 1, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Cluster technologies are becoming increasingly important to ensure service offerings meet the requirements of the enterprise. Windows 2000 and Windows Server 2003 support three cluster technologies to provide high availability, reliability and scalability. These technologies are: NLB, CLB and Server cluster. These technologies have a specific purpose and are designed to meet different requirements.

- **Server cluster** provides failover support for applications and services that require high availability, scalability and reliability, and is ideally suited for back-end applications and services, such as database servers. Server cluster can use various combinations of active and passive nodes to provide failover support for mission critical applications and services.

- **NLB** provides failover support for IP-based applications and services that require high scalability and availability, and is ideally suited for Web tier and front-end services. NLB clusters can use multiple adapters and different broadcast methods to assist in the load balancing of TCP, UDP and GRE traffic requests.

- **Component Load Balancing** provides dynamic load balancing of middle-tier application components that use COM+ and is ideally suited for application servers. CLB clusters use two clusters. The routing cluster can be configured as a routing list on the front-end Web servers or as separate servers that run Server cluster.

Cluster technologies by themselves are not enough to ensure that high availability goals can be met. Multiple physical locations may be necessary to guard against natural disasters and other events that may cause complete service outage. Effective processes and procedures, in addition to good architecture, are the keys to high availability.

# Introduction (Implementing and Administering Certificate Templates in Windows Server 2003)

Updated: August 13, 2009

Applies To: Windows Server 2003 with SP1

**Scope**

The scope of this white paper is to discuss the best practices in designing, administering, and implementing version 2 Certificate Templates using Windows Server 2003, Enterprise Edition and Enterprise Certification Authorities (CAs).

**Terms Used in this White Paper**

**Application Constraints** A constraint that limits what purposes a certificate can be used for in a qualified subordination configuration. A presented certificate must contain the required application constraint to be accepted by the partner organization.

**Authority Information Access (AIA)** A certificate extension that contains URL locations where the issuing CAs certificate can be retrieved. The AIA extension can contain HTTP, FTP, LDAP, or FILE URLs.

**Certificate Revocation List (CRL)** A digitally signed list issued by a CA that contains a list of certificates issued by the CA that have been revoked. The list includes the serial number of the certificate, the date that the certificate was revoked, and the revocation reason. Applications can perform CRL checking to determine a presented certificates revocation status; also referred to as a base CRL.

**CRL Distribution Point (CDP)** A certificate extension that indicates where the certificate revocation list for a CA can be retrieved. This extension can contain multiple HTTP, FTP, FILE, or LDAP URLs for the retrieval of the CRL.

**Delta Certificate Revocation List (delta CRL)** A type of CRL that contains the list of certificates revoked since the last base CRL was published. Delta CRLs are often used in environments where numerous certificates are revoked to optimize bandwidth utilization.

**Issuance Policy Constraints** A constraint that defines what issuance practices must be followed for certificates to be trusted by your organization. Issuance policy object identifiers in your organization are mapped to the matching object identifiers in a partner organization, so that object identifiers in presented certificates are recognized by your public key infrastructure (PKI).

**Name Constraints** A constraint that limits what names are permitted or excluded in certificate requests submitted to a CA.

**Online Certificate Status Protocol (OCSP)** A protocol that allows real-time validation of a certificates statusthe CryptoAPI makes a call to an OCSP responder and the OCSP responder provides an immediate validation of the revocation status for the presented certificate. Typically, the OCSP responder uses CRL checking for maintaining its status information.

**Public Key Infrastructure (PKI)** A PKI provides an organization with the ability to securely exchange data over a public network using public key cryptography, thus ensuring privacy by preventing the interception of communications. A PKI consists of Certification Authorities (CAs) that issue digital certificates, directories that store the certificates (including Active Directory in Windows 2000 and Windows Server 2003), and X.509 certificates that are issued to security entities on the network. The PKI provides validation of certificate-based credentials and ensures that the credentials are not revoked, corrupted, or modified.

**Security Principal** A user, security group, or computer account that can be assigned permissions in a Windows Server 2003 discretionary access control list (DACL).

**Subject Key Identifier (SKI)** A certificate extension included in CA certificates that contains a hash of the CA certificates public key. This hash is placed in the Authority Key Identifier (AKI) extension of all issued certificates to facilitate chain building.

# Certificate Template Overview

Updated: August 13, 2009

Applies To: Windows Server 2003 with SP1

Windows 2000 introduced the concept of using certificate templates to define the format and content of a certificate. Certificate templates are used by Windows 2000 Enterprise CAs to define what certificates can be issued by the Windows 2000 Enterprise CAs. Associated with the certificate template is a discretionary access control list (DACL) that defines which security principals have permissions to read, enroll, and configure the certificate template. Enterprise CAs are integrated into Active Directory. The certificate templates and the DACLs of the certificate template objects are defined in Active Directory with a forest-wide validity. If more than one Enterprise CA is running in the Windows forest, permission changes would have an impact on all Enterprise CAs.

The certificate templates used by Windows 2000 Enterprise CAs are known as version 1 certificate templates. Windows 2000 shipped with a number of predefined version 1 certificate templates, but modification of these default certificate templates is not allowed. The only modification that is enabled is the changing of permissions to allow enrollment of the certificate template. The version 1 certificate templates are created by default when an Enterprise CA is installed.

Windows Server 2003 extends certificate templates by introducing version 2 templates. Version 2 templates allow customization of most settings in the template. Several preconfigured version 2 templates are supplied in the default configuration and more can be added as necessary. This allows complete configuration flexibility for administrators. Alternatively, a version 1 certificate template can be duplicated, resulting in a version 2 certificate template that can be modified and secured separately.

| **Note** |
| --- |
| Similar to Windows 2000, Windows Server 2003 supports only version 1 templates. Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition support both version 1 and version 2 templates. Certificates based on version 2 templates can only be issued by an Enterprise CA running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition. |

When a certificate template is defined, the definition of the certificate template must be available to all CAs in the forest. This is accomplished by storing the certificate template information in the Configuration naming context (CN=Configuration,DC=*ForestRootName*). The replication of this information depends on the Active Directory replication schedule, and the certificate template may not be available at all CAs until replication is completed. This storage and replication is accomplished automatically by Windows Server 2003 family computers.

**Requirements**

To set up a Windows Server 2003 CA, the Active Directory schema must be upgraded to the Windows Server 2003 schema. You cannot install a Windows Server 2003 CA into a Windows 2000based schema.

The schema is updated to the Windows Server 2003 schema by running ADPREP /Forestprep at a Windows 2000 domain controller with the Windows Server 2003 CD-ROM in the CD-ROM drive.

**Upgrading from Version 1 to Version 2 Certificate Templates**

When you install Windows Server 2003 CA into a Windows Server 2003based Active Directory, the current certificate templates are updated during the upgrade process. The update modifies default settings for the Windows 2000 version 1 certificate templates that implement better security defaults. If a Windows Server 2003, Enterprise Edition CA is installed in addition several, version 2 certificate templates are created.

The upgrade process of an Enterprise CA must be performed by an account that is a member of the forest root Domain Admins group and the Enterprise Admins universal group. This is because the upgrade makes modifications to the Configuration naming context in Active Directory. Specifically, the account performing the upgrade must have the following permissions through group memberships (these are the default permissions):

- Full control permissions over the CN=Certificate Templates, CN=Public Key Services,CN=Services,CN=Configuration, DC=*ForestRootDomain*" container

- Full control permissions over the CN=OID,CN=Public Key Services,CN=Services,CN=Configuration, DC=*ForestRootDomain* container

- Full Control permissions for each certificate template object in the CN=Certificate Templates, CN=Public Key Services,CN=Services,CN=Configuration, DC=*ForestRootDomain*" container

| **Note** |
| --- |
| Delegation over the Certificate Templates container will have no effect on individual certificate templates. In other words, the ACL on certificate templates is not inherited from the ACL on the container. |

To upgrade the certificate templates, perform the following procedure after the upgrade for a Certification Authority to Windows Server 2003 or the installation of a new Windows Server 2003 CA on the network:

1. Upgrade to the Windows Server 2003 schema.

2. Log on as a user account that is a member of the forest root Domain Admins group and the Enterprise Admins group.

3. At a Windows Server 2003, Enterprise Edition CA (the CA can be running on Windows Server 2003, Windows Server 2003, Enterprise Edition, or Windows Server 2003, Datacenter Edition configured as a member-server or Domain Controller), run the Certificate Templates MMC console (certtmpl.msc).

   | **Note** |
   | --- |
   | Alternatively, the Certificate Templates MMC console can be run from a Windows XP Professional computer with the Windows Server 2003 Administration Pack (Adminpak.msi) installed. The same permissions apply as noted previously. |

4. When prompted to write new certificate templates, click OK.

To verify that the upgrade is successful, open the Certificate Templates MMC console and confirm that there are 29 certificate templates. The Version # of templates should all exist and be in the format of xxx.xxx, for example, 100.2. Version 1 certificate templates use a single digit for the primary version number, for example, the Administrator certificate template version number is 3.1. Version 2 certificate template primary version numbers are three digits in length. For example, the Key Recovery Certificate Template version number is 105.0.

| **Note** |
| --- |
| An upgrade of the certificate templates is performed run if a new Windows Server 2003 CA is installed in the forest. If a Windows 2000 CA is upgraded to Windows Server 2003, the template upgrade is not performed automatically and will only be performed when the certificate templates MMC snap-in is opened for the first time. You can still verify that the update has taken place, but the process is performed automatically. |

**Default Templates**

Once the upgrade to Windows Server 2003 certificate templates is completed, the following preconfigured certificate templates are listed in the Certificate Templates MMC console.

| **Name** | **Description** | **Key Usage** | **Subject Type** | **Published to AD** |
| --- | --- | --- | --- | --- |
| Administrator | Allows trust list signing and user authentication | Signature and encryption | User | Yes |
| Authenticated Session | Subject can authenticate to a Web server | Signature | User | No |
| Basic EFS | Used by Encrypting File System (EFS) to encrypt data | Encryption | User | Yes |
| CA Exchange | Used to store keys that are configured for private key archival | Encryption | Computer | No |

| | | | | |
|---|---|---|---|---|
| CEP Encryption | Allows the holder to act as a registration authority (RA) for simple certificate enrollment protocol (SCEP) requests | Encryption | Computer | No |
| Code Signing | Used to digitally sign software | Signature | User | No |
| Computer | Allows a computer to authenticate itself on the network | Signature and encryption | Computer | No |
| Cross-Certification Authority | Used in cross-certification and qualified subordination | Signature | CrossCA | Yes |
| Directory E-mail Replication | Used to replicate e-mail within Active Directory | Signature and encryption | DirEmailRep | Yes |
| Domain Controller | All-purpose certificates held by domain controllers | Signature and encryption | DirEmailRep | Yes |
| Domain Controller Authentication | Used to authenticate Active Directory computers and users | Signature and encryption | Computer | No |
| EFS Recovery Agent | Allows the subject to decrypt files previously encrypted with EFS | Encryption | User | No |
| Enrollment Agent | Used to request certificates on behalf of another subject | Signature | User | No |
| Enrollment Agent (Computer) | Used to request certificates on behalf of another computer subject | Signature | Computer | No |
| Exchange Enrollment Agent (Offline request) | Used to request certificates on behalf of another subject and supply the subject name in the request | Signature | User | No |
| Exchange Signature Only | Used by Microsoft Exchange Key Management Service to issue certificates to Exchange users for digitally signing e-mail | Signature | User | No |
| Exchange User | Used by Microsoft Exchange Key Management Service to issue certificates to Exchange users for encrypting e-mail | Encryption | User | Yes |
| IPSEC | Used by IP Security (IPSec) to digitally sign, encrypt, and decrypt network communication | Signature and encryption | Computer | No |
| IPSEC (Offline request) | Used by IP Security (IPSec) to digitally sign, encrypt, and decrypt network communication when the subject name is supplied in the request | Signature and encryption | Computer | No |
| Key Recovery Agent | This certificate can recover private keys archived on the certification authority. | Encryption | KRA | Yes |
| Root Certification Authority | Used to prove the identity of the root certification authority | Signature | CA | Yes |

| **Name** | **Description** | **Key Usage** | **Subject Type** | **Published to AD** | **Template Version** |
|---|---|---|---|---|---|
| Router (Offline request) | Used by a router when requested through SCEP from a CA that holds a CEP Encryption certificate | Signature and encryption | Computer | No | 3.1 |

| | | | | | |
|---|---|---|---|---|---|
| Smartcard Logon | Allows the holder to authenticate using a smart card | Signature and encryption | User | No | 5.1 |
| Smartcard User | Allows the holder to authenticate and protect e-mail using a smart card | Signature and encryption | User | Yes | 9.1 |
| Subordinate Certification Authority | Used to prove the identity of the root certification authority, issued by the parent or root certification authority | Signature | CA | Yes | 4.1 |
| Trust List Signing | The holder can digitally sign a trust list. | Signature | User | No | 2.1 |
| User | Certificate to be used by users for e-mail, EFS, and client authentication | Signature and encryption | User | Yes | 2.1 |
| User Signature Only | Allows users to digitally sign data | Signature | User | No | 3.1 |
| Web Server | Proves the identity of a Web server | Signature and encryption | Computer | No | 3.1 |

# Administering Version 1 Certificate Templates

Updated: August 13, 2009

Applies To: Windows Server 2003 with SP1

In Windows 2000, certificate management was very limited because only the templates security permissions could be set. This was done through advanced view of the Active Directory Sites and Services MMC snap-in.

With Windows Server 2003, certificate template management is done through the Certificate Templates MMC snap-in rather than through the Active Directory Sites and Services MMC snap-in.

# Administering Version 2 Certificate Templates

Updated: August 13, 2009

Applies To: Windows Server 2003 with SP1

Version 2 certificate templates allow you to define specific attributes for certificates that meet your organization's business needs. For example, certificate templates allow you to

- Define whether the private key associated with a certificate can be exported.
- Define whether the certificate request must be approved by a certificate manager, and define how many managers must approve a request before the certificate is issued.
- Define what cryptographic service providers (CSPs) are supported by a certificate template.
- Define issuance and application policy for issued certificates.

The following sections detail the specific information that can be configured for a version 2 certificate template using the Certificate Templates MMC console (certtmpl.msc). To create a new certificate template, you start by duplicating an existing certificate template that is similar in functionality to the required certificate template. Selecting the correct initial template is important so that the current certificate template settings will serve as a starting point for your certificate template configuration.

| **Note** |
| --- |
| Since certificate templates exist only once within a forest, all changes made apply on a forest-wide level. If several CAs exist within one forest, templates can be assigned to CAs via the publishing mechanism. Nevertheless, all CAs within a forest use one set of templates. |

**The General Tab**

The General tab (Figure 1) is the first tab that appears when you duplicate an existing certificate template.

**Figure 1: The General Tab**

On the General tab, you can configure the following attributes of the certificate template:

- **Template display name** The display name shown in the Certificate Templates console, Certificates console, and in the

Certification Authority console.

- **Template name** The name of the certificate template object created in the CN=Certificate Templates,CN=Public Key Services,CN=Services,DC=*ForestRootDomain* container.

| **Note** |
| --- |
| The template display name and template name attributes cannot be changed once the certificate template is created. |

- **Validity period** Defines the validity period for an issued certificate. The validity period must not be defined to be greater than the validity period of the CA's certificate. The minimum renewal period is 80% of the certificate lifetime or 6 weeks, whichever is greater.

- **Renewal period** The time before the validity period expires when the certificate will be renewed if re-enrollment is supported for the certificate template.

- **Publish options** You can choose whether to publish the certificate to Active Directory based on the certificate template. The certificates are published as an attribute of the security principal contained in the subject of the issued certificate.

- **Reenrollment option** If the certificate template is published to Active Directory, you can prevent re-enrollment if a valid certificate of the same certificate template exists for the security principal indicated in the subject.

| **Note** |
| --- |
| Re-enrollment settings mainly affect auto-enrollment design in a Windows Server 2003 network. See the Windows 2000 Certificate Autoenrollment in Windows XP white paper at http://www.microsoft.com/technet/prodtechnol/winxppro/maintain/certenrl.mspx |

**The Request Handling Tab**

The Request Handling tab (Figure 2) defines the purpose of the certificate template, the supported cryptographic service providers (CSPs), minimum key length, exportability, auto-enrollment settings, and whether strong private key protection should be required.

**Figure 2: The Request Handling Tab**

**Certificate Purposes**

The certificate purpose defines the intended primary use of the certificate. The certificate purpose can be one of four settings:

- **Encryption** A certificate with this purpose will contain cryptographic keys for encryption and decryption.
- **Signature** A certificate with this purpose will contain cryptographic keys for signing data only.
- **Signature and encryption** A certificate with this purpose covers all primary uses of a certificate's cryptographic key, including encryption of data, decryption of data, initial logon, or digitally signing data.
- **Signature and smartcard logon** A certificate with this purpose allows for initial logon with a smart card, and to digitally sign data; it cannot be used for data encryption.

| **Note** |
| --- |
| The certificate purpose setting will determine whether key archival can be enabled for a certificate template. Key archival is only possible if the certificate purpose is set to Encryption or Signature and encryption. The recovery of a private key for digitally signing information may result in identity theft and is not supported. Key archival is not supported by most smart card CSPs. |

**Archive Settings**

When subjects lose their private keys due to user profile corruption or stolen computers, any information that was persistently encrypted with the corresponding public key is inaccessible. To help avoid this, Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition have the ability to archive a subject's keys in its database when certificates are issued. These keys are encrypted and stored by the CA. If subjects lose their keys, the information can be retrieved from the database and securely provided to the subjects. This allows the encrypted information to be recovered instead of lost.

The following Key Archival settings are defined in the Request Handling tab:

- **Archive subject's encryption private key** If the issuing Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition certification authority is configured for key archival, the subject's private key will be archived.
- **Allow private key to be exported** When this option is specified, the subjects private key can be exported for backup or transportation.
- **Deleting revoked or expired certificates (do not archive)** If a certificate is renewed due to expiration or revocation, the previously issued certificate is removed from the subject's certificate store. By default, the certificate is archived.
- **Include symmetric algorithms allowed by the subject** When the subject requests the certificate, they can supply a list of supported symmetric algorithms. This option allows the issuing certification authority to include those algorithms in the certificate, even if they are not recognized or supported by that server. The algorithms are used by applications like secure e-mail.

To enable key archival and recovery, the following configuration settings in the certificate template and at the Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition CA must be made:

- The specific certificate template must be configured to allow key archival.
- One or more key recovery agents must be identified on the certification authority and key recovery agent certificates must be issued to those agents.
- Key archival must be configured on the certification authority.

**User Input Settings**

The Request Handling tab also allows several user input settings to be defined for a certificate template. These settings include:

- **Enroll subject without requiring any user input** This option allows auto-enrollment without any user interaction and is the default setting for both machine and user certificates. This option must not be enabled for machine certificates.

- **Prompt the user during enrollment** Although useful when testing initial auto-enrollment deployments, typically, this option is disabled. By disabling this option, users do not have to provide any input for the installation of a certificate based on the certificate template.

- **Prompt the user during enrollment and require user input when the private key is used** This option enables the user to set a strong private key protection password on the users private key when the key is generated and requires the user to use it whenever the certificate and private key are used. This option must not be enabled for machine certificates or smart card user certificates.

| **Note** |
| --- |
| To enable smart card auto-enrollment, the **Prompt the user during enrollment** option must be enabled so that the user is prompted to insert the smart card in the smart card reader when required. |

| **Important** |
| --- |
| Strong private key protection with auto-enrollment is not supported or enabled for machine certificates and is only available on Windows XP Service Pack 1 client computers. |

In addition, with Windows 2000 Service Pack 4 and Windows XP Service Pack 1, it is possible to force strong private key protection for all CSPs through the registry. Three new keys can be added to "HKLM\Software\Policies\Microsoft\Cryptography" in the registry:

**ForceKeyProtection** This key will force DPAPI to grey-out the option that would allow the user the choice of using a password when UI was selected. When set, the user MUST enter a password.

<**"0"**> = do not force UI on key protection
<**"1"**> = default to UI, but let user change selection
<**"2"**> = force UI on key protection, grey-out option for user

**CachePrivateKeys** Contains a 1, if (and only if) the following registry key is used:

**PrivateKeyLifetimeSeconds** Contains the number of seconds that a key will remain cached without being used. The key cache timer will be reset on every successful use in the CSP.

| **Caution** |
| --- |
| Requiring the use of strong private key protection and user prompting on all new and imported keys will disable some applications, such as EFS and wireless (802.1x authentication) which cannot display UI. For more information, refer to the following Knowledge Base Article: http://support.microsoft.com/default.aspx?scid=kb;en-us;320828 |

#### Other Request Handling Settings

In addition to key archival settings, some general options that affect all certificates, including those that do not enable key archival, can be defined. These include

- **Minimum key size** This specifies the minimum size, in bits, of the key that will be generated for this certificate.

- **Cryptographic service providers** This is a list of cryptographic service providers (CSPs) that will be used to enroll certificates for the given template. Selecting one or more CSPs configures the certificate to only work with those CSPs. If you do not select a specific CSP, the certificate enrollment will work with any installed CSP, but will use the first CSP from the enumeration list. The CSP must be installed on the client workstation for the CSP to be used during enrollment. If a specific CSP is chosen and not available on a client computer, enrollment will fail.

| **Note** |
| --- |
| You can add third-party CSPs by installing the manufacturers CSP-related files. The newly installed CSP will appear in the list of available CSPs when the certificate templates snap-in is opened after CSP installation. |

**The Subject Name Tab**

When establishing a certificate template, the subject name must be defined. This is included in the issued certificate template and must uniquely identify the subject. The subject name can either be built automatically during the certificate request using the authentication name of the subject, or explicitly defined by the subject and included in the certificate request (Figure 3).

**Figure 3: The Subject Name Tab**

A number of options can be included with the subject name, as well as specific configuration settings for the subject name when the subject name is built from Active Directory information during the certificate request process. The format of the subject name can be defined as

- **None** Does not enforce any name format for this field.
- **Common name** The certification authority creates the subject name from the common name (CN) of the requestor obtained from Active Directory. These should be unique within a domain, but may not be unique within an enterprise.
- **Fully distinguished name** The certification authority creates the subject name from the fully distinguished name

obtained from Active Directory. This guarantees that the name is unique within an enterprise.

In addition, you can choose to include the e-mail name in the subject name. This information is populated from the E-mail attribute of an account, and is included with either the common name or fully distinguished name as part of the subject name.

In addition to the subject name, you can also choose what name formats are included in the alternate subject name attributes of issued certificates. The alternate subject name formats that are available include

- **E-mail name** If the e-mail name field is populated in the Active Directory user object, that e-mail name will be used for user accounts.

| **Note** |
| --- |
| The e-mail name is required for user certificates. If the e-mail name is not populated for a user in Active Directory, the certificate request by that user will fail. |

- **DNS name** The fully qualified domain name (FQDN) of the subject that requested the certificate is used for computer accounts.

- **User principal name (UPN)** The user principal name is part of the Active Directory user object and will be used for user accounts.

- **Service principal name (SPN)** The service principal name is part of the Active Directory computer object and will be used for computer accounts.

If the Subject Name option is set to **Supply in the request**, you should set one or more Issuance Requirements for the template to prevent subjects from requesting certificates using any subject name. This would allow subjects to impersonate other subjects easily. Issuance requirements ensure that the certificate request is inspected and validated before the certificate is issued.

The only case in which a subject can request a certificate with a different subject name is when the request holds a certificate based on the Enrollment Agent template. The Enrollment Agent template allows a subject to request a certificate on behalf of another subject.

| **Note** |
| --- |
| No user interface exists on the client to supply a subject name in the certificate request. If you require the ability to provide the subject name, you must perform the certificate request programmatically using the XEnroll.dll ActiveX control. |

**The Issuance Requirements Tab**

The Issuance Requirements tab (Figure 4) allows higher assurance level certificates to be placed in a pending state until the certificate is reviewed before issuance. This allows for multiple signers of a CMC request to exist. For more information about CMC, see RFC 2797 Certificate Management Messages over CMS.

**Figure 4: The Issuance Requirements Tab**

When CA certificate manager approval is enabled, the certificate is placed into a pending state, rather than being issued immediately. In its pending state, the certificate request can be reviewed by certificate managers, ensuring a higher level of assurance for the issued certificate.

The following settings configure the authentication and signature requirements for issuance certificates that are based on a template:

- **CA certificate manager approval** All certificates are placed into the pending container for a certificate manager to issue or deny. Any defined certificate manager can issue or deny a certificate request of this type.

- **This number of authorized signatures** This setting requires the CMC certificate request to be digitally signed by one or more authorized parties before it can be issued.

| **Note** |
| --- |
| Defining the number of authorized signatures enables several other configuration parameters. |

- **Policy type required in signature** This option is only enabled when the number of authorized signatures value is set. This option defines which specific application policy, issuance policy, or both are required in the signing certificate. This is how the certification authority determines whether the signature is appropriate for authorizing the issuance of the subject's certificate.

- **Application policy** This option specifies the application policy that must be included in the signing certificate used to sign the certificate request. It is enabled when Policy type required in signature is set to either Application policy or both application and issuance policy.

- **Issuance policy** This option specifies the issuance policy that must be included in the signing certificate used to sign the certificate request. This option is enabled when Policy type required in signature is set to either Issuance policy or both application and issuance policy.

An example of where issuance requirements are defined is for the issuance of Cross-Certification Authority certificates. This certificate template requires that the signing certificate includes the Qualified Subordination Application Policy object identifier as shown in Figure 5.

**Figure 5: Issuance Requirements for a Cross-Certification Authority Certificate**

As you can see, the Cross-Certification Authority certificate request must be signed by a certificate containing the Qualified Subordination object identifier.

In addition, you can also determine whether the same issuance requirements are upheld for certificate renewal, or if the existence of a valid existing certificate of the same template in the certificate store meets the minimum requirements for certificate issuance.

| **Note** |
| --- |
| For information about including application and issuance policy object identifiers in an issued certificate, see The Extensions Tab section. |

**The Superseded Templates Tab**

The Superseded Templates tab (Figure 6) allows you to supersede existing certificate templates with a modified version 2 certificate template.

**Figure 6: The Superseded Templates Tab**

The Superseded Templates tab allows you to redeploy version 2 certificates and ensure that the updated certificates replace previous versions of the certificate or other certificate templates that were used for the same purposes. You can supersede

- A version 1 certificate template with a version 2 certificate template
- A version 2 certificate template with a version 2 certificate template
- Multiple existing certificate templates with a common version 2 certificate template

| **Note** |
| --- |
| You can force the application of the updated certificate template by forcing all certificate holders to re-enroll the updated certificate template. For more information, see the Re-Enroll Certificate Holders section. |

**The Extensions Tab**

The Extensions tab (Figure 7) allows you to define specific application policies, issuance policies, certificate subject types, and key usage attributes for a certificate template. The following sections detail the specifics on each form of extension defined in a certificate template.

**Figure 7: The Extensions Tab**

**Application Policies**

Application policies enable you to decide which certificates can be used for certain purposes. You can issue certificates widely without being concerned that they are misused for an unintended purpose.

Application policies are settings that inform a target that the subject holds a certificate that can be used to perform a specific task. They are represented in a certificate by an object identifier that is defined for a given application. This object identifier is included in the issued certificate. When a subject presents its certificate, it can be examined by the relying party to verify the application policy and determine if it can perform the requested action.

| **Note** |
| --- |
| Application policies are similar to the *extended key usage* attribute in version 1 certificate templates. Because some implementations of PKI applications may not understand application policies, both application policies and enhanced key usage sections appear in certificates issued by a Microsoft CA. |

The following table shows some of the more commonly used application policies and their related object identifiers.

| Application Policy | Object Identifier |
| --- | --- |
| Client Authentication | 1.3.6.1.5.5.7.3.2 |
| CA Encryption Certificate | 1.3.6.1.4.1.311.21.5 |
| Smart Card Logon | 1.3.6.1.4.1.311.20.2.2 |
| Document Signing | 1.3.6.1.4.1.311.10.3.12 |
| File Recovery | 1.3.6.1.4.1.311.10.3.4.1 |
| Key Recovery | 1.3.6.1.4.1.311.10.3.11 |
| Microsoft Trust List Signing | 1.3.6.1.4.1.311.10.3.1 |
| Qualified Subordination | 1.3.6.1.4.1.311.10.3.10 |
| Root List Signer | 1.3.6.1.4.1.311.10.3.9 |

**Certificate Policies**

Certificate policies, also referred to as issuance policies, define the level of assurance for an issued certificate. A CA processes

each certificate request by a defined set of rules. The certification authority may issue some certificates with no proof of identification and require subjects of another type to submit some proof. This provides different levels of assurance for different certificates. These levels of assurance are represented in certificates as issuance policies.

| **Note** |
| --- |
| Certificate policies refer to the certificate policies extension identifier described in RFC 2459. |

An issuance policy is a group of administrative rules that are implemented when issuing certificates. They are represented in a certificate by an object identifier that is defined at the certification authority. This object identifier is included in the issued certificate. When a subject presents its certificate, it can be examined by the target to verify the issuance policy and determine if that level of issuance policy is sufficient to perform the requested action.

An issuance policy describes the conditions under which a certificate is issued. This provides a level of assurance that the subject's certificate request was verified in a specific way.

One or more issuance policies may be selected for a certificate template. Because these issuance policies are simply text labels with an associated object identifier, no options are associated with them. The only special issuance policy is **All issuance policies**, which indicates that this policy includes all others. This is normally reserved for certificates held by certification authorities.

Issuance policies are often used when configuring Qualified Subordination (cross-certification) between PKI hierarchies to ensure that certificates recognized by another organization's PKI meet issuance requirements required by your organization.

**Certificate Template Information**
The certificate template information, also referred to as the Certificate subject type, defines the purpose of a certificate template. Six subject types are recognized by Windows Server 2003 CAs:

- Key recovery agent
- Directory e-mail replication
- Cross-certified certification authority
- Certification authority (CA)
- Computer
- User

The certificate template information extension cannot be edited. If you require a specific subject type to be applied to a certificate, you should clone from a certificate template that includes the required subject type. Some of the internal flags that are defined for specific subject types limit the display of the certificate template to computers or users. Choosing to clone an incorrect certificate template will prevent the certificate template from being displayed to the desired enrollment audience. For example, a computer certificate template cannot be enrolled for use by a user account.

**Key Usage**
A certificate enables the subject to perform a specific task. To help control the usage of a certificate outside its intended purpose, restrictions are automatically placed on certificates. Key usage is a restriction method and determines what a certificate can be used for. This allows the administrator to issue certificates that can only be used for specific tasks or certificates that can be used for a broad range of functions. If no key usage is specified, the certificate can be used for any purpose.

For signatures, key usage can be limited to one or more of the following purposes:

- Digital signature
- Signature is a proof of origin (nonrepudiation)
- Certificate signing

- CRL signing

For encryption key usage, the following options are available:

- Key exchange without key encryption

- Key exchange only with key encryption

**The Security Tab**
The Security tab (Figure 8) allows you to define the DACL for a specific certificate template. The permissions that you assign to the certificate template define which security principals can read, modify, enroll, or auto-enroll for a specific certificate template.

**Figure 8: The Security Tab**

The permissions that you can assign to a certificate template include

- **Full Control** This permission allows a security principal to modify all attributes of a certificate template, including the permissions for the certificate template.

- **Read** This permission allows a security principal to see the certificate template when enrolling for certificates. It is required for a security principal to enroll or auto-enroll a certificate; it is required by the certificate server to find the certificate templates in Active Directory.

- **Write** This permission allows a security principal to modify the attributes of a certificate template, including the permissions assigned to the certificate template.

- **Enroll** This permission allows a security principal to enroll for a certificate based on the certificate template. To enroll for a certificate, the security principal must also have Read permissions for the certificate template.

- **Autoenroll** This permission allows a security principal to receive a certificate through the auto-enrollment process. Auto-enrollment permissions require that the user has both Read and Enroll permissions in addition to the Auto-enroll permission.

**Note**

It is recommended that certificate template permissions be assigned only to global groups or universal groups. Because the certificate template objects are stored in the Configuration naming context, you cannot assign permissions using domain local groups. To simplify administration, it is never recommended to assign certificate template permissions to individual user or computer accounts.

It should be considered a best practice to keep Read permission assignment for the Authenticated Users group. This permission assignment allows all users and computers to view the certificate templates in Active Directory. This includes the CA running under the SYSTEM context of a machine account to view the certificate templates when issuing certificates to users and computers.

**Note**

A version 2 certificate template can be distributed to Windows Millennium Edition and Windows 2000 with Service Pack 2 clients through the Web enrollment pages.

# Deploying Certificate Templates (Implementing and Administering Certificate Templates in Windows Server 2003)

Updated: August 13, 2009

Applies To: Windows Server 2003 with SP1

After creating a version 2 certificate template, the next step is to deploy the certificate template. Deployment includes publishing the certificate template at one or more Certification Authorities, defining which security principals have Enroll permissions for the certificate template, and deciding whether to configure auto-enrollment for the certificate template.

**Publishing Certificate Templates**

Once a certificate template is created in the Certificate Templates MMC and the certificate template has replicated to all domain controllers in the forest, it can now be published for deployment. The main decision in publishing certificate templates is deciding which Certification Authority or Authorities will issue the certificates based on this certificate template.

| **Note** |
| --- |
| Remember that version 2 certificate templates can only be issued by Enterprise CAs running on Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition. |

An Enterprise CA can only issue certificates based on certificate templates that exist in the Certificate Templates container in the Certification Authority MMC console (Figure 9).

**Figure 9: Defining the Certificate Templates Published at the EntCA Certification Authority**

**Permission Design**

Certificate templates are published to the configuration naming context, which is stored on every domain controller in the forest in the path CN=Certificate Templates, CN=Public Key Services,CN=Services,CN=Configuration,DC=*ForestRootDomain*. Each certificate template exists as an object in the configuration naming context and has an associated DACL, which defines what specific operations a security principal can do with the certificate.

Use the following recommendations for permissions assignments:

- Assign permissions only to global groups or to universal groups. Certificate templates are defined in the configuration naming context. Permissions should only be assigned to global groups or to universal groups. It is not recommended to assign permissions to domain local groups. They are only recognized in the domain where the domain local group exists and can result in inconsistent application of permissions. It is recommended to never assign permissions directly to an individual user or computer account.

- To enable auto-enrollment, a user or computer must belong to domain groups that are granted Read, Enroll, and Autoenroll permissions.

- To enable enrollment via the Certificates MMC console, through Web-based enrollment, or through auto-renewal, set either domain or universal groups with **Read** and **Enroll** permissions.

- For certificate renewal, a user or computer must belong to a domain security group with Read and Enroll permissions. This is true whether the certificate is manually renewed or the renewal is implemented using auto-enrollment.

- Restrict Write and Full Control permissions to CA managers to ensure that the templates are not improperly configured.

**Auto-Enrollment Considerations**

Auto-enrollment allows a CA administrator to configure users and computers to automatically enroll for certificates, retrieve issued certificates, and renew expiring certificates without requiring subject interaction. The auto-enrollment process can be configured to function as a background task that does not require any user input.

To properly configure subject auto-enrollment, the administrator must plan the configuration of the certificate template that will use auto-enrollment. Several settings in the certificate template directly affect the behavior of subject auto-enrollment, as follows:

- **User input requirements** On the Request Handling tab (Figure 2) of the desired certificate template, the Require user input for auto-enrollment check box changes the behavior of auto-enrollment. When this check box is selected, subjects are prompted for any necessary information for obtaining or renewing a certificate. When this check box is cleared, auto-enrollment operates silently, without any notice to the subject.

| **Note** |
| --- |
| Because smart cards must prompt the user for their PIN, this option must be selected when a smart card CSP is selected. |

- **Limit the number of CSPs for an auto-enrollment certificate template** If more than one smart card CSP is selected on the Request Handling tab (Figure 2), users may receive more than one dialog box when a Windows XP client retrieves the auto-enrolled certificate and begins to install it on the smart card. It is recommended that only one CSP be selected from this list for each template.

- **Do not enable subject creation based on request information** If the Supply in the request option is enabled on the Subject Name tab (Figure 3), auto-enrollment is disabled. This is because enabling the option prompts the subject to interactively create the subject name in the request, which will not work with auto-enrollment.

- **Do not require more than one authorized signature for issuance** Configuring more than one authorized signature in the Issuance Requirements tab (Figure 4) of the desired certificate template disables subject auto-enrollment based on this template. If the authorized signatures value is set to one, the requestor must sign the request with a private key from a valid certificate in their certificate store. This certificate must contain the application and/or issuance policies specified in the Application policy and Issuance policies lists on the same tab. If an appropriate certificate exists in the requestor's certificate store, auto-enrollment signs the request with this certificate's private key and will obtain and install the requested certificate automatically. For example, to increase the security for EFS certificate distribution, you can create a custom version 2 certificate template that requires the existence of the Smart Card Logon OID (1.3.6.1.4.1.311.20.2.2) in the signing certificate's Application policy.

- On the Issuance Requirements tab (Figure 4) of the desired certificate template, the Valid existing certificate option may affect subject auto-enrollment. This option tells the CA that the subject does not need to meet issuance requirements when renewing a valid certificate. Subjects who may have been unable to auto-enroll for the initial certificate may be able to use auto-enrollment to renew that certificate. For example, a user whose distinguished name has changed may still auto-enroll a certificate based on an existing valid certificate, rather than on their new credentials.

| **Note** |
| --- |
| For more information about configuring auto-enrollment, see the Certificate Autoenrollment in Windows XP white paper at http://www.microsoft.com/technet/prodtechnol/winxppro/maintain/certenrl.mspx |

**Delegating Template Management**

You can delegate the ability to manage individual certificate templates or to create any certificate templates by defining appropriate permissions to global groups or universal groups that a user belongs to.

To delegate modification of a specific certificate template, assign a global or universal group the Read and Write permissions on the Security tab (Figure 8) of the certificate template. If you also wish to delegate administration permissions to the security groups, assign Full Control permissions so that the security group can modify the DACL for the certificate template.

To delegate the ability to create certificate templates to users who are not members of the Domain Admins group in the forest root domain, or members of the Enterprise Admins group, it is necessary to define the appropriate permissions in the Configuration naming context of the Active Directory.

To delegate the administration of all certificate templates, including the ability to duplicate and create new certificate temples, you must make the following permission assignments to a global or universal group that the user is a member of:

- CN=Certificate Templates,CN=Public Key Services,CN=Services,CN=Configuration,DC=*ForestRoot* container = Full Control permissions

- Full Control permissions to every certificate template in the CN=Certificate Templates,CN=Public Key Services,CN=Services,CN=Configuration,DC=*ForestRoot* container. The permissions assigned to the Certificate Templates container are not inherited by the individual Certificate Templates.

- Full control permissions to the CN=OID,CN=Public Key Services,CN=Services,CN=Configuration,DC= *ForestRoot* container.

| **Note** |
| --- |
| To create or duplicate existing certificate templates, users only need the Create Child permission for the CN= Certificate Templates,CN=Public Key Services,CN=Services,CN=Configuration,DC=*ForestRoot* and CN=OID, CN=Public Key Services,CN=Services,CN=Configuration,DC= *ForestRoot* containers. |

# Planning Considerations

Updated: August 13, 2009

Applies To: Windows Server 2003 with SP1

This section looks at the topics that must be considered when planning all aspects of version 2 certificate templates. The section provides design guidelines for the creation of certificate templates and best practices to implement when working with certificate templates.

**Design Guidelines**

When creating a version 2 certificate template, consider the following design guidelines:

- **Defining the subject name** The holder of the private key associated with a certificate is known as the *subject*. This can be a user, a computer, a program, or virtually any object or service. Because the subject can vary greatly depending on who or what it is, you need some flexibility when providing the subject name in the certificate request. A Windows Server 2003 CA can either build the subject name automatically or request it from the subject. If it automatically provides the subject name, it obtains the information from Active Directory. You can configure this process to include or exclude information that is useful in the environment. If it is configured to manually provide the subject name, the subject supplies that information in the certificate request using the Web-based enrollment pages.

- **Defining the certificate lifetime** Certificate-based cryptography uses public-key cryptography to protect and digitally sign data. Over time, it is theoretically possible to collect data protected with the public key and attempt to derive the private key from it. Given enough time and resources, this private key could be compromised, effectively rendering all protected data unprotected. Because certificates can be compromised over time, a finite certificate lifetime should be established.

- **Determining certificate usage** It is possible to issue many specific certificates that can only be used for a single purpose or to issue fewer certificates that have broad usage. This decision depends on the environment, the level of administration desired, and the possible effects on the subjects, as well as the effects of multiple certificates on applications that will use them.

  One strategy of certificate administration creates a number of specific templates one for each job function, such as file encryption or code signing. Subjects can then enroll for each certificate as needed for the appropriate function. This allows subjects to start with few certificates and only obtain new certificates that they need over time. The drawback to this strategy is that the subject may end up with a large number of certificates and private keys that become harder to manage over time.

  Alternatively, you could create a few broad certificate templates that encompass job functions for most common groups of subjects. For example, if most employees use their certificates for mail signing and encryption as well as file encryption, create one template that allows all those functions in the same certificate. This allows most subjects to obtain a single, all-purpose certificate. The drawback to this strategy is that there is no detailed control of the usage of the certificates. The administrator cannot decide that subgroups cannot encrypt mail without modifying the template or changing the strategy.

- **Determining which CSP to implement** A version 2 certificate template allows you to define one or more cryptographic service providers (CSPs) as usable by a template. This allows the administrator to control what types of cryptography subjects can use within an enterprise. This is very useful when security is of paramount importance. Because subjects use the CSP for both portions of any cryptographic serviceeither encryption and decryption or signing and confirming signatureit is necessary to ensure that all subjects can use the same CSP. The easiest way to do this is to configure each certificate template to identify exactly one CSP. Which CSP should be identified is up to the administrator and depends on the level of security required, the intended purposes of the certificate, and the presence of security hardware, such as smart cards.

- **Determining key length** Each CSP provides one or more cryptographic algorithms for encryption or digital signature. You can define a minimum key size allowed for a certificate template. In general, larger keys provide more protection over shorter keys for the same algorithm, but larger keys take longer to generate and use. You should select a minimum key size that ensures the necessary amount of protection without affecting performance.

- **Determining smart card usage** Each type of smart card has at least one associated CSP that must be implemented by the certificate template to allow the smart card to be used. If the correct smart card CSP is not associated with the template, the smart card will not be recognized and the template will fail. Ensure that you enable all smart card CSPs for the smart cards deployed in your environment within the certificate template.

- **Planning deployment methods** Certificates are typically deployed manually or automatically. Manual enrollment can take place using either the Web enrollment pages, the Certificates MMC console, or through CryptoAPI or CAPICOM programming interfaces. Auto-enrollment requires the configuration described in the Auto-Enrollment Considerations section.

- **Planning Key Archival** Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition CAs can provide key archival of private keys. When planning key archival settings for a certificate template, consider the following settings:

    - **Enabling archival of the subject's private key** This option is only available when the issuing CA is running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition, and the CA is configured for key archival.

    - **Define whether the private key can be exported** If this option is enabled, the subject can export the private key for backup purposes or move the private key and certificate to another computer. If key archival is centralized, you may not want to enable this option because it allows the key to be recovered in a decentralized manner.

**Best Practices**

When planning certificate template deployment, use the following best practices:

- Do not delete the Certificate Publishers security group.

  The Certificate Publishers security group contains each certification authority's computer account and is used when publishing certificate templates to Active Directory. If this group is removed, the certification authority may not publish certificates to Active Directory correctly. To avoid this, the group should not be deleted and its membership should not be modified.

- Add the CA machine accounts to every Cert Publishers group.

  The Cert Publishers group is a domain local group that exists in every domain in the forest. In each domain, all CA computer accounts should be added to the Cert Publishers group.

- Do not exceed the certificate lifetime of the issuing certification authority.

  Certificate lifetimes work as a subset of the certification authority's (CA) certificate lifetime. All certificates, including the CA certificate, have an expiration date after which they are no longer valid. As a result, a certificate cannot be issued with a lifetime that exceeds the lifetime of the issuing CA. Issuing such a certificate would allow it to be valid for longer than the issuing CA certificate, which violates certificate chaining rules. A CA will therefore continue to issue certificates until the CA's certificate expires or until the requested template's renewal period is greater than the CA's certificate remaining lifetime. If a certificate template requires a lifetime greater than the lifetime of the CA certificate, the validity period of the issued certificate is truncated to the amount of time left in the lifetime of the CA certificate.

- Plan certificate templates before deployment.

  Certificates can be issued to subjects in many ways, including manual enrollment, auto-enrollment, and Web enrollment. In addition, there are many certificate strategies including issuing one all-inclusive certificate to all subjects and issuing several application-specific certificates to subjects as needed. Because there are so many options, planning should be done well in advance of certificate deployment.

- Upgrade the certificate templates in Active Directory before upgrading from Windows 2000.

  Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition certification authorities use

newer versions of certificate templates than those used by Windows 2000 CAs. These templates must be upgraded before the certification authorities are upgraded to ensure proper operation.

- Duplicate new templates from existing templates closest in function to the intended template.

  New certificate templates are duplicated from existing templates. Many settings are copied from the original template. Because of this, duplicating one template to another of a totally different type may carry over some unintended settings. When duplicating a template, examine the subject type of the original template and ensure that you duplicate one that has a similar function to that of the intended template. Although most settings for certificate templates can be edited once the template is duplicated, the subject type cannot be changed.

- Determine publication points for certificate templates.

  Determine which CAs will issue specific certificate templates based on both the administration model implemented by the organization and the usage of the certificate template. For example, if the administration model is a project-based management model, it would be appropriate to only assign the certificate template to CAs associated with the project. On the other hand, if the certificate template is widely used throughout the organization, it may be appropriate to have all CAs issue the certificate template to provide fault tolerance if a CA is unavailable.

- Minimize the number of issued certificates.

  Consider using multi-purpose certificates that can be used for more than one job task rather than issuing separate certificates for each job task that must be performed. This reduces the number of issued certificates and reduces the complexity when a user must select which certificate to present to an application.

# Walkthroughs (Implementing and Administering Certificate Templates in Windows Server 2003)

Updated: August 13, 2009

Applies To: Windows Server 2003 with SP1

**Creating a Version 2 Certificate Template**

To create a new version 2 certificate template

1. Log on as a member of the Enterprise Admins or the forest root domain's Domain Admins group, or as a user who has been granted permission to perform this task.
2. Open the Certificate Templates MMC console (Certtmpl.msc).
3. In the details pane, right-click an existing certificate that will serve as the starting point for the new certificate, and then click Duplicate Template.
4. On the General tab, enter the Template display name and the template name, and then click OK.
5. Define any additional attributes for the newly created version 2 certificate template.

**Defining Application and Issuance Policies**

When you create a version 2 certificate template, you can define which application and issuance policies are included in the issued certificates. Defining application and issuance policies requires the completion of three tasks:

- Acquiring Object Identifiers for the application and issuance policies
- Defining the application and issuance policies
- Mapping issuance policies between PKI hierarchies

**Acquiring Object Identifiers**

If you define a custom application policy or issuance policy, you must obtain an object identifier for the policy.

To acquire an object identifier

1. Log on as a member of the Enterprise Admins or the forest root domain's Domain Admins group, or as a user who has been granted permission to perform this task as described in the Delegating Template Management section.
2. Open the Certificate Templates MMC console (Certtmpl.msc).
3. In the details pane, right-click the certificate template you wish to modify, and then click Properties.
4. On the Extensions tab, click Application Policies, and then click Edit.
5. In the Edit Application Policies Extension dialog box, click Add.
6. In Add Application Policy, ensure that the application you are creating does not exist, and then click New.
7. In the New Application Policy dialog box, provide the name for the new application policy, note the generated object identifier, and then click OK.

**Note**

You could also add new object identifiers by editing Certificate Policies rather than Application Policies.

**Establishing Application Policies**

Once you have defined any custom application policies, you can then associate the application policy with the certificate template using the following procedure:

1. Log on as a member of the Enterprise Admins or the forest root domain's Domain Admins group, or as a user who has been granted permission to perform this task.
2. Open the Certificate Templates MMC console (Certtmpl.msc).
3. In the details pane, right-click the certificate template you want to change, and then click Properties.
4. On the Extensions tab, click Application Policies, and then click Edit.
5. In Edit Application Policies Extension, click Add.
6. In Add Application Policy, click the desired application policy, and then click OK.

**Establishing issuance Policies**

Once you have defined any custom issuance policies, you can then associate the issuance policy with the certificate template using the following procedure:

1. Log on as a member of the Enterprise Admins or the forest root domain's Domain Admins group, or as a user who has been granted permission to perform this task.
2. Open the Certificate Templates MMC console (Certtmpl.msc).
3. In the details pane, right-click the certificate template you want to change, and then click Properties.
4. On the Extensions tab, click Certificate Policies, and then click Edit.
5. In Edit Issuance Policies Extension, click Add.
6. In Add Issuance Policy, click New.
7. Provide the requested information.

**Mapping Issuance Policies between PKI Hierarchies**

When performing qualified subordination, it may be necessary to associate issuance policies in your organization with issuance policies defined in another organization. The policy mappings are defined in the policy.inf file used to generate the Cross-Certification Authority certificate.

In the policy.inf file, you must include a [PolicyMappingsExtension] that maps the policies listed in the policy.inf file with policies defined in the other PKI hierarchy. The following code example shows a section of a policy.inf file that maps issuance policies for high, medium, and low assurance between two organizations.

```
[PolicyStatementExtension]
Policies = HighAssurancePolicy, MediumAssurancePolicy, LowAssurancePolicy
CRITICAL = FALSE
[HighAssurancePolicy]
OID = 1.3.6.1.4.1.311.21.8.256.257.258.259.1.402
[MediumAssurancePolicy]
OID = 1.3.6.1.4.1.311.21.8.256.257.258.259.1.401
[LowAssurancePolicy]
OID = 1.3.6.1.4.1.311.21.8.256.257.258.259.1.400
[PolicyMappingsExtension]
1.3.6.1.4.1.311.21.8.256.257.258.259.1.400 =
```

```
1.3.6.1.4.1.311.21.8.354.232.582.111.1.400
1.3.6.1.4.1.311.21.8.256.257.258.259.1.401 =
1.3.6.1.4.1.311.21.8.354.232.582.111.1.401
1.3.6.1.4.1.311.21.8.256.257.258.259.1.402 =
1.3.6.1.4.1.311.21.8.354.232.582.111.1.402
critical = yEs
```

This example maps the object identifiers for the high assurance, medium assurance, and low assurance policies to object identifiers that exist in the other organization's PKI. The other organization must define a policy.inf file that maps the object identifiers in the opposite direction so that the object identifiers are recognized by both organizations.

**Configuring Permissions for a Certificate Template**

This section explains how to define permissions for specific certificate templates and also for delegating permission for the management of certificate templates.

**Allowing for Enrollment**

To define permissions to allow a specific security principal to enroll for certificates based on a certificate template

1. Log on as a member of the Enterprise Admins or the forest root domain's Domain Admins group, or as a user who has been granted permission to perform this task.

2. Open the Certificate Templates MMC console (Certtmpl.msc).

3. In the details pane, right-click the certificate template you want to change, and then click Properties.

4. On the Security tab, ensure that Authenticated users is assigned Read permissions.

   This ensures that all authenticated users on the network can see the certificate templates.

5. On the Security tab, click Add. Add a global group or universal group that contains all security principals requiring Enroll permissions for the certificate template, and then click OK.

6. On the Security tab, select the newly added security group, and then assign Allow permissions for the Read and Enroll permissions.

7. Click OK.

**Allowing for Auto-Enrollment**

To define permissions to allow a specific security principal to auto-enroll for certificates based on a certificate template

1. Log on as a member of the Enterprise Admins or the forest root domain's Domain Admins group, or as a user who has been granted permission to perform this task.

2. Open the Certificate Templates MMC console (Certtmpl.msc).

3. In the details pane, right-click the certificate template you want to change, and then click Properties.

4. On the Security tab, click Add. Add a global group or universal group that contains all security principals requiring Enroll permissions for the certificate template, and then click OK.

5. On the Security tab, select the newly added security group, and then assign Allow permissions for the Read, Enroll, and Auto-enroll permissions.

6. Click Apply.

| **Note** |
| --- |
| For more information about configuring certificate auto-enrollment, see the Certificate Autoenrollment in Windows XP white paper at http://www.microsoft.com/technet/prodtechnol/winxppro/maintain/certenrl.mspx |

**Allowing Creation and Modification of any Certificate Template**

To delegate administration of all templates (which includes the ability to duplicate and create new templates)

1. Log on as a member of the Enterprise Admins or the forest root domain's Domain Admins group, or as a user who has been granted permission to perform this task.

2. Open the ADSIEdit console (Adsiedit.msc).

3. In the console tree, right-click ADSI Edit, and then click Connect to.

4. In the Connection dialog box, in the Connection Point section, click Naming Context, select Configuration Container from the list below Naming Context, and then click OK.

5. In the console tree, expand ADSI Edit.

6. In the console tree, expand Configuration Container.

7. In the console tree, expand CN=Configuration,DC=*ForestRootDomain* (where *ForestRootDomain* is the LDAP distinguished name of your forest root domain).

8. In the console tree, expand CN=Services.

9. In the console tree, expand CN=Public Key Services.

10. In the console tree, right-click CN=Certificate Templates, and then click Properties.

11. In the CN=Certificate Templates Properties dialog box, on the Security tab, click Add. Add a global or universal group that contains the users you wish to delegate certificate creation and management permissions to, and then click OK.

12. On the Security tab, select the newly added security group, ensure that the security group is assigned Allow permissions for the Full Control permission, and then click OK.

13. In the console tree, right-click CN=OID, and then click Properties.

14. In the CN=OID Properties dialog box, on the Security tab, click Add. Add a global or universal group that contains the users you wish to delegate certificate creation and management permissions to, and then click OK.

15. On the Security tab, select the newly added security group, ensure that the security group is assigned Allow permissions for the Full Control permission, and then click OK.

16. Close ADSI Edit.

17. Ensure that the security group assigned full control permissions to the CN=Certificate Templates and CN=OID containers is also assigned full control permissions for all certificate templates listed in the Certificate Templates MMC console (Certtmpl.msc).

**Publishing a Certificate Template**

To define which certificate templates are issued by a Certification Authority

1. Log on as a member of the Enterprise Admins or the forest root domain's Domain Admins group, or as a user who has been granted permission to perform this task.

2. From Administrative Tools, open the Certification Authority MMC console.

3. In the console tree, expand *CAName* (where *CAName* is the name of your Enterprise CA).

4. In the console tree, select the Certificate Templates container.

| Note |
| --- |
| If working with a Windows 2000 CA, the container is named Policy Settings. |

5. Right-click Certificate Templates, and then click New, Certificate Template to Issue.

6. In the Enable Certificate Templates dialog box, select the certificate template(s) you wish the CA to issue, and then click OK.

| Note |
| --- |
| If a certificate template is not listed in the Enable Certificate Templates dialog box, the CA is either already configured to issue the certificate template, or replication of the certificate template is not completed to all domain controllers in the forest. |

The newly selected certificate template(s) will appear in the details pane.

**Removing a Certificate Template from a CA**
Removing a certificate template only unlinks a certificate from a CA instead of deleting it physically from the certificate template store.

To remove a certificate template from the certificate templates currently issued by a Certification Authority

1. Log on as a member of the Enterprise Admins or the forest root domain's Domain Admins group, or as a user who has been granted permission to perform this task.

2. From Administrative Tools, open the Certification Authority MMC console.

3. In the console tree, expand *CAName* (where *CAName* is the name of your Enterprise CA).

4. In the console tree, select the Certificate Templates container.

| Note |
| --- |
| If working with a Windows 2000 CA, the container is named Policy Settings. |

5. In the details pane, right-click the certificate template you wish to remove from the CA, and then click Delete.

6. In the Disable Certificate Templates dialog box, click Yes.

The certificate template no longer appears in the details pane.

**Replace an Existing Certificate Template with a New Certificate Template**
This process, also referred to as superseding an existing template, defines which existing templates a version 2 certificate is replacing.

1. Log on as a member of the Enterprise Admins or the forest root domain's Domain Admins group, or as a user who has been granted permission to perform this task.

2. Open the Certificate Templates MMC console (Certtmpl.msc).

3. In the details pane, right-click the certificate template you want to change, and then click Properties.

4. Click the Superseded Templates tab.

5. Click Add.

6. Click one or more templates to supersede, and then click OK.

**Re-Enroll Certificate Holders**

If you make modifications to a certificate template that you wish implemented immediately for all existing certificate holders, you can force re-enrollment by using the following procedure:

1. Log on as a member of the Enterprise Admins or the forest root domain's Domain Admins group, or as a user who has been granted permission to perform this task.

2. Open the Certificate Templates MMC console (Certtmpl.msc).

3. In the details pane, right-click the certificate template that you wish to re-enroll for all certificate holders, and then click Reenroll all Certificate Holders.

# Appendix A: Wireless Certificates

Updated: January 17, 2011

Applies To: Windows Server 2003 with SP1

Windows XP introduced native support for 802.1x and wireless networks. To enable strong security, both users and computers need authentication certificates to authenticate to a RADIUS (IAS Server) authorization point. Windows 2000 certification authorities support 802.1x certificate requirements for computers with the version 1 Machine certificate template and user certificates with any of the certificate templates that contain the Client Authentication EKU. If version 2 templates are used for computer auto-enrollment, it is important to configure the certificate template properly. When the Machine template is cloned to a version 2 template, the administrator MUST ensure that the DNS name is included in the subject name (CN) of the certificate. The Windows XP wireless client requires the DNS name of the computer to be contained in the subject for proper usage and authentication to the IAS server (RADIUS).

| **Important** |
| --- |
| If the DNS fully qualified domain name is longer than 64 characters, the name will be truncated during certificate enrollment and the name will be invalid for wireless authentication. |

For more information, see the white paper at Securing Wireless LANs with Certificate Services (http://go.microsoft.com/fwlink/?LinkId=14843)

# Appendix C: Certificate Template Schema Additions

Updated: August 13, 2009

Applies To: Windows Server 2003 with SP1

The Certificate Templates container contains the certificate templates that are defined within an Active Directory forest. Each certificate template is of the class pKICertificate. Each Certificate Template is managed by using the Certificate Templates MMC snap-in. Windows 2000 includes 24 default certificate templates; Windows Server 2003 includes 29 default templates. Each template is stored in the following location in the Configuration naming context:

CN=<name of template>,CN=Certificate Templates,CN=Public Key Services,CN=Services,CN=Configuration,DC=*ForestRootDomain*

**Version 1 Certificate Template Attributes**

The following version 1 certificate templates attributes are defined in the Active Directory schema.

| Attribute | Description |
|---|---|
| **Cn** | Common name of the certificate type. |
| **distinguishedName** | Distinguished name of the certificate type. |
| **displayName** | Display name of a cert type. |
| **pKIExtendedKeyUsage** | Array of enhanced key usage object identifiers. |
| **pKIDefaultCSPs** | Default CSP list. DWORD, CSP name. |
| **pKICriticalExtensions** | List of critical extensions. |
| **revision** | Major version of the templates. |
| **templateDescription** | Obsolete attribute. |
| **flags** | General enrollment flags. |
| **pKIDefaultKeySpec** | Specifications of the Default Key length and construct. |
| **NTSecurityDescriptor** | Security Descriptor name. |
| **pKIKeyUsage** | Key Usage extension. |
| **pKIMaxIssuingDepth** | Basic Constraints. DWORD value. |
| **pKIExpirationPeriod** | Validity period. Negative FILETIME value. |
| **pKIOverlapPeriod** | Renewal period. Negative FILETIME value. |

**Version 2 Certificate Template Attributes**

The following version 2 certificate templates attributes are defined in the Active Directory schema.

| Attribute | Description |
|---|---|
| **msPKI-Template-Schema-Version** | Schema version of the templates. |
| **msPKI-Template-Minor-Revision** | Minor version of the templates. |
| **msPKI-RA-Signature** | Number of RA signatures required on a request referencing this template. |
| **msPKI-Minimal-Key-Size** | Minimal key size required. |

| | |
|---|---|
| **msPKI-Template-Cert-Template-OID** | Object identifier of this template. |
| **msPKI-Supersede-Templates** | Name of the template that this template supersedes. |
| **msPKI-RA-Policies** | RA issuer policy object identifiers required. |
| **msPKI-RA-Application-Policies** | RA application policy object identifiers required. |
| **msPKI-Certificate-Policy** | The certificate issuer policy object identifiers are placed in the OID_CERT_POLICIES extension by the policy module. |
| **msPKI-Certificate-Application-Policy** | Certificate application policy object identifiers. |
| **msPKI-Enrollment-Flag** | Enrollment flags. |
| **msPKI-Private-Key-Flag** | Private key flags. |
| **msPKI-Certificate-Name-Flag** | Subject name flags. |

**Flags**

The following enrollment flags are defined in the Active Directory schema.

| Flag | Description |
|---|---|
| **CT_FLAG_INCLUDE_SYMMETRIC_ALGORITHMS**<br>• **0x00000001** | Include the S/MIME symmetric algorithms in the requests. |
| **CT_FLAG_PEND_ALL_REQUESTS**<br>• **0x00000002** | All certificate requests are pended. |
| **CT_FLAG_PUBLISH_TO_KRA_CONTAINER**<br>• **0x00000004** | Publish the certificate to the KRA (key recovery agent container) in Active Directory. |
| **CT_FLAG_PUBLISH_TO_DS**<br>• **0x00000008** | Publish the resultant certificate to the userCertificate property on the user object in Active Directory. |
| **CT_FLAG_AUTO_ENROLLMENT_CHECK_USER_DS_CERTIFICATE**<br>• **0x00000010** | The Auto-enrollment client will not enroll for a new certificate if the user has a certificate previously published to the userCertificate attribute in Active Directory with the same template name. |
| **CT_FLAG_AUTO_ENROLLMENT**<br>• **0x00000020** | This cert is appropriate for auto-enrollment. |
| **CT_FLAG_PREVIOUS_APPROVAL_VALIDATE_REENROLLMENT**<br>• **0x00000040** | A previously issued certificate will valid subsequent enrollment requests. |

| | |
|---|---|
| **CT_FLAG_DOMAIN_AUTHENTICATION_NOT_REQUIRED**<br>• **0x00000080** | Obsolete. |
| **CT_FLAG_USER_INTERACTION_REQUIRED**<br>• **0x00000100** | User interaction is required to enroll using auto-enrollment. |
| **CT_FLAG_ADD_TEMPLATE_NAME**<br>• **0x00000200** | Obsolete. |
| **CT_FLAG_REMOVE_INVALID_CERTIFICATE_FROM_PERSONAL_STORE**<br>• **0x00000400** | Remove invalid (expired or revoked) certificate from personal store on the local client computer during auto-enrollment. |

The following subject name flags are defined in the Active Directory schema.

| Flag | Description |
|---|---|
| **CT_FLAG_ENROLLEE_SUPPLIES_SUBJECT**<br>• **0x00000001** | The enrolling application must supply the subject name. |
| **CT_FLAG_ENROLLEE_SUPPLIES_SUBJECT_ALT_NAME**<br>• **0x00010000** | The enrolling application must supply the subjectAltName in request. |
| **CT_FLAG_SUBJECT_REQUIRE_DIRECTORY_PATH**<br>• **0x80000000** | Subject name should be full distinguished name based on the Active Directory path. |
| **CT_FLAG_SUBJECT_REQUIRE_COMMON_NAME**<br>• **0x40000000** | Subject name should be the common name. |
| **CT_FLAG_SUBJECT_REQUIRE_EMAIL**<br>• **0x20000000** | Subject name includes the e-mail name. |
| **CT_FLAG_SUBJECT_REQUIRE_DNS_AS_CN**<br>• **0x10000000** | Subject name includes the DNS name as the common name. |
| **CT_FLAG_SUBJECT_ALT_REQUIRE_DNS**<br>• **0x08000000** | Subject alt name includes the DNS name. |
| **CT_FLAG_SUBJECT_ALT_REQUIRE_EMAIL**<br>• **0x04000000** | Subject alt name includes the e-mail name. |

| | |
|---|---|
| **CT_FLAG_SUBJECT_ALT_REQUIRE_UPN**<br>• **0x02000000** | Subject alt name requires UPN. |
| **CT_FLAG_SUBJECT_ALT_REQUIRE_DIRECTORY_GUID**<br>• **0x01000000** | Subject alt name requires directory GUID (used by domain controllers). |
| **CT_FLAG_SUBJECT_ALT_REQUIRE_SPN**<br>• **0x00800000** | Subject alt name requires SPN (service principal name). |

The following template private key flags are defined in the Active Directory schema.

| **Flag** | **Description** |
|---|---|
| - Private Key Flags | |
| CT_FLAG_ALLOW_PRIVATE_KEY_ARCHIVAL<br>• 0x00000001 | Archival of the private key is allowed/required. |
| CT_FLAG_EXPORTABLE_KEY<br>• 0x00000010 | Mark the private key as exportable. |

The following template general flags are defined in the Active Directory schema:

| **Flag** | **Description** |
|---|---|
| CT_FLAG_MACHINE_TYPE<br>• 0x00000040 | Machine cert type. |
| CT_FLAG_IS_CA<br>• 0x00000080 | CA certificate type. |
| CT_FLAG_IS_CROSS_CA<br>• 0x00000800 | Cross-CA certificate type. |
| CT_FLAG_IS_DEFAULT<br>• 0x00010000 | Default cert type that is set on all V1 templates that cannot be changed. |
| CT_FLAG_IS_MODIFIED<br>• 0x00020000 | The type has been modified (read only). |
| CT_MASK_SETTABLE_FLAGS<br>• 0x0000ffff | Obsolete. |

# Server Clusters: Quorum Options - Windows Server 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Microsoft Corporation

Published: March 2003

**Abstract**
The goal of this document is to explain the two types of quorums available in Windows Server 2003 clusters – standard and majority node set (MNS) clusters. Currently, the standard quorum that is used by the Microsoft Cluster Service (MSCS) in Microsoft® Windows NT® Server 4.0 and Windows® 2000 Server family of products is sufficient for the majority of situations users will encounter. With the introduction of Windows Server 2003, Microsoft has introduced the MNS quorum, which is primarily for advanced users and other software vendors to create more sophisticated end-to-end solutions.

**In This White Paper**

Background (Server Clusters: Quorum Options - Windows Server 2003)

Types of Quorums

Quorum Uses

Frequently Asked Questions (Server Clusters: Quorum Options - Windows Server 2003)

# Background (Server Clusters: Quorum Options - Windows Server 2003)

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before giving an explanation of what a cluster quorum is, it is important to understand the background to Windows Clustering Technologies.

Starting with Microsoft® Windows NT® 4.0 Enterprise Edition, Microsoft introduced the idea of a cluster, which is simply a group of servers that are presented as one virtual server. For example, you can configure two servers, server A and server B, in a cluster, and present them to the outside world as server C (a virtual server). If, for example, server A dies, server B is used to ensure that the virtual server (server C) and the services it offered, are still available to clients, thereby providing transparent access to the user.

Microsoft offers two types of clustering solutions in its Windows server products:

Server clusters – uses a shared-nothing architecture, which means that a resource can be active on only one server in the cluster at any one time. Because of this, it is well suited to applications that maintain some sort of state (for example, a database).

Network Load Balancing (NLB) – uses a load balancing architecture, which means that a resource can be active on ALL servers in the cluster at any one time. Because of this, it is well suited to applications that *do not* maintain state (for example, a Web server).

Quorums are only used in the MSCS now known as server cluster. Hence, any references to clusters in the remainder of this document are referring to the server clusters. The following sections explain what a cluster quorum is, and why it is important.

**What Is It?**
Each cluster has a special resource known as the *quorum resource*. A quorum resource can be any resource that does the following:

- Provides a means for arbitration leading to membership and cluster state decisions.
- Provides physical storage to store configuration information.

A quorum log is simply a configuration database for the server cluster. It holds cluster configuration information such as which servers are part of the cluster, what resources are installed in the cluster, and what state those resources are in (for example, online or offline). The quorum log is located by default in \MSCS\quolog.log.

**Why Is It Important?**
There are two main reasons why the quorum is important in a cluster. These are outlined below.

Consistency

Since the basic idea of a cluster is multiple physical servers acting as a single virtual server, it is critical that each of the physical servers have a consistent view of how the cluster is configured. The quorum acts as the definitive repository for all configuration information relating to the cluster. In the event that the Cluster service is unable to read the quorum log, it will not start, as it is not able to guarantee that the cluster will be in a consistent state, which is one of the primary requirements for a cluster.

Tie-breaker

The quorum is used as the tie-breaker to avoid “split-brain” scenarios. A split-brain scenario happens when all of the network communication links between two or more cluster nodes fail. In these cases, the cluster may be split into two or more partitions that cannot communicate with each other. The quorum is used to guarantee that any cluster resource is only brought online on only one node. It does this by allowing the partition that “owns” the quorum to continue, while the other partitions are evicted from the cluster.

# Types of Quorums

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Standard Quorum**
As mentioned above, a quorum is simply a configuration database for MSCS, and is stored in the quorum log file. A standard quorum uses a quorum log file that is located on a disk hosted on a shared storage interconnect that is accessible by all members of the cluster.

| **Note** |
| --- |
| It is possible to configure Server clusters to use the local hard disk on a server to store the quorum, but this is only supported for testing and development purposes, and should not be used in a production environment. Each member connects to the shared storage through some type of interconnect (for example, SCSI or Fibre Channel), with the storage consisting of either external hard disks (usually configured as RAID disks), or a storage area network (SAN), where logical slices of the SAN are presented as physical disks. |

| **Note** |
| --- |
| It is important that the quorum uses a physical disk resource, as opposed to a disk partition, as the entire physical disk resource is moved during failover. |

Standard quorums are available in Windows NT 4.0 Enterprise Edition, Windows 2000 Advanced Server, Windows 2000 Datacenter Server, Windows Server 2003 Enterprise Edition and Windows Server 2003 Datacenter Edition.

The following is a sample diagram of a standard quorum in a four-node cluster.

*Figure 1: Standard quorum in a four-node cluster*

**Majority Node Set Quorums**
A majority node set (MNS) quorum is a single quorum resource from a server cluster perspective. However, the data is actually stored by default on the system disk of each member of the cluster. The MNS resource takes care to ensure that the cluster configuration data stored on the MNS is kept consistent across the different disks.

Majority node set quorums are available in Windows Server 2003 Enterprise Edition, and Windows Server 2003 Datacenter Edition.

The following is a sample diagram of an MNS quorum in a four-node cluster.

*Figure 2: MNS quorum in a four-node cluster*

While the disks that make up the MNS could in theory be disks on a shared storage fabric, the MNS implementation that is provided as part of Windows Server 2003 uses a directory on each node's local system disk to store the quorum data. If the configuration of the cluster changes, that change is reflected across the different disks. The change is only considered to have been committed, that is, made persistent, if that change is made to:

(<Number of nodes configured in the cluster>/2) + 1

This ensures that a majority of the nodes have an up-to-date copy of the data. The cluster service itself will only start up and therefore bring resources online if a majority of the nodes configured as part of the cluster are up and running the cluster service. If there are fewer nodes, the cluster is said not to have quorum and therefore the cluster service waits (trying to restart) until more nodes try to join. Only when a majority or quorum of nodes are available, will the cluster service start up, and bring the resources online. In this way, because the up-to-date configuration is written to a majority of the nodes regardless of node failures, the cluster will always guarantee that it starts up with the latest and most up-to-date configuration.

In the case of a failure or split-brain, all partitions that do not contain a majority of nodes are terminated. This ensures that if there is a partition running that contains a majority of the nodes, it can safely start up any resources that are not running on that partition, safe in the knowledge that it can be the only partition in the cluster that is running resources (because all other partitions are terminated).

Given the differences in the way the shared disk quorum clusters behave compared to MNS quorum clusters, care must be taken when deciding which model to choose. For example, if you only have two nodes in your cluster, the MNS model is not recommended, as failure of one node will lead to failure of the entire cluster, since a majority of nodes is impossible.

# Quorum Uses

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Standard Quorums**
Standard quorums should be sufficient for the majority of situations that users will encounter. Typical situations include:

- *Highly available data in a single location* – most customers that require their data to be highly available only need this on a per site basis. If they have multiple sites, each site has its own cluster. Typical applications that use this type of cluster include Microsoft SQL Server™, Exchange Server, file shares, printer queues, and network services (e.g. DHCP & WINS).

- *Stateful applications* – applications or NT services that require only a single instance at any time and require some sort of state to be stored, typically use standard quorums, as they already have some sort of shared storage for maintaining the state.

**Majority Node Set Quorums**
While majority node set quorums are an exciting new feature of Windows Server 2003 clusters, they do have very strict requirements to ensure they work correctly, and therefore should only be considered by people who fully understand the issues involved in using MNS based clusters. The following are the key situations that the product team thought of when creating MNS quorums:

- *Geographically Dispersed Clusters* – this involves a single MSCS cluster that has members in multiple geographic sites. While geographic clusters are possible using a standard quorum (for example, there is a separate geographic cluster Hardware Compatibility List (HCL)), a number of issues arise in terms of presenting the quorum as a single, logical shared drive between all sites. Majority Node Set quorums solve these issues by allowing the quorum to be stored on the local hard disk.

- *Clusters with No Shared Disks* – there are some specialized configurations that need tightly consistent cluster features without having shared disks. For example:

    - Clusters that host applications that can failover, but where there is some other, application-specific way to keep data consistent between nodes (e.g. database log shipping for keeping database state up-to-date; file replication for relatively static data, etc.).

    - Clusters that host applications that have no persistent data, but need to cooperate in a tightly coupled way to provide consistent volatile state.

    - Independent Software Vendors – by abstracting storage from the Cluster service, it provides independent software vendors with much greater flexibility in how they design sophisticated cluster scenarios.

# Frequently Asked Questions (Server Clusters: Quorum Options - Windows Server 2003)

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**What is a Majority Node Set cluster?**

It is a cluster that has a quorum based on local disks in each node, rather than a shared disk.

**How is the quorum information located on the system disk of each node kept in synch?**

The server cluster infrastructure ensures that all changes are replicated and updated on all members in a cluster.

**Can this method be used to replicate application data as well?**

No, that is not possible in this version of clustering. Only Quorum information is replicated and maintained in a synchronized state by the clustering infrastructure.

**Can I convert a standard cluster to an MNS cluster?**

Yes. You can use Cluster Administrator to create a new Majority Node Set resource and then, on the cluster properties sheet **Quorum** tab, change the quorum to that Majority Node Set resource.

**What is the difference between a geographically dispersed cluster and an MNS cluster?**

A geographic cluster refers to a cluster that has nodes in multiple locations, while an MNS-based cluster refers to the type of quorum resources in use. A geographic cluster can use either a shared disk or MNS quorum resource, while an MNS-based cluster can be located in a single site, or span multiple sites.

**What is the maximum number of nodes in an MNS cluster?**

Windows Server 2003 supports 8-node clusters for both Enterprise Edition and Datacenter Edition.

**Do I need special hardware to use an MNS cluster?**

There is nothing inherent in the MNS architecture that requires any special hardware, other than what is required for a standard cluster (for example, there must be on the Microsoft Cluster HCL). However, some situations that use an MNS cluster may have unique requirements (such as geographic clusters), where data must be replicated in real time between sites.

**Does a cluster aware application need to be rewritten to support MNS?**

No, using an MNS quorum requires no change to the application. However, some cluster aware applications expect a shared disk (for example SQL Server 2000), so while you do not need shared disks for the quorum, you do need shared disks for the application.

**Does MNS get rid of the need for shared disks?**

It depends on the application. For example, clustered SQL Server 2000 requires shared disk for data. Remember, MNS only removes the need for a shared disk quorum.

**If I have a 2-node MNS cluster, and lose one server, will the cluster continue to function?**

No, in order to keep an MNS cluster running, it must have a majority of nodes online, i.e. (<Number of nodes configured in the cluster>/2) + 1. The following table shows the various combinations of configured nodes and node failures:

| Number of nodes configured in the cluster | Number of node failures |
|---|---|
| 1 | 0 |
| 2 | 0 |
| 3 | 1 |
| 4 | 1 |
| 5 | 2 |

| | |
|---|---|
| 6 | 2 |
| 7 | 3 |
| 8 | 3 |

**How do I back up and restore an MNS cluster?**

There is a separate white paper on backing up and restoring clustered configurations. It will be published at the same location as this paper.

**Is there a way I can allow for a "minority set" to take control of the cluster?**

Yes, there is a way for a "minority" set to be allowed to start up and initialize the cluster. But this is a manual process and has to be done in a specified manner. Details on the same are available in "help".

**What happens if majority count is lost?**

The cluster service will gracefully shutdown the cluster and all resources. Clients will lose connectivity and access to any of the clustered services. This is done to prevent the "split-brain" scenario.

**Are there any limitations with regard to network latency and topography in an MNS cluster?**

Requirements are the same as that for vanilla clusters. With regard to topography, we envisage the MNS feature to be predominantly used in geographically dispersed clustering scenarios. This normally means specific semantic requirements in terms of storage usable and management. OEMs provide prescriptive guidance on the same and customers should carefully read the same.

For the latest information about Windows Server 2003, see the Windows Server 2003 Web site at http://www.microsoft.com/windowsserver2003.

# Server Clusters: Storage Best Practices for Windows 2000 and Windows Server 2003

Updated: January 1, 2003

# Storage Topologies

Updated: January 1, 2003

Applies To: Windows Server 2000, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

There are two types of Storage I/O technologies supported in Server clusters: Parallel SCSI and Fibre Channel. With the release of Microsoft Windows Server 2003, support will be provided for SCSI interconnects and fibre channel arbitrated loops for two nodes only. For larger configurations (greater than two), you will need to use a switched fibre channel (fabric) environment.

**Issues**

Parallel SCSI

Only supported in Windows 2000 Advanced Server up to two-nodes

SCSI Adaptors and storage solutions need to be certified

SCSI cards that are hosting the interconnect should have different SCSI IDs normally (6 and 7). Ensure device access requirements are in-line with SCSI IDs and priorities

SCSI adaptor BIOS should be disabled

If devices are daisy-chained, ensure that both ends of the shared bus are terminated

Use physical terminating devices and do not use controller-based or device-based termination

SCSI hubs are not supported

Avoid the use of connector converters (e.g. 68-pin to 50-pin)

Avoid combining multiple device types (single ended and differential, etc.)

Fibre Channel

Fibre Channel Arbitrated Loops (FC-AL) supported up to two nodes

Fibre Channel Fabric (FC-SW) supported for all higher combinations

Components and configuration need to be in the Microsoft Hardware Compatibility List (HCL)

Multi-cluster environment

Fault tolerant drivers and components also need to be certified

Virtualization engines need to be certified.

The switch is the only component that is not currently certified by Microsoft and it is recommended that the end user get the appropriate interoperability guarantees from the switch vendor before implementing switch fabric topologies. In complicated topologies, where multiple switches are used and connected through ISLs, it is recommended that the customer work closely with Microsoft and the switch and storage vendors during the implementation phase to ensure that all of the components work well together.

**Supported and Qualified Configurations**

All server clusters must be qualified to be supported by Microsoft. A qualified configuration has undergone extensive testing using a hardware compatibility test, provided by Microsoft. All qualified solutions appear on the HCL, available at http://www.microsoft.com/whdc/hcl/default.mspx. Only cluster solutions listed on the HCL are supported by Microsoft. The complete cluster solution must be listed on the Cluster HCL list. The complete solution includes the servers, the storage adapters, the interconnect type, the storage controllers firmware and driver versions. All of the components must match exactly, including any software, driver or firmware versions, for the solution to be qualified. The HCL contains a set of qualified cluster components. A solution built from qualified components does NOT imply that the solution is qualified.

The cluster components lists have been a source of confusion in the past and Microsoft will be removing the cluster component lists (such as Cluster/RAID) from the HCL for Windows Server 2003.

**Storage Interconnects**

Ensure that all storage interconnects used in Server Clusters are in the HCL. This also applies for any additional software that is

used to provide fault tolerant or load balancing features for adaptors and interconnects.

**Multiple paths to the storage for high availability**: This is a very common feature implemented by almost all storage vendors. This feature allows for users to implement multiple fabrics (normally two), and use them in fault tolerant or load balancing configurations. In the past, each vendor had their own implementations that varied greatly from one another and also required specific configuration/driver combinations. With the release of Windows Server 2003, Microsoft has developed and supplied vendors with a multi-path driver that will be used by them, in place of custom-made drivers. The driver will ship as part of the individual vendor product, but it is expected that all vendor products (that Microsoft will support) will incorporate this driver. If they insist on using their own driver, it will need to be certified and listed in the HCL.

#### Server Cluster and SANs

Storage Area Networks (SANs) are increasingly being used to host storage that is managed by server clustering. There are some specific requirements driven from the implementations of clusters and the fact that all storage on the SANs may not be owned by nodes in a cluster. Some issues that can be translated into best practices are:

Ensure that the SAN configurations are in the Microsoft HCL (multi-cluster section).

When configuring your storage the following **must** be implemented:

**Zoning**- Zoning allows users to sandbox the logical volumes that will be used by a cluster. Any interactions between nodes and storage volumes will be isolated to the zone and other members of the SAN will not be affected by the same. This feature can be implemented at the controller or switch level and it is important that users have this implemented before installing clustering

**LUN masking**- This feature allows users to express at the controller level, a specific relationship between a LUN and a host. In theory, no other host should be able to see that LUN or manipulate it in any way. However, various implementations differ in functionality and as such; one cannot assume that LUN masking will always work. Therefore, it cannot be used *instead* of zoning. One can combine zoning and masking however, to meet some specific configuration requirements.

**Firmware and driver versions**- Some vendors implement specific functionality in drivers and firmware and it is recommended that users pay close attention to what firmware/driver combinations are compatible with the installation they are running. This is valid not only when building a SAN and attaching host to it but also to the entire life span of the system (hosts and SAN components). Close attention should be paid to issues coming out of applying service packs or vendor specific patches and/or upgrades.

**Hardware verses software zoning**- Zoning can be implemented in hardware/firmware on controllers or on software on the hosts. It is recommended that controller-based zoning be used since this allows for uniform implementation of access policy that cannot be interrupted or compromised by node disruption or failure of the software component.

**Hardware versus software LUN masking**- Some vendors also offer software-based masking facilities. Please make sure that any such software that is closely attached to storage and is involved with the presentation of the storage to the operating system needs to be certified. For the same reasons mentioned above, this is also not considered to be a very good thing to do if one cannot guarantee the stability of the software component.

**Boot from SAN**- This is an increasingly demanded feature and will be supported by Microsoft in Windows Server 2003. Some factors to consider are :

Configurations require support from the Host Bus Adaptor (HBA) and storage vendors. The HBA driver needs to be a Storport driver. Storport drivers improve performance over SCSIPORT, both in terms of throughput and in terms of the system resources that are utilized. It also adds a manageability infrastructure for configuration and management of host-based RAID adapters and is a new implementation in Windows Server 2003. These features are required if the operating system is to successfully boot from a SAN, and more importantly, the vendors that have an implementation need to get them certified by Microsoft.

Such solutions have limited scaling capacities and any additional complexities such as storage replication, recovery mechanisms etc. need to be addressed by the hardware vendors.

Server clusters have enabled a feature that will allow the startup disk, pagefile disks and the cluster disks to be hosted on the same channel. There are other performance and operational implications that need to be considered before implementation.

Please also read KB article 305547 *Support for Booting from a Storage Area Network (SAN)* which discusses this feature.

#### Storage Configuration and Setup

If this is a fresh cluster installation, you need to ensure that you do not have applications running. When creating a cluster or adding nodes to a cluster, the Wizard enumerates all of the storage on the node and clusters all storage that is not somehow determined to be non-clusterable. Non-clusterable storage includes all drives on any storage bus that has any system file on it

(boot, system, page file, crash dump, or hibernate file), LDM drives, and those drives that respond positively to the IOCTL IOCTL_SCSI_MINIPORT_NOT_QUORUM_CAPABLE.

If this is an existing cluster that is being upgraded, then all configuration settings are honored and rolling upgrade from Windows 2000 is a fully supported option.

**Server Clusters and Fault-Tolerant Disks (RAID)**
Creation of fault-tolerant volumes such as striped, mirrored, and RAID-5 volumes in Windows Server 2003 requires the volumes to be dynamic disks. Dynamic disks are not supported out-of-the-box in Server cluster, however Veritas has a product (Veritas Volume Manager) that allows for similar functionality and is supported. NTFS is supported as a format type. If disks are not configured as basic and formatted in NTFS, clustering will not recognize the disks and will not be able to manage them. Server clustering also does not support GPT (GUID Partition table) disks, which was introduced as part of the EFI initiative.

Clustering, however, supports hardware based fault-tolerant disks. This means that the configuration of physical disks into fault-tolerant sets (JBOD, RAID 5, RAID 0+1 etc.) is done at the controller level and the set can be made visible either as a whole or carved into smaller pieces (volumes) and made available to hosts. The hosts are completely unaware of the physical implementation and treat the volume as a disk. It is for this reason that we recommend that usage characteristics be taken into consideration before implementing FT sets. For example, if you think the logical volume will host data that is being read and updated constantly, you should perhaps implement the fault-tolerant set as a RAID 0+1 instead of a RAID 5. Another thumb rule to follow would be associating the logical volume size as closely as possible to the physical set size. So carving out fewer logical volumes generally helps contribute to performance.

Volume expansion is also a regular requirement since data growth is not often considered up-front. Cluster disks can be extended without rebooting if the controller supports dynamic LUN expansion. This feature allows for the physical expansion to be implemented without disruption and users can use tools (diskpart) provided by Microsoft to allow for the change to be seamlessly applied at the logical level as well. There are separate versions of diskpart for Windows 2000 and Windows Server 2003. The Windows 2000 version is available as a free download on the web and the Windows Server 2003 version is shipped on the distribution CD.

**Handling Storage Cable Disconnects in a Cluster**
This document has been written up to answer the various queries we get about Microsoft not supporting manual disconnection of storage cable as a valid test for testing failover mechanisms. Microsoft software fully supports the validity of the test but is not responsible for guaranteeing the results. The main reason for this is that the reactions of the concerned devices (HBAs, switches, Storage solutions etc.) are controlled by lower level device drivers that are written by third party vendors. Different vendors implement storage drivers in different ways and it is upto them to implement features that will allow for such tests to work. At the time of writing this document not all vendors have device drivers that support this test. You should check with your vendor (storage and adapter) to ensure that pulling the storage adapter cable is correctly handled by their device drivers. If the drivers are written to specification made available by Microsoft this issue will be handled cleanly and the tests should work.

This document is specific to Fibre Channel based storage and the issue of storage cables being disconnected or broken and has been created to clearly state the position of the cluster product team with regard to the same. One would see similar issues with SCSI bus implementations but since a majority of implementations these days are fibre channel based we will be scoping our discussion that type of storage network.

Essentially there are usually 2 sets of connections between servers and storage. Servers and storage solutions are connected to switches/hubs. As such there can be 2 places disconnects can occur, one between the server (HBA) and the switch, and the other between the storage solution and the switch. And since there are many cluster and non cluster components involved when such an event happens we will try and map the events to the components thus establishing clear areas of responsibilities.

To begin with Server clusters product team fully understand the fact that storage cable disconnects leading to disruption in host connectivity is a valid scenario and can happen at customer sites. The product (Server clusters), fully supports handling such events gracefully and failing over resources (disk and related). However there are set of events that need to happen before Server clusters can detect the event and failover resources. There is also an additional set of events that need to happen for the resources to fail back to the original node. These set of events depend on the behavioral characteristics of certain components (lower level device drivers) that are not part of the server cluster product. Unfortunately there is no standardization of the required characteristics of these drivers and as such the behavioral semantics might differ from configuration to configuration. But the basic behavior linked to a cable disconnect (that of a failure being detected causing the disks to fail over) should always work.

We will state some of the requirements and issues in this document so as to give the reader an understanding on how all this works together and what questions to ask of whom to ensure that their systems have this functionality.

**Disconnecting storage cables (HBA to switch)**

We will first address the issue of a storage cable between the server (HBA and the switch) being disconnected.

Here is a rough diagram of what the storage stack will look like on a server running Windows and Server clusters. The stack could include scsiport drivers supplied by Microsoft and miniport drivers supplied by the HBA vendor or a full port driver that complete functionality and replaces the scsiport drive:

**Case 1**

**Case 2**

In the first case when the cable is disconnected, if the HBA miniport drivers report the correct status (**BusChangeDetected** - This notification indicates that a target device might have been added or removed from a dynamic bus.) the scsiport drivers can do the right thing and the non availability (or availability) of disks is efficiently detected. If a device was reported as being not available PnP will do a scan and tear down all device objects that are not available) and the server cluster disk driver will get the required notifications. This will lead to the cluster service failing over the disk resources to another valid member of the cluster who has access to the devices in question.

If the HBA miniport driver instead reports a generic status (**ResetDetected** - all this indicates is that the HBA has detected a reset on the SCSI bus and after this notification, the HBA miniport driver is still responsible for completing any active requests). In such a case the cluster disk driver will eventually detect the fact that the disk is no longer available in the course of the monitoring tests (LooksAlive, IsAlive1) it perfumes on a periodic basis. This will cause to detect that the disks are no longer accessible leading it to fail over the disks to another member in the cluster that has valid access to the disks in question. The minimum time required to detect this is approximately three seconds when a reserve issued by clusdisk (the cluster disk driver) fails. The maximum time required is not quantifiable since that will depend on the behavioral and operational characteristics of the lower level device drivers. But the non availability of the disk will always be eventually detected causing the disks to fail over to a valid cluster node.

The frequency for running LooksAlive and IsAlive is tunable, meaning one can increase the frequency of the checks so has to have a smaller detection window but this has other (resource utilization) implications that needs to be carefully considered, especially in enterprise environments where server clusters might need to monitor a large number of resources.

The same is also valid if the out-of-the-box scsiport drivers are replaced by a vendor specific scsiport driver or of the SCSIport /Miniport combination is replaced by a monolithic Fullport driver as shown in Case 2. Such drivers are written by vendors to cater to specific requirements their storage solutions might have. Microsoft cannot guarantee the functionality of full port drivers Microsoft support will not be able to debug related issues if full port drivers are used.

**Disconnecting storage cables (Switch to storage):**
Here again the behavior depends on the implementations. Upon cable disconnect or device removal the HBA gets an RSCN from the switch and should notify the operating system of any changes it detects. Detection is a very complex operation and has a lot of external dependencies and may not always work correctly. In the worst case scenario the HBA may fail the IO or return BUSY. In such cases as well the worst case scenario applies which means that the LooksAlive/IsAlive checks will fail and the cluster service will wither failover the disks or fail them completely.

**Reconnecting Storage Cables (HBA to switch):**
Reconnecting the storage cables and expecting the resources to fail back is also a complicated issue. If the HBA miniport driver or the full port driver sends the right status then PnP will rescan the bus create device objects and allocate resources (such as I/O ports, memory addresses, and interrupts) for that device. These resources are supplied back to the miniport, which must then use these resources. In such cases reconnecting the storage cable is detected and is all that needs to be done to allow for the resources to fail back to the original node.

If the miniport driver or the full port driver does not implement the above then again fail back should just work because the physical device objects exist. If there are issues the user will need to initiate a manual scan (by going into Disk Management MMC and initiating a rescan of disks). Once this is done a failback should work

**Reconnecting Storage Cables (Switch to storage controller):**
Getting information (on cable reconnects) back from the switch is dependant on various conditions (have devices changed, has the name server detected this etc.) and does not always work as expected. A manual rescan should also work in such cases.

In either case the full functionality is provided by the miniport or the full port drivers (depending on what is being used) both of which are written by the storage or HBA vendor.

The above is also valid for fault tolerant solutions that implement features like multiple paths from servers to storage solutions. The behavior should be the same in event of **both paths** on a host failing. Single failure instances should be masked by the multi path driver and should not be visible to higher level subsystems.

To sum it up disconnecting storage cables will cause disks managed by server clusters to fail over to another member of a cluster no matter what driver types are used. Failing the disks back to the original node however is a feature that can only be guaranteed by HBA vendors for the simple fact that they own the drivers that incorporates the functionality that is primarily responsible for correctly handling this situation.

**Adding new disks to a cluster**- Adding new disks to a cluster does not require a rebooting nodes or restarting the cluster service post Windows 2000 SP3 and in Windows Server 2003. Any node can scan and mount the new disk to begin with and once it has been formatted to NTFS all that is required is the creation of a new physical disk resource using Cluster

The above is valid post Windows 2000 SP3 (2 hotfixes) and Windows Server 2003. The hotfixes are supplied by Microsoft Support.

# Storage Features in Windows Server 2003 and Clustering

Updated: January 1, 2003

Applies To: Windows Server 2000, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Volume Mount Points**
Server clustering in Windows Server 2003 supports volume mount points, which are directories on a volume that an application can use to "mount" a different volume, that is, to set it up for use at the location a user specifies. This feature is not supported in Windows NT 4.0 or Windows 2000.

**EFS**
With Windows Server 2003, the encrypting file system (EFS) is supported on clustered file shares. To enable EFS on a clustered file share, you must perform a number of tasks to configure the environment correctly:

EFS can only be enabled on file shares when the virtual server has Kerberos enabled. By default, Kerberos is not enabled on a virtual server. To enable Kerberos you must check the Enable Kerberos Authentication check box on the network name resource that will be used to connect to the clustered file share.

| **Note** |
| --- |
| Enabling Kerberos on a network name has a number of implications that you should ensure you fully understand before checking the box. |

All cluster node computer accounts, as well as the virtual server computer account, must be trusted for delegation. See online help for how to do this.

To ensure that the users private keys are available to all nodes in the cluster, you must enable roaming profiles for users who want to store data using EFS. See online help for how to enable roaming profiles.

Once the cluster file shares have been created and the configuration steps above have been carried out, users data can be stored in encrypted files for added security.

**Disk Quotas**
Configuring disk quotas on shared disks is supported in Windows 2000 and Windows Server 2003.

**Autochk/Chkdsk/Chkntfs** - Every time Windows restarts, Autochk.exe is called by the Kernel to scan all volumes to check if the volume dirty bit is set. If the dirty bit is set, autochk performs an immediate chkdsk /f on that volume.

Chkdsk is a native Windows tool that can determine the extent of file and file system corruption. If Chkdsk runs in write-mode, it will automatically attempt to remedy disk corruption.

The Chkntfs.exe utility is available in Microsoft Windows NT 4.0 Service Pack 2 and later versions of Windows. It is designed to disable the automatic running of chkdsk on specific volumes, when Windows restarts from an improper shutdown. Chkntfs can also be used to unschedule a chkdsk if chkdsk /f was used to schedule a chkdsk on an active volume on the next system restart.

All of the above are supported to run in specific configurations in Server Clusters. The relevant KB articles that explain the procedures in detail are:

174617 - *Chkdsk runs while running Microsoft Cluster Server Setup*

176970 - *How to Run the CHKDSK /F Command on a Shared Cluster Disk*

160963 - *CHKNTFS.EXE: What You Can Use It For*

**Virtual Disk Service** - The Virtual Disk Service will ship in Server 2003. It provides an interface for software volume management, hardware RAID cabinet management, multi-path and device allocation in a SAN. VDS will be supported in Server Clusters. Additional providers (supplied by ISVs like Veritas) are required to enable cluster functionality.

**Virtual Snap Shot and TimeWarp** - VSS is a Windows service that allows users to snapshot data. It does this with the help of hardware or software providers that actually implement the functionality. VSS coordinates requestors, providers, and writers. The Volume Shadow Copy service is abbreviated as VSS. Software providers are implemented as a user-mode component plus a kernel-mode driver. I/Os are intercepted by the driver that instantiates snapshot volumes. The driver may be a storage filter driver or a component of a volume manager. A writer is any application that stores persistent information on one or more

volumes, and participates in snapshot synchronization. Typically this might be a database (e.g. SQL Server) or system service (e.g. Certificate Services) or a backup program (Backup). VSS implementation in NT backup is fully supported by server clusters. Timewarp is another specific use of snapshots for simple file un-delete and is a feature available in Windows Server 2003. This is also fully supported in clustering and the whole feature set can be enabled on clustered and non clustered disks in the same fashion. End user experience remains unchanged.

# Hardware Based Storage Features

Updated: January 1, 2003

Applies To: Windows Server 2000, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Hardware snapshots or business recovery volumes**- Hardware snapshots are totally transparent to clustering and are supported if implemented correctly. The only requirement we have is that the snapshot copy and the original should not be exposed to the cluster at the same time.

**NAS as shared storage**- We fully support building clustered solutions using the Microsoft NAS offering called the Server Appliance Kit. The kit is supplied to OEMs who will ship predefined solutions, some of which may be clustered (for example, clustered file servers).

**Geographical clusters (storage implications)**- With geographic clusters, their storage configurations can tend to get very complicated depending upon the level of service users require. All solutions need to be in the Geographic Cluster HCT in order to be supported by Microsoft. Features like data replication, storage management, recovery procedures etc. are entirely the responsibility of the hardware vendor implementing the solution. We also have an HCT test available for free download on the web that can be used to validate production systems.

**Replication (synchronous, asynchronous)**- FRS, the OOB replication mechanism, is not really used at the application data replication level. Server cluster is replication agnostic and does not take the feature into consideration when it is running. If ISVs (hardware or software) choose to implement this feature, they should make sure the semantics required by Server clusters at the storage level are honored. It is their responsibility that all application requirements are met with regard to data replication and consistency.

# Storage Tools and Services

Updated: January 1, 2003

Applies To: Windows Server 2000, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remote Storage**- Remote storage services are not supported by Server Cluster.

**Removable Storage**- Removable storage services are not supported by Server Cluster.

**Backup**- NTBackup and any backup solution that use the Cluster Backup APIs are supported for Server Cluster Backup scenarios. Using the APIs allows for consistent backup and restore of cluster configuration data. Shared disks can only be backed up on the node that owns the disk at the time of backup.

**Indexing**- Indexing is not supported by Server Cluster. It also has serious implications with regard to resource utilization and careful consideration must be given before turning it on.

**Distributed File System**- DFS is fully supported by Server Cluster. In Windows Server 2003, multiple DFS roots can be hosted in a cluster.

**Offline Files**- Client-side caching can be enabled on clustered file share in Windows Server 2003. This feature is not available in Windows 2000 or NT 4.0. This is meant for user shares only and not for application data.

# Backup and Restore (Server Clusters: Storage Best Practices for Windows 2000 and Windows Server 2003)

Updated: January 1, 2003

Applies To: Windows Server 2000, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As stated earlier, any backup solution that uses the cluster backup APIs are supported.

**Tape devices or other non-disk devices** the SAN fabric as the cluster: currently we do not support managing any non-disk devices (tapes, optical media etc.) by Server clusters. Tapes or optical media may very well be used as any other SAN component but they cannot be managed by Server clusters as a resource.

**Serverless backup**- Serverless backup, or SAN-based backup as it is sometimes called, is not supported in Server clusters. This is because nodes in a cluster own physical disk volumes and maintain their ownership through reservations, and this blocks serverless backup mechanisms. In addition backup devices translate incorrectly interpret bus resets leading them to rewind tapes loaded in the drives. This will have serious implications in enterprise backup environments where large data sets are being backed up.

**Using backup agents**- Some ISVs implement backup agents which are really filter agents that are used to overcome file locking issues. They are also sometime called open file agents. Stability and reliability of the agents and the operating system is the responsibility of the vendor if such solutions are implemented.

**Hardware Snapshots**- Hardware snapshots are not supported in clustered environments. Clustering software identify disks thru their disk signatures. Disk snapshots or clones are identical copies of the parent disks which means that 2 disks with similar signatures would get exposed to the operating system and clustering software. This could cause unexpected disruptive behavior.

# Storage Management

Updated: January 1, 2003

Applies To: Windows Server 2000, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Storage management is a very complex area and is implemented by different vendors differently. This can be done on a piecemeal basis (each component managed differently) or as a whole (one management solution for the entire storage infrastructure). The later is still not commercially available and as such, most implementations are of the former kind. Some issues that one should take note of are:

**SAN Management**- Most vendors supply their own tools/applications to manage the SAN. This may or may not include all the components (like switches) that are required to keep the SAN up and running as well. Users need to make sure that no matter which tool they use, they get a consistent view of the SAN from a configuration and operational perspective. Management stations (the nodes that the management software runs on) could be a node connected to the SAN or could be talking to SAN components through a network (using TCP/IP). Each of the above methods have their advantages and disadvantages and users must make sure that management is tightly bound by operational procedures.

**Storage Controller Management**- Some controllers allow for in-band and/or out-of-band management. Users need to makes sure that management procedures at the controller level are in synch with SAN level and node level (application) management procedures. This is especially relevant in clustered environment where disconnected events could trigger failovers or application shut downs.

**Switch Management**- A switch is a central component in a SAN and controls all access from nodes to storage. In addition to what has been mentioned earlier, users also need to make sure that switch state changes are propagated to both the nodes and the storage controllers. These are highly specialized configurations and are normally owned by a single vendor. Users need to make sure the complete operational system is implemented by the vendor before signing off on the installation. Any configuration changes, like firmware or driver updates, need to be validated by the vendor and Microsoft.

**Node Management**- Nodes can be used to manage the SAN or just have a few management components installed to react to specific state changes sent from a SAN. Needless to say, the functionality of the agents needs to be validated in order to make sure that they do not interfere with the operating system or clustering functionality.

# Server Clusters: Security Best Practices, Windows 2000 and Windows Server 2003, General Assumptions

Updated: January 1, 2003

Applies To: Windows Server 2003 with SP1

Published: January 1, 2003

**Also In This White Paper**

Server Clusters: Security Best Practices, Windows 2000 and Windows Server 2003, Deployment and Operations

**General Assumptions**

There are a number of general assumptions and operational best practices that should be in place for the infrastructure to ensure a secure environment in which to run server clusters.

1. Servers and storage are in physically secure locations.

2. Practical security implementations to detect irregular traffic, such as firewalls, network probes and management tools, are in place.

3. Best practices/common sense in terms of security are adhered to in areas like administration, storage of logs, backup and restore etc.

4. Platform level security best practices are adhered to in terms of assigning administrative permissions, ACLing resources, and other housekeeping roles.

5. The network infrastructure services such as Active Directory, DNS, DHCP, WINS etc. must be secure. Any compromise of these infrastructure services can lead to a compromise of the cluster service itself.

6. The cluster administrator must ensure that applications that call the cluster APIs (ClusAPI) are run from trusted computers. Any compromise on the computers on which the applications are executing (that the cluster administrator runs) can compromise the cluster. For example, if there are untrusted users with elevated privileges on the workstation from where the administration tools are run, untrusted or malicious code can be run against the cluster by the cluster administrator without the cluster administrator realizing.

7. Access to the set of objects created and maintained by the cluster service must not be compromised by adjusting the default settings placed on these objects to a less restrictive setting. The cluster service utilizes a set of objects in the operating system such as files, devices, registry keys etc. These objects have a default security setting that ensures non-privileged users cannot impact the cluster configuration or the applications running on the cluster. Changing these security settings to less restrictive security settings can lead to the cluster being compromised and the application data being corrupted.

# Server Clusters: Security Best Practices, Windows 2000 and Windows Server 2003, Deployment and Operations

This section of the white paper contains the following subsections:

Cluster administrators

Remotely managing and configuring clusters

Cluster service account

Changing the Password

Using Kerberos Authentication in a Server cluster

Creating Computer Objects

Disabling Computer Objects

Renaming Computer Objects

Password Rotation

Caveats, Issues and Considerations

Network Security

NTLM V1 and NTLM V2

NetBIOS

IPSec

Cluster Disks

Managing file shares in a cluster

Cluster Server nodes as Domain Controllers

Summary of security attributes

Majority Node Set considerations

Upgrading to Windows Server 2003 considerations

Developing Cluster-aware Applications

Calling the Server cluster APIs

Backup/Restore APIs

**Cluster administrators**

Administrators can specify groups or individuals that are allowed to manage the cluster. In current versions of Server cluster, there are no fine details of control; either a user has rights to administer the cluster or the user does not. To grant a user or group rights to administer the cluster, the user or group must be added to the cluster security descriptor. This can be done through cluster administrator or the cluster.exe command line tool.

**Note**

| |
|---|
| Apart from the local Administrators group on a node, all other members of the cluster security configuration MUST be either domain user accounts or global groups. This is to ensure that the account is the same, well defined and authorized account on all nodes in the cluster. |

By default, the local Administrators group is added to the cluster service security descriptor.

Adding a user or group to the cluster security descriptor means that the user can manage all aspects of the cluster configuration including (but not limited to):

- Taking resources offline and bringing resources online
- Shutting down the cluster service on nodes
- Adding and removing nodes from the cluster
- Adding and removing resources from the cluster

Because of the scope of impact on the applications and services running in the cluster, careful consideration must be taken when adding a user to the cluster security descriptor.

The cluster service runs the code associated with a resource under the cluster service domain user account (this should not be confused with the account used to administer the cluster). Since a cluster administrator can add new resources to a cluster and since those resources run as the cluster service account, a cluster administrator can install code that runs with local administrator rights on the machine.

**Best Practices**

- Cluster administrators should use a different account than the cluster service account to administer the cluster. This allows different policies (such as password expiration etc.) to be applied separately to the cluster service account and the domain account(s) used to administer the cluster.
- You should only add users with local Administrator rights to the cluster service security descriptor.

  | **Note** |
  |---|
  | By adding a domain user or global group to the local Administrator group, that group or account will automatically be a cluster administrator. |

- Do not remove the local Administrator group from the cluster service security configuration.

**Remotely managing and configuring clusters**
Administration tools or other applications that call the Server cluster APIs (ClusAPI) can be run from remote workstations. The general assumption is that the cluster administrator must ensure that the applications are run from trusted computers. Any compromise on the computers on which the applications are executing (that the cluster administrator runs) can compromise the cluster.

When a cluster is created or the configuration is changed (such as adding a new cluster node), the Cluster Configuration Wizard will create a log file on the machine on which the wizard is run so that in the event of failures, the administrator can use the log for debugging and troubleshooting. This log file can contain cluster configuration data such as cluster IP addresses, network names etc. This data could be used to extend the attack surface if it is read by unauthorized users.

**Cluster service account**
The cluster service account is the account under which the cluster service is started. The credentials for this account are stored in the service control manager (SCM) which is the Windows component that is responsible for starting the cluster service when the cluster nodes are booted.

The cluster service account must be the same on all nodes in a cluster and it must be a domain-level account that also has local administrative rights to each node in the cluster. The domain account must exist before the cluster is created and the Cluster Configuration Wizard will prompt you for an existing account to be used. If the account is not already a member of the local

Administrators group, the Cluster Configuration Wizard will automatically add it to the local Administrator group when the cluster is created. Likewise, when nodes are added to the cluster, the cluster service account will be added to the local Administrators group. If a node is evicted from a cluster or the last node is removed, the cluster service account is not removed from the local Administrators group.

You need to be aware of these semantics to avoid unintentionally granting a domain account local administrator rights to a given set of nodes.

| **Note** |
| --- |
| Evicting a node from a cluster does NOT remove the cluster service account from the local Administrators group. When you have removed a node from the cluster, you should manually remove the cluster service account from the local Administrators group to avoid having stale accounts with local administrator rights to a machine. |

The nodes in a Server cluster use authenticated communication mechanisms to ensure that only valid members of the cluster can participate in the intra-cluster protocols. It is essential that each node in the cluster has the same cluster service account in order to provide authentication consistency. It is also a requirement of the cluster service account password utility introduced in Microsoft Windows Server 2003.

**Required Privileges**
As well as being a member of the local Administrator group, the cluster service account requires a set of additional, locally granted privileges:

- Act as part of the operating system (required for Windows 2000 and beyond).
- Back up files and directories.
- Increase quotas.
- Increase scheduling priority.
- Load and unload device drivers.
- Lock pages in memory.
- Log on as a service.
- Restore files and directories.

You should NOT remove any of these privileges from the cluster service account. If you remove any of these required privileges, the cluster service may not start up or operate correctly.

During the cluster server setup process, these privileges are granted locally to the account. If you ever need to manually re-create the cluster service account, you must also grant these additional privileges. *KB article 269229: How to Manually Re-Create the Cluster Service Account* describes the steps necessary to re-create the cluster service account.

**Password Policies**
The cluster service account is just like any other domain account, it has a password that can have password expiration policies associated with it. If the password has expiration policies assigned to it, then the cluster account password must be changed before it expires. Failure to do so will cause the cluster to stop functioning when the password expires (since the intra-cluster communication can no longer be successfully authenticated).

**Changing the Password**
In most production deployments, domain accounts will have password expiration policies that force the password to be changed relatively frequently (for example every 30 days). Changing the cluster service account password requires careful planning.

**Windows 2000**
The cluster service account on ALL nodes in the cluster must match to ensure that the intra-cluster communication can be successfully authenticated. The cluster service itself sends messages between cluster nodes under a variety of conditions and if any of those communications fail, the cluster node will be removed from the cluster (i.e. the cluster service will be stopped). It is

not possible to determine when the cluster service will establish communication and therefore there is no clear window that allows the cluster service account to be changed in a reliable way while ensuring that the cluster remains running.

On Windows 2000, the cluster account password can only be reliably changed using the following steps:

1. Stop the cluster service on ALL nodes in the cluster
2. Change the password of the cluster service account at the domain controller
3. Update the service control manager password on ALL cluster nodes
4. Re-start the cluster service on all of the cluster nodes

**Windows Server 2003**

The cluster.exe command on Windows Server 2003 has the ability to change the cluster account password dynamically without shutting down the cluster service on any of the nodes. The cluster.exe command changes the domain account password and updates the service control manager account information on all nodes in the cluster.

| **Note** |
| --- |
| This command will only work for Windows Server 2003 nodes. If there are any Windows 2000 nodes in the cluster, their cluster service account password will not be changed. |

**Cluster /cluster**:*cluster_name1*[,*cluster_name2*,] **/changepassword**[:*new_password*[,*old_password*]] [**/skipdc**] [**/force**] [**/**options]

The command arguments have the following meanings:

| **Argument** | **Description** |
| --- | --- |
| **cluster**:*cluster_name1* [,*cluster_name2*,] | Identifies the cluster(s) for the account password change. If multiple clusters are specified, they must use the same cluster service account. If some nodes are unavailable, the password is not change on any of the nodes or at the domain controller. |
| **/changepassword** [:*new_password* [,*old_password*]] | Changes the cluster service account password on the domain controller and all cluster nodes from old_password to new_password. If the passwords are not supplied on the command line, you will be prompted to provide them. |
| **/skipdc** | Changes the cluster service account password only on the cluster nodes. |
| **/force** | Forces the execution of the password change on the available nodes even if some nodes are not available.<br>**Note**<br>This command will only work for Windows Server 2003 nodes. If there are any Windows 2000 nodes in the cluster, their cluster service account password will not be changed. |

The details of the command are documented in the on-line help available from the Cluster Administrator tool.

**Best Practices**

- The cluster service account should NOT be a domain administrator account.
    - All accounts should be given the minimal possible rights and privileges to avoid potential security issues if a given account is compromised.
    - Use delegation to give administration rights to specific accounts on ALL nodes of a cluster.
- If there are multiple clusters in a single domain, using the same cluster service account on all nodes makes administration easier.

    - You need to balance the ease of management with the potential security risks associated with using a single account for many clusters. If the account is compromised, the scope of the impact depends on how many clusters are involved.

    - With Windows Server 2003, the cluster service account password can be changed on multiple clusters at the same time.

- If you have set password expiration policies on your cluster service accounts you should NOT use this account for other services.

    - Do not use the cluster service account for SQL Server 2000 or Exchange 2000, for example, if you have set password expiration policies. If you have multiple services using the same account, coordinating the password change across the cluster service and other services is complex and will lead to the complete cluster and/or service being unavailable during a password rotation. It is better to have a dedicated account for each service, each of which can be maintained independently.

    - With Windows Server 2003, the cluster service account password can be changed online without taking the cluster down ONLY if there are no services using the same service account.

- Changing the cluster service account password on Windows 2000 requires the cluster to be shut down completely before the account password is changed. Shutting down and re-starting the cluster may mean that the cluster cannot meet the availability requirements. For example 99.999% uptime requires less than five minutes downtime *per year* for the applications and services. This level of availability cannot be achieved if the cluster is shutdown for password rotation. In these high availability environments, with Windows 2000, the cluster service account should have a password expiration policy of never expiring.

- With Windows 2000 SP3 and Windows Server 2003, the cluster service can publish virtual servers as computer objects in Active Directory. To ensure correct operation, the cluster service account should have appropriate access rights or privileges to be able to create and manipulate these objects in the Active Directory Computers container.

  See section Using Kerberos Authentication in a Server cluster.

- If you intend to deploy multiple clusters using different cluster service accounts, you should create a Global or Universal group which implements all of the policies and has all of the privileges described above. Each cluster service account should then be placed into the group.

    - This eases management of the cluster service accounts by providing a single container for all cluster service accounts and a single point of management for changing account policies.

**Using Kerberos Authentication in a Server cluster**

Kerberos authentication was released as part of the Windows platform in Windows 2000. It is the primary (and default) security mechanism for the Windows platform moving forward and it has a number of benefits over the previous authentication mechanisms (such as NTLM):

- **Provides mutual authentication of client and server**: The server ensures that the client has access to the service or applications provided at the server and the client can be sure that the server it is communicating with really is the server that it was expecting it to be.

- **Allows delegation of authentication across multiple machines**: Allows end-to-end impersonation based on the credentials associated with the original request in a multi-tiered application deployment. For example, a web site may contain an IIS web server front-end, business objects at the middle-tier and a database back-end. Kerberos allows the original client authentication to be carried across all of the tiers from the web server to the database for end-to-end authentication and authorization.

- An industry standard allowing a common authentication mechanism across multiple platforms.

For more information about Kerberos and how it works, see the TechNet web site:
http://www.microsoft.com/windows2000/techinfo/howitworks/security/kerberos.asp

In a Server cluster, applications are deployed in *virtual servers*. A virtual server is a Server cluster resource group that contains an IP Address resource and a Network Name resource as well as any resource required for a given service or application. Clients connect to the clustered service using the IP Address or Network Name associated with the service. When an application fails over from one node to another, so do the IP Address and Network Name resources, thus the client continues to use the same target location for a service or application regardless of which machine in the cluster is currently hosting it.

For Server clusters in Windows 2000 (up to SP2), the only mechanism available for authenticating a client against a virtual server name is NTLM, thus the benefits provided by Kerberos are not available to deployments that contain Server clusters.

In Windows 2000 SP3 and Windows Server 2003, Kerberos authentication will be available to cluster server applications, allowing end-to-end impersonation in a highly available deployment.

**Virtual Server Computer Objects**
Kerberos authentication requires a backing computer object (CO) to be published in Active Directory. In Windows 2000 SP3 and beyond, the network name cluster resource has the ability to publish a computer object in Active Directory for the virtual server. This is controlled through the new resource property **RequireKerberos** with the following values:

- RequireKerberos = 0

  The Network Name resource does not create an object in Active Directory. This provides the same semantics as Windows 2000 (up to SP2) and is the default value for backward compatibility as well as ensuring correct behavior during rolling upgrade.

  (In the case of a network name that is required for MSMQ, RequireKerberos is enabled by default to ensure that MSMQ continues to work as expected after the upgrade is complete.)

- RequireKerberos = 1

  The Network Name resource does create an object in Active Directory thus enabling Kerberos authentication against the virtual server computer name.

The full semantics for this property are described later in this section.

| **Note** |
| --- |
| Although the Network Name resource publishes a computer object in Active Directory, that computer object should NOT be used for administrations tasks such as applying Group Policy. The ONLY role for the virtual server computer object in Windows 2000 and Windows Server 2003 is to allow Kerberos authentication and delegation and for cluster and Active Directory-aware services (such as MSMQ) to publish service provider information. |

**The Lifetime of a Computer Object**
Network Name resource controls the creation and deletion of computer objects as dictated by a number of factors including resource property settings and the resources own lifetime.

**Creating Computer Objects**
The Network Name resource creates a computer object when the RequireKerberos resource property is set to one (the default value is zero). Setting this value to one requires that the cluster service account has access to Active Directory either by having the *Add Workstations to the Domain* privilege or by granting specific access to Active Directory. If the account does not have access, the Network Name resource will fail to come on line.

Domain administrators can pre-create computer objects for virtual servers (in a separate OU if required) to avoid giving the *Add Workstations to the Domain* privilege to the cluster account. In this case, the computer object must have an Access Control Limit (ACL) that allows the cluster service account to reset the password and write to the DnsHostName and ServicePrincipalName attributes (which have individual access rights).

If an orphan computer object or a computer object created by the domain administrator exists in Active Directory corresponding to the virtual computer name, and the cluster service account has the appropriate access rights to the object and the object is not disabled, the network name resource will hijack the existing computer object. This is the same behavior that is visible if a new computer is added to a domain that contains an old and unused computer object with the same name.

The Network Name resource sets the DnsHostName attribute of the computer object to the fully qualified DNS name of the Network Name resources Name property and the primary DNS suffix of the node. (All nodes in a cluster must be in the same NT and DNS domain.)

**Disabling Computer Objects**
Computer objects are disabled when either Kerberos authentication is no longer required (the RequireKerberos property is changed from one to zero) or when the resource itself is deleted. If the computer object still exists, but the Network Name resource is brought online without Kerberos authentication enabled, client authentication will fail. When removing Kerberos authentication from a Network Name resource, the system administrator must make an explicit decision to delete the corresponding computer object. Note that Active Directory-aware applications hosted in the virtual server (such as Exchange server and MSMQ) may have attached their own information to the computer object. If the computer object is deleted, those properties will also be deleted and the applications may no longer function correctly. Extreme care should be taken when removing Kerberos authentication from a network name.

When the Network Name resource is deleted or Kerberos authentication is removed, the Network Name resource makes a one-time best effort to disable the computer object. All disable operations, along with their final status, are logged in the cluster and system event logs. If disabling the computer object fails for any reason, no other attempt is made to disable it.

**Renaming Computer Objects**
The computer object is intimately tied to the virtual network name exposed by the Network Name resource. If the *Name* property of the network name resource is changed, that change must be reflected in the computer object. These changes are tightly coupled and synchronized; for that reason, changing the Name property can occur only when the Network Name resource is offline. If renaming the computer object fails for any reason, the change to the Name property is also failed.

There is one caveat to this: the Network Name resource allows property values to be changed while the Network Name resource is online; in this case, the rename operation is deferred until the name is taken offline. If that rename attempt fails, the operation is retried as part of the online process. The name will not be brought online until the rename operation is successful.

| **Note** |
| --- |
| Many applications and services such as MSMQ and SQL Server do NOT support changing the *Name* property on the Network Name resource. |

**Password Rotation**
The computer object maintains a password used for authentication when issuing Kerberos tickets. In the current implementation for Windows 2000 SP3 and Windows Server 2003, the password on the computer object is not changed once the computer object is created.

**Caveats, Issues and Considerations**
**Orphan Computer Objects**
Many operating system services and applications use the *Negotiate* security package which is a component provided by the Windows platform that allows a client to authenticate with a service. This package hides the particulars of any given authentication scheme and allows a client to try Kerberos authentication, and if that is unavailable, it falls back to NTLM authentication. If there is a computer object in Active Directory that corresponds to the target name that the client is using, the negotiate package will assume that Kerberos authentication is *required*. (In an all Windows Server 2003 domain this will work as expected.) If a virtual computer object exists in Active Directory (disabled or not) future client connections to that virtual server name will NOT fail-back to NTLM.

If authentication fails against a virtual server and that virtual server should be using NTLM, then you should check whether there is an orphaned or old computer object in active directory corresponding to the virtual server name.

**Cluster-Aware and Active Directory-Aware Services**
There are some services that are both cluster-aware and Active Directory-aware, in particular, SQL Server 2000, Exchange 2000 and MSMQ. Some of these services attach service information to the computer objects. MSMQ in particular attaches service information to the virtual server computer object.

When removing Kerberos authentication from a Network Name resource, the computer object will be disabled, leaving the system administrator with an explicit decision to delete the computer object. If the computer object is deleted, properties attached by Active Directory-aware applications will also be deleted and the applications may no longer function correctly. Extreme care should be taken when removing Kerberos authentication from a Network Name resource.

**Active Directory Replication Delays**
Thus far, we have talked about Active Directory as though it were a single, highly consistent infrastructure. In a production environment, multiple domain controllers are deployed to ensure that the domain infrastructure is highly available. Changes to

Active Directory are replicated across nodes and in some cases that replication delay can be large. This can cause some seemingly inconsistent effects that you will need to be aware of:

- **Clients cannot see the computer object for a network name resource**

  Different nodes may access different domain controllers. If a computer object is created on one domain controller, it may not be visible to the clients until it is replicated to other domain controllers.

**Best Practices**

- Plan your use of Kerberos authentication in a cluster carefully:

  - Enable Kerberos authentication on those virtual servers that make sense for your deployment.

  - You should not disable Kerberos authentication on a virtual server unless you fully understand the services using that virtual server and the implications that will have on the service. The computer object and any service information attached to it WILL be deleted (assuming correct privileges) which may lead to a service being unavailable or unrecoverable.

- The cluster service account should have the *Add workstations to the domain* privilege to allow it to create computer objects in Active Directory. If you do not wish to grant that privilege to the cluster service account, you MUST create the computer object by hand in Active Directory before enabling Kerberos authentication.

| **Note** |
| --- |
| The *Add workstations to the domain* privilege allows a default of 10 computer objects to be created from that account. In addition, the *Add workstations to the domain* by itself does NOT allow the account to delete or rename the computer object. |

- The cluster service account should have *Write all properties* access rights to allow it to rename the computer object.

- Many services, including MSMQ and SQL Server 2000 do not support changing the Network *Name* resource Name property. You should only ever change this property if you fully understand the implications. In some cases changing the Network Name resources *Name* property can lead to loss of data or failure of a service.

- You should ensure that the domain controllers have had a chance to replicate newly created computer objects associated with Network Name resources before allowing clients to access them or before failing over the resource to another node in the cluster. Failure to do this can lead to unpredictable results (see section Active Directory Replication Delays).

**Network Security**
**Network Flooding**
The cluster service uses UDP port 3343 for intra-cluster communication. This communication includes heartbeat traffic to detect node failure and cluster control operations. Some of these operations (such as heartbeats) are time-sensitive. If there is significant load on the ports due to network flood attacks, it can result in false node failure detection and therefore cause unnecessary failover operations which will lead to application downtime.

**Port Squatting**
It is possible for a rogue application to hijack or squat on port 3343. This will stop the cluster service from starting up. In this case, the only option is to kill processes using the port. Port 3343 is registered exclusively for the cluster service.

**Rogue Servers**
The cluster service provides remote management capabilities through the cluster APIs so that a cluster can be managed from a management station. The cluster APIs use NTLM to authenticate with the server. This allows the server to authenticate that the client has sufficient rights and privileges to manage the cluster, however, it does not provide mutual authentication. In other words, the client has no cast-iron guarantee that the node or cluster that the client connected to is the real cluster. If a rogue machine were to appear on the network with the same IP address or network name (if the DNS information were compromised), then the rogue machine could masquerade as the cluster. If that rogue machine also appeared to implement the cluster service APIs, any management commands sent to the cluster would be intercepted by the rogue machine. In many cases, this does not represent a threat since the administrator would simply receive a false positive or negative that an action

was performed. However, there are sensitive operations (such as changing the cluster configuration) where an unauthorized recipient could potentially collect cluster configuration data which may help to extend the attack surface.

This type of attack requires a number of factors to occur:

1. The rogue computer must be visible on the same subnet as the target cluster and respond to traffic to the cluster IP address (this may be the IP address of the physical computer or may be the IP address of virtual servers hosted by the computer).

2. In a typical environment, the rogue computer can only take over the IP address if the cluster node or virtual server is not running.

3. The rogue computer must appear to implement the cluster APIs. For a typical management operation, the client application makes several calls to the server and in some cases, returns handles for subsequent calls.

4. The administrator/operational procedure must change the configuration that includes the sensitive data (e.g. the administrator must change the cluster account password).

**Best practices**
Attacks that compromise the cluster typically involve being on the same subnet as the cluster. To protect against these attacks, the subnets should be protected:

- **Client-access networks**

  The subnet used by the cluster nodes should not extend beyond the set of nodes that can be physically secured or trusted. You must ensure that rogue or potentially insecure machines cannot be attached to the subnet containing the clusters. Since this network may contain domain controllers, DNS servers, WINS servers, DHCP servers and other network infrastructure, you must take steps to ensure that these infrastructure servers are also secure.

  Typical network security procedures should be put in place such as firewalls that only allow specific application requests etc. Securing networks and infrastructure servers is beyond the scope of this document.

- **Private networks**

  Only nodes in the cluster should be visible on a private network (multiple clusters can use the same private network). No other network infrastructure servers or other application servers should be on the private subnet. This can be achieved by either:

  - Physically constraining the network itself (e.g. the private network is a LAN that is only connected to the cluster nodes).

  - Isolating the cluster private networks using VLAN-capable switches.

**NTLM V1 and NTLM V2**
**Windows 2000**
Windows 2000 clusters (up to and including SP2) must use NTLM V1 authentication between cluster nodes. There are several lockdown tools and policies (such as HiSecDC) that apply different policies to the nodes, forcing NTLM V2 as the default security profile. If these policies or tools are applied to a Windows 2000 cluster, the cluster service will fail. The default security profile must be reset to Send LM and NTLM responses. This is detailed in KB articles 295091 and 272129.

**Windows Server 2003 and Windows 2000 SP3 (and above)**
In Windows 2000 SP3 and above, as well as Windows Server 2003, the cluster service is capable of using NTLM V2. Security policies that enable NTLM V2 will not compromise the cluster.

**NetBIOS**
Security of a system is dependent on the number of ways into the system. In Windows Server 2003, the cluster service does not require NetBIOS, however a number of services are affected if NetBIOS is disabled. You should be aware of the following:

- By default, when a cluster is configured, NetBIOS is enabled on the cluster IP Address resource. Once the cluster is created you should disable NetBIOS by clearing the check box on the parameters page of the Cluster IP Address resource

property sheet.

- When you create additional IP Address resources you should clear the NetBIOS checkbox.

- With NetBIOS disabled, you will not be able to use the Browse function in Cluster Administrator when opening a connection to a cluster. Cluster Administrator uses NetBIOS to enumerate all clusters in a domain.

- Print and File services are disabled no virtual names are added as redirector endpoints.

- Cluster Administrator does not work if a cluster name is specified. Cluster Administrator calls GetNodeClusterState which uses the remote registry APIs which, in turn, use named pipes based on the virtual name.

**IPSec**

Although it is possible to use Internet Protocol security (IPSec) for applications that can failover in a Server cluster, IPSec was not designed for failover situations and we recommend that you do NOT use IPSec for applications in a Server cluster.

The primary issue is that Internet Key Exchange (IKE) Security Associations (SAs) are not transferred from one server to the other if a failover occurs because they are stored in a local database on each node.

In a connection that is protected by IPSec, an IKE SA is created in phase-I negotiations. Two IPSec SAs are created in phase II. A time-out value is associated with the IKE and IPSec SAs. If Master Perfect Forward Secrecy is not used, the IPSec SAs are created by using key material from the IKE SAs. If this is the case, the client must wait for the default time-out or lifetime period for the inbound IPSec SA to expire and then wait for the timeout or lifetime period that is associated with the IKE SA.

The default time-out for the Security Association Idle Timer is five minutes. In the event of a failover, clients will not be able to reestablish connections until at least five minutes after all resources are online, using IPSec.

Although IPSec is not optimally designed for a clustered environment, it may be used if your business need for secure connectivity outweighs client downtime in the event of a failover.

**Cluster Disks**

In general, cluster disks (i.e. disks that have a corresponding resource in the cluster configuration) are just like any other disks hosted by Windows; however, there are some additional considerations that you need to understand:

**General Best Practices**

- Cluster server only supports the NTFS file system on cluster disks. This ensures that file protection can be used to protect data on the cluster disks. Since the cluster disks can failover between nodes, you must only use domain user accounts (or Local System, Network Service or Local Service) to protect files. Local user accounts on one machine have no meaning on other machines in the cluster.

- Cluster disks are periodically checked to make sure that they are healthy. The cluster service account MUST have write access to the top level directory of all cluster disks. If the cluster account does not have write access, the disk may be declared as failed.

**Quorum Disk**

- The quorum disk health determines the health of the entire cluster. If the quorum disk fails, the cluster service will become unavailable on all cluster nodes. The cluster service checks the health of the quorum disk and arbitrates for exclusive access to the physical drive using standard I/O operations. These operations are queued to the device along with any other I/Os to that device. If the cluster service I/O operations are delayed by extremely heavy traffic, the cluster service will declare the quorum disk as failed and force a regroup to bring the quorum back online somewhere else in the cluster. To protect against malicious applications flooding the quorum disk with I/Os, the quorum disk should be protected. Access to the quorum disk should be restricted to the local Administrator group and the cluster service account.

- If the quorum disk fills up, the cluster service may be unable to log required data. In this case, the cluster service will fail, potentially on all cluster nodes. To protect against malicious applications filling up the quorum disk, access should be restricted to the local Administrator group and the cluster service account.

- For both reasons above, the quorum disk should NOT be used to store other application data.

**Cluster Data Disks**

- As with the quorum disk, other cluster disks are periodically checked using the same technique. If malicious applications flood the cluster application disks with I/Os, the cluster service health check may fail, thus causing the disk (and any applications dependent on the disk) to be failed over to another cluster node. To avoid denial of service attacks like this, access to the cluster disks should be restricted to those applications that store data on the specific disks.

**EFS and Server clusters**
With Windows Server 2003, the encrypting file system (EFS) is supported on clustered file shares. To enable EFS on a clustered file share, you must perform a number of tasks to configure the environment correctly:

1. EFS can only be enabled on file shares when the virtual server has Kerberos enabled. By default, Kerberos is not enabled on a virtual server. To enable Kerberos you must check the Enable Kerberos Authentication check box on the network name resource that will be used to connect to the clustered file share.

   | **Note** |
   | --- |
   | Enabling Kerberos on a network name has a number of implications that you should ensure you fully understand before checking the box. |

2. All cluster node computer accounts, as well as the virtual server computer account, must be trusted for delegation. See online help for how to do this.

3. To ensure that the users private keys are available to all nodes in the cluster, you must enable roaming profiles for users who want to store data using EFS. See online help for how to enable roaming profiles.

Once the cluster file shares have been created and the configuration steps above carried out, users data can be stored in encrypted files for added security.

**Managing file shares in a cluster**
**Normal file shares**
Normal file shares are the most flexible and easily understood in terms of security. The only real difference is that you administer share level security using the cluster user interface instead of Windows Explorer. You administer NTFS security settings on files on the cluster disks using standard Windows tools such as Windows Explorer. For more information about administering cluster file shares, see the online documentation for Server clusters.

File shares created through Cluster Administrator are created with the same default protection as a single node unless the ACL is set using the cluster administration tools. See file services documentation for default ACL for a file share.

| **Note** |
| --- |
| Always use the cluster administration tools to change security of a clustered file share. If you use the file share management tool, any configuration will be lost when the file share is failed over to another node in the cluster. |

**Shared Subdirectories**
Subdirectory shares are available in versions of Windows later than Windows NT 4.0 Service Pack 4. Shared subdirectories allow administrators to rapidly create directories to host large numbers of shares such as home directories with a single cluster resource. A root share is specified, and all of the subdirectories one level below the specified root are created as regular file shares.

There is no way to specify different security attributes for each shared subdirectory and therefore each share inherits the same share level permissions as the root share. Because each share is typically used by a different user, the share-level permissions should be left to everyone, and file-based security at the file system level should be used to control who has access to which files.

**DFS roots**
DFS roots are available in Windows 2000 onwards. Server clusters only support standalone DFS roots as cluster resources. (Note that does NOT mean you cannot create domain roots on cluster nodes since a cluster node is just like any other server,

however, they are not cluster resources.) You can use share level permissions for the root through the Cluster Administrator user interface and you can administer each link through file share permissions on the appropriate server. However, this method of controlling access can be difficult for DFS trees spanning a large number of servers and links. We recommend you administer DFS trees by leaving file share level permissions open and use NTFS file system permissions to restrict access.

**Cluster Server nodes as Domain Controllers**
To have Server clusters function properly (where the cluster service starts on each node), the node that is forming the cluster must be able to validate the cluster service domain account, which is the account that you configure when the cluster is configured. To accomplish this, each node must be able to establish a secure channel with a domain controller to validate this account. If the account cannot be validated, the cluster service does not start. This is also true for other clustered programs that must have account validation in order for services to start, such as Microsoft SQL Server and Microsoft Exchange.

If a cluster deployment is such that there is no link with either a Windows NT 4.0 domain, a Windows 2000 domain or a Windows Server 2003 domain, you have to configure the cluster nodes as domain controllers so that the cluster service account can always be validated to allow for proper cluster functionality.

If the connectivity between cluster nodes and domain controllers is such that the link is either slow or unreliable, consider having a domain controller co-located with the cluster, or configuring the cluster nodes as domain controllers. Microsoft does not recommend using cluster nodes as domain controllers.

If you must configure the cluster nodes as domain controllers, consider the following important notes:

- If one cluster node in a 2-node cluster is a domain controller, all nodes must be domain controllers. It is recommended that you configure at least two of the nodes in a 4-node Datacenter cluster as domain controllers.

- There is overhead that is associated with the running of a domain controller. A domain controller that is idle can use anywhere between 130 to 140 megabytes (MB) of RAM, which includes the running of Server clustering. There is also replication traffic if these domain controllers have to replicate with other domain controllers within the domain and across domains. Most corporate deployments of clusters include nodes with gigabytes (GB) of memory so this is not generally an issue.

- If the Windows 2000 cluster nodes are the only domain controllers, they each have to be DNS servers as well, and they should point to each other for primary DNS resolution, and to themselves for secondary DNS resolution. You have to address the problem of the ability to not register the private interface in DNS, especially if it is connected by way of a crossover cable (2-node only). For information about how to configure the heartbeat interface refer to KB article 258750. However, *before* you can perform step 12 in KB article 258750, you must first modify other configuration settings, which are outlined in KB article 275554.

- If the cluster nodes are the only domain controllers, make them all Global Catalog servers. For background information about the placement of Global Catalog servers, see:

  http://go.microsoft.com/fwlink/?LinkId=91432

- The first domain controller in the forest takes on all flexible, single master operation roles (refer to KB article 197132). You can redistribute these roles to each node. However, if a node fails over, the flexible, single master operation roles that the node has taken on are no longer available. You can use Ntdsutil to forcibly take away the roles and assign them to the node that is still running (refer to KB article 223787). Review KB article 223346 for information about placement of flexible, single master operation roles throughout the domain.

- If a domain controller is so busy that the cluster service is unable to gain access to the quorum drive as needed, the cluster service may interpret this as a resource failure and cause the cluster group to fail over to the other node. If the quorum drive is in another group (although it should *not* be), and it is configured to affect the group, a failure may move all group resources to the other node, which may not be desirable. For more information regarding Quorum configurations, please refer to the KB article 280345 listed in the "Reference" section.

- Clustering other programs such as SQL or Exchange in a scenario where the nodes are also domain controllers, may not result in optimal performance due to resource constraints. You should thoroughly test this configuration in a lab environment prior to deployment.

- You must promote a cluster node to a domain controller by using the Dcpromo tool *prior* to creating a Server cluster or

adding a node to the cluster.

- You must be extremely careful when demoting a domain controller that is also a cluster node. When a node is demoted from a domain controller, the security settings and the user accounts are radically changed (user accounts are demoted to local accounts for example).

**Generic resources**

The generic resources types, Generic Application, Generic Service and Generic Script, allow existing non-cluster aware applications to be monitored and failed over with little or no effort. (Generic script is available on Windows Server 2003 only.) A file name path is used to identify the application or script. The cluster service runs the resource DLL under the cluster service account and therefore they are run with elevated (local administrator) privileges.

When using a generic resource you should ensure that the file containing the code/script and any registry keys used by the script, application or service are protected against attacks.

- Generic Script
    - Make sure script files are secure using NTFS file system protection.
    - Specify the fully qualified path to the script to avoid spoofing issues associated with the PATH variable.
- Generic Application
    - Make sure the application is trusted and that the files, registry keys that need to be checkpointed and any other resources needed for the application to run are secure.
    - Specify the fully qualified path to the application to avoid spoofing issues associated with the PATH variable.
- Generic Service
    - Make sure the service is trusted and that any registry keys or other resources needed for the service to run are secure.

| **Note** |
| --- |
| Typically, parameters and configurations for Windows services are stored under HKEY_LOCAL_MACHINE in the registry. This document assumes that this registry hive is protected against attacks. The default security attributes of the HKLM hive ensure that the hive is secure. |

**Summary of security attributes**

This section outlines the various objects and their associated security attributes needed to ensure that the cluster service runs successfully. The section lists the minimum security requirements. If the security attributes are made more restrictive, the cluster service may not run. If the security attributes are less restrictive, it may result in malicious attacks being able to compromise the cluster or corrupt end-user data. We recommend that the security attributes on the objects not be changed from the default settings.

**Directory and file protection**

| Object | Description | Minimum recommended security attributes |
| --- | --- | --- |
| %windir%\help | Cluster Help files | BUILTIN\Users:R<br>BUILTIN\Administrators:F |

| | | |
|---|---|---|
| %windir%\cluster | Cluster directory (and subdirectories) | BUILTIN\Administrators:F<br>BUILTIN\Administrators:(OI)(CI)(IO)F<br>NT AUTHORITY\SYSTEM:F<br>NT AUTHORITY\SYSTEM:(OI)(CI)(IO)F<br>CREATOR OWNER:(OI)(CI)(IO)F |
| %windir%\cluster* | Files in cluster directory | BUILTIN\Administrators:F<br>NT AUTHORITY\SYSTEM:F |
| <quorum_drive> | Volume holding quorum data | BUILTIN\Administrators:F<br>BUILTIN\Administrators:(OI)(CI)(IO)F<br>NT AUTHORITY\SYSTEM:F<br>NT AUTHORITY\SYSTEM:(OI)(CI)(IO)F |
| <quorum_drive>:\MSCS | Quorum directory (and subdirectories) | BUILTIN\Administrators:F<br>BUILTIN\Administrators:(OI)(CI)(IO)F<br>CREATOR OWNER:(OI)(CI)(IO)F |
| <quorum_drive>:\MSCS* | Files in quorum directory | BUILTIN\Administrators:F |
| | Volumes on cluster disks | BUILTIN\Administrators:F<br>BUILTIN\Administrators:(OI)(CI)(IO)F<br>NT AUTHORITY\SYSTEM:F<br>NT AUTHORITY\SYSTEM:(OI)(CI)(IO)F |

**System resources**

The cluster service uses other system resources that are protected by default.

| Object | Description | Minimum recommended security attributes |
|---|---|---|
| HKLM* | HKLM registry hive | SYSTEM:Full control<br>BUILTIN\Administrators: Full control |

**Cluster Service Account Policies**

- Do not let the password expire. On Windows Server 2003 you can use the password change mechanism to ensure that the password is periodically cycled.
- Use strong passwords for the cluster service account.

**Active Directory**

- To ensure Kerberos authentication functions as expected, the cluster service account must have access to Active Directory. This is covered in the section Using Kerberos Authentication in a Server cluster.

**DNS**

- The cluster service account needs to be able to publish records. In a secure, DNS backed zone, the DNS administrator can chose to restrict the access rights for users. The cluster service account must be granted permission to create records or alternatively, the records can be pre-created. If the records are pre-created, you should not set the zone to dynamic updated.

**Majority Node Set considerations**
Windows Server 2003 provides a new quorum-capable resource known as Majority Node Set. The primary goal of this resource is to keep multiple copies of data spread across a cluster in sync at all times. It can be used to provide a quorum resource in a cluster without using a shared disk for the quorum data and is primarily targeted at the following scenarios:

- Geographically dispersed clusters to provide a single, common quorum mechanism for multi-site cluster configurations to allow vendors to build solutions without having to be concerned about quorum requirements.

- Clusters of appliances set of off-the-shelf machines that have no shared disks being bound into a single cluster using some other data replication technique for application and/or user data.

In a majority node set cluster there is a single majority node set resource. It is responsible for committing changes to the quorum data stored on each cluster node. Each cluster node has its own copy of the data. To access the data on the other nodes in a cluster (i.e. the ones other than the node that the resource is hosted on), the Majority Node Set resource uses the file share infrastructure. When a Majority Node Set resource is created, a file share is created on each cluster node (and on nodes that are added to the cluster).

This file share is a hidden file share that has a name constructed as follows:

```
\\<node_name>\<resource_GUID>$
```

The default security setting for this file share is:

```
BUILTIN\Administrators:F (this folder, subfolders and files)
CREATOR OWNER:F (Subfolders and files only)
```

To ensure the correct operation of a majority node set cluster:

- Do NOT delete the file share.

- Do NOT remove the cluster service account from the set of accounts that have access to the share.

- Do NOT change the default access controls for the file share

- The file share target is a directory in the %windir%\Cluster\MSCS directory. You should not change the default access permissions on the files or the directories.

- You should never put other files into the MNS target directory %windir%\Cluster\MSCS\MNS.<guid-representation>. If you put other files in this directory, they will be deleted on cleanup if the MNS resource is deleted.

**Upgrading to Windows Server 2003 considerations**
Windows 2000 and Windows NT4 have default security attributes on the %windir%\Cluster directory and the quorum directory that allow any authenticated user to read the contents. The security of the directories has been tightened in Windows Server 2003 to stop non-administrator access altogether to ensure that unauthorized users cannot gain information about the cluster configuration. On an upgrade to Windows Server 2003, however, these security attributes are not modified and therefore on an upgraded Windows Server 2003 machine, all authenticated users may have read access to these directories. You may want to consider manually setting the permissions to conform to the minimum access requirements.

**Developing Cluster-aware Applications**
Resource DLLs run within the context of the cluster service account. This account has a number of elevated privileges as well as being a member of the local Administrators group on every node in the cluster. When developing a cluster-aware application, you should consider how best to split the application between the resource DLL and an independent service or executable to ensure that the application runs with the minimal privileges and rights necessary.

Running applications and services at unnecessary privilege levels introduces a potential security risk if that application is compromised.

**Calling the Server cluster APIs**
The Server cluster APIs are protected so that arbitrary, untrusted users cannot affect the state of the cluster or the availability of applications. The cluster service maintains a security descriptor in order to control access. Only accounts that are part of the security descriptor are able to call cluster APIs (actually, the security descriptor controls which accounts can open a handle to the cluster, since other cluster server APIs require a handle to the cluster, this effectively limits access).

There is one caveat with this mechanism. The cluster configuration mechanism provided in Windows Server 2003 requires that a user who adds a node to a cluster has local administrator rights on every node in the cluster. If the user does not have local administrator rights on the existing cluster nodes, that user will not be able to successfully add a new node to the cluster. Thus, to give an account administration rights to a cluster you should:

1. Add the account to the cluster service security descriptor.

2. Make sure that the account is a member of the local Administrators group on ALL machines in the cluster.

These operations can be done programmatically using the cluster APIs and the security APIs. See the platform SDK for more details.

Security checks are done by the OpenCluster API. If the call returns successfully, the caller has a valid handle and can make any changes to the cluster configuration or enumerate the cluster configuration. There is no notion of open for read or open for write.

**Backup/Restore APIs**
The backup path specified to the backup API should be protected. The data returned by the API contains cluster configuration information that can be used to extend the attack surface (e.g. lists all cluster IP addresses).

During a restore operation, the backup API takes the cluster configuration to inject. This data must be protected as it will be used to restore the cluster by overwriting any configurations that currently exists.

**Installing resources**
Cluster aware applications may install cluster resources. Care should be taken when installing resources since they will be executed at elevated privilege and they must, therefore be protected against malicious attack by default when installed:

- Ensure that resource DLLs are protected at the file system level to allow local Administrator and the cluster service account access only.

- Be extremely careful about any paths that are specified. There are several well-known issues with paths; especially paths that contain spaces (follow recommendations on page 419 of Writing Secure Code). When in doubt, specify a fully qualified path to the resource dll when creating the resource type.

# General Assumptions

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

There are a number of general assumptions and operational best practices that should be in place for the infrastructure to ensure a secure environment in which to run Server clusters.

1. Servers and storage are in physically secure locations.

2. Practical security implementations to detect irregular traffic, such as firewalls, network probes and management tools, are in place.

3. Best practices/common sense in terms of security are adhered to in areas like administration, storage of logs, backup and restore etc.

4. Platform level security best practices are adhered to in terms of assigning administrative permissions, ACLing resources, and other housekeeping roles.

5. The network infrastructure services such as Active Directory, DNS, DHCP, WINS etc. must be secure. Any compromise of these infrastructure services can lead to a compromise of the cluster service itself.

6. The cluster administrator must ensure that applications that call the cluster APIs (ClusAPI) are run from trusted computers. Any compromise on the computers on which the applications are executing (that the cluster administrator runs) can compromise the cluster. For example, if there are untrusted users with elevated privileges on the workstation from where the administration tools are run, untrusted or malicious code can be run against the cluster by the cluster administrator without the cluster administrator realizing.

7. Access to the set of objects created and maintained by the cluster service must not be compromised by adjusting the default settings placed on these objects to a less restrictive setting. The cluster service utilizes a set of objects in the operating system such as files, devices, registry keys etc. These objects have a default security setting that ensures non-privileged users cannot impact the cluster configuration or the applications running on the cluster. Changing these security settings to less restrictive security settings can lead to the cluster being compromised and the application data being corrupted.

# Web and Application Server Infrastructure - Performance and Scalability

Updated: January 1, 2003

Applies To: Windows Server 2003 with SP1

Published: April 1, 2003

By Bill Karagounis, Microsoft Corporation

**In This White Paper**

Introduction (Web and Application Server Infrastructure - Performance and Scalability)

Programming Considerations (Web and Application Server Infrastructure - Performance and Scalability)

General Performance Considerations (Web and Application Server Infrastructure - Performance and Scalability)

Dedicated Application Scenario (Web and Application Server Infrastructure - Performance and Scalability)

Dense Hosting Scenario (Web and Application Server Infrastructure - Performance and Scalability)

Server Consolidation Scenario (Web and Application Server Infrastructure - Performance and Scalability)

Summary (Web and Application Server Infrastructure - Performance and Scalability)

# Introduction (Web and Application Server Infrastructure - Performance and Scalability)

Updated: January 1, 2003

Applies To: Windows Server 2003 with SP1

Microsoft Windows Server 2003 incorporates a significantly different Web and application server infrastructure than previous releases of Windows Server. In fact, the key theme of the release is to bring forward the fundamental capabilities of the Web application platform, with a view to laying a solid foundation for existing and future server-based Windows .NET Framework applications and Web services.

A key part of bringing forward the fundamentals of the platform is to also provide significant business benefit for existing applications and Web sites currently running on Microsoft Windows NT 4.0 and Windows 2000, when migrated to Windows Server 2003. An increase in capacity and/or scalability for these applications can be valuable from a Total Cost of Ownership (TCO) perspective (by decreasing the number of servers used or by improving capacity on existing servers). In addition to ensuring that Windows Server 2003 was optimized for Windows .NET Framework applications, specific engineering effort was put into ensuring that existing ISAPI and ASP/COM+ applications would also see a performance and scalability gain on Windows Server 2003. This paper covers performance tuning considerations for ISAPI and ASP/COM+ applications, in addition to providing tuning ideas for the Windows .NET Framework.

**Audiences for This Document**
This document is intended for operations staff, IT administrators, developers, and architects. It is broken out into four main sections:

1. Architectural Discussion on Web performance features and capabilities of Windows Server 2003
2. Programming Considerations
3. General Performance Considerations
4. Application Scenarios

For all audiences, the architectural discussion section is a useful primer. It lays the foundation and introduces concepts elaborated on in the rest of the paper.

Developers and architects should then focus on the Programming Considerations section, followed by the General Performance Considerations section.

IT administrators and operational staff should approach this paper from either the Application Scenarios section (selecting whichever scenario applies), or the General Performance Considerations section.

**Performance and Scalability a New Architecture**
From the outset, the attributes of performance and scalability were some of the key drivers pushing the new application model and design tradeoffs in Windows Server 2003 development.

Much of the application server functionality in Windows is layered on top of Internet Information Services (IIS)[1]. This discussion will begin with a comparison of IIS architecture past and present.

**Figure 1: IIS 5.0 (Windows 2000) processing architecture**

IIS 5.0 was designed to have one process, Inetinfo.exe, be the main Web server process which could farm requests out to one or more out-of-process applications, DLLHost.exe (Figure 1). In comparison, IIS 6.0 has been redesigned into three new components, which allows IIS to segment Web server code from application handling code. These three new components are: a kernel-mode HTTP listener, called HTTP.sys; a user-mode configuration and process manager, called the WWW Service Administration and Monitoring component; and the application handler, which is loaded into each worker process[2]. These worker processes, in turn, service requests for application pools[3] in HTTP.sys.

**HTTP.sys and Kernel-Mode Queuing**

| **Important** |
| --- |
| There is a very subtle point here that has significant importance. All TCP/IP connections established to IIS 6.0 are held by the kernel- mode HTTP driver (HTTP.sys). |

In this new architecture, regardless of what happens to the user mode custom application, the IIS 6.0 kernel component preserves established TCP/IP connections. Therefore, if a rich client application connects to a Web service running on Windows Server 2003, and the Web service (for whatever reason) crashes or throws a fatal exception, IIS 6.0 will maintain the TCP/IP connection and restart the application. It is unlikely that these events will be noticed by the end user (or network load balancers/switches), as the client connections will be preserved.

Windows Server 2003 introduces a new kernel-mode HTTP driver called HTTP.sys, which is specifically tuned to increase Web server performance and scalability. In IIS 6.0, HTTP.sys listens for requests and routes them to the appropriate requests queue. Each request queue corresponds to one application pool. Because no application code runs in HTTP.sys, it cannot be affected by failures in user-mode code that normally affect the status of the Web service. If an application fails, HTTP.sys continues to accept and queue new requests on the appropriate queue until one of the following: the process has been restarted and begins to accept requests, there are no queues available, there is no space left on the queues, or the Web service itself has been shut down by the administrator. Once the WWW service notices the failed application, it starts a new worker process if there are outstanding requests still waiting to be serviced for the worker processs application pool. Thus, while there may be a temporary disruption in user-mode request processing, an end user does not experience the failure, because requests continue to be accepted and queued.

**WWW Service Administration and Monitoring Component**

The WWW Service Administration and Monitoring component makes up a core portion of the WWW service. Like HTTP.sys, no application code runs in the WWW Service Administration and Monitoring component. This component has two primary responsibilities: system configuration and worker process management.

At initialization time, the configuration manager portion of WWW service uses the in-memory configuration metabase[4] to initialize the HTTP.sys namespace routing table. Each entry in the routing table contains information that routes incoming URLs to the application pool that contains the application associated with the URL. These pre-registration steps inform HTTP.sys that there is an application pool that responds to requests in a particular part of the namespace, and that HTTP.sys can request that a worker process be started for the application pool when a request arrives. All pre-registrations are done before HTTP.sys begins to route requests to individual processes. As application pools and new applications are added, the Web service configures HTTP.sys to accept requests for the new URLs, sets up the new request queues for the new application pools, and indicates where the new URLs should be routed. Routing information can change dynamically without requiring a service restart.

In the worker process management role, the WWW Service Administration and Monitoring component is responsible for controlling the lifetime of the worker processes that process the requests. This includes determining when to start, recycle, or restart a worker process, if it is unable to process any more requests (becomes blocked). It is also responsible for monitoring the worker processes, and can detect when a worker process has terminated unexpectedly.

**Worker Process Isolation Mode**

**Figure 2: IIS 6.0 (Windows Server 2003) processing architecture**

IIS 6.0 introduces a new application isolation mode for managing the processing of Web sites and applications: worker process isolation mode (Figure 2). Worker process isolation mode runs all application code in an isolated environment (W3wp.exe) without incurring a performance penalty for that isolation. Requests are pulled directly from the kernel instead of having a user-mode process pull them from the kernel for the application, and then route accordingly to another user-mode process as was the case in IIS 5.0. First, HTTP.sys routes Web site and application requests to the correct application pool queue. Then, the worker process(es) (W3wp.exe) serving the application pool pull requests directly from the application queue in HTTP.sys. This model eliminates the unnecessary process hops encountered when sending a request to an out-of-process DLLHost.exe and back again (as was the case in IIS 4.0 and 5.0), and increases performance.

In worker process isolation mode, administrators can isolate different Web applications or Web sites into separate application pools. Each application pool is separated from other application pools by process boundaries. For example, a departmental server might have Web-HR in one application pool and Web-Financing in another; an Internet Service Provider (ISP) might have http://www.adventure-works.com in one application pool and http://www.blueyonderairlines.com in another. An application that is assigned to one application pool is not affected by other application pools, and cannot be assigned to another application pool while being serviced by the current application pool. Note that applications can be easily assigned to another application pool while the server is running.

It is important to note that, in IIS 6.0, there is no longer any notion of in-process applications. All necessary HTTP application run-time services, such as ISAPI extension support, are equally available in any application pool. This design prevents a malfunctioning Web site or application from disrupting the operation of other Web applications or the server itself. With IIS 6.0 it is now possible to unload in-process components without having to take down the entire Web service. The host worker process can be taken down temporarily without affecting other worker processes serving content. There is also a benefit from being able to leverage other operating system services available at the process level (for example CPU throttling), per application pool. Additionally, Windows Server 2003 has been re-architected to support many more concurrent processes than ever before.

Worker process isolation mode prevents one application or site from stopping another. In addition, separating applications or sites into separate application pools simplifies a number of management tasks, for example: taking a site/application online or offline (independent of all other site/applications running on the system), changing a component the application uses, debugging an application, monitoring counters for an application, and throttling resources used by an application.

The IIS 6.0 request processing architecture delivers very high levels of reliability without sacrificing performance.

- **Increased reliability.** IIS 6.0 worker process isolation mode prevents Web sites and applications from affecting each other or the server as a whole.

- **Fewer server restarts.** The user will likely never need to restart the server or shut down the entire WWW service, due to a failed application or common administration operations, such as upgrading content or components, or debugging Web applications.

- **Increased application availability.** IIS 6.0 supports auto restart of failed applications and periodic restart of leaky/malfunctioning applications, or applications with faulty code.

- **Increased scalability.** IIS 6.0 supports scaling to ISP scenarios, where there may be hundreds to thousands of sites on a server. IIS 6.0 also supports Web gardens, where a set of equivalent worker processes on a server each receive a share of the requests that are normally served by a single worker process.

- **Strong application platform support.** IIS 6.0 supports the application as the unit of administration. This includes making the application the unit of robustness by enabling application isolation, and also enabling resource throttling and scaling based on the application.

The end result is a Web platform that is more reliable and always available even if applications cause their worker processes to terminate. Worker process isolation mode contains the following features which improve its robustness without a performance impact.

**Clean Separation Between User Code and the Server**
All user code is handled by worker processes, which are completely isolated from the core Web server. This improves upon IIS 5.0, because an ISAPI can be, and often is, hosted in-process to the core Web server. If an ISAPI loaded in a worker process fails or causes an access violation, the only thing taken down is the worker process that hosts the ISAPI. Meanwhile, the WWW service creates a new worker process to replace the failed worker process. The other worker processes are unaffected.

**Multiple Application Pools**
With IIS 5.0, applications can be pooled together out-of-process, but only in one application pool, which is hosted by DLLHost.exe. When IIS 6.0 operates in worker process isolation mode, administrators can create up to 2,000 application pools, where each application pool can be configured separately.

**WebGardens**
Multiple worker processes can be configured to service requests for a given application pool. By default, each application pool has only one worker process. However, an application pool can be configured to have a set of N equivalent worker processes that share the workload. This configuration is known as a *Web garden* because it is similar in nature to a Web farm, the difference being that a Web garden exists within a single server. Requests are distributed by HTTP.sys among the set of worker processes assigned to the application pool. The distribution of requests is based on a round-robin scheme, where new connections with requests for the application pool are assigned to specific worker processes in that application pool. A benefit to Web gardens is that if one worker process slows down, such as when the script engine becomes unresponsive, there are other worker processes available to accept and process requests.

**Processor Affinity**
Worker processes can have an affinity to specific CPUs to take advantage of more frequent CPU cache (L1 or L2) hits. Processor affinity, when implemented, forces IIS 6.0 worker processes to run on specific microprocessors or CPUs and applies to all worker processes serving the Web sites and applications of an application pool. Processor affinity can also be used with Web gardens that run on multiprocessor computers where clusters of CPUs have been dedicated to specific application pools. Organizing workloads on a CPU means a more efficient usage of the CPU resources.

**Demand Start**
The new IIS architecture offers the benefit of demand start. Demand start means that the server is listening on an applications request queue, but will not physically initialize the application until a client has specifically connected to the application and requested service. At that point, a worker process will be initialized and the request will be fed into the processing engine for that application.

The WWW Service Administration and Monitoring component does on-demand process starting, and generally controls and monitors the lifecycle of worker processes.

**Idle Time-out**
The converse side of demand start is *idle time-out*. If an application has not had a request arrive for a configured amount of time, it can help to optimize a system if the resources that the application was using are temporarily freed up, until a client decides to use the application at some later point in time.

Idle time-out does not mean that the application is offline (i.e., the applications network endpoint is still active) just the physical process and run-time environment for the application are given back to the operating system.

**Kernel-Mode Caching**
Kernel-mode caching is available when using IIS 6.0, both in worker process isolation mode and in IIS 5.0 isolation mode (see below). As a single point of contact for all incoming (server-side) HTTP requests, HTTP.sys provides high-performance connectivity for HTTP server applications and provides overall connection management, bandwidth throttling, and Web server logging. IIS 6.0 has been built on top of HTTP.sys and has been specifically tuned to increase Web server throughput. In addition, under specific circumstances, HTTP.sys directly processes requests in the kernel. Both static and dynamic content from Web sites and applications can be cached in the HTTP.sys cache for high-performance responses.

IIS 6.0 has advanced heuristics built in to determine the cacheable hot-set of an application or set of sites. Just because an item is cacheable, does not necessarily mean it makes sense to add that item to an in-memory cache, since there is a cost to managing the item and the memory it consumes. Therefore, IIS 6.0 uses a new heuristic to determine which items should be

cached on the basis of the distribution of requests that a particular application receives. This means that the Web server makes better use of the resources available, while sustaining the performance on frequent requests, leading to scalability improvements.

IIS 6.0 also has heuristics built in to monitor the overall state of the server, and makes decisions to increase or reduce concurrency on that basis. The central idea here is to be efficient in using concurrency. For example, when executing processor-bound requests, starting concurrent work is not always the best approach.

# Programming Considerations (Web and Application Server Infrastructure - Performance and Scalability)

Updated: January 1, 2003

Applies To: Windows Server 2003 with SP1

This section is not designed to be the comprehensive performance programming section for Microsoft Windows Server programming environments. Rather, it simply identifies changes and highlights important considerations for building Web applications or Web services on Windows Server 2003.

**General Application Design Points**
This section contains some general points that are useful to be aware of when designing and developing and application.

**Design for Multiple Instances of an Application**
This is an important attribute for scaling applications. If an application can have multiple instances of itself running on a single server or in a farm scenario, it stands a better chance of being scaled up should the need arise, for example, to get additional throughput out of the application due to changing business needs.

Windows Server 2003 also offers the capability to easily run multiple instances of Web applications and Web services through a basic configuration parameter. The considerations when building and designing for multiple instances are:

- State management
- Centralized content or a strategy for replicating and synchronizing content

**Understand the Paths a Request Will Take Throughout the System**
It is important to understand, from a physical perspective, which processes and subsystems a specific request or message will propagate through on Windows. If you notice that a request or message is bouncing from process to process (or across a server) while its being processed, the application will need further scrutiny from a performance and scalability perspective. The best case scenario is to keep a unit of work within the same process that it started. This is often an impractical goal, but any reconciliation of process hops and minimization of network hops is good for overall performance and response time latency.

**New ISAPI APIs Related to Performance**
With the IIS 6.0 re-architecture, some of the IIS programming interfaces behave a little differently, and the core (base) native code API for IIS is augmented with new performance APIs and features.

**ExecuteURL**
Normally, an HTTP redirect is accomplished when a server responds to a clients request for a resource, with an HTTP 302 response containing the new location of the resource. The client application then does a new HTTP request to access the content (sometimes on the same server).

The ExecuteURL (**HSE_REQ_EXEC_URL**) **ServerSupportFunction** now allows an ISAPI extension to easily redirect a request to another URL. It answers growing demand by ISAPI extension developers to chain together requests of different types. From a performance perspective, it is very useful, because an application can achieve redirection of a request to a new piece of content without the additional network hop, and associated latency, of delegating a redirection to the client browser or rich client application. ExecuteURL also provides functionality to replace almost all ISAPI read raw data filters.

| **Important** |
| --- |
| If your applications require read raw data filters, your server must be running in IIS 5.0 isolation mode. |

Note that the most common scenario for developing read raw data filters is the need to examine or modify the request entity body before the target URL processes it. Currently, the only way to see the entity body of a request (if you are not the target URL) is through read raw data notifications. Unfortunately, writing an ISAPI filter to accomplish this goal can be exceedingly difficult, or even impossible in some configurations. ISAPI extensions, on the other hand, provide functionality for easy retrieval and manipulation of the entity body. ExecuteURL allows an ISAPI extension to process the request entity body and pass it to a child request, meeting the needs of nearly all read raw data filter developers.

Generally speaking, a great deal of care needs to taken when writing ISAPI filters, because the filters are totally synchronous and the code in an ISAPI filter executes on a core IIS thread. For operations that are going to involve blocking or calling off into

other computers (network latency), ISAPI filters can cause problems. Therefore, when ExecuteURL is used in combination with the wildcard ScriptMap API/feature, a developer has enough programming environment infrastructure to replace the majority of ISAPI filters with ISAPI extensions.

**Wildcard Application Map**

*What is an application map?*

When IIS receives a request from a client, the Web server looks at the extension of the file that is named in the request to determine which ISAPI or Common Gateway Interface (CGI) application handles that file. By using wildcard application maps, you can intercept every request before the requested page is sent to its mapped application. The effect is like having an application mapping that handles every file name extension. This is why the term wildcard is used to name this feature. Applications using wildcard application mappping can only be ISAPI applications, which is an advantage because they can have their own thread pool, work asynchronously, and have full access to entity bodies (important when processing HTTP POST as part of a Web Service).

With IIS 6.0, it is possible to specify one (or more) wildcard (*) application maps. As implied, these wildcard application maps get executed for every extension or request coming in to a site or virtual directory. Therefore, these wildcard application maps start to take on the behavior of an ISAPI filter; they get to see every request. Combined with the ExecuteURL function, they can perform some logic to determine what should be done with the request, and then optionally call in to other types of content.

The IIS 6.0 configuration file (**%SYSTEMROOT%\system32\inetsrv\metabase.xml**) contains a section entitled ScriptMaps. This section explains the application mapping of extensions (.aspx, .asp, .shtm, etc.) to physical components for request types. The ScriptMaps section under the /LM/W3SVC node of the metabase is the parent configuration, that is, all sites virtual directories inherit from it if they do not override a value at their level.

To configure a wildcard application map, please see Installing Wildcard Application Mappings in the IIS 6.0 Help.

**VectorSend**

ISAPI developers have only two options if a response is contained in multiple buffers. They can either call the ISAPI *WriteClient()* API multiple times, or they can assemble the response in one big buffer and send that response completely. The first approach is a performance bottleneck, because there is one kernel-mode transition per buffer and potential network latency. The second approach affects scalability, in that it puts more contention on the process heap and is wasteful in terms of memory and CPU cycles. For example, if you had to assemble a 64K response from multiple response parts, to allocate the target memory block, the heap would have to search for a 64K contiguous block for your program (possibly involving an extension of the program heap in the process) and you would have to expend the CPU cycles to copy 64K worth of data into the newly-allocated memory chunk. The VectorSend (**HSE_REQ_VECTOR_SEND**) **ServerSupportFunction** in IIS 6.0 provides a solution to this problem.

VectorSend allows developers to put together a list of buffers and file handles to send, in order, and then hand off to IIS 6.0 to compile the final response. HTTP.sys sends the buffers and/or file handles as one response by assembling and sending the response on the fly from the original data buffers. This frees the ISAPI from having to do any of this buffer construction or multiple WriteClient calls. This gives the additional benefit of higher performance and better scalability. If possible, existing applications should change from using WriteClient to using VectorSend.

**FinalSend**

The VectorSend **ServerSupportFunction** also includes an optional flag that aids the performance of a high throughput site, FinalSend (**HSE_IO_FINAL_SEND**). The **FinalSend** flag is one of the flags that can be passed into VectorSend to alter the behavior.

Specifying the FinalSend flag, tells IIS that it can clean up its request context, create the log file entry, etc. when it is completing the send in kernel mode. Without an ISAPI application specifying FinalSend, IIS deduces that the application is finished sending for the current request by retuning control to the HttpExtensionProc and waiting for it to exit. The downside here is that if IIS waits for the HttpExtensionProc procedure to return, it has to do an extra system call (transition from user mode to kernel mode and back) to facilitate the request cleanup and logging for the request. The use of FinalSend does all of this at the same time the actual response is sent to the client, saving one kernel transition per request. Although not a massive amount of CPU resources, this can be a big waste if you’re trying to sustain tens of thousands of requests per second.

**Caching Responses from Dynamic Content in the Kernel**

One of the key performance features of IIS 6.0 is that it will allow an ISAPI component to cache the dynamically-generated response to a request in the kernel, called the kernel-mode response cache. This feature has the potential to dramatically improve the performance of a server if the content being served lends itself to this form of caching.

*Why would I cache the output of a dynamic request?*

There are many scenarios where it is useful to dynamically generate a response, and allow the response to be a little stale. An online store scenario is a classic example. The product catalog is a relatively expensive page to create, because it needs to call in

to a database, perform a query that is likely to involve some form of database join, and return and render the results for the specific caller. In terms of CPU cycles, creating that page would have cost many millions of CPU cycles across multiple servers. Now, imagine you're a large e-commerce application on the Internet, getting hundreds or thousands of requests per second; what is the value in regenerating this same page a few hundred times per second, when the actual content is only going to change maybe once every ten minutes? The answer is there is little value in doing this for every request. A better strategy is to generate the page once, have the server efficiently cache it, and then give the response a staleness limit (how long the page can be served from the cache without being regenerated). Once its staleness limit expires, have the server call your code again, in the standard way, to regenerate the page and store the new response for the staleness limit.

*What performance gain do I get when putting responses in the kernel?*

To provide an idea of the difference, a simple ISAPI was written that looped 10,000 times to simulate some processing, it then responded to the client with approximately 1K of data. The ISAPIs performance was baselined on an 8P server[5]. Then, the code to cache the response in the kernel was added to the VectorSend() call. The version of the ISAPI that used the kernel cache returned a throughput of over eight times the baseline*846 percent* of the throughput in the non-cached case. Additionally, the latency of responses was dramatically better. When the ISAPI was executed each time, the average TTFB/TTLB[6] was 35.57 / 35.62 milliseconds; when the responses were served from the kernel, the TTFB/TTLB was 2.01 / 2.12 milliseconds.

Of course, results will vary according to the amount of processing done and the size of the response. The point is that leveraging the kernel cache can make a dramatic difference to the performance of an application.

*What types of content can be cached in the kernel?*

Static file requests, ISAPI components, and Microsoft ASP.NET pages can all cache responses in the kernel. A caveat to this is that the only responses that will be cached in the kernel are responses to HTTP GET requests.

**How to Cache ISAPI Responses in the Kernel**
To cache ISAPI responses in the kernel, you must use the VectorSend ServerSupportFunction to send your response. In preparation for sending your response, you must add the following response headers to go out with it:

- **Last-Modified** [7] a necessary field, it must be provided in GMT time format.

- **Expires** controls the amount of time an item is held in the cache. It is recommended that this value be calculated using an algorithm of current time on the server, plus the amount of time you want the cached copy to be served from the cache. This header should also be provided to IIS in GMT time format.

To cache the response, you call the VectorSend **ServerSupportFunction**, specifying at least the following flags:

**HSE_IO_FINAL_SEND | HSE_IO_CACHE_RESPONSE**

By implication, the send that is cached has to be the one and only send to a response.

The ASP.NET v1.1 release uses this facility in IIS 6.0 to host its output cache in the kernel. So, when using the output cache directive in ASP.NET, your responses are also being served from the kernel cache.

**Synchronous or Asynchronous ISAPI Sends**
This is a key area of architectural change for Windows Server 2003 compared to previous releases of Microsoft Server operating systems. In Windows Server 2003, the IIS 6.0 HTTP.sys interfaces with TCPIP.sys in the Windows kernel. Previous versions of IIS used the Winsock user mode library (a more general purpose TCP/IP sockets library).

Before Windows Server 2003, when an ISAPI application called a synchronous API to send a response to an end browser or application, the Winsock library would buffer the complete response in the kernel and free the ISAPI application to do more work. Meanwhile, if the caller getting the response back was on the end of a very slow link, the kernel memory allocated would be held for a relatively long time and the Windows kernel would grow its memory usage.

This functionality no longer exists in Windows Server 2003. If an ISAPI calls the WriteClient or VectorSend API synchronously (blocking call), IIS and HTTP.sys will only buffer the last 2K of a response on the callers behalf, the thread will wait until all but the last 2K bytes have been sent to that Web client (possibly halfway around the world, running over a 28.8 modem link). What eventually occurs is that the IIS thread pool reaches its maximum limit and stops growing, and the performance of the particular ISAPI is likely to be affected. To rectify this situation, it is recommended that existing ISAPI applications be changed to use the asynchronous versions of the WriteClient API. VectorSend should always be called asynchronously.

**COM+ Services in ASP**
In IIS 4.0 and 5.0, Active Server Page (ASP) applications are able to use COM+ services by way of configuring the applications

Web Application Manager (WAM) object in the COM+ configuration store to use transactions and other COM+ features. In IIS 6.0, the IIS and COM+ teams have separated the COM+ services from physical components. This allows ASP applications to use COM+ services directly inline. For example, a component can enter a transaction context inline in its code, and then exit the transaction context while still processing a method. In addition to those services available in COM+ on Windows 2000, a few new services have been added and are supported in ASP.

**Apartment Model Selection**
ASP, through COM+, allows developers to determine which threading model to use when executing the pages in an application. By default, ASP uses the single-threaded apartment (STA) model. However, if the application uses poolable objects, it can be run in the multi-threaded apartment (MTA) model.

This is an important scalability gain for many existing ASP applications, because running the ASP objects in the multi-threaded apartment means fewer threads in the system, fewer context switches, and better resource usage. If your ASP application is only using COM+ objects marked as Both or Free threaded, you can safely turn on the multi-threaded apartment in IIS 6.0 for these applications.

To turn on the multi-threaded apartment for a particular site or application in IIS 6.0, navigate to the applications node in the MetaBase.xml file, and add the value: AspExecuteInMTA=1.

**High Latency ASP Pages**
The ASP programming model is fundamentally synchronous; a request comes in to an ASP script and the ASP script keeps processing until that request is completed and the response is sent. The simple nature of the programming model is such that a developer cannot start an operation that is going to take a long time, and expect the ASP page to exit, and when the operation completes, to restart from a given point.

Consequently, if an ASP page includes a COM+ object that has to perform an operation that is going to take a long time, what will likely occur is that the thread executing the page will block and idle until the I/O operation is complete. If you have a set of ASP scripts that all have high latency operations, you will likely need a large number of threads in the system to ensure good response times.

With any large multiprocessor system, it is better to minimize any surplus threads you have; more threads = more context switches = less scalability. In Windows Server 2003, COM+ has changed to take a gradual approach to starting up new threads. It looks at system parameters before making the decision to start more concurrent work. If there is an ASP-based site or application (running in the COM+ STA) that just needs to have a high number of threads started when it initializes, it is possible to make COM+ revert to the previous behavior with the following registry setting:

**HKEY_LOCAL_MACHINE\Software\Microsoft\COM3\STAThreadPool\CPUMetricEnabled = 0 (REG_DWORD)**

As per the COM+ parameter above, you may want to also increase the number of ASP thread pool threads when you have an ASP page that experiences high latency, but is running in the COM+ MTA, or uses ASP intrinsic objects that will take a long time to execute. The IIS metabase parameter is *AspProcessorThreadMax* and is set to 25 by default. This 25 number can be a little misleading; it means a maximum of 25 ASP threads per processor, so, if you're running on a 2P system, you have a maximum of 50 threads by default. *AspProcessorThreadMax* can be changed by running the following command:

for a specific site: **cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/***NumericSiteID***/AspProcessorThreadMax 5**

or, for all sites: **cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AspProcessorThreadMax 5**

**COM+ General**
With the new IIS 6.0 architecture, it is important to question some of the existing guidelines where COM+ is concerned. A major consideration is that, before Windows Server 2003, COM+ application components were configured (by default) to run out-of-processes from the caller. The default for COM+ applications is for them to run as Server Applications, executing in a DLLHost.exe process called into from the object instantiate, or over DCOM.

The performance downside of doing this for every method call, is that there are extra threads running on the system, and every call to a method must be marshaled across process boundaries. This is not noticeable on a small implementation with low request/transaction rates, but on a high volume, large multiprocessor, this kind of overhead can greatly decrease the overall scalability of the system.

Therefore, on Windows Server 2003, it is best to change the default configuration for a COM+ Server Application to Library Application[8] to aid scalability of the calling per use of that application.

**ASP.NET Environment**
There are already many existing documents on http://msdn.microsoft.com and http://www.asp.net/Default.aspx?tabindex=0&tabid=1 which discuss coding tips and techniques for building incredibly fast applications using ASP.NET. Most of

this information applies to running the ASP.NET v1.1 release on Windows Server 2003 as well. This document will emphasize some of the points that have particular relevance to Windows Server 2003.

**Kernel-Mode Response Cache**
When the Windows .NET Framework v1.1 is running on Windows Server 2003, ASP.NET will detect the enhanced capabilities of IIS 6.0 and will leverage some of the performance features available in the Windows Server 2003 platform. A key feature being leveraged is the kernel-mode response cache. ASP.NET uses the kernel-mode response cache to store its output cache responses. The table below shows an example of an ASP.NET page that generates a 4K response. One set of figures is when the page is being retrieved from the user-mode output cache in ASP.NET, and the other is when the page is being retrieved from the kernel-mode cache.

**Table 1 The difference between user-mode and kernel-mode output caches for ASP.NET pages.** [9]

| | ASP.NET User-Mode Output Cache | Kernel-Mode Output Cache |
|---|---|---|
| Requests / Sec | 1,394 | 15,416 |
| TTFB / TTLB (msec) | 70.82 / 70.97 | 3.39 / 4.02 |
| User Mode CPU % | 76.57% | 0.78% |
| Kernel Mode CPU % | 22.69% | 99.22% |
| System Calls / Sec | 20,110 | 2,101 |
| Network Util (KB / Sec) | 6,153 | 68,326 |
| Context Switches / Sec | 2,621 | 6,261 |

As you can see, the difference is substantial when the content is being served directly from the kernel-mode response cache. When the requests are going to the user-mode static-file cache, every request transitions the processor from kernel to user mode and back, and changes process page pointers and other operating system context data. If the workload stays in the kernel, a lot of system overhead is avoided.

Additionally, with the ASP.NET kernel-mode response cache, there are no changes required from a developer's perspective. If the existing .aspx page already has the following directive:

**<@ OutputCache Duration="time in seconds VaryByParam=none %>** [10]

the page output is automatically served from the kernel-mode response cache.

On a high volume Web site, setting the output cache duration to as low as one second can also make an important difference to the overall throughput of a server.

**Partial Page Caching**
Another major consideration for a Web application is which sections of dynamically generated pages can be statically cached and which parts need to be regenerated. It can be a big performance boost if expensive-to-create portions of pages can be cached, and only the parts of a page that really need to be regenerated are dynamically generated per page access.

**Exception Handling**
Exception handling should be just that, code that is executed in the exceptional case, not code that is executed all of the time. Many programmers have developed a style where they use an exception as a convenient way to execute cleanup logic on the basis of a standard condition.

A few statistics might help to drive the point of how expensive exceptions can be: on a processor level, the cost of throwing an exception in the CLR[11] can be up to 1.8 million CPU cycles[12]. Again, 1.8 million CPU cycles gone, when one comparison operation would have sufficed. Worse, throwing an exception invariably acquires a system lock for page frame manipulation. The section entitled Software Locks (Resource Contention) explains why this is a bad thing to do. The result is that an application that throws and catches a lot of exceptions will not scale on large multiprocessor servers, in addition to wasting CPU cycles.

To summarize, throwing exceptions should be done very sparingly and certainly not on your common code paths, if you want to have high performing, scalable code.

**COM+ Interop**
Many companies have an existing inventory of applications or components that have been built using COM+ over the years.

When writing new ASP.NET applications, chances are that many of the existing COM+ components will be integrated into these ASP.NET applications (why fix something that isn't broken?). Therefore, this section contains a set of guidelines regarding the use of COM+ interop in ASP.NET.

**Infrequent, Functionally-Rich Calls**

The key to efficiency when using COM+ interop with ASP.NET applications is to minimize the number of times you transition from one environment to the other. An application needs to minimize the number of housekeeping CPU cycles expended on transitioning between the world of managed code and unmanaged code. Therefore, it is better to try and have an interface that has substantial, but less frequent calls, rather than frequent, chatty calls.

**Transactional Attribute on COM+**

Two-phase commit is one of the key features of COM+. Many projects mark all of the objects involved in an application with the **Required** or **Requires New** transaction attribute. This can introduce a substantial processing and network latency cost to the application.

The reason for this is that when a new transaction is started, or when a component enlists itself in a transaction, there is a communication with the Microsoft Distributed Transaction Coordinator Service (MSDTC). If the MSDTC is running on the local server, this will involve extra context switches; if MSDTC is running on a remote server, it will also include additional network latency. Use the transaction attributes *only* when necessary. If performance is a critical concern, consider re-factoring your components appropriately.

**Single-Threaded Apartment**

If your ASP.NET solution uses COM+ components that were built using Microsoft Visual Basic 6.0 or COM+ components marked as apartment threaded, it is recommended that you mark your ASP.NET page with the **AspCompat** directive. At the top of the .aspx page, add the following to the directive line:

```
<%@ Page AspCompat="true" Language="vb" %>
```

The reason for this is that if your .aspx page detects a COM+ object, in addition to interop, it also has to run your component in its own apartment, which means additional threads and data structure marshalling,essentially more operating system housekeeping. You can avoid some of this overhead with the **AspCompat** directive.

# General Performance Considerations (Web and Application Server Infrastructure - Performance and Scalability)

Updated: January 1, 2003

Applies To: Windows Server 2003 with SP1

This section contains general performance considerations related to processing HTTP.

**Networking**
Networking is a key consideration for a high volume server and is also becoming more of a factor with recent hardware. Larger numbers of processors per server and the increase in speed of each CPU, means that a network I/O subsystem can easily become a bottleneck for a large, powerful Web or application server.

Consequently, the network I/O subsystem of a large server requires design, planning, and monitoring. If a network card becomes a bottleneck, faster processors, more processors, or more RAM will not aid your server in achieving higher throughput.

*How do you know that a network card is a bottleneck on a system?*

The most obvious sign is by looking in the Windows Task Manager under the Networking tab. Select the network interface you would like to view and check its Network Utilization statistic. If it is close to 100 percent, the card is likely a bottleneck in the performance of your application.

Next, check the CPU utilization and context switch per second parameters. If the CPU utilization is low and context/switches per second are low[13], the server is likely to be experiencing a networking bottleneck.

*What kind of maximum throughput can I get out of my network card?*

| Network Card Speed | Megabytes / Sec |
|---|---|
| 100 megabit (100Mbps) | ~11 |
| 1 gigabit (1000Mbps) | ~60 |

These general, rule-of-thumb numbers are derived through IIS team experimentation across a wide variety of hardware and differing network card combinations. Two factors that can also affect the overall throughput of a network card is the speed of the I/O bus and the number of cards put into that I/O bus. For example, on a standard symmetric multiprocessing (SMP) 8-processor server with multiple cards, gigabit cards were plugged into a 33-MHz root bus. Results showed that the gigabit cards maxed out at around 30 MB/sec, where, on a 66-MHz root bus, the gigabit network cards could achieve 50-60 MB/sec.

The bottom line is that if network card throughput is vital, bus speeds, network cards, and testing of the overall system are also vital to understand the possible throughput characteristics of a system.

**Windows, Networking, and Large Multiprocessor Servers**
As discussed in the Networking section, it is important to plan for the amount of data throughput you expect from your server. When running on a large multiprocessor server, you also need to understand a little about the Windows system internals, in order to maximize your throughput.

From a design standpoint, the Windows networking stack performs a large part of its processing of a network cards I/O on a single processor. Therefore, if you have an intensive networking load (many Web scenarios fit into this category, with thousands of requests per second, and very little CPU time spent per request), it is possible to see uneven processor utilization. Worse, it is possible to make one CPU the bottleneck for the whole server, because it is at 100 percent utilization, while the other processors are idly waiting for it to hand off the network I/O so they can process the next request.

It can be the case that the CPU handling the network interrupts is at 100 percent, but the card is not physically saturated. The variables here are the network card manufacturers driver efficiency and quality, the speed of the processor in the server, offloading (or lack of offloading) support in the network card, and the physical capacity of the network card itself. You can rectify this situation by adding an additional network card and splitting the load coming into the server across the two network cards.

There are additional considerations for networking on large multiprocessor servers covered in the Multiprocessor section.

**HTTP Compression**

HTTP Compression is not often considered as a server throughput enhancing tool, but if your sites use large amounts of bandwidth, or if you would like to more effectively use bandwidth, consider enabling HTTP compression. HTTP compression provides faster transmission time between compression-enabled browsers and IIS. You can compress either static files only, or both static files and dynamic application responses. If your network bandwidth is restricted, HTTP compression can be beneficial, at least for static files, unless your processor utilization is already extremely high.

HTTP compression can have a dramatic improvement on the latency of responses, while improving the throughput capacity of the server.

As shown in the Networking section above, it is very easy to make a network card a bottleneck on a server[14]. Compressing the responses will mean fewer bytes to send for the same response. Network cards do not discriminate on the actual bytes, therefore, to serve the same load, the network cards will be able to push through many more compressed requests per second before they become a bottleneck.

For more information about enabling HTTP Compression. see Utilizing HTTP Compression in the IIS 6.0 Help.

**Compressing Static Content**

IIS 6.0 will store the compressed representation of a static file securely on persistent storage and will serve the compressed version for clients that request the static file and ask for the content in compressed form[15]. This is highly efficient in that, for the lifetime of the content, the compressed version of the content will be served to clients that ask for it without the CPU having to compress at each request.

A further optimization for static content is that if the heuristic for caching the item in the kernel is met, the compressed version of the item is stored in the kernel. This has the added advantage that less memory is used to cache the item and it is served in the most efficient way possible.

As an example of the gains that compression can give you, the following test was devised. The hardware used was a 1 processor, 3-GHz HT[16] server with one 100-megabit network card. The content was a 10K static .xml file.

| | **Non-Compressed** | **Compressed** |
|---|---|---|
| Requests / Sec | 1,170 | 2,493 |
| CPU % | 12.2% | 19.7% |
| Network Card % | 99% | 99% |

In this case, the throughput increased by 113 percent. The additional CPU used in the compressed case was not spent on compression (the compression for the file was only done once). Rather, the additional CPU was expended in processing the additional 1,323 requests per second over the non-compressed case.

**Controlling Static File Types to Be Compressed**

When compression is enabled on IIS 6.0, by default, only files with extension .htm, .html, and .txt are compressed. This is quite a limited list, and there are other static file types that can benefit dramatically from being compressed, such as .xml, .css, and .js. You should also ensure that these files are also in the compression list for the IIS compression filter. To do this, execute the following commands at a command prompt:

**cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/Filters/Compression/deflate/HcFileExtensions htm html txt css js xml**

and

**cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/Filters/Compression/gzip/HcFileExtensions htm html txt css js xml**

If your implementation has its own static file types, feel free to add their extensions to this list as well.

| **Note** |
|---|
| Compressed format images (.gif) do not tend to gain much out of being further compressed by IIS, thus the exclusion from this list. If the extensions are excluded from this list, however, they will not be cached in the kernel. This is an area where the extension inclusion should be considered, dependant on the Web sites content. |

**Figure 3: IIS 6.0 Compression Dialog**

**Compressing Dynamic Content**

You can also enable compression for the output of dynamic content. This is enabled through the IIS configuration dialog (see above) by enabling the Compress Application Files option. The downside in using compression for dynamic content is that IIS 6.0 must run its compression routines on every response. This can have a cost in terms of CPU consumption.

From a business justification perspective, you would enable compression for dynamic content if latency for end clients was an issue, and the extra CPU utilization was acceptable to operational guidelines for a server. Implementations with large numbers of slow client connections or mobile device clients where the wireless networks typically have high propagation delays, are some scenarios where dynamic compression could be used.

The below test data provides an indication of the impact of switching on dynamic content compression. In the test, an ISAPI extension was written whose response consisted of a 10K XML-formatted response. The test with compression on was purposely gated at a max of 50 percent CPU utilization to simulate an acceptable level of CPU use on a server. The test without compression was done to see the difference in CPU utilization at the same request rate. Testing was done on a 2-GHz Intel HT computer, 512 MB RAM, one 100-megabit network card.

| | **Non-Compressed** | **Compressed** |
|---|---|---|
| Requests / Sec | 1,051 | 1,074 |
| CPU % | 23% | 50% |
| Network Card | 99% | 31% |

At roughly the same request rate, dynamic content compression (of an XML-formatted response) consumes approximately twice the CPU without compression on. In addition to less data being sent between client and server, the network card is utilized more efficiently.

As you can see, compression for dynamic content is costly and should be carefully evaluated before being enabled on a production server.

**Compression Encoder Selection**

Compression encoder strength refers to which technique Windows uses to compress the data stream. You have the option of using an incredibly strong encoder, which will typically result in a compressed stream that is smaller than what you get when the standard encoder is used. But using a stronger encoder generally means that the amount of CPU time used is also greater. The administrator should consider the overall goals of the Web or application server and the type of content being compressed.

The strength range for the encoder is between 0 and 10, with the following breakdown:

- 0-3 fast encoder

- 3-9 standard encoder
- 10 optimal encoder

By default, static content is compressed at level 10 (most optimal) and dynamic content is compressed at level 0 (1 pass), to be most efficient at CPU utilization, on the basis of how frequently these routines are called. These parameters can be modified in the IIS metabase. To change the static compression encoder strength, open the MetaBase.xml file with a standard text editor and change all instances of the *HcOnDemandCompLevel* parameter to the desired value. Similarly, to change the compression encoder strength on all dynamic content, search for all instances of the *HcDynamicCompressionLevel* parameter and change it to the desired value.

**Compression at a Site Level Rather Than Global**
IIS 6.0 also allows the enabling of compression at a site level rather than at a global level for the whole server. The properties to manipulate at a per site level are:

DoStaticCompression; and

DoDynamicCompression;

From more information about enabling compression on a per site basis, see DoStaticCompression and DoDynamicCompression in the IIS 6.0 Help.

**TCP/IP Configuration and Connections**
Windows Server 2003 can receive Web traffic via different physical TCP/IP addresses, different TCP/IP ports, or over different host headers (DNS names). A host header can be used to differentiate one site (or application) from another.

If working in a server consolidation scenario or a dense hosting scenario, the favored approach from a system resource usage perspective is to use the host header approach, rather than having a separate TCP/IP address for each site or application. Although possible to go higher, you should limit the number of TCP/IP addresses per system to around 2,000, where it is possible to support tens of thousands of host headers per system.

**Caching**
Caching is an important aspect of a Web platform. Caching can greatly improve the throughput on a server and take the pressure off back-end systems by avoiding the work of totally recreating the response on a per request basis. Figure 3 represents the caches available in Windows Server 2003 for Web sites and applications.

**Figure 4: Windows application server caches (kernel and user-mode)**

**HTTP.sys Kernel-Mode Response Cache**
HTTP.sys has the ability to cache responses to HTTP GET requests[17] in the kernel-mode response cache. The kernel-mode response cache is PAE-aware,[18] which means that it can contain a maximum 64 GB of information on an x86 system. For 64-bit systems, HTTP.sys has access to a full 64-bit address space and, at time of writing, Windows Server 2003 64-bit edition will support systems with up to 512 GB of RAM.

If the kernel-mode response cache is enabled (it is enabled by default), HTTP.sys will always consult it for a received request to see if there is a cached response available. If there is a cached response available, it will be served directly, without transitioning the processor to user mode.

HTTP.sys employs a scavenger model for the kernel-mode response cache. The scavenger runs periodically and clears out cache items that have not been recently accessed. If an item is cleared from the kernel-mode response cache, HTTP.sys sends a

subsequent request for the particular item to the user mode program that originated the initial cached response.

Most configuration of HTTP.sys is done through IIS Manager and the IIS metabase. However, the following list of items can be added to the registry to override the behavior of the kernel-mode response cache. The registry location for these values is:

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Http\Parameters** [19]

| Parameter | Range | Comment |
|---|---|---|
| *UriEnableCache* | (DWORD) 1=on; 0=off | If non-zero, the kernel-mode response cache is enabled. |
| *UriMaxCacheUriCount* | (DWORD) 0 - 0xFFFFFFFF | Determines how many responses may be cached. If zero, there is no limit. |
| *UriMaxCacheMegabyteCount* | (DWORD) 0 - 0xFFFFFFFF | Determines how much memory may be used by the kernel-mode response cache. If zero, a heuristic will be used. |
| *UriScavengerPeriod* | (DWORD) 10 - 0xFFFFFFFF seconds | Determines the frequency of the cache scavenger. The scavenger runs once every UriScavengerPeriod seconds. Any response or fragment that has not been accessed in at least UriScavengerPeriod seconds will be flushed. |
| *UriMaxUriBytes* | (DWORD) 4096(4k) 16777216(16Mb) bytes | This parameter is used when HTTP.sys tries to cache a response in the Uri cache, hence the name UriBytes. If an item size exceeds this value, it will not be cached. |

**User-Mode Static-File Cache**

In addition to the kernel-mode response cache, IIS 6.0 employs a user-mode static-file cache. The user-mode static-file cache contains all of the policy decisions about what to cache and when to cache. It has a superset of functionality and will act as a backup for the HTTP.sys cache in situations where HTTP.sys is unable to cache an item. For example, when an administrator enables authentication, content in the virtual directory cannot be cached in the kernel, therefore, the user-mode static-file cache is used.

From a performance perspective, the user-mode static-file cache cannot achieve the performance of the kernel-mode response cache, because the code path length in the server is greater and the processor needs to transition modes per request. The below shows data from a simple test performed on a 2-processor, 1-Ghz server with 1 gigabit network card. The test is for the same 2K static file content item. One test is where the item is served from the user-mode static-file cache; in the second case, the file is served from the kernel-mode response cache.

| | User-Mode Static-File Cache 20 | Kernel-Mode Response Cache 21 | Difference |
|---|---|---|---|
| Request / Sec | 8321 | 17689 | + 113% |
| CPU % | 100.00 | 92.83 | - 7.17 |
| KB / Sec | 120906 | 257159 | + 113% |

The user-mode static-file cache is capable of caching everything that is cached in the kernel-mode response cache, but it has additional caching capabilities that are useful to other scenarios. For example, static files that are cacheable and are requested by clients that have been authenticated, are served from the user-mode static-file cache. It would be inaccurate for IIS to serve a static file to a user without doing an authentication check on the content to ensure the user has rights to the content. All access checks are done in user mode.

**Caching Policy**

In direct opposition to what seems logical, it turns out that caching everything that can be cached is not as helpful as caching everything according to need. Therefore, you should only cache what is actually getting lots of requests rather than caching everything. The reason for this is that populating a cache can be quite an expensive operation, and the management of a cache with thousands or tens of thousands of items in it can also be a CPU-intensive or wasteful operation.

IIS 6.0 tracks the hit distribution of content, and if the content proves itself to be popular and worthy of being cached, IIS 6.0 will put the content in a cache. When IIS 6.0 makes this decision to cache content, it first populates the user-mode static-file cache with the content, and then optionally, depending on the circumstance, puts the item in the kernel-mode response cache.

When an item is placed in the kernel-mode response cache, all the hits are served directly by the kernel. What will likely

happen then, is the user-mode static-file cache content will time out (after 30 seconds) and be dropped from the user-mode static-file cache , as the item in the kernel takes the requests.

**Hot Content Determination and Tuning**
IIS 6.0 determines content is hot is by counting the number of times it is requested. If a cacheable static file is requested twice within a time period (referred to as the ActivityPeriod, by default 10 seconds), IIS 6.0 caches the content. As mentioned above, if the item in the user-mode static-file cache does not receive another hit within 30 seconds (default), the item will be dropped from the user-mode static-file cache.

**User-Mode Static-File Cache Parameters**
The modification of these parameters should be done with care, because an incorrect setting can cause a drastic effect on the performance of the server.

The registry location for these values is:

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Inetinfo\Parameters**

| Parameter | Range | Default | Comment |
|---|---|---|---|
| *MaxCachedFileSize* | (DWORD) n/a | 256 KB | If you are running large, dedicated Web servers, you may want to add this value to the registry to increase the file size that the cache can hold. |
| *MemCacheSize* | (DWORD) 0 – 2500 MB | Approximately one-half of available physical memory | The default value is adjusted dynamically every 60 seconds. |
| *ObjectCacheTTL* | (DWORD) 0 – 4,294,967,295 (unlimited) | 30 seconds | Setting this value to 0xFFFFFFFF allows the cached object to remain in the cache until it is overwritten. This would be appropriate if your server has enough system memory and is handling data that is relatively static. |
| *ActivityPeriod* | (DWORD) 0 – 4,294,967,295 (unlimited) | 10 seconds | If this value is set to 0, IIS always caches files. |

**Dynamic Response Cache**
Web applications built using ASP.NET and ISAPI can cache responses and have subsequent requests for content served directly from the cache (rather than regenerating the content). This can be a huge performance gain for servers, because the caching can save significant CPU cycles and significantly improve overall response time.

By default, the kernel-mode cache can store dynamic content responses. Applications must be written (or configured by developers) to take advantage of this cache. For information on the ASP.NET output cache see the section entitled Kernel-Mode Response Cache, and for information on how to get ISAPI applications to leverage the kernel-mode response cache, see the section entitled Caching Responses from Dynamic Content in the Kernel.

**Logging**
From an implementation perspective, logging has also changed for IIS 6.0. The log formats have not changed, nor the behavior in general, but the Internet log files are now created by HTTP.sys in kernel mode, rather than by user-mode IIS components. HTTP.sys knows what type of log file to create and which fields are necessary, based on information passed down from the IIS components in user mode. The configuration repository for logging stays consistent from previous releases of IIS; log file parameters are stored in the IIS metabase.

**New Format in IIS 6.0 Centralized Binary Logging**
In addition to the existing log file formats of W3C and IIS NCSA, IIS 6.0 introduces a new format, centralized binary logging. Centralized means that IIS will override all of the existing log file settings on all sites on the server, and generate one log file for all of the sites or applications on that server[22]. The log file will be generated in a binary format which is optimized to eliminate variable length strings where possible. The centralized binary logging file also has its fields aligned on the right boundaries to maximize the I/O performance.

| **Note** |
|---|
| The centralized binary log file does not log all of the fields available in the W3C format. This cannot be changed or overridden, so if you have a need for a specific field that is not included, the binary log file is not an option for you. For more information about enabling centralized binary logging, see Centralized Binary Logging in the IIS 6.0 Help. |

*Why is centralized binary logging interesting?*

There are a few reasons why you would consider using centralized binary logging. For servers that have thousands of sites, having a log file per site can be a significant bottleneck because disk head access latency can affect the overall throughput of the server. (The server struggles to write blocks widely distributed over a physical medium). With centralized binary logging, disk head access time is improved; the single log file for the server can be placed on a separate device and the disk head of that device gets to write sequential blocks to the device.

The centralized binary logging format is optimized, and offers performance gains over the standard text-based logging format, while being smaller in size.

When IIS is logging in standard text mode, a 64K log buffer per log file is allocated for performance reasons[23]. If you have 20,000 sites on a server, by default, you might be allocating over 1 GB of RAM for the log file buffers. However, IIS 6.0 does allow for the log file buffer size to be decreased, so that if you have 20,000 sites on a server, you might peak at a little over 200 MB for the log file buffers[24]. When using centralized binary logging, you have exactly one 64K log buffer for the whole server, regardless of how many sites you put on that server. Therefore, there can be a significant memory benefit when using centralized binary logging.

| **Note** |
| --- |
| The term might is used, because the memory allocation numbers quoted above can happen if the server receives hits across all of the sites in a short period of time. Log buffers are timed out depending on how frequently log records are written to the buffer. |

Having a single log file can simplify the log file management on a server. You manage one log file rather than tens, hundreds, or thousands of log files per server.

Microsoft has released Log Parser v2.0 that can read the binary log file and generate W3C log files for the individual sites contained in the binary log file. With Log Parser, the binary log file can be copied to another computer for processing. Therefore, there is no need to invest the CPU cycles to do the formatting of the log file at run time, those CPU cycles can be better used on a different, non-production computer for log file interrogation and reporting. For more information, see the LogParser section of this document.

Logging is an area that has differing functional importance, depending on the scenario. For an ISP scenario, logging is a key mechanism in determining how many hits of usage a site has had for billing and capacity analysis purposes. For an average commerce application, the logs would not be analyzed constantly, but rather stored to help track down issues or do site analysis if necessary. On the basis of differing usage scenarios, operational staff have some options to consider when determining how logging will work for their particular implementation, and have some flexibility on how they can affect its overall performance.

The first thing to remember is that the best performance option is to disable logging; this relieves processing cycles dedicated to generating log files, and saves physical disk space and extra I/O associated with persisting the log files. This is done through the Enable Logging option on the Web Site Tab on the web site properties dialog.

Note, however, for many implementations this is not an option.

**Performance**

From a performance perspective, the most costly part of logging is the long, variable-length strings. These strings lead to inefficiencies in log buffer use and more physical bytes to write to the disk. The main perpetrators in the W3C log, are the User-Agent and UserName fields, and a few other fields.

If you are running a server that has a high throughput rate (peaks of thousands of requests / sec), you can get a throughput boost by just taking out the variable-length text strings.

**Straight W3C Optimization over W3C Default**

The data in the table below is from tests involving the execution of an ASP.NET page on a 900-MHz, 8-processor server. One test was done with the default logging settings; the second test was done with the User-Agent field of the W3C format disabled (Optimized W3C).

| | **Default W3C Logging** | **Optimized W3C** |
| --- | --- | --- |
| Requests / Sec | 5716 | 6115 |
| CPU % | 98.49 | 98.93 |

| | | |
|---|---|---|
| Log file Size (MB) | 263.63 | 165.02 |

The difference in taking out this one field is quite noticeable, throughput increased by approximately 7 percent and the resulting log file was 37 percent smaller than the original. Note that the User-Agent field value in this case was the string that represented Microsoft Internet Explorer 6.0 (approximately 70 characters).

In this same scenario, the centralized binary log file performs very similarly to the optimized W3C~7 percent more throughput than the default, and a smaller resultant log file. The reason that the binary log file is similar to the optimized W3C log file, in this case, is that 100 percent of the requests in the test actually executed the page (in user mode). This means that the binary log file has to write the Uniform Resource Identifier (URI) into every line item in the binary log file. When a 4K file was cached and served from the kernel, the binary log file increased server throughput by 2 percent over the optimized W3C format. The log file size was 7 percent smaller than the optimized W3C log file.

**Parallelism in Logging**

You should also consider, when configuring a log file subsystem on a server, logs for busy sites should be separated onto separate devices with separate controllers. The goal is to split out the I/O for busy sites so that log buffer writes for one busy site are not queuing behind log buffer writes for a different site, with both being written to the same device. If this is the case, the overall logging process has a much higher latency.

To determine the busy sites on a server, there are a few parameters you can monitor. In System Monitor, select the **Web Service** object. In **select counters from list**, select the **Total Method Requests** item. Then, in **select instances from list**, select the sites you want to inquire on.

The **Total Method Requests** item displays how many requests the site has had since IIS was started. From here you can quickly deduce which sites are the busy sites and start planning the log file subsystem accordingly.

**Heap Fragmentation**

One phenomenon that causes significant performance and scalability issues in ASP/COM+ and ISAPI applications is a condition called heap fragmentation. Heap fragmentation is frequently misdiagnosed as a memory leak when the system seems to be running out of memory resources and long-running applications slow down. Heap fragmentation is not a memory leaka developer could spend weeks trying to hunt down memory leaks in the application and not find any, and yet this condition would still exist. Heap fragmentation occurs when a memory heap (which is used for memory allocations) is expanded and continues to grow until it hits a system addressing barrier. What usually causes this heap fragmentation is memory requests of wildly differing sizes being made to the same memory heap.

When a memory heap has a request for a small memory block (say 30 bytes) followed by another request for a large memory block (say 100 KB), it will satisfy both and the heap will have a 30-byte allocation followed by a 100-KB allocation next to it. Now imagine the 30 bytes were de-allocated and a new request for 2,048 bytes came in. The system cannot allocate the 2,048 bytes in the space where the 30 bytes were; it must go to the end of the heap, possibly extend its size[25], and satisfy the allocation there.

Imagine a scenario where over a long period of time, Windows has to keep growing the heap. For each allocation request, the heap manager has a lot of searching to do, and it will eventually get to a point where it cannot allocate any more addresses (2-GB address limit). The heap manager will then fail the heap extension and pass back the memory allocation error to the application.

The way to rectify this situation is to form buckets for allocations across a number of heaps and only allocate the same size for each heap. This will resolve the heap fragmentation issue. Another alternative is to use Low Fragmentation Heap,[26] Microsofts implementation of the above, to rectify heap fragmentation issues.

**What Can I do as an Administrator?**

The discussion so far has focused on the cause and the remedy, unfortunately, there isn't much to address the symptoms and keep an application going when it is slowing down and exhausting memory resources. With IIS 6.0, an administrator can keep this condition at bay without having to baby-sit the server or take it offline.

To detect an application that is fragmenting the heap, you can use System Monitor. The signature of an application that is fragmenting the heap is the worker process in which it is executing increases its use of virtual memory over time, while its private bytes stay static. You can detect this issue by logging the *Process(w3wp#)->Virtual Bytes and Process(w3wp#)->Private Bytes* for the specific worker process instance you are interested in.

Once the issue is detected, keeping heap fragmentation at bay until developers can rectify the situation, means setting the recycle parameters on the application pool to recycle once the application exceeds acceptable virtual memory use limits.

**Note**

Avoid setting the virtual memory limit recycle setting on ASP.NET applications; the ASP.NET runtime takes care of heap fragmentation intrinsically.

The Recycle tab of the Application Pool dialog (Figure 4) enables recycling on Virtual memory use and Real memory use (private bytes).

**Figure 5: Parameter to control applications that display heap fragmentation**

**Multiprocessor Servers**

This section contains considerations and areas of focus for situations when Windows Server 2003 is running on large multiprocessor servers.

**Localized Loads**

When running on a large multiprocessor server[27], it is important to understand the physical hardware bus architecture and the costs of having a workload distributed across processors. Many large multiprocessor computers are built using a building block approach. A 32-processor computer can have a four-CPU base unit, with an interconnection architecture that links eight of these four-CPU building blocks to an I/O back plain, a common RAM area, etc. Note, however, that the interconnections between the building block processing unit (and the caches around the building block unit), impose a cost when breached.

In the above diagram, a workload that processes for a while on processor 0, then context-switches to processor 23, incurs a much heftier tax than if the workload context switched to processor 1. By going to processor 23, the hardware has to facilitate the transfer and cache-coherence of any data the workload was referencing in the caches surrounding processors 0-3, to the caches surrounding processors 20-23 before it can be re-scheduled to run. Often, depending on the specific hardware architecture, the process of synchronizing the processor caches can also stall other processors in the two building block units to ensure that the caches are not randomly polluted before the transfer operation completes. Therefore, the transfer also has an impact on workloads outside the initial workload.

**Application Silos**

Windows Server 2003 allows an administrator to configure a server to minimize the impact of the above processing locality issue when running Web services or Web applications. This can be done within a single instance of the operating system.

In order to preserve locality on a large multiprocessor, IIS 6.0 offers the ability to configure an application pool to have affinity for a specific processor. In the above example, an administrator can set up eight application pools to have affinity with the building block processors. The below illustrates what this code would look like:

```
<IIsApplicationPool   Location ="/LM/W3SVC/AppPools/BuildingBlock0"  //Procs 0-3
SMPAffinitized="TRUE"
SMPProcessorAffinityMask28="15"
>

**Figure 6 IIS 6.0 metabase configuration sample for processor silos** [29]

By assigning an application to an application pool, that application will then automatically maintain its locality. Items of work assigned to that application will not go outside the building block and pollute other caches or minimize the necessary operating system housekeeping.

Note that this is not an optimal setup for all scenarios, because an application could require more than four CPUs to process, and in the above setup, would be limited to four. Additionally, the above setup does not address reliability aspects at all. You may want to configure a separate application pool for an application purely to ensure that it is isolated from other applications. Of course, you can define an application pool for one application and establish affinity between that application pool and a processor.

The other consideration here is networking. If your application is hosted in an application pool locked to processors 20-23, having your entire network I/O for the application come in on processor 0 is still going to introduce cross-processor transfers. Most of these large multiprocessor servers allow configurable I/O so you can wire in the network card(s) processing loads on behalf of the application to one of the physical processors in the processor group where the application is being executed. Using the above example, if the application was accepting load on two gigabit network adapters, those network adapters would ideally be wired into processors 20 and 21. You can also use the Network Interrupt Filter (available with the Windows Server 2003 Resource Guide companion CD) to bind a specific network card to a specific processor.

**Software Locks (Resource Contention)**

A potential issue to be aware of when putting an application on a large multiprocessor server is inherent software locking internal to the custom application itself. A software lock is when two independent pieces of work contend over a certain resource during the application run time. The first one to ask for the resource will gain access to it, and the second item will have to wait until the first one has finished using the resource before it can gain access.

The net result of this contention can be that when the specific application has more processors to execute on, it may not display any additional throughput, because all of the work is being funneled through a single resource.

A classic sign that you might have a contention problem in an application is a high system performance counter System-> Context Switches/Sec. When multiple work items hit the contention point, the typical Windows operating system response is to swap out the thread on which the item is executing, from the processor it is executing on, and a new thread will be swapped in to the processor (context switch). If all the work items execute for a short time and hit the contended resource, you will likely see high context switch rates[30].

*How can you alleviate software locks?*

The best way to fix an application that has high contention, unfortunately, is to get a software engineer, skilled in performance tuning, to analyze the common usage scenarios (common code paths for the application). The engineer would assess the locks[31] (contention points) at run time and re-architect those contention points so they offer greater parallelism.

**WebGardens**

Web gardens are designed to help alleviate the effect of an application that has serious software contention issues without needing an application redevelopment exercise. The approach is relatively simple; a Web garden alleviates the contention on a resource by indirectly creating multiple instances of the resource and evenly distributing the load throughout them. The creating of a new instance is controlled through the application pool configuration.

To create a Web garden, you set the number of worker processes property in the application pool configuration. The default number of worker processes for each application pool is one. By changing that default, you create a Web garden with however many worker processes you select[32].

IIS then distributes the load to the specific instances of the application. In a Web garden, the requests for a specific TCP/IP connection are all sent to one worker process, but every new connection is sent to the next worker process in a round robin fashion. This has the effect of localizing workload related to a specific client, but spreading out the workload across all of the worker processes of the Web garden. By spreading out the workload, you also alleviate some of the contention on the shared resources.

Using a Web garden consisting of four worker processes, the following pattern would be achieved:

- Requests from connection 1 go to Worker Process 1
- Requests from connection 2 go to Worker Process 2
- Requests from connection 3 go to Worker Process 3

- Requests from connection 4 go to Worker Process 4
- Requests from connection 5 go to Worker Process 1

This pattern is represented in Figure 5.

**Figure 7: Assignment of HTTP connections to Web garden process members**

**WebGardens and Affinity**
A Web garden can help relieve software contention without the use of hard affinity. It is possible, however, to have an application pool with affinity to a set of processors, and then run multiple worker process instances. All worker process instances of the application pool will share the same affinity to processors.

**SSL Implementation**
The SSL implementation on Windows Server 2003 is different architecturally to SSL in previous Windows Server releases. The good news is that the design of the SSL implementation on Windows Server 2003 is self tuning and aware of the incoming load.

A frequently asked question is How much will HTTPS (SSL) cost me, compared to straight HTTP? The following test was devised to demonstrate the cost of SSL. The test hardware used was an 8-processor, 900-MHz server with 2 gigabit network cards. The SSL certificate key length was 1024 bit, the content used was an 8K static file, with six requests sent per connection. Each new connection performed a separate SSL handshake. The results of the test are below:

| | **Without SSL** | **With SSL (1024-bit key)** | **Difference** |
|---|---|---|---|
| Requests / Sec | 9368.30 | 2462.10 | ~ -74% |
| CPU | 47.81 | 51.72 | ~ 8% |

The test above was purposely done to consume around 50% CPU to show what could be achieved in both configurations from a throughput perspective, at a CPU range that would be acceptable in a number of operational environments. The conclusion, for this load type, is that the throughput for HTTPS is roughly a quarter of what the straight HTTP case is. NOTE: The throughput will vary depending on the size of the data, the number of full SSL handshakes occurring, and the speed of the CPU.

**SSL Accelerator cards**
An SSL accelerator card can be a very effective acquisition to offload the CPU-intensive computations associated with SSL. SSL accelerator cards are now relatively cheap, and can be a great investment for improving the SSL throughput on a server.

A test was performed to gauge the throughput-enhancing capabilities of an SSL accelerator card with a new-generation, very fast CPU computer. The target server was a 1-processor, 3-Ghz HT (2 logical processors), with a 100-megabit network card and 512 MB of RAM.

The test characteristics were six requests to a piece of content that returned a 2K response per SSL connection, with a full SSL handshake after every six requests. The SSL public key length was 1024 bits. The results are below:

| | SSL in Software | SSL Accelerator Card | Difference |
|---|---|---|---|
| Requests / Sec | 1281.39 | 3075.20 | +139.99% |
| CPU % | 100.00 | 76.90 | - 23.10% |

As represented in the table above, the impact of an SSL accelerator card was quite significant to this load. Even when a high-speed processor is used, the SSL accelerator card outperforms substantially. The SSL accelerator card could have done even better, in terms of throughput, but its network interface was bottlenecked in the test.

| **Note** |
|---|
| This test is not a real world test. It is a test designed to show the best-case effect of SSL accelerator cards. |

**Remote (or Centralized) Content**

Many implementations prefer to have one copy of content stored on a Network Attached Storage (NAS) device or file server and have the Web server or application server access the remote content over a private network between it and the source content (Figure 6).

**Figure 8: Remote content scenario**

The main advantages with this scenario are that one copy of content is present and managed in a farm of servers. This might not seem like a big administrative chore, but when the server population reaches over 10 servers, this can quickly become an administrative concern.

Windows Server 2003 is a very good platform for this physical separation of the content from the server that processes the request and the server that stores the content. However, there are some performance considerations to be made, as the latency between when a piece of content is requested and returned grows in this scenario.

**Caching**

| **Important** |
|---|
| There is a very subtle point here. Given that the IIS static file handler is the component that does the file attribute checks on remote content, all requests for remote content need to be funneled through the static file handler to ensure the content being served is not stale (changed on the remote device). |

As the static file handler is a user-mode component, the implication here is that *all* requests for static content (hosted on a remote server) are *not* cached in the kernel-mode response cache. Rather, the user-mode static-file cache is used to cache these files.

If the device that is actually storing the files is a Windows file server, IIS 6.0 can be configured to cache the files in the kernel (see below for details).

There is typically a bigger impact on static content than dynamic content in the remote content scenario. Dynamic content is generally loaded in memory, or compiled and cached. Therefore, one of the big focus areas for IIS 6.0 was the rework of the caching algorithms for remote static content.

**Last-Modified Caching**
The user-mode static-file cache has implemented a new caching algorithm where, by default, instead of asking for change notification for each directory structure (i.e., the remote device tells all of the servers that a directory has changed), the user-mode static file cache simply asks the file system for the last-modified date and time on the cached file. If the file is new, or the file has changed, the cache entry is updated with the new content and served. If the file is the same as before, the cached version of the file is sent out. As a further optimization, IIS adds a staleness check to avoid having to do this last-modified check on a per request basis. Therefore, the last-modified check occurs only every five seconds[33].

**Use of Directory Change Notification for Remote Content**
As mentioned above, Directory Change Notification is the more expensive way to configure remote content (if that content resides on a Windows file server), because the change notifications need to be active and using redirector resources. However, by using this mechanism, remote content can be stored in the IIS kernel-mode response cache and IIS will be informed by the content server that the content has changed and will refresh the kernel-mode response cache.

It is recommended that you test this implementation before using it. If a server is connected to large numbers of UNC paths, this can reduce the servers ability to get change notifications.

To enable the Directory Change Notification, set the following registry key:

**HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\InetInfo\Parameters\ DoDirMonitoringForUnc (DWORD). 1=on 0=off.**

**Implications of Switching to Change NotificationBased Caching**
Several significant tradeoffs need to be considered when deciding which caching mechanism to use. The most reliable and secure method is to use the default, last-modified time-based caching. It is reliable, because it does not rely on the change notification functionality of the file server, and will scale well on a wide application structure (where your Web server has lots of applications pointing at different file structures). Last-modified time-based caching is more secure because share level permission changes will be honored (the cache will access the file often, which automatically triggers the authorization check against the current file system Access Control List (ACL) and the current share ACL).

However, if you are using a file server that reliably reports change notifications *and* you have a small number of sites or virtual directories, using change notification is significantly faster. For example, if you have a single Web site with a couple of applications that include all your content, stored on a Windows .NET file server, it is recommended that you use the change notification method of caching.

**General Performance Tools**
This section introduces some basic tools that can be used to diagnose how applications are performing, system performance and a level of information from the operating system that can identify the workloads and state of the operating system.

**Event Tracing Enhancements**
Event tracing provides a mechanism for managing data that is useful to performance monitors, capacity planning tools, and other applications that analyze information relating to system resource utilization. Event tracing is enabled by running new command-line tools that control event trace log scheduling, collection, and analysis on local and remote computers. Log files can be taken from the server for analysis. Event tracing is a very high-performance implementation of tracing through core Windows components. A benefit of event tracing for Windows for Web and application server loads is that an administrator can enable event tracing on a production server and have it generate detailed statistics and information on the running load, without a dramatic impact on the performance of the production load.

Listed below is some of the information that can be extracted at run time from a server:

- Most-requested URLs
- Slowest URLs
- URLs with the most CPU usage
- URLs with the most bytes sent
- Clients with the most requests

- Clients with the slowest responses
- Statistics on all the running processes (kernel CPU, user CPU, number of threads, etc.)
- Disk statistics
- Files causing most disk I/Os

For more information about event tracing, see Tracerpt in the Windows Server 2003 product documentation.

**System Performance Monitor**
System Monitor is one of the key tools that display the internal system information of Windows at run time. It is a primary tool to use in performance analysis of the Windows platform and should be used as the master source of information about Windows Server internals when doing performance analysis.

The objects that are of particular interest, in the context of this paper, are counters that belong under the following objects:

- .NET CLR LocksAndThreads
- ASP pages
- ASP.NET v1 applications
- Network interface
- Physical disk
- Process
- System
- Web service
- Web service cache

In addition to offering live information about what is happening in the system, System Monitor also offers the ability to log performance information and generate alerts.

**Windows Task Manager**
The Windows Task Manager, another useful tool, provides similar information to System Monitor, but displays it in a summary fashion. Additionally, the Windows Task Manager only displays Windows system information. System Monitor is extensible and will therefore load many third-party libraries when calibrating performance information; however, it does not load any third-party code.

The Windows Task Manager gives an administrator a low-cost way to see the process internals, how busy network cards are, etc.

**LogParser v2.0**
LogParser is a versatile tool that makes it possible to run SQL-like queries against different input sources, and have the results written to the screen or to different output targets.

With LogParser, it is possible to:

- Quickly search for data and patterns in files of various formats, including IIS log files, Windows event log files, generic comma separated value (CSV) files, W3C files, and text files.
- Create formatted reports and XML files containing data retrieved from different sources.
- Export data to SQL tables. You can export entire files or filter the data to obtain only relevant entries.

- Convert data from one log file format to another.

LogParser is composed of three main components:

1. An input source generates records from the specified source. The following input sources are implemented:

    - All the IIS log file formats (W3C, IIS, IISMSID, NCSA, centralized binary logging, and ODBC), and the UrlScan and HTTP Error log formats
    - The NT event Log
    - W3C log files (e.g. personal firewall, WMS, etc.)
    - Generic CSV files
    - Directory structure information
    - Generic text files

2. The SQL engine processes these records; filtering, grouping, and ordering them according to the specified SQL-like query.

3. An output target writes these processed records to the specified target; the following output targets are implemented:

    - Native log format (a generic format to display results primarily to the screen)
    - Generic W3C log format text files
    - XML files
    - IIS log format text files
    - Direct output to SQL tables
    - Text files formatted according to user-defined templates
    - Generic CSV format text files

In SQL terms, LogParser treats an Input Source as a relational table, whose field types and names depend on the particular Input Source selected.

The LogParser can be found at: http://go.microsoft.com/fwlink/?LinkID=100882.

# Dedicated Application Scenario (Web and Application Server Infrastructure - Performance and Scalability)

Updated: January 1, 2003

Applies To: Windows Server 2003 with SP1

The Dedicated Application scenario describes when a server is predominantly used for serving a single, large, specific application. Generally, this application serves some critical business purpose and typically has multiple servers set up as copies of one another with some software splitting out the load and distributing it throughout the physical servers running the application.

| **Important** |
| --- |
| While many customers prefer this kind of administration approach where a single application is placed per server, this is not the preferred Microsoft architecture for application servers. Generally, we find that this approach leads to inefficient use of computing resources; most of the server deployment done in this design uses grossly under-utilized server hardware. Worse, this deployment style leads to higher costs in a data center, given TCO is directly mapped to the number of operating system instances being managed, regardless if they are running on the same hardware or virtualized in a host-operating system (VMWare). |

Windows Server 2003 has been redesigned to inherently support many applications running side-by-side on the same hardware and in the same instance of the operating system, and if possible, should be configured in such a way as to minimize TCO costs. See the documents referred to in the More Information section for greater detail.

A defining characteristic of the Dedicated Application scenario is that all settings of the application environment, the application itself, and the operating system, can be tuned to get better performance out of the application. This is relevant in that there is no application sociability with other applications that requires consideration when tuning the application.

**Considerations**
This sections covers relevant considerations for the Dedicated Application scenario.

**Application and Content Types**
**Managed Code Applications**
A managed code application refers to applications that are built onto the Microsoft Common Language Runtime (CLR). The CLR offers many services that allow application developers to build applications in a very efficient manner.

Examples are applications built in languages such as Microsoft Visual C# and VB.NET, and using the Microsoft Visual Studio .NET Tools.

**ASP.NET Web Applications (ASPX)**
ASP.NET Web applications are managed code applications that tend to be built as a thin client. For instance, a browser sends a request to a server, and the server platform performs business processing, application navigation, and generates the user interface in HTML. The HTML is then sent back to the client browser and the browser renders the interface for the application. The browser then accepts the next user request and sends a new request to the server.

In this scenario, the vast majority of the processing is being done on the server platform; therefore, it is vital that the request cost is minimized dramatically (in order to get substantial throughput on a server). It is also important that applications are further analyzed for scalability issues.

One of the tools available for additional scalability can be the Web garden feature, which is discussed in detail in the Software Locks (Resource Contention) section.

*When Should I consider the use of a Web garden rather than a single worker process?*

Whenever rich applications are being built, there is a chance that the application developer can inadvertently introduce software contention in an application. See the Software Locks (Resource Contention) section for a description of this effect.

To illustrate this effect and the assistance a Web garden can offer, an ASP.NET page was written where every request had to navigate a linked list with 2000 objects in it to manipulate a particular item in the list. When one request was accessing the list, another request had to wait. This application was placed on an 8-processor, 900-MHz server and had 2,600 simulated clients throw load at the applications. Each client had a think time of 50 milliseconds between each request. The results are below:

| | Single Worker Process | 8 Worker Process Web Garden | Difference |
|---|---|---|---|
| Requests / Sec | 2626.57 | 2961.20 | +12.7% |
| TTLB (milliseconds) | 49.19 | 43.63 | -11.3% |
| CPU % | 92.48 | 100.00 | +7.52% |
| Context Switches | 6808.19 | 3204.87 | -52.9% |

As can be seen, when pushing the server as hard as possible, the test run with one worker process was only able to get up to 92% CPU utilization. This is an indicator of a lock contention problem, no matter how much load you throw at a server, you cannot get it to 100% CPU utilization. With the addition of extra load, IIS would have started throwing back server too busy status codes when the kernel queues became full, and requests would be rejected.

The 8-processor Web garden distributes the 2,600 connections to the 8 worker processes serving the application, 325 connections to each worker process. Because all of the clients were sending in the same load, the requests were evenly distributed across the 8 worker processes in the Web garden. Although still bad, the really bad contention (queuing) behind one lock was split out into 8 locks with smaller queues behind them, thus the 12% gain in performance when the same request load was attempted.

It is important to note that a Web garden is not a silver bullet solution. There is a substantial memory cost to initializing a Web garden. The non-Web garden case had a real memory usage of approximately 35 MB (typical memory usage of a worker process running managed code), while the 8 worker process Web garden had a memory usage multiplied by 8; close to 280 MB used for the application. On a large, 8-processor server that is dedicated to one application, this might be acceptable, but it is a necessary tradeoff that must be considered.

If the actual problem is not software contention within a process, a Web garden will likely have a negative effect on throughput. If, for example, the contention problem for the application is a lock to gain access to a database page on a remote database server, an increase in worker processes is unlikely to have a positive affect. In fact, the additional threads per process are likely to increase overall context switch rates and decrease overall performance. The bottom line is not to assume that a Web garden will help. There are instances where it will, but its utility is in the nature of the contention problem. The only way to know is to test the Web garden configuration in a stress environment with expected loads before going into production.

**ASP.NET Threading Settings and High Latency Workloads**

If an application accesses slow resources, like a mainframe doing large, complicated queries, the threads of the ASP.NET subsystem can get blocked and, for a busy application, ASP.NET itself can run out of threads. If all ASP.NET threads are blocked, performance suffers, as there is no ability for ASP.NET to pick up new work. The work gets queued until other requests complete, and the situation ends up affecting user response times.

It is possible to override the number of threads ASP.NET is using to process requests. The parameter is found in the ASP.NET configuration system and can be changed at the root of the configuration system (the machine.config file), or specifically for the one instance of the application (the Web.config file in the virtual directory of the application). The threads parameter is in the following section of the configuration:

```
<httpRuntime>
minFreeThreads="[count]"
</httpRuntime>
```

**ASP.NET Applications and Queuing**

This section identifies how ASP.NET requests are queued in Windows Server 2003. The pipeline is complicated, but useful to understand when performing performance tuning changes.

1. HTTP requests come in off the network and are received by HTTP.sys.

2. After looking at the request, HTTP.sys places the request in a queue for an application pool.

3. The worker process servicing that application pool picks up the request and makes a decision on what type of processing environment that request needs to be executed. For ASP.NET Web applications, the worker process hands them to the ASP.NET handler.

4. The ASP.NET handler places them on a queue, and ASP.NET threads pick up individual requests and process them.

As you can see, there are a few places where a request could end up being en-queued, depending on how capable of

processing additional requests the subsequent layers are. The queue referred to in step 2 is controlled in the IIS 6.0 application pool dialog box (Figure 7).

**Figure 9: Kernel-Mode Queue Dialog (application pool properties)**

The queue referred to in step 4 is controlled through the machine.config / Web.config configuration system. For busy servers, it might be worthwhile to try increasing this parameter. The parameter is:

```
<httpRuntime>
appRequestQueueLimit=[count]
</httpRuntime>
```

The default queue length is set to 100.

| **Note** |
| --- |
| This parameter also applies to ASMX (Web services). |

**ASP.NET Web Services (ASMX)**

Rich client devices such as cell phones, PocketPCs, tablet devices, etc. have the ability to run rich applications, which communicate over public networks, using a Web service style of application integration. With this in mind, rich client applications connecting to Web services over HTTP have a few subtle differences to the traditional HTTP browser client. These differences can affect their performance.

If you were to trace the network packets associated with a Web service request over a physical network, and compare it to a standard ASPX Web application request made by a browser, you would notice a few differences:

1. The typical size of packet a browser would send is quite small (~400 - 500 bytes). It consists of the TCP/IP headers, an HTTP GET verb, the requested URI (/downloads/downloads.aspx), a few request headers that the browser uses to communicate content length, and a few other attributes of the request.

   Given the fact that browsers typically display data and/or graphics, the browser request usually gets back a large response (text/HTML, tens of KB of data) with embedded references to other large content (.gif/.jpeg) files. The browser then requests these individually.

   A Web service behaves a little differently. When a Web service client is communicating to a Web service server, the client is actually invoking a component, therefore the client end is supplying data (a set of parameters) to call the server program. The server program processes the request, generates a response, and sends the response back to the client. Therefore, with a Web service running over the HTTP protocol, you have a situation where the client is sending an HTTP POST (rather than a HTTP GET), and the client is sending an entity body that contains an XML serialized set of parameters, data structure, and other attributes of the request as part of the POST[34]. Therefore, the client side typically sends larger requests and does not typically get back huge responses.

2. The physical packets put on the wire, and the interaction between client and server, will differ. When a browser-style application makes a HTTP GET request, the request is in one packet, the server responds with a number of packets containing the response to the GET (the response is typically much larger than what can fit in one frame: 1,500 bytes).

   As the Web service client is potentially going to be sending large amounts of data to the server, it behaves differently. Given that Web service clients are likely to be non-computer devices, running on high latency networks with the potential of a per-byte charge on the data sent and received, the Web service stack sends a packet with the HTTP POST, URI, standard headers, and a special header: the Expect100Continue header. This is the equivalent of the client pinging the server to make sure it is worthwhile to send the bulk of its call. If the server responds with 100Continue it is telling the client that everything is OK and the client should send the body of its call. The server then picks up the request, processes the request, and sends back a response. Figure 8 depicts the Web service interaction.

**Figure 10 Expect100Continue packet interaction**

These different behaviors can really make the Web service client interaction efficient, because the client does not spend noticeable amounts of time sending requests that would eventually fail and frustrate the user.

However, when running on an internal network, where cost per byte might not be a concern, the additional latency introduced by the default Expect100Continue behavior, can slow down an applications responsiveness and the overall throughput of a server. As an example, a Web service test was created to measure the difference between the Expect100Continue communication mechanism and the same request done as a single HTTP POST. The table below summarizes the results for one Web service invocation:

| | Default (Expect100Continue) Behavior | All in one HTTP POST | Difference |
|---|---|---|---|
| Total Data (bytes) | 13329 | 11733 | -13.6% |
| Total Ethernet Frames | 31 | 21 | -47.6% |

The data numbers themselves are not necessarily a concern on a fast network, the bigger issue is the latency associated and potentially experienced at the client side, especially given that the TCP/IP client stack will, at times, invoke its nagling[35] behavior and delay small packets from being sent, in the hope that the application will fill the buffer of a packet more and make the overhead of transmission smaller.

If there is a perceived slowness from users (perceived high latency in applications), the above discussion is worthy of investigation. First, a network sniff on the client side of the application should be performed, and the parameters manipulated accordingly.

**How to Change Expect100Continue and Nagling Behavior**

Both the Expect100Continue behavior and nagling behavior can be changed on a per server or per application basis in Windows Server 2003. By default, both behaviors are on, that is, the value in the configuration system is true. To change the parameters for a system, you need to edit the following file:

%SYSTEMROOT%\Microsoft.NET\Framework\vVersion of the framework\CONFIG\machine.config

In the following section you need to add the properties and override them.

```
<system.net>

<settings>

<servicePointManager expect100Continue="true"|"false" useNagleAlgorithm="true"|"false"/>

</settings>
```

</system.net>

To change for a specific application, you modify the app.config file in the same directory as the application. The same change as above is made.

| **Note** |
| --- |
| Expect100Continue and useNagleAlgorithm are changed on the client side of the Web serviceor the consumer of the Web servicenot the server side. The server will behave accordingly to whatever behavior the client displays when interacting with the server. |

**.NET Remoting vs. Web Services**
Applications will often have many component parts. For scalability reasons, these component parts are sometimes separated onto different servers. This predicates a need for some form of object-based communication mechanism to glue the component parts of an application together. In the managed code world, two possible options are .NET Remoting and the use of Web services.

There are some functional differences between the two, which might force the use of one over the other. Assuming no functional restrictions, the use of .NET Remoting, using TCP/IP as a transport and making inter-object calls using the binary formatter, is the most performant option. This is discussed in depth (along with operational and functional tradeoffs) in the document:

http://msdn.microsoft.com/library/en-us/dnbda/html/bdadotnetarch14.asp.

**Unmanaged Applications**
Unmanaged applications are those that do not run on the Windows .NET Framework. This is the previous generation of applications (circa Windows NT 4.0 and Windows 2000), which are comprised of binaries compiled directly from Microsoft Visual C++ and other compilers, and also includes applications that are hosted under the VBScript and other script engines (interpreted applications). The tools used to build unmanaged applications include the following, among others:

- Visual C++ 6.0 and earlier
- Visual Basic 6.0 and earlier
- ASP (Script engine)
- PowerBuilder
- Microsoft Visual J++

The unmanaged code environment is much less forgiving for an application developer, because features such as automatic garbage collection, memory coalescence, pointers, and other productivity language features, are not available.

**ASP Scripts**
ASP technology (.asp) is the predecessor to the ASP.NET page (.aspx). A little known fact is that ASP pages are actually compiled. The high-level process for executing an ASP page is:

1. The ASP page (raw) is read by the ASP subsystem in IIS. That page is converted into what is called a template (the ASP page with all included code inserted and syntactically put together, and read for a script compiler to execute).
2. The template is then sent to the relevant script engine (VBScript or JScript) for compilation and execution.

The ASP subsystem caches both templates and script engines. Like any other cache, this avoids processing costs associated with executing a page again. For example, overriding the *ASPScriptFileCacheSize* metabase parameter, allows ASP to cache more of the templates referred to above, saving the cost of converting the raw script into a template.

Overriding the *AspScriptEngineCacheMax* metabase parameter allows ASP to store more instances of VBScript and JScript script engines in memory. If these engines had been used in the recent past, to execute a page for a different user, a further gain would have been realized, since the script engine does not need to recompile the page. The in-memory, already-compiled page is executed.

| Note |
| --- |
| A single script engine can only execute one page at a time, therefore, if 10 concurrent users all requested the same page at the same time, the system would have 10 concurrent copies of the script engine in memory. |

**Persisted ASP Template Cache**
In IIS 6.0, a further enhancement for ASP templates was undertaken. Templates can be written to disk to avoid the overhead of keeping them in memory and having to regenerate them.

If a site consists of numerous ASP pages, this cache de-allocates the oldest templates from memory to free space for new ones. If one of these ASP files gets requested again, the ASP engine loads the template instead of loading the ASP file and spending additional CPU processing.

**ASP/COM+ Applications**
Many ASP applications instantiate and call into COM+ components. The idea is that the ASP page provides HTML formatting, navigation, and can call into COM+ application components, which contain business logic. An additional advantage of using COM+ components, is that the COM+ components can be re-used in client and server-based applications, without modification.

Threading Model

One of the key things to be aware of in tuning an ASP/COM+ application on Windows Server 2003 is the threading model. The major applicable threading models are Apartment, Free, and Both. Apartment threaded components are COM objects that cannot function with two separate callers inside the component simultaneously; only one caller can be in the context of a method at a time. The converse is true for free threaded components. A free threaded component internally protects its data structures so that any client can call in at any time. Both threaded components can exist in other modes and will typically inherit the mode of objects that are calling into them.

As a typical guideline, COM components developed in Visual Basic 6.0 or Microsoft Visual J++, are all apartment threaded, while components built using Visual C++ 6.0 can be any of the threading models. These components should be inspected for appropriate threading.

The COM+ environment in which ASP executes is, by default, running in the single-threaded apartment (STA). Therefore, COM objects that are instantiated are placed in an apartment separate from ASP code execution. This isn't generally a bad thing, except that for execution control to transaction to the COM+ object, the operating system must stop a thread and perform a context switch. This can become a performance issue when it occurs thousands of times a second.

On Windows Server 2003, a new feature for ASP has been developed for ASP/COM+ applications that only involve COM+ components that are both or free threaded. Windows Server 2003 allows ASP scripts themselves to run in the multi-threaded apartment (MTA). This means that the ASP script itself will call directly into a free or both threaded COM+ object without having to cause a context switch and add threads to the system. This helps the scalability and overall system performance.

The most important consideration here is that the components called by the ASP page must be free or both threaded. For example, an ASP script that calls into the **ADODB.RecordSet** object can do so, without problem, under the MTA, since the **ADODB** object has a threading model of both.

After checking the components an application uses for its threading model and ensuring theyre either both or free threaded, an administrator can enable all applications on the server to run in the multi-threaded apartment by performing the following:

**cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AspExecuteInMTA 1**

Administrators can also run the above command in the specific application directories (for example, W3SVC/1/AspExecuteInMTA) to make the setting for a particular application.

Synchronous Execution

Given the nature of ASP, all execution is done synchronously, therefore, when an ASP application accesses resources off the server or resources that have a natural high latency, ASP can quickly run out of threads. Once ASP exhausts its thread allotment, the response time of a system can be drastically affected.

This is an area where an administrator or operations person should have knowledge of the application. Guidelines for how to handle highly synchronous applications can be found in the section entitled High Latency ASP Pages.

**Large Multiprocessor Single Application Scalability**
For the Dedicated Application scenario, the scale up of a single application is very similar to the considerations for scale up of applications on Windows platforms in general. Please see the Multiprocessor section for more information.

# Dense Hosting Scenario (Web and Application Server Infrastructure - Performance and Scalability)

Updated: January 1, 2003

Applies To: Windows Server 2003 with SP1

This scenario is the opposite of the Dedicated Application scenario. The objective for the Dense Hosting scenario is to get as many different applications or sites on a physical server as possible, with only one operating system instance to manage, to minimize hardware and management (traditional TCO) costs. This is by far the most efficient way to run. Any form of virtualization and operating system partitioning[36] in this scenario is giving away precious processor cycles and RAM resources, which is contrary to the objective of cheap, efficient processing.

This form of dense hosting is prevalent at Internet Service Providers (ISPs), and can also be found in some enterprise environments where a central IT group identifies many non-critical applications executing on separate servers and brings them into a central environment. Note the term non-critical application: hundreds or thousands of applications can be hosted on a single piece of hardware, but should a hardware failure occur, many applications would experience some form of downtime while the servers hardware was being rectified. In an enterprise environment, this could be an extremely cost-effective way of providing service to a number of Tier 3 applications, where a 99.999 up time SLA (Service Level Agreement) is not required.

Windows Server 2003 has been tested with a 20,000+ defined applications or sites per operating system instance. This means that the server can easily support that number of applications defined. It does not mean that if these applications all have high resource needs, it will support them. If one of the 20,000+ application is not gated in its resource usage, it can consume 100 percent of the resources on the server, not allowing the other applications to function efficiently.

**Considerations**

This section contains relevant considerations for the Dense Hosting Scenario.

**Application Pools Shared vs. Independent**

One of the central tenets to be observed in this scenario is the level of application isolation. Note that the fundamental unit of isolation in Windows is the process. The process object in the Windows kernel offers operating system and processor instruction protection from one process to another. If one application faults in process A, another application running in process B will not suffer due to application As fault[37].

In IIS, the fundamental unit of isolation is the application pool. Administrators need to determine whether all applications/sites need to be put in their own application pool or can some applications share an application pool with other applications.

If you choose to have multiple applications sharing the same application pool, there is a chance that, at some stage, some of them will experience downtime when one application has an issue.

**Running Different Application Types Side-by-Side or Within the Same Process Space**

Windows Server 2003 offers the ability to mix different kinds of application types together in the same application pool. This means that you can take an existing ASP/COM+ application and run it in the same application pool as an ASP.NET (or managed) application. This also means that you can host native, compiled applications (ISAPI or Win32) in the same application pool as these other application types.

Note that running many different application types in the same process can save system resources (memory and CPU processing), as there is a fixed cost per process for these resources in the Windows operating system. Imagine you had two ASP.NET and one classic ASP/COM+ applications. By pooling these three applications together in the same application pool, you get the following memory footprint:

| All Applications Pooled in Single Process | Each Application Per Process |
|---|---|
| Base Process / IIS fundamentals | Base Process / IIS fundamentals |
| ASP.NET/CLR Runtime | ASP.NET/CLR Runtime |
| ASP Runtime | ASP.NET Application 1 |
| COM+ Runtime | Base Process / IIS fundamentals |
| ASP.NET Application 1 | ASP.NET/CLR Runtime |

| ASP.NET Application 2 | ASP.NET Application 1 |
|---|---|
| ASP/COM+ Application | Base Process / IIS Fundamentals<br>ASP.NET/CLR Runtime<br>ASP.NET Application 2<br>Base Process / IIS Fundamentals<br>ASP Runtime<br>COM+ Runtime<br>ASP/COM+ Application |

As you can see, to run the same three applications in separate application pools, you incur a substantially different set of costs in the isolated case vs. the shared case. But, the reliability tradeoff can be a factor in the decision of which application environments you configure in a shared or isolated way.

From an administrative perspective, the decision can be based on a number of different factors:

- **End customer.** You might decide that each business unit needs to run all of their applications in the same application pool because an application failure would likely be the fault of one of their applications. This would put the emphasis on each business unit to correct their own applications so that they do not incur outage themselves. In this case, the other business units running on the server would not incur outage, because they would be running in different application pools. For an ISP scenario, replace the term business unit above with customer, so that all applications from one customer run together in one application pool.

- **Known, problematic applications.** You might start off with a policy to keep all applications running together in the same pool to minimize the resources utilized, and when applications start to display issues (or failures), you could partition out the problematic applications. It is quite possible to segregate a specific virtual directory containing a particular application into its own application pool, with the rest of the related applications executing in a separate application pool.

- **Everything isolated until the limit.** In this scenario, all applications/sites are put in their own isolated application pools. Then, when the server resource utilization exceeds the administrative policy defined for servers in that environment, you consider which applications/sites could be pooled together. An effective strategy at that stage could be to start pooling together ASP.NET (or managed code) applications into the same application pool, or start pooling ASP-only applications into one application pool.

**All Application Pools Running with Unique Identity**

Another benefit of the IIS 6.0 re-architecture is that the administrator gets to assign the base identity of a worker process. This does not mean that custom code running in the worker process will run with this identity. IIS will still impersonate the caller when calling custom code (ASP, ASP.NET, ISAPI) if the caller is authenticated, or, if the caller is anonymous, IIS will run the custom code under the IUSR_<*computername*> identity. The application pool identity will be used when the IIS code is running in the worker process.

The default identity is the intrinsic account Network Service, which has rights approximating a member of the Users group of a server, but this identity can be set on a per application pool basis (Figure 9).

**Figure 11: Worker process identity tab on application pool dialog**

One consideration that needs to be made clear is that there is a limit to the number of concurrently running desktops in Windows Server. In order to scale this to hundreds or thousands of different identities running concurrently, the following registry key can be set to allow the different identities to share the same desktop.

**HKEY_LOCAL_MACHINE\System\Currentcontrolset\Services\w3svc\UseSharedWPDesktop to be set to (DWORD)1.**

| **Note** |
| --- |
| Sharing a desktop can be a security issue if critical data is being stored or manipulated. Physical windows and other graphical resources are shared on a per-desktop basis. Therefore, the security risk of sharing a desktop is dependant on what data and resources are being stored in desktop objects. For example, if sensitive data is being stored on a window title bar, as an intermediary for an application, other processes that have access to that desktop can gain access to the window title bar, and (if they have enough context) can get at that information. |

**Number of Worker Processes**

Depending on the isolation policy for your application or sites, as discussed above, Windows Server 2003 offers some additional tuning parameters to assist in effective resource management (Windows Server 2003 tries to only have applications running if they are processing actual load).

As discussed in the TCP/IP section, physical TCP/IP connections are managed by HTTP.sys, that is, all connections are held by the System process: PID 4. The effect of this is that, if Windows Server 2003 has 20,000+ applications defined on it, it can be listening on the endpoints and can accept TCP/IP connections for any one of those sites, regardless of whether the actual application is physically initialized. In fact, Windows Server 2003 can accept hundreds of connections without even having one physical worker process running.

The other side of this equation is that Windows Server 2003 can idle out the running application if it has been idle, without dropping TCP/IP connections that have sent requests to that application. This is a very useful feature for administrators looking to trim resource usage on a server.

**Demand Start and Idle Time-out**

Windows Server 2003 always performs a demand start for applications. When IIS 6.0 initializes, no worker processes are running, they only start when a client request for the application pool is received. The default idle time-out for application pools is 20 minutes. This means that if a set of applications running in a specific application pool has not received one request in 20 minutes, IIS 6.0 will spin down the worker process and give those resources back to the operating system.

Administrators can make this setting more aggressive. For applications that have very infrequent use, the idle time-out setting can be set to five or less minutes. Idle time-out can be found on the Performance tab of the Application Pool properties dialog box, or can be set through the adsutil command-line utility:

for a specific application pool:

**cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AppPools/** *ApplicationPoolName* **/IdleTimeout 5**

or, for all application pools:

**cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AppPools/IdleTimeout 5**

**Process Gating**

Some administrators prefer to simplify the administrative model and have all applications or sites totally isolated from each other. This configuration can greatly simplify administration and overall management; however, a downside with this approach can be forecasting the specific traffic pattern and usage of all applications (unless you have a small number of total application pools). This means that there can be a potential issue in having an excessive[38] number of concurrently-running processes in the system at a given time.

Therefore, Windows Server 2003 offers a process gating feature, which allows an administrator to set a high water mark for the number of active processes in the system at any given moment. The administrator can simply reset this value to be appropriate for the type of hardware the administrator has (the number of concurrent processes Windows Server 2003 can support is mostly limited by the amount of physical RAM in a system).

**How does process gating work?**

When a request is sent to an application pool that has not been started (or has idled out), IIS 6.0 makes a check of the number of concurrently-running processes. If the total number of processes, including the new one, would go over the threshold, the worker process is not started and a 503 Service Unavailable error response is sent to the request originator.

The process gating feature is not available through the IIS UI management tool. It is set in the IIS 6.0 metabase only. To override the process gating feature to have a maximum of 100 concurrently active application pools, run the following command at the Windows command prompt:

**cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/DemandStartThreshold 100**

to remove the override to get IIS 6.0 back to its standard behavior, run the following command:

**cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs delete W3SVC/DemandStartThreshold**

| **Note** |
| --- |
| The process gating feature is not on by default. This means that IIS will not gate processes by default and it is possible to get as many worker processes started as there are application pools. Further, if application pools are configured to run as Web gardens, it is possible to get even more concurrent worker processes than the total number of application pools (dependant on the number of worker processes set per Web garden). |

**IIS Logging Considerations with Thousands of Sites per Server**

On IIS 6.0, whenever a site is defined, W3C logging is established for that site. In order to not affect performance, every log file generated gets a 64K buffer assigned to avoid writing log entries to disk too often. This way, many log records are buffered and all written at one time.

When thousands (or tens of thousands) of sites are defined on a server, the memory use due to these log buffers can be substantial (64K per site). Therefore, to conserve memory, there is a way to control the size of the log buffers. Obviously, when the log buffers are decreased in size, the frequency of I/O to the disk is increased, but for sites that get infrequent hits, this may not be a massive impact on performance.

The parameter to manipulate the size of *all* log buffers on Windows Server 2003 is:

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Http\Parameters\LogBufferSize (DWORD)**

with a range of: 12,288 (12K) 65,536 (64K). The value the parameter is set to must be divisible evenly by 4,096, otherwise it will be discarded and the 64K default will be used.

| **Note** |
| --- |
| Log buffer size cannot be changed for specific sites; the change is global for all sites on a server. |

**Centralized Binary Logging**

When running thousands of sites on a server experiencing high request rates, the centralized binary logging feature is very useful. Centralized binary logging alleviates a disk I/O bottleneck; it makes the log file size smaller and saves CPU in formatting

the log file information.

From a functional perspective, there are some restrictions on the centralized binary log file format (in terms of the fields logged), which cannot be changed. For more details on the binary logging implementation and comparison data, see the New Format in IIS 6.0 Centralized Binary Logging section.

**Connection Management Discussion**
Running a server with many sites can cause the server to hold onto many connections. The reason for this is that the majority of clients today are browsers. Most browsers send HTTP requests over the HTTP 1.1 protocol with a Connection: KeepAlive header in the request. This directive tells the server that once the browser->server connection is established, it should remain open. The reason for keeping the connection open is to forgo the connection establishment and latency for subsequent requests.

However, from a server perspective, having many connections established (tens of thousands per server possible) means that the server is investing some CPU in managing those connections, and the network infrastructure has an additional load in sustaining them. For these reasons, many very large implementations turn off keep alive connections at the server end, which means that exactly one request is sent per connection. Browsers and other clients need to go through the session establishment process for every request.

Administrators should gain an understanding of how their production servers behave with the KeepAlive header off as well as with it on. The resources to monitor are CPU, memory, network utilization, and latency at the client end. The right decision is based on operational policy for the organization.

For information about how to disable and enable HTTP Keep-Alive connections, see Enabling HTTP Keep-Alives and AllowKeepAlive in the IIS 6.0 Help.

**IP Addresses or Host-headers**
When placing many sites on Windows Server 2003, it is important to have a strategy for how sites are to be addressed. If the server is to support thousands of sites, the preferred mechanism to address them is via host-headers, rather than TCP/IP addresses or different ports.

For a detailed discussion of the considerations behind the way sites are addressed, see the TCP/IP Configuration and Connections section.

**Remote Content Considerations and Tuning**
Before you set up an IIS server that will have hundreds or thousands of sites on it, you must first decide where the content is going to be located. IIS 6.0 supports both local and remote content models. Local means that the physical files that make up each site are located on a disk attached to the system. Remote means that the content files are physically located on a remote file system (file server, NAS device, etc.)

The advantage to having remote content in this environment is that it becomes even more straightforward to reorganize which server is handling the requests for a specific site. If there is a need for reorganization, the server configuration for the site and DNS needs updating. The physical content is untouched and unmoved. If the content was local, it would require moving, and backing up that content might also require reconfiguration.

Even though the remote content case looks good, there are some performance and scalability considerations when using content on a remote share such as latency on content and access patterns. The Remote (or Centralized) Content section also introduces a discussion regarding the caches and parameters to control for the caches.

**Latency**
When content is hosted on a local server, the average access time of a piece of content is usually measured in milliseconds. When a content request is going across a network (even a very fast one), you might get to the content in milliseconds, or it might take seconds. This can have a dramatic impact on the responsiveness perceived by the user. Of course, once IIS 6.0 has seen the content, it will try to optimize its access patterns to make subsequent accesses much more efficient.

**Data Volume**
Similar to IISs ability to saturate several gigabit network cards, with the data being sent back to many thousands of clients, it is also possible to saturate the network between an IIS server and a NAS (file server or other computer), and hold the raw content. If a network card on either the Web/application server or shared content server is saturated, the overall performance of all the servers accessing that central server can be affected. This must be planned for in your design.

**Questions to Answer When Testing a Remote, Centralized Content Scenario**

- What is the likely profile of requests over a period of time to the Web/application servers? (LogParser v2.0 can use existing, typical IIS logs to help deduce a reasonable answer to this question.)

- What is the networking between my Web/application server and my central store?
- How many Web/application servers hit my central store at once?
- How will a server cope that is in a cold state,[39] just added to production? How does the server cope when all of the content is local? What happens when all of its content is on a remote server?

**Errors with UNC Content Under High Load**

If the Web server and the remote file server are not configured properly for high stress conditions, administrators might notice some errors. The following errors can show up on browsers, in the system event log on the IIS server/remote file server, and in the IIS logs.

- *Not enough server storage is available to process this command. Error code: 0x8007046.*
- *Windows cannot find the network path. Verify that the network path is correct and the destination computer is not busy or turned off. If Windows still cannot find the network path, contact your network administrator. Error code: 0x80070033.*
- *The network location cannot be reached. For information about network troubleshooting, see Windows Help. Error code: 0x800704CF.*

**MaxUserPort Setting**

The last two errors can be returned when the IIS server has a shortage of outbound TCP ports while making the UNC connection to the remote file server/NAD device. The Web/application server will then return HTTP 500 errors for all requests, until TCP ports are available again. To fix this problem, you can use the MaxUserPort registry setting (on the Web/application server) to increase the number of available ports.

For instance, if there are a large number of concurrent authenticated users (Basic, Digest, Kerberos/NTLM, Microsoft .NET Passport) a different Server Message Block (SMB) connection is opened for each individual user, from the Web/application server to the remote file server. Every SMB connection uses ports. By default, you are limited to ports from 1,024 to 5,000 for outbound TCP connections (a little less than 4,000 ports available), so you may need to increase this value to a higher number, such as 10,000 or 20,000, to allow for additional ports. Be aware that this may cause problems with other applications creating sockets on these higher ports. The following MSDN document discusses this further: http://www.microsoft.com/windows2000/techinfo/howitworks/communications/networkbasics/tcpip_implement.asp.

**Windows-based Remote Content Store**

This section only applies when a Windows Server is being used to house the content that several Web/application servers are accessing over Windows UNC file shares.

The first error message above (*Not enough server storage is available to process this command. Error code: 0x8007046A.*), requires a check of the Windows file server settings. Usually, that IIS error accompanies event log messages like the examples below:

- The server was unable to allocate from the system non-paged pool because the pool was empty.
- The server was unable to allocate a work item <n> times in the last 60 seconds.

Normally, those messages mean that the file server was set to use too much non-paged system memory. This can be quickly verified by opening Windows Task Manager, going to the Performance tab, and looking at the non-paged value under Kernel Memory frame. You should throttle it back and limit the amount of kernel memory the Server service should use.

When troubleshooting this class of errors, you will need to check these performance counters on the Web/application server:

- Server\Files Open
- Server\Server Sessions
- Server\Work Item Shortages

The last class of errors above can typically be fixed by tuning the following registry entries related to SMB[40] configuration, namely: **MaxCmds**, **MaxMpxCt**, **MaxWorkItems**.

Between two Windows servers, for each user, one SMB connection is used; however, within that SMB connection, there are a finite number of work items. Work items can be consumed in a variety of ways and for varying amounts of time. For example, doing an operation against a file (for example CreateFile or GetFileAttributes) only takes up an I/O work item for a short amount of time, but asking for a change notification on a directory structure will consume a work item for as long as the connection is established.

Here are some general details about work item configuration:

- Only one SMB connection is created per Web server / file server connection, per user.
- Each change notification instance uses a work item until the connection is closed.
- Each request from the Web/application server to the file server is going to temporarily use a work item.
- The registry settings at this location: **HKLM\System\CurrentControlSet\Services\LanmanServer\Parameters** can be updated on the remote file server, and the registry settings at: **HKLM\System\CurrentControlSet\Services\LanmanWorkstation\Parameters** can be updated on the Web/application server.
- For these registry values to take effect, you must stop and start the server service on the remote file server and the workstation service on the Web/application server. The servers do *not* require a reboot.
- Each work item typically takes up about 20K of non-paged pool memory. Although certain KB articles may specify setting the **MaxWorkItems** value to 16,000 this could consume up to around 320 MB of non-paged pool memory, which could starve the system. Always set this number lower to increase the reliability of your system.
- The rule of thumb for calculating **MaxCmds** is as follows: (# of distinct physical directories that IIS needs to monitor for change notifications) * (1 (if static files exist) + 1 (if ASP content exists) + 1 (if ASP.NET content exists)) + 50 (for concurrent default/regular File I/O).

| **Note** |
| --- |
| This calculation merely hints at the recommended setting. You may need to bump your settings higher depending on concurrent traffic. |

The following are the default and maximum registry values for some SMB settings on Windows Server 2003 (same as on Windows 2000):

| Registry Setting | Default Value | Maximum Value |
| --- | --- | --- |
| **MaxCmds** | 50 | 65535 |
| **MaxMpxCt** | 50 | 65535 (Windows 2000 SP2+; max 125 on W2Kpre-SP2) |
| **MaxWorkItems** | scaled on memory size, usually between 1K 4K | 65535 |

**ASP.NET Web Applications and Web Services in Dense Hosting Environments**

The richness of the managed code environment also means that the memory cost of running that environment is bigger than the cost of running applications in an unmanaged environment. When running managed code applications in a hosted environment, the first consideration is the deal the customer signed up for. If part of that deal is to have a very high level of reliability, it would be pragmatic to put that application in its own application pool.

If applications do not have stringent isolation requirements, it is fine to have a strategy of putting managed code applications into the same application pool. In this case, ASP.NET will place these applications into their own application domain within the worker process regardless; however, the risk is that if they are sharing application pool with an unmanaged component that happens to cause a failure, all applications in that application pool are be affected. Additionally, maintenance on any application in the application pool that requires a recycle will also temporarily affect the responsiveness of all other applications in that

application pool.

It is very important to understand what the maximum number of processes and memory footprint is on a server. This information can help an administrator size the server adequately so that the server has resource when many of the applications are initialized. This can be done by selectively pinging each possible application pool on a server and seeing what the impact is on memory, CPU utilization, and disk I/O overall responsiveness. When a comfortable threshold is reached, an administrator can consider using the (worker) Process Gating parameter[41] to lock down the maximum number of concurrent worker processes on a system. See the section entitled Number of Worker Processes for more information about Process gating.

# Server Consolidation Scenario (Web and Application Server Infrastructure - Performance and Scalability)

Updated: January 1, 2003

Applies To: Windows Server 2003 with SP1

The Server Consolidation scenario is a special case of dense hosting in that the goal of this scenario is to put several unrelated Web applications or Web services on the same server. The big distinguishing factor is that in the Server Consolidation scenario, typically, the applications have much higher reliability requirements. Additionally, the applications will typically have higher request rates and there will be fewer applications per server than the Dense Hosting scenario.

Server consolidation is becoming more and more popular; it is quite common to find companies having many servers running a single application. Even though many of these applications are mission critical, they do not have high request rates or large processor or memory needs. In fact, they barely use the resources available to them on the servers they are running. The management cost of these servers can be improved proportional to the number of operating system instances being managed. Therefore, by consolidating these applications on a single server, a company decreases management costs and sometimes gets better operational management of the remaining operating systems.

| **Note** |
| --- |
| The following discussion will focus on the homogeneous consolidation of Web applications and services, not the heterogeneous consolidation of Web applications with e-mail, database, etc. This discussion does not focus on the versioning and side-by-side considerations of the server consolidation scenario. |

**Considerations**

This section contains considerations relevant for tuning Windows Server 2003 in an (Web application) Consolidation scenario.

**Independent Application Pools and Independent IIS Sites for Applications**

This is a very likely configuration option in a Server Consolidation scenario. Given the reliability needs of applications, having them in separate application pools isolates failures and outages due to other applications. Applications can be managed separately; if they have bugs, they only have an impact on themselves, they can be put out of service for maintenance independently, without affecting other applications still online.

Having different applications or Web services running in their own application pool is also useful from a performance tuning perspective. Many settings are based on the application pool setting properties.

**Independent Sites**

The other setup configuration option, besides separate application pools, for a server consolidation scenario, is to have separate applications (or Web services) placed into separate IIS sites (Figure 10). There are additional settings and properties that can be controlled which are set at the site level. Examples include compression, bandwidth throttling, and total allowable connections to an application.

Creating an independent site for each application is simple. Each application must be accessed through a separate TCP/IP address, server port, or DNS name. The preferred approach is to use a separate DNS name per application, as this is much more efficient than using a separate IP address. Using a separate server port makes accessing applications a little more tedious (the port must be appended to all requests) when users are using a browser to access applications. If the application in question is a Web service, this is not as great a concern, since the separate port is usually ed away by a rich client or other program calling into the Web service.

**Figure 12: Site, application, and Web service isolation capabilities**

**Resource Control**

The application pool construct allows many settings to be applied per application. Many of these settings are resource controlled, but they also have performance impacts.

**CPU**

This is a primary resource control performance tuning parameter. The CPU utilization control available on the application pool object controls what percentage of the total CPU of the server that specific application gets.

The CPU control on the application pool object is the average amount of CPU the application should consume over unit time. So, if the CPU control on an application pool is set to CPU Utilization: 20%, for Time: 4 minutes, and an application consumes 40 percent for 2 minutes, the action for the application pool is fired. That means that if the application pool is set to Shutdown (should the CPU utilization be exceeded), the application pool will be shut down for 4 minutes, until the next period determined by the CPU occurs. Then, the application pool will be reactivated. If the action is set to No action, the excessive utilization will log an event in the system event log.

It is also possible to control the CPU utilization of a specific application in a server consolidation scenario, by configuring affinity between a processor and an application. For a discussion of affinity and large multiprocessor servers, see the Multiprocessor section (above). By establishing affinity between a specific application and CPU, you automatically limit the CPU available to an application. For example, if you are running on a 16-processor server, and the application has affinity with 4 processors, the maximum CPU that application has access to is 25 percent[42].

| **Note** |
| --- |
| Notice that the default IIS capabilities do not allow true throttling of the CPU on an application pool. For throttling, see the Windows System Resource Manager Tool discussion below. |

**Memory**

Memory utilization is an important performance parameter of an application. IIS 6.0 allows for the control of the memory utilization on a specific application, by limiting the Private memory and Virtual memory threshold settings. If these parameters are set too low, and the application exceeds the threshold frequently, the application will be recycled every few minutes, which will have a performance impact, given the system overhead of spinning up and warming up new processes and libraries.

In a server consolidation scenario, it is a good idea to have some excessive capacity on the server where you first place an application. Give the application an above-average amount of resources and monitor it for a few days, under normal usage. This will give an impression of the resource needs of the application. Then, select the resources you expect to constrain on the application and constrain them one by one. All the while, continue measuring the impact of the change, by assessing if the average response time of the application has increased. If so, you may have set one of the resources too aggressively for the application.

**Identity**

This is another property set on a per application pool basis. If set as a domain account, there will be slightly higher latency when starting processes, given the additional latency involved with communicating with a domain controller to log on the base process identity. This doesn't mean that the identity will be accessed per request, only at process startup.

**Logging**

This is an important consideration in the Server Consolidation scenario. The decision is between having a single log file for all the applications on the server or having a separate log file per application.

Having a single log file per server is efficient if it is getting many requests (high throughput rate), because the centralized binary log file allows administrators to place the log file on a separate device dedicated to logging. That style of logging is most efficient: the disk subsystem gets to optimize its writes for the one, sequentially-written log file. The downside with the centralized binary log file is the need to use the LogParser utility to separate out log entries for specific applications (all applications on the server have their log items in the same file). For more information, see the New Format in IIS 6.0 Centralized Binary Logging section (above).

By contrast, leaving the standard logging on will generate a separate log file for every site on the server, but this could also mean high disk latencies in a disk I/O subsystem. The determination is largely dependant on the operational policy, the needs of logging in the environment, and the request rate experienced by the server.

To better understand the behavior and performance consideration of the Logging subsystem, see the Logging section (above).

**Data Bandwidth Throttling**
This can also be a key consideration when supporting many important applications on a single, physical piece of hardware. It is good practice to understand the total bandwidth available on the server and to restrict applications in terms of the maximum bandwidth they can use on a server.

This is not a reservation scheme; an application is not guaranteed that amount of bandwidth, each application (or site) is limited in terms of how much bandwidth they can consume. Further, just because the network devices in a server have published data rates, does not mean it is possible to achieve that data rate given the limitation of the number of physical cards on a root bus, and the speed of the bus. For a deeper discussion of the capabilities and considerations of the networking subsystem of an Internet server, see the Networking section.

**Windows System Resource Manager (WSRM)**
WSRM also allows you to manage CPU and memory utilization on a per application basis, but it provides a mechanism for implementing rich application policies and integrating them with a schedule. This means that an administrator can run multiple applications on a server with greater safety.

WSRM policies can be applied according to a time/date schedule. This allows administrators to free up CPU and memory for maintenance applications during non-peak hours, and for mission critical applications during peak hours.

The WSRM accounting feature allows administrators to generate, store, view, and export resource utilization reports for systems management, and service level agreement (SLA) tracking and billing purposes.

WSRM enhances the base IIS 6.0 by providing the ability to throttle the CPU use of a specific application pool. With WSRM, you can enable a situation where an IIS 6.0 application pool uses up to 20 percent of the CPU, regardless of the load coming in.

**Tuning Parameters for Independent Applications**
By placing separate applications in independent application pools, many of the control and tuning parameters are available to administrators when setting up the Server Consolidation scenario. IIS 6.0 allows many different Web application types to run side-by-side. For example, it is possible to take an ISAPI application, ASP/COM+ application, ASP.NET Web application, ASP.NET Web service, and a third-party application environment[44], and run them all concurrently, side-by-side, on IIS 6.0.

Note, however, that for some of the Microsoft application technologies, additional configuration schemes contain some of the performance tuning parameters. For example, the ASP.NET technology also has a series of text files which contain configuration settings. The root configuration file for ASP.NET is the machine.config file (found in **%SYSTEMROOT%\Microsoft.NET\Framework\vvvv\CONFIG**). When an ASP.NET application is run, the properties from this file are read and overrides are applied in the application directories (to modify the machine.config file). Some of the parameters are thread-related and connection-related. This document references machine.config parameters; these files might require settings in addition to IIS 6.0 specific parameters.

Information about the ASP.NET configuration system inheritance can also be found at:

http://msdn.microsoft.com/library/en-us/cpguide/html/cpconconfigurationinheritance.asp.

**Large Multiprocessor Servers**
When consolidating important or mission-critical applications, it is not uncommon to use a large multi-processor server, as there is a greater capacity potential on that server and the hardware will also typically have additional reliability features built into it.

The Multiprocessor section (above) provides a detailed look at the performance, troubleshooting, and setup of large multiprocessor servers.

# Summary (Web and Application Server Infrastructure - Performance and Scalability)

Updated: January 1, 2003

Applies To: Windows Server 2003 with SP1

Windows Server 2003 offers significant gains on performance and scalability, over its predecessor operating systems, when used in Web and application server scenarios. Additionally, Windows Server 2003 has many new features for the configuration, management, and tracing of applications running over the HTTP protocol.

**More Information**

1 The following resources contain in-depth information about IIS.

- Technical Overview of Internet Information Services (IIS) 6.0 at http://www.microsoft.com/windowsserver2003/techinfo/overview/iis.mspx
- Microsoft Server Consolidation Kit at http://www.microsoft.com/windowsserversystem/articles/consolidation/default.mspx
- What's New in IIS 6.0 at http://www.microsoft.com/windowsserver2003/evaluation/overview/technologies/iis.mspx
- IIS 6.0 Help at http://www.microsoft.com/technet/prodtechnol/WindowsServer2003/Library/IIS/848968f3-baa0-46f9-b1e6-ef81dd09b015.mspx

For the latest information about Windows Server, see the Windows Server Web site at http://www.microsoft.com/windowsserver2003/default.mspx.

| **Note** |
| --- |
| IIS 6.0 is wholly contained and ships as a component of Windows Server 2003. IIS 5.0 is wholly contained and ships as a component of Windows 2000. It is not possible to interchange IIS 5.0 onto Windows Server 2003 or IIS 6.0 onto Windows 2000, as both versions of IIS are tightly integrated into their respective operating system release. |

2 **worker process:** all Web application processing, including loading of ISAPI filters and extensions as well as authentication and authorization, is done by a new Web service DLL. This DLL is loaded into one or more host processes called *worker processes*, or *instances of W3wp.exe*. For more information about how worker processes interact with IIS 6.0, see the section entitled *Worker Process Isolation Mode*, following this section.

3 **application pool:** an application pool is a grouping of one or more URLs served by one or more worker processes. An application pool corresponds to one request queue within HTTP.sys and one or more worker processes. An application pool can serve requests for one or more unique Web applications. These applications are assigned to the application pool based on their URL. There can be multiple application pools operating at the same time. For more information about application pools, see the section entitled *Worker Process Isolation Mode*, following this section.

4 The IIS metabase is an XML file stored at: **%SYSTEMROOT%\system32\inetsrv\metabase.xml**.

5 8-processor, 900-MHz server (Saber class), 3 gigabit network cards.

6 TTFB/TTFB = Time to first byte/Time to Last byte response time latency from the client perspective.

7 See RFC2616 for a description of HTTP response headers (values, ranges, and purpose.)

8 If possible from a functionality perspective.

9 Test performed on Proliant DL360 2-processor (900-MHz) computer, running Windows Server 2003, Enterprise Edition (build 3700); 1 BCM5701 gigabit Ethernet adapter.

[10] Only ASP.NET pages with VaryByParam=none are cached in the kernel.

[11] CLR = Common Language Runtime, the underpinning of ASP.NET.

[12] This is CPU cycles measured on the physical processor. This number does not relate to the physical number of instructions counted in Microsoft intermediate language (MSIL). This is the resultant processor spins (stalls), cacheline flushes, etc. to get that handful of MSIL instructions executed on a busy system.

[13] A low context switch rate is less then 5,000 context switches per second, per processor. So, an 8-processor server with an overall context switch rate of 1,500 context switches per second would qualify as having a low context switch rate.

[14] When performance testing the Unisys ES/7000 platform (32 processor slots), the IIS test team frequently used 8 gigabit adapters per one operating system instance (32 processors). In some test cases, the 8 gigabit cards were still the bottleneck.

[15] Web browsers and other clients can ask IIS to send back a compressed response by including the Accept-Encoding: gzip, deflate request header in the initial content request.

[16] HT stands for Hyper-Threading technology from Intel where a single processor core is represented as 2 virtual processors in the operating system.

[17] The HTTP.sys cache will only cache HTTP GET requests that are anonymous. This includes unauthenticated SSL encrypted responses.

[18] PAE = Physical Address Extensions. An extended addressing scheme for x86 based systems that allows access to greater than 4 GB of RAM.

[19] This location is accurate for the initial release of Windows Server 2003. Microsoft reserves the right to change this location and parameters in future releases or service packs.

[20] Bottleneck is CPU.

[21] Bottleneck is gigabit network card.

[22] IIS will preserve existing per-site log-file settings when the CBL mode is selected, so if you want to revert back, you do not lose any log-file configuration.

[23] IIS will fill a 64K log buffer before physically writing it to disk.

[24] The registry key **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\Http\LogBufferSize**, controls the size of the log buffers allocated by HTTP.sys. When this registry key is not present, HTTP.sys will allocate 64K for each log buffer. When this registry key is present, HTTP.sys will validate and use the size nominated as the log buffer. The valid range is 12K-64K.

[25] Windows will reserve large sections of virtual addresses from which to sub-allocate requests, when memory requests come in. This extension doesn't happen on a per-allocation request basis.

[26] See: http://msdn.microsoft.com/library/en-us/memory/base/low_fragmentation_heap.asp

[27] For the purposes of this discussion, a large multiprocessor server refers to a server with more than four physical CPU cores. Note, this is an arbitrary distinction I have made to discuss concepts in this paper. It is not uncommon to consider a large multiprocessor server having greater than 16 CPU cores.

[28] **SMPProcessorAffinityMask** is the decimal conversion of the binary number representing the processors to be used. For example, if an administrator wanted to establish affinity between an application pool and processors 4-7 of a multiprocessor server, the binary number representing that would be 1111 0000. Converting this binary number to decimal yields a value of 240. Therefore, the setting for that application pool would be **SMPPrcoessorAffinityMask=240**.

[29] SMP affinity can only be enabled/disabled through manipulation of the **SMPAffinitized** and **SMPProcessorAffinityMask** properties in the IIS metabase. These values can be manipulated through direct modification of the XML or by using the adsutil utility.

[30] Greater than 5,000 context switches per second, per processor (i.e., more than 40,000 / sec on an 8-processor server) is

generally considered a high context switch rate. Note, however, that context switch rates should also be considered on the request throughput at the time of calibration. For example, if a server is processing 50,000 requests / sec, a context switch rate of 40,000 is quite good (less than one per request).

[31] Example of tools a developer would use to assess locks at run time would be Microsoft Visual Studio .NET 2003 Analyzer or Intel VTune.

[32] An application must be able to be multi-instanced for Web gardens to work.

[33] This five-second interval can be configured; it can be overridden by adding the **HKEY_LOCAL_MACHINE\System\CurrentControlSet\ Services\Inetinfo\Parameters\FileAttributeCheckThreshold (REG_DWORD)** registry key. This value will take effect when a worker process is recycled, so it can be changed in production on the fly.

[34] Because the Web service security standard is built out, some of the data items sent across, per method call, will be the large public/private key encryption values and many other SOAP envelope headers.

[35] Nagling is where a TCP/IP stack only has a small number of bytes to send, so instead of adding all of the TCP headers to a very small payload, TCP/IP will wait for 200 milliseconds in the hope that the application will give it more data to send. If no more data is passed down, TCP will send the small packet. This phenomenon has a higher probability of occurring in Web service interactions, given the split of the packets.

[36] VMWare is an example of an operating system virtualization that consumes significant amounts of system resources on a server, while still maintaining another operating system image.

[37] Assuming the two applications did not have a dependency on one another.

[38] Excessive is a relative term. Having 50 concurrently-running application pools on a server with 128 MB of physical RAM is excessive; having 50 concurrently-running applications on the exact same server with over 1 GB of RAM, would not be excessive.

[39] Cold in this context means a server that has just had IIS initialized, with all the IIS caches empty and no custom components initialized.

[40] SMB stands for Server Message Block protocol. This is the standard protocol used by Windows clients and file servers to share files and printers.

[41] The Process Gating parameter can be found at the W3SVC\MaxProcesses location in the IIS 6.0 metabase.

[42] Given that HTTP.sys does a lot of caching and performs some of the processing for an application, and the CPU use of HTTP.sys is not attributed to an application pool, CPU usage will not be perfect. For example, if an application has affinity to two processors on a 4-processor server and that application is driven as hard as possible, the overall processor utilization will be slightly over 50 percent, given the processing that HTTP.sys does.

[43] Only available for Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition.

[44] Examples include Macromedia ColdFusion, IBM Websphere, and BEA WebLogic. NOTE: At time of writing, third-party vendors had not approved their application environments on Windows Server 2003.

# Planning and Implementing Cross-Certification and Qualified Subordination Using Windows Server 2003

Updated: August 13, 2009

Applies To: Windows Server 2003 with SP1

By Brian Komar and David Cross

Microsoft Corporation

Microsoft Windows XP Professional and Windows Server 2003 provide an integrated, public key infrastructure (PKI) that enables you to securely exchange information across the Internet, extranets, intranets, and applications. This white paper provides a technical reference and planning guide for PKI administrators who wish to perform PKI cross-certification, deploy bridge Certification Authorities (CAs), and understand how to implement qualified subordination in Windows Server 2003.

**In This White Paper**

# Introduction (Planning and Implementing Cross-Certification and Qualified Subordination Using Windows Server 2003)

Updated: August 13, 2009

Applies To: Windows Server 2003 with SP1

Qualified subordination is the process of cross-certifying Certification Authority (CA) hierarchies using basic, policy, naming, and application constraints to limit which certificates are accepted from partner CA hierarchies or a secondary hierarchy within the same organization. True cross-certification of CA hierarchies in a Windows 2000 network was not possible. The only available alternative was to define Certificate Trust Lists (CTLs) that trusted specific CAs and restricted certificate usage. By using qualified subordination, a CA administrator can clearly define which certificates issued by a partners PKI are trusted by the CA administrators organization. Qualified subordination also provides methods for compartmentalizing and controlling certificate issuance within an organization according to policy guidelines. Examples of both scenarios will be explained in this white paper.

For the purposes of this white paper, the term qualified subordination refers to a cross-certification between two CAs that implements basic constraints, name constraints, application constraints, policy constraints, or a mix of the four constraints. This limits which certificates are trusted from a partner or secondary CA hierarchy according to the rules and definitions defined in RFC 2459 and subsequently RFC 3280.

#### Scope

The scope of this white paper is to describe the ways that qualified subordination is used to govern the relationship between multiple organizations PKI hierarchies. The white paper describes the various constraints that can be implemented to define the relationship between PKI hierarchies, presents qualified subordination scenarios, and provides walkthroughs of the qualified subordination process.

#### Terms Used in This White Paper

**Application Constraints** A constraint that limits what purposes a certificate can be used for in a qualified subordination configuration. A presented certificate must contain the required application constraint to be accepted by the partner organization.

**Authority Information Access (AIA)** A certificate extension that contains URL locations where the issuing CAs certificate can be retrieved. The AIA extension can contain HTTP, FTP, LDAP, or FILE URLs.

**Authority Key Identifier (AKI)** A certificate extension used by the certificate chaining engine to determine what certificate was used to sign a presented certificate. The AKI can contain the issuer name and serial number, public key information, or no information at all. By matching the information in a certificates AKI extension to a CA certificates Subject Key Identifier (SKI) extension, a certificate chain can be built.

**CaPolicy.inf** A configuration file stored in the %SystemRoot% folder that defines configuration settings for CAs when they are installed and when the CAs certificate is renewed.

**CRL Distribution Point (CDP)** A certificate extension that indicates where the certificate revocation list for a CA can be retrieved. This extension can contain multiple HTTP, FTP, File, or LDAP URLs for the retrieval of the CRL.

**Certificate Trust List (CTL)** A method of restricting certificates chaining to a designated CA for limited time periods or usages. It is used more prevalently in a Windows 2000 network. In a Windows Server 2003 environment, qualified subordination is the preferred method for restricting certificate usage between organizations.

**Certificate Revocation List (CRL)** A digitally signed list issued by a CA that contains a list of certificates issued by the CA that have been revoked. The listing includes the serial number of the certificate, the date that the certificate was revoked, and the revocation reason. Applications can perform CRL checking to determine a presented certificates revocation status.

**Cross-Certification** The process of issuing subordinate CA certificates for existing CAs that link two root CAs.

**Cross-Certification Authority Certificate** A certificate issued by one CA for another CA's signing key pair (that is, for another CA's public verification key).

**Name Constraint** A constraint that limits what names are permitted or excluded in certificate requests submitted to a CA.

**Issuance Policy Constraint** A constraint that defines what issuance practices must be followed for certificates to be trusted by your organization. Issuance policy object identifiers (OIDs) in your organization are mapped to the matching object identifiers in a partner organization, so that object identifiers in presented certificates are recognized by your PKI.

**Policy.inf** A configuration file that defines the constraints that are applied to a CA certificate when qualified subordination is defined.

**Public Key Infrastructure (PKI)** A PKI provides an organization with the ability to securely exchange data over a public network using public-key cryptography. A PKI consists of CAs that issue digital certificates, directories that store the certificates (including Active Directory in Windows 2000 and Windows Server 2003), and X.509 certificates that are issued to security entities on the network. The PKI provides validation of certificate-based credentials and ensures that the credentials are not revoked, corrupted, or modified.

**Qualified Subordination** The process of configuring cross-certification with basic constraints, name constraints, application constraints, and issuance policy constraints to govern what certificates are trusted from a partner organization.

# Overview (Planning and Implementing Cross-Certification and Qualified Subordination Using Windows Server 2003)

Updated: August 13, 2009

Applies To: Windows Server 2003 with SP1

Qualified subordination allows an organization to extend its PKI trust hierarchy to other organizations and secondary hierarchies within the same organization. Qualified subordination is also sometimes referred to as cross-certification. While extension of PKI trust was possible in a Windows 2000 network using CTLs, CTLs were limited in how restrictions could be defined between the two organizations. Qualified subordination provides a more flexible and manageable trust mechanism.

When implemented using qualified subordination, each qualified subordinate CA can have rules defined that do the following:

- Define the namespaces for which your PKI hierarchy will issue and accept trusted certificates
- Specify the acceptable uses of certificates issued by a qualified subordinate CA
- Define what issuance practices must be followed for a certificate issued by the qualified subordinate CA to be considered valid
- Create a managed trust between separate certification hierarchies

Windows Server 2003 Enterprise Edition provides the necessary tools to configure qualified subordination between CAs, so that two organizations can define how certificates will be trusted between the organizations. These tools include the following:

- **Version 2 certificate template** Allows CA administrators to modify certificate templates to meet their business purposes. Qualified subordination requires the use of version 2 certificate templates to include policy constraints. Modifications to version 2 templates can include:
    - Creating a new certificate template by duplicating and renaming an existing template
    - Modifying template properties such as certificate validity period, renewal period, cryptographic service provider (CSP), key size, and key archival settings
    - Establishing and applying enrollment policies, issuance policies, and application policies
- **Cross-Certification Authority Certificate** A version 2 certificate template that is issued from one CA to another CA establishing qualified subordination between the two certificates. The certificate used to sign the cross-CA certificate enforces the constraints defined in the certificate.
- **Qualified Subordination Signing Certificate** A version 2 certificate template that must be manually created; it contains the Qualified Subordination application policy object identifier. This certificate template validates that the holder is approved to sign cross-certification authority certificates.
- **Certutil.exe** A command-line program that is installed as part of Certificate Services. It is used to dump and display CA configuration information, configure Certificate Services, back up and restore CA components, and verify certificates, key pairs, and certificate chains.
- **Certreq.exe** A command-line program that is installed as part of Certificate Services. It is used to request certificates from a CA. In qualified subordination, certreq.exe is used to request the cross-certification authority certificate at the issuing CA.

# Understanding Constraints

Updated: August 13, 2009

Applies To: Windows Server 2003 with SP1

The key to qualified subordination is restricting what certificates issued by the qualified subordinate CA, or by CAs that chain through the qualified subordinate CA, are trusted by your organization. This is accomplished by defining basic constraints, name constraints, issuance policy constraints, or application policy constraints in one of two ways:

- Constraints can be defined during the installation of the CA. By including the sections defined below in the CAPolicy.inf file, the basic constraints, name constraints, issuance policy constraints, and application policy constraints are defined at the CA during the installation of the CA or during the certificate renewal process at a CA.

- Constraints can also be defined during the cross-certificate request process by defining the constraints in the Policy.inf file. The Policy.inf file defines the constraints implemented in the cross-certification certificate used to define the qualified subordination.

Appendix A contains an example of a Policy.inf file. Appendix B contains a sample of the CAPolicy.inf file.

| **Note** |
| --- |
| Constraints are defined in section 4.2 "Standard Certificate Extensions" in RFC 2459. |

| **Note** |
| --- |
| For more information about how the certificate chaining engine uses constraint information when building certificate chains, see Certificate Revocation and Status Checking (http://go.microsoft.com/fwlink/?LinkID=27081). |

**Basic Constraints**

Basic constraints allow a CA administrator to limit path length for a certificate chain. You can specify a basic constraint that defines the maximum number of CAs that can exist below the CA where the basic constraint is assigned. For example, if you define a path length of zero, the CA can only issue end-entity certificates and is not permitted to issue SubCA certificates.

Figure 1 shows a CA where a basic constraint is applied that limits the path length to two.

**Figure 1: Applying Basic Constraints**

The basic constraint ensures that the maximum path length for certificates that chain to the CorpCA that are trusted is two deep. This means that only two more layers of CAs can exist below the CA where the basic constraint is defined. In this example, the AsiaCA is restricted so that it can only issue trusted end-entity certificates. If a certificate issued to the JapanCA or any certificate issued by the JapanCA is presented, the chain would fail chain verification, because the certificate would result in a chain with a path length greater than two. Whenever a CA issues a certificate to another CA, it can reduce the path length, but never increase the permitted length.

| **Note** |
| --- |
| Basic constraints are fully defined in section 4.2.1.10 of RFC 2459. |

**Best Practice** A best practice that can be applied in regards to basic constraints is to only restrict the path length in a subordinate CA certificate, not a root CA certificate. The reason this is more commonly employed is that a change in the root requires a complete redeployment of the hierarchy and the root certificate should a change in the path length be desired. Therefore, in the previous example, the RegionCA certificate would be issued with a PathLength = 1 and have no length defined in the root CA certificate.

**Name Constraints**

Name constraints allow you to designate which namespaces are either permitted or excluded for certificates issued by CA where qualified subordination is defined. When a request is received at the qualified CA, the names present in the subject and the subject alternate name fields are compared to the configured name constraints to determine whether the namespace is permitted or excluded. In other words, the CA enforces all constraints defined in the CA certificate.

| **Note** |
| --- |
| If the name presented in the request is not present in the list of constraints, the request will be rejected by the qualified CA. All names in a certificate request must be within permitted namespaces and none may be within an excluded namespace for the certificate to be issued. |

Name constraints allow you to control what namespaces are managed by each CA in your organization and those that you trust from other organizations. When you deploy a qualified subordinate CA, you must carefully consider what namespaces you wish to allow the CA to issue, and more importantly in some cases, what namespaces you wish to prevent the qualified subordinate CA from supporting.

For example, when you configure qualified subordination between your organization and a partner organization, you would typically not want your partners CA infrastructure to issue certificates containing names in your organizations namespace. Remember that a valid certificate that contains a UPN for your organization is mapped to the user account with the UPN as an attribute. It does not matter which CA issues the certificate, only that the certificate chains to a CA certificate in the NTAuth store. The use of name constraints can ensure that your namespace, and all recognized formats of your namespace, are excluded for certificates issued by your partners CA hierarchy.

In the case where both permitted and excluded name constraints exist, the excluded name constraints will always take precedence. For example, if you create a permitted DNS name constraint for the namespace .microsoft.com and an excluded DNS name constraint for .subdomain.microsoft.com, all certificates for subdomain.microsoft.com will be rejected, even though the microsoft.com namespace is permitted.

| **Important** |
| --- |
| The default policy of a Microsoft client validating a certificate with name constraints asserted is that all names have to be explicitly permitted. For example, if a name constraint does not specify the e-mail name as a permitted type, and a certificate request contains an e-mail name, the request will be rejected. It is possible to relax this policy and implicitly allow names not defined in the name constraint extension by configuring the CA policy in the registry. |

The certificate request is only accepted if each name in the certificate request matches at least one of the permitted name constraints configured at the qualified subordinate CA. In other words, if the certificate request contains the requestors name in both an LDAP distinguished name format and in a UPN format, both names must match permitted name constraints. If one of the presented names does not match, the certificate request fails.

**Name Constraint Processing**

When a certificate request is presented to a subordinate CA under qualified subordination rules, all name forms in the certificate request must be within the permitted namespaces. In addition, the subject names must not be within an excluded

namespace. The permitted and excluded name constraints are processed separately.

The following rules are followed by the qualified subordinate CA:

- A certificate request is successful if all names in the certificate request succeed in matching the corresponding permitted name constraints.
- A certificate request is unsuccessful if any names in the certificate request succeed in matching the corresponding excluded name constraint.
- A certificate request containing names that cannot be matched with either the permitted or excluded names is considered excluded and fails.
- Comparison of the name identifying the subject entity with the qualified subordinate CA's name constraints is performed using the following rules:
    - The comparison is not case-sensitive if the name or part of the name is encoded with an IA5 string. If it is encoded as a Unicode or UTF8 string, the comparison will be a binary match of the content.
    - Name constraints are applied to the Subject name field and any existing Subject Alternate Name extensions.
    - A qualified subordinate CA's name constraints cannot permit names excluded by its parent CA. For example, if the parent CA excludes the DNS name .microsoft.com, then its qualified subordinate CA cannot permit the DNS sub-domain .example.microsoft.com. The name constraints are checked by the CA to ensure that its chain is valid by calling CryptoAPI.
    - Name constraints apply to all names contained in subject and subject alternate name extensions in an end certificate. Each name in the subject or subject alternate name extensions must match at least one of the name constraints listed for that name type. A subject name or subject alternate name that does not match a listed name type is rejected.
    - Constraints apply only when the namespace types specified as name constraints are present in the certificate request. If no namespace of the specified types is in the certificate request, the certificate is acceptable. For example, a CA is configured with the following name constraints:

```
[NameConstraintsExtension]
Include = NameConstraintsPermitted
Exclude = NameConstraintsExcluded
Critical = True

[NameConstraintsPermitted]
DirectoryName = "DC=Microsoft, DC=Com"
email = @microsoft.com
UPN = .microsoft.com
UPN = @microsoft.com

[NameConstraintsExcluded]
```

In this configuration, if the CA receives a request with the e-mail name of user1@northwindtraders.com, the request would be rejected. Likewise, the request would be rejected if the subject alternate name contained user1@northwindtraders.com while the subject name contained CN=user1,OU=Contractors,DC=Microsoft,DC=Com. Remember that all subject names must match the name constraints for a certificate to be issued. The default policy as mentioned previously requires all names to be defined unless otherwise configured on the certification authority.

| **Note** |
| --- |
| If you do not specify permitted or excluded names, you are creating a wildcard (*) name constraint for those name constraint formats. |

When the name constraint processing is completed, the validation process will result in one of the following outcomes:

- **Permitted** The end certificate contains a name that is listed as permitted in an issuers name constraints extension.
- **Not permitted** The end certificate contains a name that is not listed as permitted in an issuers name constraints extension.
- **Excluded** The end certificate contains a name that is listed as excluded in an issuers name constraints extension.
- **Not Defined** The issuer certificate does not list a constraint for a specific name type (such as Directory Name or IP Address).

| **Note** |
| --- |
| Windows Server 2003 CAs will have constraints set to permit all namespaces for a particular name type, unless specified otherwise in the name constraints extension in the Policy.inf file. |

**Applying Name Constraints**

The following naming and addressing format are natively supported for use in Policy.inf when defining name constraints:

- Relative distinguished name
- DNS domain name
- Universal Resource Identifiers (URI)
- E-mail name and User principal name (UPN)
- IP address

Additional name constraint forms may be enforced using the Other Name forms, which are identified by name and object identifier that are UTF8 or ASN.1 encoded. Other Names can be used to represent names that are outside of the standard name types such as Rfc822Name, DNS, or X.500 Directory Name. It consists of an object identifier and a binary blob. The most common Other Name is the Universal Principal Name (UPN) Name, which has the constant OID_NT_PRINCIPAL_NAME as the object identifier. The version 2 "Domain E-mail Replication" template certificates and the Version 1 "Domain controller" certificates have a subjectaltname extension that contains the constant OID_NTDS_REPLICATION as other name type and the GUID representation of the DC as the blob. In Windows 2000, only the UPN was present in the other name constraint. However, now in Windows Server 2003, the other name constraint has been expanded to support even the domain controller GUIDs. The following is the syntax where the first part is the object identifier, followed by a qualifier identifying the encoding of the following data as UTF8 or octet or ASN.1:

OtherName=1.2.3.4.99.100,{utf8}ssss

OtherName=1.2.3.4.99.101,{octet}ABCD

OtherName=1.2.3.4.99.102,"{asn}BAgAAQIDBAUGBw=="

OtherName=1.3.6.1.4.1.311.25.1

One scenario where this may be useful is when you have smartcard logon across forests, wherein the other domain has Windows 2000 domain controllers. In this case, you can provide an additional name constraint as "OtherName=1.3.6.1.4.1.311.25.1" to allow all Domain e-mail replication certificates and restrict the namespace using the DNS name constraint. It is technically possible to restrict the GUID of a domain controller as another name but that would not be a generic constraint but a specific constraint to only one domain controller.

**Configuration**

The name constraints are configured in one of two locations. When creating a new CA, you can define name constraints for that CA by configuring CAPolicy.inf to impose name constraints. Likewise, if you are creating a qualified subordinate CA

certificate, you would define name constraints in the Policy.inf file. In both cases, the following syntax is used:

```
[NameConstraintsExtension]
Include = NameConstraintsPermitted
Exclude = NameConstraintsExcluded
Critical = TrUe

[NameConstraintsPermitted]
DNS = ""
email=""
UPN=""

[NameConstraintsExcluded]
DNS = .nwtraders.com
email = @nwtraders.com
UPN = .nwtraders.com
UPN = @nwtraders.com
URI = ftp://.nwtraders.com
DIRECTORYNAME = "DC=NWtraders, DC=com"
```

| **Note** |
| --- |
| The critical = True in the [NameConstraintsExtension] indicates that this extension is marked as critical. If the validating computer cannot parse the extension, it must reject the certificate chain. |

**Relative Distinguished Name Constraints**

Relative distinguished names are used to identify the names of objects stored in directories such as Active Directory or X.500 directories. Using Relative distinguished name constraints allows you to restrict a qualified subordinate CA to issue certificates only to specific users or computers in Active Directory by using the objects Relative distinguished name. The distinguished name can be very specific, where the permitted or excluded Relative distinguished name references a specific object. Or, the distinguished name can be a wildcard value that references all the objects within a specific container, domain, or organizational unit.

The name constraint must be included in either the Policy.inf file used to create a qualified subordinate CA or in the CAPolicy.inf file used when installing a new subordinate CA. Table 1 shows some examples of LDAP name constraints and defines what objects the constraints refer to.

**Table 1 Name Constraint Examples**

| Relative Distinguished Name Constraint | Includes |
| --- | --- |
| `DC=example,DC=microsoft,DC=com` | All objects in the example.microsoft.com domain |
| `CN=Users,DC=example,DC=Microsoft,DC=com` | All objects in the Users container in the example.microsoft.com domain |
| `CN=Brian Komar,CN=Users,DC=microsoft,DC=com` | The user object Brian Komar in the Users container in the microsoft.com domain |
| `OU=Marketing,DC=Microsoft,DC=Com` | All objects in the Marketing OU of the Microsoft.com domain |
| `CN=Servers,CN=Sites,CN=Configuration,DC=Microsoft,DC=Com` | All domain controllers in the microsoft.com forest |
| `OU=Domain Controllers, DC=Redmond,DC=Microsoft,DC=Com` | All domain controllers in the Redmond.microsoft.Com domain. |

The range of characters in the allowed name constraint is defined by the relative distinguished name (also known as RDN) type. Most relative distinguished names (such as O=, OU=,CN=, and so on) support international (UTF8) characters, where relative distinguished names that include (DC=,C=,e-mail, and so on) support IA5 character types. A Relative name constraint will appear in either the permitted or excluded name constraints using the following format:

```
DIRECTORYNAME = "DC=NWtraders, DC=com"
```

**DNS Name Constraints**

DNS name constraints compare any DNS names contained in certificate requests to the list of permitted and excluded DNS name constraints. As with LDAP distinguished name constraints, the name in the certificate request must match one of the permitted names for the certificate to be issued.

The DNS domain names accepted by the subordinate CA must follow the standard DNS naming conventions as specified in RFCs 1034 and 1035, and are listed in either the Policy.inf or CAPolicy.inf file used. Therefore, the DNS name constraint cannot contain international character sets.

When configuring a DNS name constraint, you can either designate a specific DNS host name, for example, host.example.microsoft.com, or you can designate a DNS namespace. For example, the DNS name constraint .example.microsoft.com indicates all hosts that have a DNS name that ends with example.microsoft.com. The preceding period (.) indicates that any DNS name that ends with example.microsoft.com matches the name constraint.

**Note**

This does not include a host that does not have a period preceding example.microsoft.com. For example, the host named ourexample.microsoft.com would not result in a match when compared to the name constraint .example.microsoft.com.

Table 2 demonstrates the results for submitted DNS names against configured DNS name constraints.

**Table 2 Evaluating DNS Name Constraints**

| Submitted DNS Name | DNS Name Constraint | Evaluation |
|---|---|---|
| `www.example.microsoft.com` | `.example.microsoft.com` | Match |
| `www.south.example.microsoft.com` | `.example.microsoft.com` | Match |
| `example.microsoft.com` | `.example.microsoft.com` | No Match |
| `Ourexample.microsoft.com` | `example.microsoft.com` | No Match |
| `www.example.microsoft.com` | `example.microsoft.com` | Match |

**Important**

Evaluate your DNS constraints carefully. Remember that all excluded name constraints take precedence over a permitted name constraint. For example, if you permitted .example.microsoft.com and excluded .microsoft.com, a request from www.example.microsoft.com will be rejected. This DNS name matches both the excluded and permitted name constraints. Because there is a match on the excluded name constraint, the permitted name constraint is not observed.

A DNS name constraint will appear in either the permitted or excluded name constraints using the following format:

```
DNS = .nwtraders.com
```

**Uniform Resource Identifier (URI) Constraints**

Uniform Resource Identifiers (URIs) identify resources on the Internet that use identifiers such as URL, FTP, HTTP, telnet, mailto, news, and gopher. The URI naming conventions supported for name constraints must follow the syntax specified in RFC 2396.

When a qualified subordinate CA validates a URI name, the protocol element in the URI is ignored. For example, if the submitted URI is http://www.example.microsoft.com and the URI name constraint is URL=ftp://.example.microsoft.com, the actual comparison performed is between the host name www.example.microsoft.com and the name constraint .example.microsoft.com. In this case, the result would be a match, even though the protocols differ.

As with DNS constraints, a URI constraint can reference either a host or a domain. If a preceding period is included in the URI constraint, the domain name must include the entire suffix defined in the name constraint. For example, if the URI constraint is .example.microsoft.com, then matches are achieved for west.example.microsoft.com and for east.example.microsoft.com.

The most frequent application of URI name constraints is the validation of certificate requests for Web Server certificates, where the Web servers URL is submitted in the certificate request. For example, if the Web Server certificate request has a name of http://www.microsoft.com and the qualified subordinate CA's permitted URI name constraint is URL=http://www.microsoft.com, then this URI constraint would permit the certificate request for the Web Server certificate.

A URI name constraint will appear in either the permitted or excluded name constraints using the following format:

```
URL = "http://.microsoft.com"
```

**RFC 822, E-mail, and UPN Constraints**

RFC 822 and e-mail constraints must follow RFC 822 naming conventions and use IA5 encoding of character strings. User Principal Names (UPNs) use the same syntax but are encoded using UTF8. Although RFC 822 names, UPNs, and E-mail addresses share the same syntax, you must provide separate examples in the name constraints listing of Policy.inf to differentiate between requests using e-mail addresses and requests using UPN names.

When defining RFC 822, E-mail, or UPN constraints, you can specify constraints for individual addresses or for addresses that end with a specific domain.

For example, to create a name constraint for the e-mail address for a Joe Smith at Northwind Traders, you could create a E-mail address constraint for jsmith@nwtraders.com. To create a name constraint for all e-mail users at Northwind Traders, you would set the e-mail constraint to be @nwtraders.com. By not placing any text to the left of the ampersand, the e-mail constraint becomes a wildcard representing all e-mail addresses in the nwtraders.com domain.

Table 3 shows some examples of RFC822, E-mail, and UPN constraints and how they evaluate.

**Table 3 RFC 822, E-mail, and UPN Constraint Evaluation**

| Submitted Address | UPN/E-Mail Constraint | Evaluation |
|---|---|---|
| jsmith@nwtraders.com | jsmith@nwtraders.com | Match |
| bjsmith@nwtraders.com | jsmith@nwtraders.com | Match |
| jsmith@nwtraders.com | @nwtraders.com | Match |
| jbsmith@nwtraders.com | bjsmith@nwtraders.com | No Match |

**Note**

UPN name constraints should always be entered as two separate entries in the list of name constraints. One entry should include the ampersand character (such as @nwtraders.com); the second entry should replace the ampersand with a period (.), so this entry would be .nwtraders.com. This format allows for the possibility of having a UPN of subdomain.nwtraders.msft.

E-mail and UPN name constraints will appear in either the permitted or excluded name constraints using the following format:

```
email = @nwtraders.com
UPN = .nwtraders.com
UPN = @nwtraders.com
```

**IP Address Constraints**

IP address constraints allow you to specify either specific IP addresses or ranges of IP addresses that a CA can successfully receive certificates from a qualified subordinate CA. The format of the IP addresses in the constraints must follow either RFC 791 (for IPv4 addresses) or RFC 2460.

When a certificate request is received by a qualified subordinate CA, the source IP address in the certificate request is compared to the IP address constraints to determine if the IP address is permitted or excluded by the name constraints.

To specify a range of IP addresses, you must specify both the IP address and associated subnet mask in each constraint. For example, if you wanted to create an IP address constraint for the 192.168.3.0 network, the constraint would be 192.168.3.0/255.255.255.0.

An IP address constraint will appear in either the permitted or excluded name constraints using the following format:

```
IPADDRESS = 192.168.3.0/255.255.255.0
IPADDRESS = 192.168.2.254/255.255.255.255
IPADDRESS = 172.16.8.0/255.255.248.0
```

The first constraint includes all computers in the 192.168.3.0 network. The second constraint is a host-specific constraint that only includes the host with IP address 192.168.2.254. The final constraint is a Classless Internet Domain Routing (CIDR) example that includes all hosts with addresses between 172.16.8.1 and 172.16.15.254.

**Issuance Policy**

Issuance policies are used to identify the extent to which your organization trusts the identity presented in a certificate issued

by another organizations CA hierarchy. For example, an issuance policy may describe that you only trust certificates that were issued during a face-to-face meeting with a network administrator, such as the issuance of a smartcard certificate. Each issuance policy is described by an object identifier. The inclusion of an issuance policy object identifier in an issued certificate indicates that the certificate was issued meeting the issuance requirements associated with the issuance policy object identifier.

| **Note** |
| --- |
| Issuance policy is the Microsoft term for Certificate Policies defined in part 4.2.1.5 in RFC 2459 and is contained in the certificatePolicies extension of a certificate. |

For a specific certificate template, you can define one or more issuance policy object identifiers that are included in issued certificates. There is a special issuance policy, the *All issuance Policies* object identifier, commonly reserved for CA certificates, that indicates the issuance policy contains all other issuance policies.

Windows Server 2003 includes four predefined issuance policies:

- **All Issuance (2.5.29.32.0)** The all issuance Policy indicates that the issuance policy contains all other issuance policies. Typically, this object identifier is only assigned to CA certificates.

- **Low Assurance (1.3.6.1.4.1.311.21.8.x.y.z.1.400)** The low assurance object identifier is used to represent certificates that are issued with no additional security requirements. The *x.y.z* portion of the object identifier is a randomly generated numeric sequence that is unique for each Windows Server 2003 forest.

- **Medium Assurance (1.3.6.1.4.1.311.21.8.x.y.z.1.401)** The medium assurance object identifier is used to represent certificates that may have additional security requirements for issuance. For example, a smartcard certificate that is issued in a face-to-face meeting with a smartcard issuer could be considered a medium assurance certificate and contain the medium assurance object identifier. The *x.y.z* portion of the object identifier is a randomly generated numeric sequence that is unique for each Windows Server 2003 forest.

- **High Assurance (1.3.6.1.4.1.311.21.8.x.y.z.1.402)** The high assurance object identifier is used to represent certificates that are issued with the utmost security. For example, a key recovery agent certificate allows the holder to recover private key material from a Windows Server 2003 Enterprise Edition CA. The issuance of a key recovery agent certificate may require additional background checks and a digital signature from a designated approver. The *x.y.z* portion of the object identifier is a randomly generated numeric sequence that is unique for each Windows Server 2003 forest.

- **Best Practice** Technically, Issuance Policies can be added to any version 2 template that is issued from a Windows Server 2003 certification authority running Enterprise Edition. However, it is a best practice to apply issuance policies in the Policy.inf file for the qualified subordinate CA to ensure consistent policy for the CA. This is to avoid issuing templates with different policies unintentionally.

| **Note** |
| --- |
| A root CA automatically implies that all issuance policies are defined. For understanding how policy is evaluated in certificate chains, see the Certificate Status and Revocation white paper at http://www.microsoft.com/technet/security/topics/crypto/tshtcrl.mspx |

If your organization has existing object identifiers issued, they may be used for this purpose. In addition, you can create your own object identifiers to represent custom issuance policies. For example, two organizations involved in a purchaser/seller relationship may define custom object identifiers to represent digital signature certificates for specific purchase amounts. For example, object identifiers may be defined for purchase between $100,000 and $500,000, and another object identifier for purchases greater than $500,000. These object identifiers could then be used by applications to recognize whether a person had the appropriate signing authority for a specific volume purchase.

```
[PolicyStatementExtension]
Policies = HighAssurancePolicy, MediumAssurancePolicy, LowAssurancePolicy
CRITICAL = FALSE

[HighAssurancePolicy]
OID = 1.3.6.1.4.1.311.21.8.2473717464.1095930238.502626717.506190032.1.402

[MediumAssurancePolicy]
```

```
OID = 1.3.6.1.4.1.311.21.8.2473717464.1095930238.502626717.506190032.1.401

[LowAssurancePolicy]
OID = 1.3.6.1.4.1.311.21.8.2473717464.1095930238.502626717.506190032.1.400
```

**Note**

Issuance policy extensions are only recognized by Windows XP and Windows Server 2003 clients. If the extension is marked critical, CAPI passes the extensions to the application. It is up to the calling application to understand the extension when it calls with a specific policy provider. The behavior will vary by application. In the case of Outlook on Windows 2000, a critical issuance policy will cause Outlook to generate an error as it does not understand the extension. But on Windows XP, the issuance policy is recognized and does not cause an error.

**Policy Mapping**

When qualified subordination is configured between two CAs that use issuance policy, the object identifiers between the two organizations must be mapped. Policy mapping establishes what object identifiers in one organization are equivalent to object identifiers defined in a different organization's CA hierarchy. The policy mapping allows the object identifiers generated in certificates in one organization to be recognized in another organization through the creation of cross-certification certificates.

Policy mapping ensures that only authorized object identifiers from a partner organization are allowed in certificates issued by the partner organization. The policy mapping will associate the partner organization's object identifier with an object identifier defined in your organization's PKI hierarchy.

Figure 2 shows how policy mapping is defined in the Policy.inf file when cross certificates are issued to allow certificates to be used between the two CA hierarchies.

**Figure 2: Policy Mapping**

In this figure, the Northwind Traders is configured with an issuance policy named MillionDollar that has been assigned the object identifier 1.3.6.4.1.311.21.8.1.124. This issuance policy is mapped to the issuance policy named BigOrder configured at the Contoso Consulting CA.

If a certificate is issued by the Northwind Traders CA with an issuance policy other than the MillionDollar policy, the certificate is rejected by the Contoso CA because the policy does not map to an approved issuance policy object identifier.

When cross certificates are created to link the two organizations' CA hierarchies, the code snippets shown in the figure must be included in the Policy.inf files used to generate the cross-certification certificate at each CA. The Policy.inf files exist at the *issuer* CA. The object identifier that is mapped is the object identifier from the *subject* CA that is the object identifier for the matching issuance policy at the partner organization.

Before you perform the policy mapping, you must configure the issuer CA with the issuance policies and associated object IDs. This is done by configuring the CAPolicy.inf file and either installing the CA or renewing the CA certificate using the configured CAPolicy.inf file with the required object identifiers as shown in the following code sample:

```
[PolicyStatementExtension]
Policies = HighAssurancePolicy, MediumAssurancePolicy, LowAssurancePolicy
CRITICAL = FALSE

[HighAssurancePolicy]
OID = 1.3.6.1.4.1.311.21.8.2473717464.1095930238.502626717.506190032.1.402

[MediumAssurancePolicy]
```

```
OID = 1.3.6.1.4.1.311.21.8.2473717464.1095930238.502626717.506190032.1.401

[LowAssurancePolicy]
OID = 1.3.6.1.4.1.311.21.8.2473717464.1095930238.502626717.506190032.1.400
```

In this example, the High, Medium, and Low Assurance issuance policies are defined at the subject CA. The object identifiers can be retrieved from the Certificate Templates console by right-clicking Certificate Templates in the console tree and selecting View Object Identifiers from the pop-up menu.

| **Note** |
| --- |
| Appendix B contains a sample CAPolicy.inf file. |

The renewal of the CA certificate using the CAPolicy.inf file ensures that the issuance policies are now defined at the CA. At this point, the cross certificates can be generated that perform the policy mapping between the two organizations. The following process is used to perform the qualified subordination between the two CA hierarchies:

1. Determine the organization with which you want to establish a trust relationship. If more than two organizations exist in the relationship, the trust relationships must be defined in pairs.

2. Through discussions with the partner organization, establish the equivalence between the assurance levels used by the two organizations involved in the trust relationship.

3. Exchange the issuance policy object identifiers defined for each assurance level used in both organizations involved in the trust relationship.

4. Map the issuance policy object identifiers in the separate organizations in the Policy.inf file at each CA and define their policy constraints in the CA certificate request for the qualified subordinate CA you are installing for your organization.

5. Install the qualified subordinate CA with the policies, policy mappings, and policy constraints you wish to deploy in your organization.

When a user or computer in the organization where the *issuing* CA exists receives a file signed by a user in the organization where the *subject* CA exists, the certificate will be chained to the root CA in the *issuing* CA using the qualified subordination path. If the object identifier for the issuance policy in the certificate maps to the required issuance policy object ID in your organization, the certificate chain is considered valid. If the user or computer in the issuing CAs organization receives a certificate with a non-mapped object identifier, the certificate chain is assigned a lesser value by the validation process and is typically rejected by the application.

**Constraining Policy Mapping to Prevent Unexpected Trust**

You can further constrain issuance policy by defining parameters that define how the issuance policy defined in the qualified subordination affects other CAs below the qualified subordinate CA. There are two settings that can define the relationship:

- **Require explicit policy** Specifies the number of certificates that can exist in the hierarchy below the certificate with the policy constraint extension. For example, if the explicit policy is configured with a value of three, this means that the defined issuance policy must exist for three layers of the hierarchy with the CA, where the qualified subordination is defined being the first level.

- **Inhibit policy mapping** Specifies the number of additional certificates that can appear in the path before policy mapping is no longer permitted. An inhibit policy mapping value of three only restricts the policy mapping to three levels of CAs below the qualified subordinate CA.

These settings exist to prevent unexpected trust relationships. For example, Figure 3 shows the same qualified subordination configured previously between Northwind Traders and Contoso Consulting with the addition of a new CA at Fabrikam Corporation.

**Figure 3: Preventing Unexpected Trust**

If qualified subordination is configured between the Contoso Consulting CA and the Fabrikam Corp CA, mapping the BigOrder issuance policy to the SpecialSig issuance policy, it is possible that a certificate issued by the Fabrikam Corp CA could be accepted by the Northwind Traders CA. This is because the object identifier for SpecialSig would be mapped first to the BigOrder object identifier. Then, the BigOrder object identifier would be mapped to the MillionDollar object identifier.

This behavior is prevented by configuring the following Policy Constraint Extensions at the Northwind Traders CA.

```
[PolicyConstraintsExtension]
RequireExplicitPolicy = 1
InhibitPolicyMapping = 1
```

By assigning InhibitPolicyMapping a value of one, only certificates issued by the ContosoCA are recognized through the MillionDollar object identifier mapping defined at the Northwind Traders CA. A certificate issued by the Fabrikam Corp CA with the SpecialSig object identifier will fail the InhibitPolicyMapping =1 setting defined at the Northwind Traders CA. This prevents the certificate issued by the Fabrikam Corp CA from being accepted by the Northwind Traders CA.

**Policy Qualifiers**

You can provide additional information about the Issuance policies implemented at a CA by configuring policy qualifiers. Policy qualifiers provide information directly, or provide links to information, that describe the purpose of the issuance policy. The following code shows both formats of the policy qualifier:

```
[LegalPolicy]
OID = 1.3.6.1.4.1.311.21.43
Notice = "Legal policy statement text"
URL = "http://www.example.microsoft.com/policy/isspolicy.asp"
```

When viewing the certificate in an application, a person can follow the URL and read the description of the issuance policy in a Web browser. If a text message is used as a policy qualifier, the application will display the message.

**Best Practice:** It is recommended that URLs be implemented for certificate practice statements, rather than to use notice text. This provides several key benefits.

- It allows modification of the practice statement without having to re-issue the CA certificate.
- URLs do not dramatically increase the size of the certificate, unlike notice text.

**Application Policy**

Application policies included in certificates allow applications to determine if a certificate can be used when authenticating a user, encrypting data, or signing a device driver. An application can be coded to only accept certificates that contain specific application policies. When the application receives signed information from a user, the application will review the certificate associated with the private key used to sign the information and verify that the certificate chain has the required object identifier as a valid application policy.

Application policies are similar to the Enhanced Key Usage (EKU) extension in a certificate as both use one or more object

identifiers to prescribe how the public key in a certificate must be used. EKU is still supported by Windows XP and the Windows Server 2003 family to provide for PKIs that use this extension, but application policies are a replacement. The following rules are used when combining EKU and Application Policy extensions:

- If a certificate is presented that contains an EKU extension, but does not contain a separate Application Policy extension, the EKU extension will be treated as an Application Policy extension by Windows XP and Windows Server 2003 clients.
- If a certificate has an extension containing an application policy and also has an EKU extension, the EKU extension is ignored.
- If a certificate has an Application Policy extension and an EKU property, the effective policy for the certificate is the common policy between the EKU property object identifiers and the application policy object identifiers.

| **Note** |
| --- |
| If issuing certificates that include both Application Policy and EKU extensions, ensure that the two extensions are identical in their assignment of object identifiers so that the two extensions do not conflict with each other. This ensures consistent application of policy, when either Application Policy or EKU extensions are used. This is especially important in issuing cross certificates or in using templates that do not have predefined application policies. |

Application policies may be defined in qualified subordination certificates to limit what purposes certificates from a trusted organization can be used for. For example, you can create an application policy that only allows certificates with the Secure Mail object identifier to be recognized if they chain through the qualified subordinate CA.

When application policy is defined for a CA, the object identifiers associated with the application policy are included in all issued certificates.

| **Note** |
| --- |
| The All Applications object identifier indicates that the application policy includes all application policies. This application policy is normally reserved for certificates issued to CAs. For understanding how policy is evaluated in certificate chains, see the Certificate Status and Revocation white paper at http://www.microsoft.com/technet/security/topics/crypto/tshtcrl.mspx |

The following Application Policy object identifiers are recognized by Windows Server 2003.

| | |
| --- | --- |
| • Server Authentication (1.3.6.1.5.5.7.3.1) | • Client Authentication (1.3.6.1.5.5.7.3.2) |
| • Code Signing (1.3.6.1.5.5.7.3.3) | • Secure E-mail (1.3.6.1.5.5.7.3.4) |
| • IP Security End System (1.3.6.1.5.5.7.3.5) | • IP Security Tunnel Endpoint (1.3.6.1.5.5.7.3.6) |
| • IP Security User (1.3.6.1.5.5.7.3.7) | • Time Stamping (1.3.6.1.5.5.7.3.8) |
| • IP Security IKE Intermediate (1.3.6.1.5.5.8.2.2) | • All Application Policies (1.3.6.1.4.1.311.10.12.1) |
| • Microsoft Trust List Signing (1.3.6.1.4.1.311.10.3.1) | • Qualified Subordination (1.3.6.1.4.1.311.10.3.10) |
| • Key Recovery (1.3.6.1.4.1.311.10.3.11) | • Document Signing (1.3.6.1.4.1.311.10.3.12) |

**Note**

A list of available object identifiers can be viewed in the Certificate Templates console by right-clicking Certificate Templates in the console tree and selecting View Object Identifiers from the pop-up menu. Alternatively, custom application policy object identifiers can be defined and used in custom-developed applications.

To define application policies in a Policy.inf file, the following sections must be created:

```
[ApplicationPolicyStatementExtension]
Policies = AppEmailPolicy, AppCodeSignPolicy, AppAuthPolicy
CRITICAL = FALSE

[AppEmailPolicy]
OID = 1.3.6.1.5.5.7.3.4 ; Secure Email

[AppCodeSignPolicy]
OID = 11.3.6.1.5.5.7.3.3 ; Code Signing

[AppClAuthPolicy]
OID = 1.3.6.1.5.5.7.3.2 ; Client Authentication
```

The [ApplicationPolicyStatementExtension] section defines all application policy setting sections that exist in the Policy.inf file. In this case, three application policy sections are defined. For each [*AppPolicy*] section, the object identifier associated with the application policy is defined.

If a custom application policy object identifier is defined, an [ApplicationPolicyMappingsExtension] section must be defined. This section uses the same format, where the local object identifier is mapped to the object identifier used by the other organization participating in the qualified subordination as shown in the following code sample:

```
[ApplicationPolicyMappingsExtension]
1.3.6.1.4.1.311.21.64 = 1.2.3.4.98
1.3.6.1.4.1.311.21.65 = 1.2.3.4.100
critical = true
```

As with issuance policies, you can also configure limitations on how deep in the hierarchy explicit policy must exist and whether the defined application policies can be mapped to other application policies. These settings are defined in the [ApplicationPolicyConstraintsExtension] section as follows:

```
[ApplicationPolicyConstraintsExtension]
; consists of two optional DWORDs
; They refer to the depth of the CA hierarchy that requires explicit policy
; and inhibits Policy Mapping
RequireExplicitPolicy  = 6
InhibitPolicyMapping = 10
```

# Qualified Subordination Deployment Scenarios

Updated: August 13, 2009

Applies To: Windows Server 2003 with SP1

This section looks at some of the more common certificate services deployments that use qualified subordination, including the following scenarios:

- Using qualified subordination to restrict certificate issuance to specific namespaces
- Configuring qualified subordination between two organizations; specifically two configurations:
  - Allowing trust between all CAs in the two organizations
  - Limiting trust to specific CAs in the CA hierarchy
- Configuring qualified subordination using a bridge CA

This section covers both the design of the scenarios and how to deploy the scenarios.

| **Note** |
| --- |
| This section looks at the design process of qualified subordination. The Walkthrough section provides the actual deployment steps involved when defining qualified subordination between two CA hierarchies. |

**Restricting Namespaces**

The first example is a common scenario in large organizations where certificate services administration is decentralized. In a decentralized environment, it may be desired to restrict certificate issuance to only specific objects in Active Directory. Use of name constraints is an effective way to ensure specific CAs can only issue to a well-defined subset of users framed by a namespace.

Assume that Contoso uses the forest structure in Figure 4 to provide decentralization of administration to regional subsidiaries.

**Figure 4: Contoso.coms Forest and Domain Structure**

Within Contoso.com, several CAs have been deployed for certificate services deployments. Figure 5 shows the current CA hierarchy used by Contoso.com.

**Figure 5: A Proposed CA Hierarchy for Contoso Corporation**

In this example, the CA named RegionCA exists to allow decentralized management of certificate deployment for Europe and Asia. The EuropeCA and AsiaCA are installed on member servers in the europe.contoso.com and asia.contoso.com domains. Qualified subordination can be used to restrict the issuance of certificates by the AsiaCA to only security principals (users, computers, services) located in the asia.contoso.com domain.

To do this, the AsiaCA must be installed with a CAPolicy.inf file in the %SystemRoot% folder with the following settings:

```
[NameConstraintsExtension]
Include = NameConstraintsPermitted
Exclude = NameConstraintsExcluded
Critical = True

[NameConstraintsPermitted]
DNS = .asia.contoso.com
email = @asia. contoso.com
UPN = .asia.contoso.com
UPN = @asia.contoso.com
DIRECTORYNAME = "DC=asia,DC=contoso,DC=com

[NameConstraintsExcluded]
```

These name constraints will only allow security principals from the asia.contoso.com domain to receive certificates issued by the AsiaCA certification authority. If a request is received from a security principal from a different namespace, the certificate request will be denied due to the configured name constraints.

| **Note** |
| --- |
| Alternatively, as mentioned earlier when defining the types of constraints, the AsiaCA can obtain a subordinate CA certificate from the RegionCA that includes the defined name constraints. Either method would provide the necessary name constraints to issued certificates. |

For example, Figure 6 shows the name constraints in place for AsiaCA restricting certificate issuance to the asia.contoso.com namespace.

**Figure 6: Applying Name Constraints at AsiaCA**

In this example, the certificate request by user3@asia.contoso.com is approved because Noels UPN is included in the permitted name constraints. In comparison, the request by user5@europe.contoso.com is denied because the UPN Europe.contoso.com is not listed in the permitted name constraints and is considered to be an excluded name constraint.

Enterprise CAs enforce name constraints during certificate requests based on the authenticated security principal performing the certificate request. The credentials of the security principal are used to extract the names of the user from Active Directory and these names are compared with the defined name constraints. In this case, user3 would be logged on to the network and performing the successful certificate request.

**Creating Trust Between Two Organizations**

The second scenario where cross-certification may be used is to allow certificates to be used and trusted between two organizations. Before the cross-certification is performed between the two organizations, the first thing that must be decided is what certificate usage will be trusted between the organizations. For example, you could require that certificates be trusted from the other organization(s) only for secure e-mail. Or, you could allow secure e-mail, client authentication, and server authentication.

This must be decided and included in the Policy.inf file when the qualified subordination is configured between CAs in the two organizations.

| **Note** |
| --- |
| For more information about how to perform the qualified subordination, see the Walkthrough section. |

When configuring the cross-certification between the two organizations, you also must decide whether all CAs in the other organizations CA hierarchy are to be trusted or only a specific grouping of CAs in the hierarchy.

| **Important** |
| --- |
| Cross-certification of a CA hierarchy may create very long certificate chains that can increase the size of network traffic for IPSEC, Secure Mail (s/mime), SSL, and so on. Use caution so as to not increase the chain length and overall certificate chain byte size to exceed an application limit. |

**Implementing Qualified Subordination to Trust All CAs**

In the first example, qualified subordination will be configured so that all CAs in the two organizations are trusted by the other organization. Figure 7 shows the two CA hierarchies.

**Figure 7: Two Non-Connected CA Hierarchies**

In this scenario, there is a business need for user 1 and user 2 to exchange secure e-mail using Outlook and S/MIME. Due to increased cooperation between Northwind Traders and Contoso Consulting, it is decided that qualified subordination be used to permit secure e-mail certificates issued by either organization to be trusted by both Northwind Traders and Contoso Consulting. In addition, the secure e-mail certificates can be issued by any CA in the individual CA hierarchies.

To accomplish this, two different methods can be used:

- Cross-certification between root Cas

  In this design, the root CAs issue cross-certification certificates to the other hierarchy's root CA. This is the easiest method to cross-certify organizations and is the easiest to understand when troubleshooting qualified subordination problems.

- Cross-certification between subordinate and Root Cas

  Many organizations are unwilling to issue certificates from their root CA to other organization's root CA. In this case, the cross-certification certificates can be issued by a subordinate CA to the root CA in the partner organization's CA hierarchy.

Both methods allow for complete trust between the CA hierarchies, subject to the constraints defined in the Policy.inf files. The decision factors will be based on whether your organization is willing to issue a cross-certification certificate to a partner organization's root CA from your root CA. Another consideration is that Root CAs generally publish their CRL less frequently than subordinate CAs. If there is a possibility that the cross-certification authority certificate may be revoked, it is preferable to issue the certificate from a subordinate CA than from a root CA. A certificate issued from a subordinate CA will have less lag time between the time the certificate is revoked and the revocation being recognized by all clients.

**Cross-Certification Between Root CAs**

If your organization is willing to perform cross-certification between the root CAs, the configuration in Figure 8 can be used.

**Figure 8: Configuring Complete Trust Between Root CAs**

In this example, the root CA for each organization is cross-certified with the root CA in the other organization. To create this configuration, the qualified subordination must be performed twice:

1. The PartnerCA at Contoso Consulting must be cross-certified using qualified subordination with the CorpCA at Northwind Traders.

2. The CorpCA at Northwind Traders must be cross-certified using qualified subordination with the PartnerCA at Contoso Consulting.

The qualified subordination will require that the following be in place:

- A Policy.inf is configured at each root CA. The Policy.inf must define any name constraints, issuance constraints, and application constraints defined between the two organizations and is used during the cross-CA certificate request as described in the Walkthrough section.

- The user account that is performing the qualified subordination must obtain a certificate with the Qualified Subordination application policy object identifier to sign the qualified subordination request between the two organizations. The signing certificate must be obtained from the CorpCA or any CA that is trusted on the CorpCA and PartnerCA computers for the first request and from the PartnerCA or any CA that is trusted on the CorpCA and PartnerCA computers for the second request.

The configuration shown in Figure 8 allows certificates issued by either CA to chain to a root that is trusted by each respective organization. For example, the certificate issued to User1 will validate up to the CorpCA if verified by a security principal at Northwind Traders as follows:

If the same certificate is validated by a computer in the Contoso Consulting organization, the certificate will validate up to PartnerCA.

Similarly, the certificate issued to User2 will chain to a trusted root in each organization. If the certificate is validated by a computer at Northwind Traders, the certificate chain will be as follows:

However, the same certificate would validate differently and use the PartnerCA root CA as the trust anchor when validated by a computer in the Contoso Consulting organization:

| **Note** |
| --- |
| In all cross-certification designs, a single certificate will chain to different roots depending on which organization's computers are validating the certificate. In both examples, a certificate validated by computers at Contoso Consulting will chain to the PartnerCA root, while certificates validated by computers at Northwind Traders will chain to the CorpCA root. |

The advantage of this design is that it also allows trust of new CAs installed into the CA hierarchies at either organization. For example, Figure 9 shows the addition of a new CA at Northwind Traders.

**Figure 9: Adding an Additional CA to the Hierarchy**

In this case, the certificate issued to User4 is trusted in both organizations. In Northwind Traders, the certificate chains to the CorpCA root CA.

While at Contoso Consulting, the certificate chains to the trusted PartnerCA.

**Cross-Certification Between Subordinate and Root CAs**

The same level of trust can be established between two organizations by issuing the cross-certification authority certificate from a subordinate CA in your CA hierarchy. This strategy is recommended if your organization's security policy prohibits the issuance of crossCA certificates by the root CA, your organization is simply unwilling to issue cross-certification certificates at the root CA, or there is a possibility that the cross-certification authority certificate may be revoked, and the CRL publication period for the root CA is a long interval. In these cases, the configuration shown in Figure 10 can be used to create complete trust between the two CA hierarchies, subject to defined qualified subordination constraints.

**Figure 10: Configuring Complete Trust Between Subordinate and Root CAs**

In this example, the Root CA for each organization is cross-certified with the subordinate enterprise CA in the other organization. To create this configuration, the qualified subordination must be performed twice:

1. The PartnerCA at Contoso Consulting must be cross-certified using qualified subordination with the IssuingCA at Northwind Traders.

2. The CorpCA at Northwind Traders must be cross-certified using qualified subordination with the PolicyCA at Contoso Consulting.

The qualified subordination will require that the following be in place:

- A Policy.inf is configured at each subordinate CA. The Policy.inf must define any name constraints, issuance constraints, and application constraints defined between the two organizations and is used during the cross-CA certificate request as described in the Walkthrough section.

- The user account that is performing the qualified subordination must obtain a certificate with the Qualified Subordination application policy OBJECT IDENTIFIER to sign the qualified subordination request between the two organizations. The signing certificate must be obtained from the IssuingCA or any CA that is trusted on the CorpCA and PartnerCA computers for the first request and from the PolicyCA or any CA that is trusted on the CorpCA and PartnerCA computers for the second request.

The following configuration allows certificates issued by either CA to chain to a root that is trusted by each respective organization. For example, the certificate issued to User1 will validate up to the CorpCA if verified by a security principal at Northwind Traders.

If the same certificate is validated by a computer in the Contoso Consulting organization, the certificate will validate up to PartnerCA.

Similarly, the certificate issued to User2 will chain to a trusted root in each organization. If the certificate is validated by a computer at Northwind Traders, the certificate chain will be as follows:

While, the same certificate would validate up to the PartnerCA root CA when validated by a computer in the Contoso Consulting organization.

**Note**

In all cross-certification designs, a single certificate will chain to different roots depending on which organization's computers are validating the certificate. In both examples, a certificate validated by computers at Contoso Consulting will chain to the PartnerCA root, while certificates validated by computers at Northwind Traders will chain to the CorpCA root.

As with the model where the cross-certification is established between root CAs, this design also allows trust of new CAs installed into the CA hierarchies at either organization. Figure 11 shows the addition of a new CA at Northwind Traders.

**Figure 11: Adding an Additional CA to the Hierarchy**

In this case, the certificate issued to User4 is trusted in both organizations. In Northwind Traders, the certificate chains to the CorpCA root CA.

While at Contoso Consulting, the certificate chains to the trusted PartnerCA.

**Implementing Qualified Subordination to Limit Trust to Specific CAs**

In some situations, two organizations may wish to restrict the cross-certification to specific CAs or to specific portions of the CA hierarchy, for example, where an organization uses outside consulting services. The organization (Northwind Traders) and consulting firm (Contoso) may wish to restrict the cross-certification to specific CAs in the hierarchy.

Figure 12 shows the scenario where the qualified subordination is performed to limit the trust between specific CAs in the organization.

**Figure 12: Configuring a Limited Trust Relationship**

With this configuration, the certificates issued by the IssuingCA and the PolicyCA will validate up to a trusted root CA in both organizations.

At Northwind Traders, the certificate issued to user1 will chain as follows:

The certificate issued to user2 will chain as follows:

At Contoso Consulting, the certificates will chain with the PartnerCA being the trusted Root CA. For the user1 certificate, the following chain will be selected by a validation process:

For the user2 certificate, the validation process will also select the chain that chains to the PartnerCA root CA.

The major difference between this qualified subordination design and the design that allowed total trust between CAs in the two hierarchies is best shown by investigating an additional CA added to the Northwind Traders CA hierarchy as shown in Figure 13.

**Figure 13: Adding an Additional CA to the Hierarchy**

In this case, the ProjectCA was added to the Northwind Traders CA hierarchy. To a computer in the Northwind Traders network, the certificate issued to user4 is valid because it chains to a trusted root CA, the CorpCA.

When a computer from the Contoso Consulting organization is presented the user4 certificate, only a partial chain can be built and the chain does not terminate at a trusted root certificate.

**Types of Constraints**

Qualified subordination allows constraints to be applied to a cross-certification configuration. Rather than implicitly trusting all certificates issued by another organizations CA hierarchy, qualified subordination allows you to define application, naming, and issuance constraints.

For example, when qualified subordination is established between two organizations, some of the constraints they may wish to configure include:

- **Application policy** Rather than allowing all certificates to be trusted, specific application purposes can be defined for the issued crossCA certificate by defining what object identifiers are required in certificates from the other organization. For example, if an organization wishes to only accept S/MIME certificates from a partner organization, an application policy can be defined to only accept certificates with the Secure E-mail object identifier (1.3.6.1.5.5.7.3.4) in the application policy extension or in the EKU extension.

| **Note** |
| --- |
| Enhanced Key Usage is defined in part 4.2.1.13 in RFC 2459. |

- **Name Constraints** Whenever qualified subordination is used between two organizations, the organization issuing the CrossCA certificate should include a name constraint that excludes its namespace through the cross-certification. This prevents the partner organization from submitting a certificate using the other organizations namespace. For example, Northwind Traders would implement a name constraint that prevents Contoso from presenting certificates that are issued to a user from Northwind Traders. In other words, if a CA in the Contoso hierarchy issued a certificate with a subject name of user1@northwindtraders.com, the name constraint would exclude the nortwindtraders.com e-mail address and would invalidate the certificate.

| **Note** |
| --- |
| Name Constraints are defined in part 4.2.1.11 in RFC 2459. |

- **Policy Constraints** To ensure a level of trust for partner certificates, policy constraints (sometimes referred to as issuance policy) can be defined and must be included as attributes of presented certificates to be accepted by the partner organization. For example, if two partner organizations are involved in a buyer/seller relationship, a Million Dollar object ID can be defined. For purchases of 1,000,000 USD or more, the signing certificate must contain the Million Dollar object identifier. Because the object identifier must be defined in both organizations, the Policy.inf file must map the object identifier from one organization to the other organizations object identifier. Likewise, constraints can be applied to whether the object identifier can be mapped to other object identifiers, or whether the object identifier must be issued from a specific CA or limit how many layers below the cross-certified CA can issue a certificate containing the object identifier.

| **Note** |
| --- |
| Policy Constraints is defined in part 4.2.1.5 in RFC 2459 and are referred to as the Certificate Policies extension in the RFC. |

| **Important** |
| --- |

If different combinations of policy and name constraints are required for application policies, you may have to perform the qualified subordination multiple times. For example, if you are willing to accept any Secure E-mail certificates, but will only accept High and Medium Assurance object identifiers for Client and Server authentication certificates, two separate Policy.inf files must be defined and the qualified subordination process must be executed twice—once for each Policy.inf file. This results in two separate Cross-Certification Authority certificates being issued—one for Secure E-mail certificates and one for Client and Server Authentication certificates. The cross-certification certificates are ultimately trusted for different purposes. Applications will verify the policy object identifiers when making authentication or authorization decisions.

**Creating Trust Between Multiple Organizations**

When you require trust between more than two, three, or more organizations, it is sometimes easier to design the qualified subordination by using a Bridge CA. The Bridge CA will act as a link between the CA hierarchies in each organization. Each organization will validate certificates issued by other organizations that use chains that include the Bridge CA. The Bridge CA design also reduces the complexity involved when new organizations are included in the trust.

A Bridge CA has several advantages over configuring separate trust relationships between multiple organizations, including

- A Bridge CA reduces the complexity for defining trust between CA hierarchies when three or more CA hierarchies exist.
- It is easier to add an additional organization to an existing Bridge CA trust relationship. The only tasks that must be performed are as follows:
    1. Issue the Bridge CA a cross-certification certificate using qualified subordination from each organization.
    2. Issue a cross-certification certificate from the Bridge CA for the root CA of the new organization.
    3. Publish the Bridge CA issued certificate in all other organizations to complete the web of trust created by the BridgeCA.
- The Bridge CA can offer a method to manage trust between subsidiary organizations by a holding company.

**Important**

Even if a BridgeCA is implemented, there is still nothing preventing two organizations participating in the Bridge CA structure from using qualified subordination to define a separate relationship between their hierarchies. For example, while Secure Mail certificates may be validated through the Bridge CA for e-mail sent between Northwind Traders and Contoso Consulting, a separate qualified subordination may be established between CAs in the two organizations to define specific policy constraints that must exist in certificates for signing purchase orders for transactions greater than 1 million dollars between the two organizations. Depending on the certificates attributes, the validation process will select the appropriate certificate chain based on the certificates usage and the defined qualified subordinations between the two organizations.

A common design for the Bridge CA deployment is shown in Figure 14.

**Figure 14: Using a Bridge CA**

In this design, total trust is established between all CAs in the three organizations, subject to any name, issuance, and application policies defined in the qualified subordination.

To achieve this, qualified subordination is defined so that the Bridge CA receives a subCA certificate defining all application, naming, and policy constraints from the subordinate enterprise CA in each organization. In addition, the root CA in each organization receives a subCA certificate defining all application, naming, and policy constraints from the Bridge CA.

| **Note** |
| --- |
| Alternatively, the cross-certification can be performed between the root CA of each organization and the BridgeCA. Again, the decision will be based on the security policy of each organization using the bridge CA, whether the organizations are willing to issue a cross-certification certificate from their root CA to the bridge CA, and the CRL publication period of the root CAs. |

| **Important** |
| --- |
| Cross-certification of a CA hierarchy may create very long certificate chains that can increase the size of network traffic for IPSEC, Secure Mail (s/mime), SSL, and so on. Use caution so as not to increase the chain length and overall certificate chain byte size to exceed an application limit. |

**Viewing Certificates from the Three Organizations**

The result is complete trust between the organizations using the BridgeCA for the certificate purposes defined in the qualified subordination. As long as an issued certificate meets all defined application, name, and policy constraints, the certificate will be considered valid in any organization connected to the Bridge CA in this manner.

In this example, the user1 certificate would chain to the CorpCA trusted root for all computers at Northwind Traders as follows:

The user1 certificate would chain to the OrgCA trusted root for all computers at Fabrikam Inc. as follows:

If the same certificate is evaluated by the certificate chaining engine at a computer in the Contoso organization, the resulting certificate chain would be as follows:

Likewise, the certificates for user6 and user2 would chain to the trusted root for each of the three organizations, based on what organization the computer evaluating the certificate belongs to.

**Adding New CAs to Existing CA Hierarchies**

This design for Bridge CA deployment allows for the addition of new CAs to the hierarchies at any of the participating organizations, without having to modify the existing qualified subordination using the Bridge CA. For example, if the Project CA is added to the Northwind Traders CA hierarchy as shown in Figure 15, the certificate issued to user4 would be trusted by

computers in the Northwind Traders, Fabrikam Inc., and Contoso Consulting organizations, subject to application, naming, and policy constraints.

**Figure 15: Adding a New CA to the Northwind Traders CA Hierarchy**

In this case, the user4 certificate would chain to the CorpCA trusted root for the computers in the Northwind Traders organization.

The certificate would chain to the OrgCA trusted root for the computers in the Fabrikam Inc. organization.

Finally, the certificate would chain to the PartnerCA trusted root for the computers in the Contoso Consulting organization.

**Using Name Constraints with Bridge CAs**

To prevent CAs in the other organization from creating certificates with subject names from your organizations namespace, name constraints should be created to exclude your namespace from certificates trusted through the BridgeCA.

For example, for the cross-certification authority certificate issued to BridgeCA from the CorpCA, the following name constraints could be added to the Policy.inf file at the CorpCA:

```
[NameConstraintsExtension]
Include = NameConstraintsPermitted
Exclude = NameConstraintsExcluded
Critical = TrUe

[NameConstraintsPermitted]
DNS = ""
email=""
UPN=""

 [NameConstraintsExcluded]
DNS = .northwindtraders.com
email = @northwindtraders.com
UPN = .northwindtraders.com
UPN = @northwindtraders.com
DIRECTORYNAME = "DC=Northwindtraders,DC=com"
```

These name constraints will ensure that all namespaces except the NorthwindTraders namespace will be permitted.

| **Note** |
| --- |
| Additional name constraints could be defined for NameConstraintsPermitted to restrict what specific namespaces are allowed into the organization through the BridgeCA. |

**Policy Constraints and Policy Constraint Mapping**

The qualified subordination between the organizations may also require specific policy constraints to exist for trusted certificates. If a specified policy constraint is not included in a certificate, the application should not select the chain including that certificate.

The problem with policy constraints is that for each CA hierarchy, the policy constraint may have a different name and it will have a different object identifier. To make the policy constraints interoperate between the CA hierarchies, the policy constraints must be defined and mapped in the Policy.inf file.

For example, if the BridgeCA will function to only allow Low and Medium Assurance certificates to be passed between the organizations, the policy constraints must be defined in each cross-certification certificate issued between CAs.

For the cross-certification authority certificate issued to CorpCA by the BridgeCA, the Policy.inf file must contain the following lines to define the medium and low assurance object identifiers. These object identifiers may be obtained from the Certificate Templates console or from the IANA:

```
[PolicyStatementExtension]
Policies = MediumAssurance, LowAssurance
CRITICAL = FALSE

[MediumAssurance]
OID = 1.3.6.1.4.1.311.21.8.1608391590.1259233725.355412102.3300744578.1.401

[LowAssurance]
OID = 1.3.6.1.4.1.311.21.8.1608391590.1259233725.355412102.3300744578.1.400
```

In addition to defining the object identifiers for its CA hierarchy, the Policy.inf file must also map the Medium and Low Assurance object identifiers to the object identifiers used at the BridgeCA. This is accomplished through the [PolicyMappingsExtension] section of the Policy.inf file:

```
[PolicyMappingsExtension]

1.3.6.1.4.1.311.21.8.1608391590.1259233725.355412102.3300744578.1.401 =
1.3.6.1.4.1.311.21.8.2812900009.1258984576.2698790533.44255976.1990074901.2398624335

1.3.6.1.4.1.311.21.8.1608391590.1259233725.355412102.3300744578.1.400 =
1.3.6.1.4.1.311.21.8.2812900009.1258984576.2698790533.44255976.572751058.2135922791

critical = yEs
```

This section maps the object identifier ID for medium assurance to an object ID defined at the BridgeCA. The object identifier does not have to be for the MediumAssurance policy constraint. In fact, it can be for a user-defined policy object identifier, as the previous example shows.

To complete the policy mappings, the following lines must be included in the Policy.inf file used by the BridgeCA to receive a cross-certification authority certificate from the IssuingCA:

```
[PolicyStatementExtension]
Policies = SecLevel1, SecLevel2
CRITICAL = FALSE

[SecLevel1]
OID =
1.3.6.1.4.1.311.21.8.2812900009.1258984576.2698790533.44255976.1990074901.239862
433

[SecLevel2]
OID =
1.3.6.1.4.1.311.21.8.2812900009.1258984576.2698790533.44255976.572751058.2135922
791

[PolicyMappingsExtension]
1.3.6.1.4.1.311.21.8.2812900009.1258984576.2698790533.44255976.1990074901.239862
433 = 1.3.6.1.4.1.311.21.8.1608391590.1259233725.355412102.3300744578.1.401

1.3.6.1.4.1.311.21.8.2812900009.1258984576.2698790533.44255976.572751058.2135922
791 = 1.3.6.1.4.1.311.21.8.1608391590.1259233725.355412102.3300744578.1.400

critical = yEs
```

As you can see, custom object identifiers were defined for the policies named SecLevel1 and SevLevel2. In the

[PolicyMappingsExtension] section, the same object identifiers are mapped with the order reversed from the Policy.inf file used by the CorpCA to receive a cross-certification authority certificate from the BridgeCA.

Figure 16 shows another example of policy constraint mapping.

**Figure 16: Policy Constraint Mapping**

In this figure, the NorthwindCA is configured with a MillionDollar object identifier, 1.3.6.1.4.1.311.21.8.1.124. This object identifier is mapped to the BigOrder object identifier, 1.3.6.4.1.204.22.33.44, at the ContosoCA. Although the certificate issued to v-user1 contains a different issuance policy object identifier from the certificate issued to user2, the policy constraint mapping makes the object identifiers equivalent and the object identifiers are recognized by both CA hierarchies.

**Application Policy**

The final policy that could be applied in this scenario is the application policy. Application policy will limit which purposes certificates issued by another organizations CAs can be used for. By defining application policy, you can prevent certificates for specific usages from being accepted for use in your organization.

For example, if you only want to allow certificates for S/MIME, client authentication, and server authentication to be recognized through the BridgeCA, you can add the following sections to the Policy.inf file:

```
[ApplicationPolicyStatementExtension]
; list of user defined policies
Policies = AppOIDPolicy1, AppOIDPolicy2, AppOIDPolicy3

[AppOIDPolicy1]
OID = 1.3.6.1.5.5.7.3.4 ; Secure Email

[AppOIDPolicy2]
OID = 1.3.6.1.5.5.7.3.1 ; Server Authentication

[AppOIDPolicy3]
OID = 1.3.6.1.5.5.7.3.2 ; Client Authentication

CRITICAL = FALSE
```

These application policies would prevent the use of an EFS certificate between the organizations. An EFS certificate would not chain in a trusted manner because the defined application policies define an application policy for EFS encryption services.

**Note**

Remember that these application policies also are combined with name constraints and policy constraints when applied to a certificate presented from another CA hierarchy. If you require different combinations, you must request multiple cross-certification authority certificates using separate Policy.inf files for each request. For example, you may not wish to implement policy constraints for e-mail certificates, but want to ensure that low or medium assurance object identifiers exist in client and server authentication certificates. This would require two separate cross-certification authority certificate requests—one for Secure E-mail and one for Client and Server Authentication.

# Walkthrough (Planning and Implementing Cross-Certification and Qualified Subordination Using Windows Server 2003)

Updated: August 13, 2009

Applies To: Windows Server 2003 with SP1

This section provides detailed implementation steps involved in defining qualified subordination between two CA hierarchies.

**Creating an Offline Bridge CA**

The following process can be used to deploy an offline root CA for your organization. The following is required before you establish your offline Bridge CA:

- Configure a CAPolicy.inf file to define the following settings for the offline Bridge CA.
    - Authority Information Access locations
    - CRL Distribution Point locations
    - Certificate Practice Statement
    - All issuance policies required to cross the Bridge CA
- Determine the CAs distinguished name.
- Determine what Cryptographic Service Provider (CSP) will be used for certificate creation and signing.

**Configuring the CAPolicy.inf File**

The Offline Bridge CA must include the following sections in a CAPolicy.inf file stored in the %Systemroot% folder. This example shows an addition of three policy settings for the Offline Bridge CA. The OIDs for the three policies were obtained from the organization's Active Directory. Alternatively, the OIDs could be obtained from the IANA at http://www.iana.org/cgi-bin/enterprise.pl.

```
[Version]
Signature= "$Windows NT$"

 [certsrv_server]
CRLPeriod = weeks
CRLPeriodUnits = 26

[PolicyStatementExtension]
Policies = HighAssurancePolicy, MediumAssurancePolicy, LowAssurancePolicy
CRITICAL = FALSE

[HighAssurancePolicy]
OID = 1.3.6.1.4.1.311.21.8.2473717464.1095930238.502626717.506190032.1.402

[MediumAssurancePolicy]
OID = 1.3.6.1.4.1.311.21.8.2473717464.1095930238.502626717.506190032.1.401

[LowAssurancePolicy]
OID = 1.3.6.1.4.1.311.21.8.2473717464.1095930238.502626717.506190032.1.400

[PolicyConstraintsExtension]
RequireExplicitPolicy = 0
InhibitPolicyMapping = 0

[BasicConstraintsExtension]
PathLength = 0
```

**Note**

R As mentioned previously, it is not a best practice to place policy OIDs in root CA certificates. It is also not a best practice to place CDP or AIA extensions in the root CA certificate as most applications do not check for root CA revocation.

**Installing Certificate Services**

The actual installation process of a root CA is performed using the following steps:

1. Ensure that the updated CAPolicy.inf file is saved to the %systemroot% folder.

   **Note**

   Appendix B contains an example of a CAPolicy.inf file.

2. On the Start menu, click Settings, and then click Control Panel.

3. On the Control Panel, double-click Add or Remove Programs.

4. In the Add or Remove Programs window, click Add/Remove Windows Components.

5. In the Windows Components Wizard, on the Windows Components page, select the Certificate Services check box.

6. In the Microsoft Certificate Services dialog box, click Yes to accept that you cannot rename the computer or change its domain membership.

7. On the Windows Components page, click Next.

8. In the CA Type page (Figure 17), click Stand-alone root CA, select the Use custom settings to generate the key pair and CA certificate check box, and then click Next.

**Figure 17: Defining the CA Type Configuration**

9. On the Public and Private Key Pair page (Figure 18), select the CSP and the Key length (for the private and public key pair), and then click Next.

**Figure 18: Defining the Public and Private Key Pair Properties**

10. On the CA Identifying Information page (Figure 19), enter the Common name and Validity period (for the Root CA certificate), and then click Next.

**Figure 19: Defining the Common Name of the CA and Setting the Validity Period**

| **Note** |
| --- |
| The Cryptographic Key is now generated based on the provided information in the preceding dialog boxes. Depending on the length of key defined on the Public and Private Key Pair page, this may take some time. |

11. On the Certificate Database Settings page (Figure 20), accept the default locations, and then click Next.

**Figure 20: Defining the Database and Log Storage Locations**

12. In the Microsoft Certificate Services dialog box, click Yes to stop the Internet Information Services.

    The Configuring Components dialog box appears as the installation proceeds.

13. If the Files Needed dialog box appears (Figure 21), in the Copy files from box, enter the CD-ROM drive path or the network share path where the distribution files are located, and then click OK.

**Figure 21: Providing the Location of the Installation Files**

14. In the Windows Components Wizard, click Finish.

15. In the Add or Remove Programs dialog box, click Close.

16. Close the Control Panel.

**Disabling Delta CRLs at the Root CA**

Typically, the root CA for a CA hierarchy is removed from the network for security purposes. Periodically, the CA must be accessed for the publication of updated CRLs. The goal of delta CRLs is to publish the newly revoked certificates at a more frequent interval than the publication period for the base CRL. By disabling delta CRLs, you reduce the number of times that the offline root CA must be accessed for CRL publication. It is typically not an issue that the delta CRLs are not published, as the number of certificates issued by the root CA is minimal.

| **Important** |
| --- |
| If cross-certification is performed between root CAs, it is possible that there may be a delay between the revocation of a former partner's cross-certification certificate and the recognition of the revocation by the clients accessing the base CRL. |

1. On the Start menu, point to Programs, point to Administrative Tools, and then click Certification Authority.

2. In the Certification Authority console, in the console tree, expand *CAName* (where *CAName* is the name of your offline Bridge CA).

3. In the console tree, right-click Revoked Certificates, and then click Properties.

4. In the Revoked Certificates Properties dialog box, click to clear the Publish Delta CRLs check box, and then click OK.

5. In the console tree, right-click Revoked Certificates, click All Tasks, and then click Publish to publish a new base CRL that does not reference a Delta CRL.

6. In the Publish CRL dialog box, click OK.

**Removing the Non-Required AIA and CDP Extensions**

Once the offline Bridge CA is installed, the CDP and AIA locations for issued certificates must be modified to ensure that the certificate chaining engine can find the CRL and certificate for the offline Bridge CA. Because the CA is removed from the network, these default AIA and CDP extensions do not reference valid locations for the publication points. By removing the offline root CA from the network, you effectively remove the default publication points.

To remove non-required CDP and AIA extensions

1. In the Certification Authority console tree, right-click CAName, and then click Properties.

2. In the CAName Properties dialog box, click the Extensions tab.

3. In the Select extension box, ensure that the box contains CRL Distribution Point (CDP).

4. In the list of CDP locations, select the CDP location beginning with ldap:///, and then click Remove.

5. In the Confirm removal dialog box, click Yes to verify the removal.

6. In the list of CDP locations, select the CDP location beginning with http://, and then click Remove.

7. In the Confirm removal dialog box, click Yes to verify the removal.

8. In the list of CDP locations, select the CDP location beginning with file://\\, and then click Remove.

9. In the Confirm removal dialog box, click Yes to verify the removal.

| **Important** |
| --- |
| Do not delete the CDP location referencing c:\windows\System32. This location is required by the CA to locally publish update Certificate Revocation lists. |

10. On the Extensions tab, select Authority Information Access in the Select extension box.

11. In the list of AIA locations, select the AIA location beginning with ldap:///, and then click Remove.

12. In the Confirm removal dialog box, click Yes to verify the removal.

13. In the list of AIA locations, select the AIA location beginning with http://, and then click Remove.

14. In the Confirm removal dialog box, click Yes to verify the removal.

15. In the list of AIA locations, select the AIA location beginning with file://\\, and then click Remove.

16. In the Confirm removal dialog box, click Yes to verify the removal.

| **Important** |
| --- |
| Do not delete the AIA location referencing c:\windows\System32. This location is required by the CA to locally publish renewed Certificates. |

17. Click OK.

18. In the Certification Authority dialog box, click Yes to restart Certificate Services.

**Adding Required AIA and CDP Extensions**

The offline Bridge CA must add required CDP and AIA extensions to allow Active Directory clients and other clients to find the CAs certificate and CRL. You must modify the extensions to include paths that are available when the offline Bridge CA is removed from the network.

The examples provided in this white paper are not mandatory, but should be considered when defining the AIA and CDP extensions for the offline root CA.

| **Note** |
| --- |
| The AIA and CDP extensions are required by the certificate chaining engine to build certificate chains for validation. For more information about the certificate validation process, see Certificate Revocation and Status Checking (http://go.microsoft.com/fwlink/?LinkID=27081). |

**Adding the LDAP CDP Extension**

The first CDP extension that needs to be added is the LDAP:// CDP extension. This CDP extension allows Active Directory and other LDAP clients to acquire the CRL from an LDAP service available to the Internet.

| **Note** |
| --- |
| In some Windows 2000 and Windows Server 2003 deployments, a separate Active Directory forest is deployed in the extranet to prevent external access to the corporate Active Directory. If a separate LDAP service is used in the extranet, the LDAP URL must reference this Active Directory service. Otherwise, the LDAP URL must reference a link that is accessible by all clients that require access to the CRL. |

To add the CRL to Active Directory, you will need the following information from the forest root domain of Active Directory that will maintain a copy of the offline Root CAs CRL:

```
ForestRootDomain   The LDAP representation of the forest root domain. For example
security.nwtraders com would be represented as DC=security,DC=Nwtraders,DC=com.
```

You will also require some information from the offline Bridge CA. Specifically, you require the following:

```
CAName:    The name assigned to the CA during installation of the CA.
CAMachineName:    The NetBIOS name of the computer hosting the CA.
```

You will need to add the two following LDAP paths to the CDP extensions list:

```
ldap:///CN=CAName,CN=CAMachineName,CN=CDP,CN=Public Key Services,
CN=Services,CN=Configuration,CAForestName?certificateRevocationList
?base?objectClass=cRLDistributionPoint

and

ldap://ldap.company.com/CN=CAName,CN=CAMachineName,CN=CDP,CN=Public Key Services,
CN=Services,CN=Configuration,CAForestName

where ldap.company.com is an URL that refers queries to TCP port 389 to the
server hosting the LDAP service, typically a Windows 2000 domain controller.
```

For example, for the following information:

- *CAName*: BridgeCA
- *CAMachineName*: BridgeComp
- *ForestRootDomain*: extranet.nwtraders.com

The following are the LDAP paths you must add to the list of CDP extensions:

```
ldap:///CN=BridgeCA,CN=BridgeComp,CN=CDP,CN=Public Key Services,
CN=Services,CN=Configuration,DC=extranet,DC=nwtraders,DC=com?certificateRevocati
onList?base?objectClass=cRLDistributionPoint
```

and

```
ldap://ldap.extranet.nwtraders.com/CN=BridgeCA,CN=BridgeComp,CN=CDP,CN=Public
Key Services,CN=Services,CN=Configuration,DC=extranet,DC=nwtraders,DC=com
```

| **Note** |
| --- |
| The LDAP:/// URL is a local LDAP path that binds to the current domain controller used by the client computer. This LDAP URL will not work with external clients, therefore, the second LDAP URL is added to provide the URL to the LDAP server for external clients. |

1. In the Certification Authority console tree, right-click CAName, and then click Properties.
2. In the CAName Properties dialog box, click the Extensions tab.
3. Ensure that the Select Extensions list contains CRL Distribution Points (CDP), and then click Add.
4. In the Add Location dialog box (Figure 22), in the Location box, type the LDAP path as described previously, and then click OK.

**Figure 22: Adding an LDAP CDP Extension**

| **Note** |
| --- |
| Consider creating the path in a text file beforehand and then copying and pasting the complete LDAP URL into the Location box. There is no control to allow editing of the LDAP path if it is incorrectly typed in the console. |

5. On the Extensions tab, select the LDAP CDP extension. Select the Include in all CRLS. Specifics where to publish in the Active Directory when publishing manually and Include in the CDP extension of issued certificates check boxes as shown

in Figure 23. The first option is recommended when publishing offline CA CRLs to Active Directory. The second option ensures that all issued certificates include the updated paths to the CRL.

**Figure 23: Configuring the Properties of the LDAP Extension**

```
Repeat the process using the LDAP URL
ldap://ldap.company.com/CN=CAName,CN=CAMachineName,CN=CDP,CN=Public Key Services,
CN=Services,CN=Configuration,CAForestName
```

6. Leave the dialog box open to allow the addition of an HTTP CDP extension.

| **Note** |
| --- |
| It is recommended to include an HTTP CDP extension to ensure that non-LDAP clients can access the offline CA's CRL. It also is easier to deploy the CRL to external clients using the HTTP protocol than the LDAP protocol. |

**Adding the HTTP CDP Extension**

Additionally, at least one CDP extension should be added for the HTTP protocol that references an available Web server hosting the CRL file for the offline CA. You should provide more than one HTTP location to provide fault tolerance in the event that the Web server referenced in the CDP extension is unavailable. The URL must reference a valid HTTP location to work correctly.

To add an HTTP CDP extension

1. In the CAName Properties dialog box, click the Extensions tab.

2. Ensure that the Select Extensions list contains CRL Distribution Points (CDP), and then click Add.

3. In the Add Location dialog box (Figure 24), in the Location box, type the HTTP path as described previously, and then click OK.

**Figure 24: Adding an HTTP CDP Extension**

| **Note** |
| --- |
| Consider creating the path in a text file beforehand and then copying and pasting the complete HTTP URL into the Location box. There is no control to allow editing of the HTTP path if it is incorrectly typed in the console. |

4. On the Extensions tab, select the HTTP CDP extension, and then select the Include in the CDP extension of issued certificates check box as shown in Figure 25.

**Figure 25: Configuring the Properties of the HTTP Extension**

5. In the CAName Properties dialog box, click OK.

6. In the Certification Authority dialog box, click Yes to restart Certificate Services.

**Adding an HTTP AIA Extension**

In addition to CDP extensions, an AIA extension should be added to allow Web clients to access the offline Bridge CAs certificate from a Web server.

To add an updated HTTP AIA extension

1. In the Certification Authority console tree, right-click CAName, and then click Properties.

2. In the CAName Properties dialog box, click the Extensions tab.

3. Ensure that the Select Extensions list contains Authority Information Access (AIA), and then click Add.

4. In the Add Location dialog box (Figure 26), in the Location box, type the HTTP path to the Root CA certificate, and then click OK.

**Figure 26: Adding an HTTP AIA Extension**

| **Note** |
| --- |
| Consider creating the path in a text file beforehand and then copying and pasting the complete HTTP URL into the Location box. There is no control to allow editing of the HTTP path if it is incorrectly typed in the console. |

5. On the Extensions tab, select the HTTP AIA extension, and then select the Include in the AIA extension of issued certificates check boxes as shown in Figure 27.

**Figure 27: Configuring the Properties of the LDAP Extension**

6. In the CAName Properties dialog box, click OK.

7. In the Certification Authority dialog box, click Yes to restart Certificate Services.

**Publishing CRLs and Certificates**
Once the CDP and AIA extensions are modified, you must publish the updated CRL referencing the new CDP locations. The previous version of the CRL still contains the default locations for the CDP and AIA extensions.

To publish the new base CRL

1. In the console tree, right-click Revoked Certificates, click All Tasks, and then click Publish to publish a new base CRL.

2. In the Publish CRL dialog box, click OK.

Once the CRL is updated, the new version must be published to the locations referenced in the CDP and AIA extensions. This requires manually copying the CRL and Certificate to the Web servers and injecting the CRL and certificate into Active Directory.

**Publishing the CRL and CA Certificate to a Web Server**
The CRL and CA Certificate can be retrieved from the \\CAMachineName\CertEnroll share and copied to a disk or to a network location. The CRL and certificate must be published to the location referenced in the CDP and AIA extensions of the CA.

For example, if the CDP extension references http://www.microsoft.com/public/rootca.crl, the CRL must be copied to this location so that a Web client can retrieve the latest version of the CRL.

Likewise, if the AIA extension references http://www.microsoft.com/public/rootca.crt, the CAs certificate file must be copied to this location so that a Web client can retrieve the CAs certificate.

By default, the IIS default Web site is stored in \inetpub\wwwroot in the same drive where the Windows Server 2003 operating system is installed. To create the paths referenced above, you can create a Public subfolder and copy the two files into the Public folder (\inetpub\wwwroot\public).

Alternatively, you can create a virtual folder and have /Public reference any folder on the Web servers disk.

Once the CRL and certificate are published, you should validate that the paths are correct in the issued certificates by connecting to the CRL and certificate using the CDP and AIA URLs.

**Publishing the CRL and CA Certificate into Active Directory**
The Certutil.exe utility is used to publish the CAs certificate and CRL into the Configuration naming context of Active Directory. The CA's certificate is published to two locations:

- CN=*CAName*,CN=Certification Authorities,CN=Public Key Services,CN=Services,

  CN=Configuration,DC=*ForestRootDomainDN*

- CN=*CAName*,CN=AIA,CN=Public Key Services,CN=Services,

  CN=Configuration, DC=*ForestRootDomainDN*

The CA's CRL is published to the following location in the Configuration naming context:

- CN=*CAName*,CN=*CAComputerName*,CN=CDP,CN=Public Key Services,CN=Services
  CN=Configuration,DC=*ForestRootDomainDN*

The Certutil.exe utility is only installed at a CA by default, but can be installed at any Windows XP client by installing the Windows Server 2003 Administration Pack (adminpak.msi).

Assuming that the CAs certificate is named RootCA.crt and that the CAs CRL is named RootCA.crl, and that the files are stored in the current directory, the following commands can be run to inject the CAs certificate and the CAs CRL into Active Directory.

To install the CAs CRL into Active Directory, use the following command:

```
certutil.exe -dspublish -f RootCA.crl
```

If the command is successful, you should see the following output in response to the command:

```
ldap:///CN=RootCA,CN=RackCluster3,CN=CDP,CN=Public Key Services,CN=Services
,CN=Configuration,DC=bkforest2,DC=nttest,DC=microsoft,DC=com?certificateRevocati
onList?base?objectClass=cRLDistributionPoint?certificateRevocationList

Base CRL added to DS store.

CertUtil: -dsPublish command completed successfully.
```

To install the CAs certificate into Active Directory, a variation of the Certutil –dspublish command is used:

```
Certutil –dspublish –f RootCA.crt RootCA
```

If successful, the command should produce the following output:

```
ldap:///CN=RootCA,CN=Certification Authorities,CN=Public Key Services,CN=Se
rvices,CN=Configuration,DC=bkforest2,DC=nttest,DC=microsoft,DC=com?cACertificate

Certificate added to DS store.

ldap:///CN=RootCA,CN=AIA,CN=Public Key Services,CN=Services,CN=Configuratio
n,DC=bkforest2,DC=nttest,DC=microsoft,DC=com?cACertificate

Certificate added to DS store.

CertUtil: -dsPublish command completed successfully.
```

| **Note** |
| --- |
| The certificate is published to both the Certification Authorities and AIA locations under Public Key Services. |

**Installing the Enterprise Subordinate CAs**

The enterprise subordinate CAs must be installed with the issuance policies defined for the CA certificate. The following processes describe the installation of the Enterprise Subordinate CA.

**Configuring the CAPolicy.inf File**

The Enterprise Subordinate CA requires that a CAPolicy.inf file be created and installed in the %systemroot% folder to apply the correct policies. If the Enterprise CA already exists, you can still use CAPolicy.inf and renew the CAs certificate to apply the modified settings. The CAPolicy.inf file must contain the following sections:

```
[RequestAttributes]
CertificateTemplate = SubCA

[PolicyStatementExtension]
Policies = HighAssurancePolicy, MediumAssurancePolicy, LowAssurancePolicy
CRITICAL = FALSE

[HighAssurancePolicy]
OID = 1.3.6.1.4.1.311.21.8.2473717464.1095930238.502626717.506190032.1.402

[MediumAssurancePolicy]
OID = 1.3.6.1.4.1.311.21.8.2473717464.1095930238.502626717.506190032.1.401

[LowAssurancePolicy]
OID = 1.3.6.1.4.1.311.21.8.2473717464.1095930238.502626717.506190032.1.400
```

| **Note** |
| --- |
| The OIDS for the assurance policies must be modified to match the OIDS for the forest where the Enterprise Subordinate CAs exist. Each forest will generate a unique OID that is used for the high, medium, and low assurance issuance policies. In this example, the unique component of each OID is 1.3.6.1.4.1.311.21.8.2473717464.1095930238.502626717.506190032.1, You must change the OIDs shown in this example to match the unique OID representing your forest. |

To modify the CAPolicy.inf file

1. Copy the modified CaPolicy.inf file to the %systemroot% folder.

2. Open the CaPolicy.inf file using Notepad.

3. Click Start, and then click Run. In the Open box, type **certtmpl.msc**.

4. In the console tree, right-click Certificate Templates, and then click View Object Identifiers.

5. In the View Object Identifiers dialog box, select High Assurance, and then click Copy Object Identifier.

6. Paste the updated object identifier for High Assurance into the CaPolicy.inf file.

7. In the View Object Identifiers dialog box, select Medium Assurance, and then click Copy Object Identifier.

8. Paste the updated object identifier for Medium Assurance into the CaPolicy.inf file.

9. In the View Object Identifiers dialog box, select Low Assurance, and then click Copy Object Identifier.

10. Paste the updated object identifier for Low Assurance into the CaPolicy.inf file.

11. In the View Object Identifiers, click Close.

12. Close the Certificate Templates console.

**Installing Certificate Services**

Once the CAPolicy.inf file is configured, the installation of the Enterprise CA can begin. The process is made up of three steps: the initial installation of the enterprise subordinate CA, the offline certificate request process, and the installation of the SubCA certificate.

**Installing the Enterprise Subordinate CA**

To perform the initial installation of certificate services on the enterprise subordinate CA

1. On the Start menu, click Settings, and then click Control Panel.

2. In the Control Panel, double-click Add or Remove Programs.

3. In the Add or Remove Programs window, click Add/Remove Windows Components.

4. In the Windows Components Wizard, on the Windows Components page, select the Certificate Services check box.

5. In the Microsoft Certificate Services dialog box, click Yes to accept that you cannot rename the computer or change its domain membership.

6. In the Windows Components page, click Next.

7. In the CA Type page, click Enterprise Subordinate CA, select the Use custom settings to generate the key pair and CA certificate check box, and then click Next.

8. On the Public and Private Key Pair page, define the CSP, Hash algorithm, and Key length the CA will use for the private and public key pair (Figure 28), and then click Next.

**Figure 28: Defining the Public and Private Key Settings**

9. On the CA Identifying Information page (Figure 29), enter the Common name for this CA, and then click Next.

**Figure 29: Defining the CA Name**

10. On the Certificate Database Settings page (Figure 30), accept the default settings, and then click Next.

**Figure 30: Defining the Certificate Database and Log Locations**

11. On the CA Certificate Request page (Figure 31), select the Save the request to a file option button, accept the default Request file name, and then click Next.

**Figure 31: Configuring an Offline Certificate Request**

| **Note** |
| --- |
| This assumes that the root CA or parent CA is offline and unable to receive online requests. |

12. In the Microsoft Certificate Services dialog box, click Yes.

13. If the Files Needed dialog box appears, enter the path to the installation files, and then click OK.

| **Note** |
| --- |
| A dialog box appears indicating that the installation is incomplete and that the request file must be submitted to the parent CA. |

14. In the Microsoft Certificate Services dialog box, click OK.

15. In the Windows Components Wizard, click Finish.

**Signing the Offline Certificate Request**

To sign the offline certificate request (These steps are performed at the offline Root CA or the offline parent CA.)

1. Copy the request file to a disk.

2. Take the disk to the offline root CA.

3. Open the request file using Notepad. You should see content similar to the following example:

```
 -----BEGIN NEW CERTIFICATE REQUEST-----
MIICJTCCAY4CAQAwPjETMBEGCgmSJomT8ixkARkWA2NvbTETMBEGCgmSJomT8ixk
ARkWA2FiYzESMBAGA1UEAxMJSXNzdWluZ0NBMIGfMA0GCSqGSIb3DQEBAQUAA4GN
ADCBiQKBgQDD7j/MtDoqG0ZWdGSkF7h+taDOD5fB8JhTqIgx31maN+YQE288n7Vm

BAMCAYYwDwYDVR0TAQH/BAUwAwEB/zANBgkqhkiG9w0BAQUFAAOBgQAl15B50lwN
AfsSgFKTuPELSalkjWmnn11ZPAmGCLHnhZ6yhQwonWntN3nRaU7F1+KfEnvoibb2
DM1x7SLoMEzQrWQ8sWneoBSCtD0Sdg24dIpWwxlnKgsImRlfGnlEQEd/VHTgyxSh
hrS1gQXYQYH0CT8giCZ8PwGsg1qr/8dMIg==
-----END NEW CERTIFICATE REQUEST-----
```

4. Copy the entire contents of the request file to the Windows Clipboard.

5. Start Internet Explorer.

6. Open the http://localhost/certsrv URL.

7. On the Welcome page, click the Request a certificate link.

8. On the Request a Certificate page, click advanced certificate request.

9. In the Advanced Certificate Request page, click Submit a certificate request by using a base-64-encoded CMC or PKCS#10 file, or submit a renewal request by using a base-64-encoded PKCS#7 file.

10. In the Submit a Certificate Request or Renewal Request page, paste the contents of the request file in the Saved Request box, and then click Submit.

11. The Certificate Pending page appears informing you that an administrator must issue the certificate. You should note the request ID for future reference.

12. Close Internet Explorer.

To issue the certificate, you must use the Certification Authority Console.

1. On the Start menu, point to Programs, point to Administrative Tools, and then click Certification Authority.

2. In the console tree, expand CAName (where *CAName* is the name of your Certification Authority), and then click the Pending Requests container.

3. In the details pane, right-click the pending request, identified by its request ID, for the previously submitted request, click All Tasks, and then click Issue.

4. Close the Certification Authority console.

To retrieve the issued certificate (These steps are performed at the offline root CA or offline parent CA.)

1. Start Internet Explorer.
2. Open the http://localhost/certsrv URL.
3. On the Welcome page, click the View the status of a pending certificate request link.
4. On the View the Status of a Pending Certificate Request page, click the Saved-Request Certificate (Date and Time) link.
5. On the Certificate Issued page, click the Download certificate chain link.
6. In the File Download dialog box, click Save.
7. In the Save As dialog box, in the file name box, type **a:\certnew.p7b**, and then click Save to save the PKCS#7 file to the disk.
8. If the Download complete dialog box appears, click Close.
9. Close Internet Explorer.

**Installing the Certificate at the Enterprise Subordinate CA**

The PKCS#7 file must now be installed at the enterprise subordinate CA using the following steps:

1. Insert the disk containing the PKCS#7 file in the disk drive.
2. On the Start menu, point to Programs, point to Administrative Tools, and then click Certification Authority.
3. In the console tree, right-click CAName (where *CAName* is the name of your enterprise subordinate CA), point to All Tasks, and then click Install CA Certificate.
4. In the Select file to complete CA Installation dialog box, in the File name box, type **a:\certnew.p7b**, and then click Open.
5. In the console tree, right-click CAName, point to All Tasks, and then click Start Service.

| **Note** |
| --- |
| It may be required to also install the offline root CA's CRL manually if the CRL cannot be accessed directly from the network. You can load the CRL file using the certutil.exe –addstore <*CRL file*> command. |

**Renewing an Existing Enterprise Subordinate CA**

1. Ensure that the modified CAPolicy.inf file is in the %SystemRoot% folder.

   This ensures that either the newly defined constraints are applied or that the existing policy constraints are retained.

2. On the Start menu, point to Programs, point to Administrative Tools, and then click Certification Authority.
3. In the console tree, right-click CAName, and then click Renew CA Certificate.
4. In the Install CA Certificate dialog box, click Yes to stop Certificate Services.

   | **Note** |
   | --- |

| |
|---|
| In addition to defining constraints, the key size, key lifetime, CDP locations, AIA locations, and other settings defined in the CAPolicy.inf file can be redefined at certificate renewal. |

5. In the Renew CA Certificate dialog box (Figure 32), click No so that the same public and private key pair is used, and then click OK.

**Figure 32: Selecting Whether to Generate a New Public and Private Key Pair**

6. In the CA Certificate Request dialog box (Figure 33), enter the Computer Name and Parent CA name for the issuing CA, and then click Cancel. This will place a *CAMachineName_CAName.req* file in the root folder of the volume where Windows Server 2003 is installed.

**Figure 33: Selecting the CA to Which the CA Will Be a Subordinate CA**

| **Note** |
|---|
| If the CA that issued the SubCAs certificate is online, you can click OK to attempt the certificate request online. |

7. Copy the *CAMachineName_CAName.req* file to a disk, and then follow the procedures for performing the offline request and certificate installation used for installing a new subordinate CA certificate.

**Verifying the Inclusion of All Issuance Policies**

Once the CA certificate is installed, the Enterprise CAs certificate should be inspected to ensure that the Issuance policies are included in the certificate.

1. On the Start menu, point to Programs, point to Administrative Tools, and then click Certification Authority.

2. In the console tree, right-click CAName (where *CAName* is the name of your CA), and then click Properties.

3. In the CAName Properties dialog box, on the General tab, click View Certificate.

4. On the General tab, ensure that the intended purposes list includes:

    - High Assurance
    - Medium Assurance
    - Low Assurance

5. If any are missing, or appear as OIDs rather than text, review the %systemroot%\CAPolicy.inf file and ensure that the correct OIDs for the domain are included in the file. An incorrect OID will result in the OID being listed here, rather than being translated to the display names.

6. In the Certificate dialog box, click OK.

7. In the *CAName* Properties dialog box, click OK.

8. Close the Certification Authority console.

**Creating a Qualified Subordination Signing Certificate at a Stand-alone CA**
A stand-alone CA does not use certificate templates. Because certificate templates are not supported by stand-alone CAs, the certificate request must inject the OID for qualified subordination during certificate enrollment. The following steps allow a qualified subordination certificate to be obtained at a stand-alone CA.

**Performing the Initial Certificate Request**
To perform the initial request for a qualified subordination signing certificate

1. At the stand-alone CA, ensure that you are logged on as the Administrator of the CA computer.

2. Start Internet Explorer.

3. Open the **http://localhost/certsrv** URL.

4. On the Welcome page, click Request a certificate.

5. On the Request a Certificate page, click advanced certificate request.

6. On the Advanced Certificate Request page, click Create and submit a request to this CA.

7. On the Advanced Certificate Request page, enter the following information in Identifying Information:

    - Name: **Administrator** (or the name of the user account currently in use)
    - E-mail: Leave blank
    - Company: **YourOrganization** (where *YourOrganization* is the name of your organization)
    - Department: **YourDepartment** (where *YourDepartment* is the name of your department)
    - City: **CityName** (where *CityName* is the name of your city)
    - State: **StateName** (where *StateName* is the name of your state or province)

- Country/Region: **CountryName** (where *CountryName* is the name of your country or region)

8. In Type of Certificate Needed, select Other from the list.
9. In the OID box, type **1.3.6.1.4.1.311.10.3.10**.
10. In Key Options, set the following options:

    - **Create a new key set**
    - CSP: **Microsoft Enhanced Cryptographic Provider v1.0** (or a different CSP if you are using a hardware CSP).
    - Key Usage: **Signature**
    - **Automatic Key container name**
    - Mark keys as exportable: **unchecked**
    - Enable strong private key protection: **unchecked**
    - Use local machine store: **unchecked**

11. In Additional Options, set the following options:

    - Request format: **CMC**
    - Hash Algorithm: **SHA-1**
    - Save request to a file: **unchecked**
    - Attributes: **empty**
    - Friendly name: **Qualified Subordination Signing**

12. Review the entries, and then click Submit.

    The Certificate Pending page appears.

**Issuing the Pending Certificate Request**

The certificate request is set to a pending status by default on a stand-alone CA. To issue the certificate, a CA administrator must use the Certification Authority console.

1. On the Start menu, point to Programs, point to Administrative Tools, and then click Certification Authority.
2. In the console tree, click the Pending Requests container.
3. In the details pane, right-click the certificate request, point to All Tasks, and then click Issue.
4. Close the Certification Authority console.

**Installing the Qualified Subordination Signing Certificate**

The final step is to install the issued certificate.

1. In Internet Explorer, open the **http://localhost/certsrv/** URL.

2. On the Welcome page, click View the status of a pending certificate request.

3. On the View the status of a pending certificate request page, click the User-EKU (1.3.6.4.1.311.10.3.10) Certificate (*Date and Time*) link.

4. On the Certificate Issued page, click Install this certificate.

   The Certificate Installed page should appear.

5. Close Internet Explorer.

**Verifying the Qualified Subordination Signing Certificate**

Once you have installed the qualified subordination certificate, you should view the certificate to ensure that it is correctly configured.

1. Open an empty MMC console.

2. On the File menu, click Add/Remove Snap-in.

3. In the Add/Remove Snap-in dialog box, click Add.

4. In the Add Standalone Snap-in dialog box, select Certificates, and then click Add.

5. In the Certificates snap-in dialog box, click My user account, and then click Finish.

6. In the Add Standalone Snap-in dialog box, click Close.

7. In the Add/Remove Snap-in dialog box, click OK.

8. In the console tree, expand **Certificates** – Current User, expand Personal, and then click Certificates.

9. In the details panel, double-click the certificate with the Template Friendly Name of Qualified Subordination Signing.

10. In the Certificate dialog box, on the General tab, ensure that the intended purposes only list Qualified Subordination.

11. In the Certificate dialog box, on the Details tab, ensure that the Key Usage indicates Digital Signature, Non-Repudiation (c0).

12. Click OK.

13. Close the console without saving changes.

**Creating a Qualified Subordination Signing Certificate at an Enterprise CA**

An Enterprise CA running on Windows Server 2003 Enterprise Edition can issue version 2.0 certificate templates. For qualified subordination, a version 2.0 template can be created to allow qualified subordination signing. If you are going to issue the Qualified Subordination Signing certificate from an Enterprise CA, the following steps will allow the creation and retrieval of a qualified subordination signing certificate at an enterprise CA.

| **Note** |
| --- |
| While the goal is the same as the previous section on creating a qualified subordination signing certificate, the method is different when issuing the certificate from an Enterprise CA. The decision on which CA type to use should be based on what CAs are available in the infrastructure. |

**Creating a Qualified Subordination version 2 Certificate Template**
To create a version 2 certificate template for Qualified Subordination Signing

1. Open an empty MMC console.

2. On the File menu, click Add/Remove Snap-in.

3. In the Add/Remove Snap-in dialog box, click Add.

4. In the Add Standalone Snap-in dialog box, select Certificate Templates, and then click Add.

5. In the Add Standalone Snap-in dialog box, click Close.

6. In the Add/Remove Snap-in dialog box, click OK.

7. In the console tree, select Certificate Templates.

8. In the details pane, right-click Enrollment Agent, and then click Duplicate Template.

9. In the Properties of New Template dialog box, on the General tab, in the Template display name box, type **Qualified Subordination Signing**.

10. On the Request Handling tab (Figure 34), make the following property changes:

**Figure 34: Setting Request Handling Attributes**

- Purpose: **Signature**

- CSPs: Clear the check boxes for **Microsoft Base Cryptographic Provider 1.0** and **Microsoft Base DSS Cryptographic Provider** and ensure that **Microsoft Enhanced Cryptographic Provider 1.0** is checked.

11. On the Subject Name tab, ensure that the Subject name format is set to Fully distinguished name and that only the User principal name (UPN) check box is selected.

12. On the Issuance Requirements tab (Figure 35), ensure that the CA certificate manager approval check box is selected. For Require the following for reenrollment, ensure that the Valid existing certificate option is set.

**Figure 35: Configuring Issuance Requirement Settings**

| **Note** |
| --- |
| Depending on the security policy of your organization, you may choose to use different issuance settings. For example, you may choose to require one or more authorized signatures for certificate issuance, or that the same approval process be used for certificate reenrollment. |

13. On the Extensions tab, in the Extensions included in this template box, select Application policies, and then click Edit.

14. In the Edit Application Policies Extension dialog box, in the Application policies box, select Certificate Request Agent, and then click Remove.

15. In the Edit Application Policies Extension dialog box, click Add.

16. In the Add Application Policy dialog box, in the Application Policies box, select Qualified Subordination, and then click OK.

| **Note** |
| --- |
| Alternatively, you could create a custom application policy with its own assigned OID. This will require a modification later in the process where you will configure the XXXX Certificate template to require your custom application policy for a signature. |

17. In the Edit Application Policies Extension dialog box, ensure that Qualified Subordination is the only policy that appears in the Application policies dialog box, and then click OK.

18. On the Security tab, ensure that only Domain Admins and Enterprise Admins have the Enroll permission for the certificate template. Alternatively, you can create a custom security group and only assign that security group the Enroll permission.

19. Click OK to apply all configuration changes to the certificate template.

**Modifying the Cross-Certification Authority version 2 Certificate Template**

Once the qualified subordination signing template is created, the cross-certification authority certificate template must be

modified.

1. In the Certificate Templates console, in the details pane, double-click the Cross Certification Authority certificate template.

2. In the Cross-Certification Authority Properties dialog box, on the Issuance Requirements tab (Figure 36), make the following changes:

**Figure 36: Modifying the Issuance Requirements for the Cross CA Certificate**

   - **This number of authorized signatures** A request can be configured to require more than one signature for issuance. You should require at least one signature.

   - **Application Policy** If a custom application policy was created, change the default application policy from Qualified Subordination to the logical name you created for your custom application policy.

3. Click OK.

4. Close the Certificate Templates console

| **Important** |
| --- |
| By default, the CrossCA template is defined to publish to Active Directory when issued. Ensure that the certificate is formatted and configured properly before issuing. Invalid or unintended constraints may cause unwanted behavior in the environment and pose security risks, if not properly prepared. |

**Configuring Windows Server 2003 Enterprise Edition to Issue the Certificate Templates**

Since only Windows Server 2003 Enterprise Edition supports version 2 certificate templates, it is required for the certificate deployment. The Windows Server 2003 Enterprise Edition must be configured to issue both the Qualified Subordination Signing and cross-certification authority certificate templates.

1. Log on as a CA Administrator at Windows Server 2003 Enterprise Edition running Certificate Services configured as an Enterprise CA.

2. On the Start menu, point to Programs, point to Administrative Tools, and then click Certification Authority.

3. In the console tree, expand CAName (where *CAName* is the logical name assigned to your CA).

4. In the console tree, right-click Certificate Templates, point to New, and then click Certificate Template to Issue.

5. In the Enable Certificate Templates dialog box (Figure 37), in the list of available templates, click Cross-Certification Authority, control-click Qualified Subordination Signing, and then click OK.

**Figure 37: Loading the Cross-Certification Authority and Qualified Subordination Signing Certificates**

6. In the details pane, ensure that the Cross-Certification Authority and Qualified Subordination Signing certificate appear.

7. Close the Certification Authority console.

**Acquiring the Qualified Subordination Signing Certificate**

Although you typically request certificates from an Enterprise CA using the Certificates MMC console, the requirement for CA Certificate manager approval in the Qualified Subordination Signing certificate template makes the use of the Certificate Services Web enrollment pages the better method to acquire the Qualified Subordination Signing certificate.

**Performing the Initial Certificate Request**

To perform the initial request for a qualified subordination signing certificate

1. Ensure that you are logged on as a user with the Enroll permissions for the Qualified Subordination Signing Certificate template.

2. Start Internet Explorer.

3. Open the **http://CAMachineName/certsrv** URL (where *CAMachineName* is the name of the Windows Server 2003 Enterprise Edition configured to issue the Qualified Subordination Signing Certificates).

4. On the Welcome page, click Request a certificate.

5. On the Request a Certificate page, click advanced certificate request.

6. On the Advanced Certificate Request page, click Create and submit a request to this CA.

7. On the Advanced Certificate Request page, in the Certificate Template section, select Qualified Subordination Signing from the list.

8. In the Key Options section, set the following options:

   - **Create a new key set**

- CSP: **Microsoft Enhanced Cryptographic Provider v1.0** (or a different CSP if you are using a hardware CSP).
- Key Usage: **Signature**
- **Automatic Key container name**
- Mark keys as exportable: **unchecked**
- Enable strong private key protection: **unchecked**
- Use local machine store: **unchecked**

9. In the Additional Options section, set the following options:

   - Request format: **CMC**
   - Hash Algorithm: **SHA-1**
   - Save request to a file: **unchecked**
   - Attributes: **empty**
   - Friendly name: **Qualified Subordination Signing**

10. Review the entries, and then click Submit.

    The Certificate Pending page appears.

**Issuing the Pending Certificate Request**

The certificate request is set to a pending status by default on a stand-alone CA. To issue the certificate, a CA administrator must use the Certification Authority console.

1. Ensure that you are logged on to the Windows Server 2003 Enterprise Edition as a CA Certificate Manager.
2. On the Start menu, point to Programs, point to Administrative Tools, and then click Certification Authority.
3. In the console tree, click the Pending Requests container.
4. In the details pane, right-click the certificate request for a Qualified Subordination Signing certificate, point to All Tasks, and then click Issue.
5. Close the Certification Authority console.

**Installing the Qualified Subordination Signing Certificate**

The final step is to install the issued certificate.

1. At the computer where the original certificate request was performed, log on as the user who made the Qualified Subordination Signing certificate request.
2. In Internet Explorer, open the **http://CAMachineName/certsrv/** URL (where *CAMachineName* is the name of the Windows Server 2003 Enterprise Edition configured to issue the Qualified Subordination Signing Certificates).
3. On the Welcome page, click View the status of a pending certificate request.

4. On the View the status of a pending certificate request page, click the QualifiedSubordinationSigning Certificate (*Date and Time*) link.

5. On the Certificate Issued page, click Install this certificate.

   The **Certificate Installed** page should appear.

6. Close Internet Explorer.

**Verifying the Qualified Subordination Signing Certificate**

Once you have installed the qualified subordination certificate, you should view the certificate to ensure that it is correctly configured.

1. Open an empty MMC console.

2. On the File menu, click Add/Remove Snap-in.

3. In the Add/Remove Snap-in dialog box, click Add.

4. In the Add Standalone Snap-in dialog box, select Certificates, and then click Add.

5. In the Certificates snap-in dialog box, click My user account, and then click Finish.

6. In the Add Standalone Snap-in dialog box, click Close.

7. In the Add/Remove Snap-in dialog box, click OK.

8. In the console tree, expand Certificates – Current User, expand Personal, and then click Certificates.

9. In the details panel, double-click the certificate with the template Friendly Name of Qualified Subordination Signing.

10. In the Certificate dialog box, on the General tab, ensure that the intended purposes only list Qualified Subordination.

| **Note** |
| --- |
| If you used a custom application policy, then the name of this application policy and its OID will appear instead of Qualified Subordination. |

11. In the Certificate dialog box, on the Details tab, ensure that the Key Usage indicates Digital Signature (80).

12. Click OK.

13. Close the console without saving the changes.

**Performing Cross-Certification**

Once the qualified subordination signing certificate is successfully installed, you can now request the Cross-Certification Authority certificate from the other CA. In this example, the following CAs shown in Figure 38 will be used.

**Figure 38: Performing the Cross-Certification**

**Gathering the Necessary Files**

The first cross-certification request is to be run from the F1CA certification authority. To perform the qualified subordination, the following is required at the F1CA before starting the process:

- The CA certificate from F2Root.
- The Policy.inf file configured at the F1CA defining the naming constraints, policy constraints, and application constraints defined for the qualified subordination.
- The user performing the qualified subordination must have a qualified subordination signing certificate issued by F1CA.

**Generating the Cross-Certification Authority Certificate Request**

Once these items are obtained, the following procedure is used to obtain a Cross-Certification Authority certificate for F2Root from F1CA. The request is performed using Certreq.exe, a command-line tool used from the Windows Server 2003 administrative tools pack that requests certificates from the command line.

| **Important** |
| --- |
| The constraints defined in Policy.inf are enforced at the signing CA where you generate the request, not at the CA whose CA certificate you use during the request. It is also important to generate the cross-certificate request in the domain in which the cross-cert will be issued. |

1. Copy the F2Root certificate and the Policy.inf file into a folder on the F1CA computer.
2. Open a command prompt window.
3. Make the folder containing the F2Root certificate and the Policy.inf file the current directory.
4. Run certreq.exe –policy. This command constructs a cross-certification or qualified subordination request from an existing CA certificate or from an existing request.

   | **Note** |
   | --- |
   | If creating a cross-certificate request from a stand-alone CA to an Enterprise CA, the following command must be specified to include the proper CrossCA template name in the template. Example: |

   ```
   certreq -policy -attrib CertificateTemplate:CrossCA  <CatoXcertify> <inf
   file> <CMCoutFile>
   ```

5. In the Open Request File dialog box (Figure 39), in the Files of Type box, select Certificate Files (*.cer, *.crt, *.der), select the requesting CAs certificate (RackCluster3_F2Root in this example), and then click Open.

**Figure 39: Selecting the Target CAs Certificate**

6. In the Open Inf File dialog box (Figure 40), select the configured Policy.inf file, and then click Open.

**Figure 40: Selecting the Policy.inf File**

| **Note** |
| --- |
| You do not have to name the file Policy.inf. In this example, the file was named xrossForest2.inf to aid in determining which Policy.inf file was required. |

7. In the Certificate List dialog box (Figure 41), select the Qualified Subordination certificate that you requested earlier, and then click OK.

**Figure 41: Selecting the Qualified Subordination Signing Certificate**

8. In the Save Request dialog box (Figure 42), in the File name box, type a name describing the Cross-Certification Authority certificate request, and then click Save.

**Figure 42: Saving the Request File**

**Processing the Cross-Certification Authority Certificate Request**

At the F1CA, the final step is to process the Cross-Certification Authority certificate request file.

1. In Administrative Tools, open Certification Authority.

2. In the console tree, right-click CAName (where *CAName* is the name of your CA), point to All Tasks, and then click Submit New Request.

3. In the Open Request File dialog box (Figure 43), select the request file that you created in the previous process, and then click Save.

**Figure 43: Choosing the Request File**

4. In the Save Certificate dialog box, indicate the name of the Certificate File, and then click Save.

   The certificate file is automatically published into Active Directory, so that the clients in Forest1 can validate certificates issued by the CAs in Forest2.

**Verifying the Existence of the Cross Certificate**

The final step is verifying that the certificate has been successfully published into Active Directory. This process uses Certutil.exe to verify the existence of the cross certificate. The following walkthrough validates the certificate with subject name ASIA SA Root CA that was issued by the Microsoft Intranet CA.

1. Open a command prompt window.

2. Type **certutil -viewstore "CN=<CAName>,CN=AIA,CN=Public Key Services,CN=Services,CN=Configuration,DC=<ForestRootDN>?crossCertificatePair**

   Where:

   - *<CAName>* The name of the CA that is issued the cross-certification authority certification. This is the subject of the cross-certification authority certificate.

   - *<ForestRootDN>* The name of the forest root LDAP distinguished name. This is the forest in which the cross-certification authority certificate exists.

   In this example, the following command was used:

```
certutil -viewstore "CN=ASIA SA Root CA,CN=AIA,CN=Public Key
Services,CN=Services,CN=Configuration,DC=corp,DC=microsoft,DC=com?
crossCertificatePair
```

| **Note** |
| --- |
| If the subject name of the CA being cross-certified does not have CN= in the subject name, the Windows Server 2003 CA will generate a hash of the binary name of the CA and publish the cross certificate to that name. For example, to perform the command in the previous step in this case, the syntax would be similar to the following where the common name is the hash of the CA name: |

```
certutil -viewstore
CN=12d2cb85c5e62f9aa7591e2ddaa44c987de5abbc,CN=AIA,CN=Public Key
Services,CN=Services,CN=Configuration,DC=ntdev,DC=corp,DC=microsoft,DC=com
```

3. In the View Certificate Store window (Figure 44), all cross-certification authority certificates with the <CAName> in the subject name are listed.

**Figure 44: The Cross-Certification Authority Certificates List**

| **Note** |
| --- |
| Multiple cross-certification authority certificates can exist when the cross-certification authority certificate is renewed when the previous certificate expires. |

4. In the View Certificate Store dialog box, select the cross-certification authority certificate that you wish to view, and then click View Certificate.

5. In the Certificate dialog box, click the Certification Path tab.

6. On the Certification Path tab (Figure 45), ensure that the certification path is the correct path. In this example, the chain is correct, as it shows the ASIA SA Root CA chaining to the Microsoft Corporate Root Authority.

**Figure 45: Validating the Certification Path of the Cross-Certification Authority Certificate**

7. In the Certificate dialog box, click OK.

8. In the View Certificate Store dialog box, click OK.

9. Close the command prompt window.

When cross-certifying with some third-party certification authorities, you may have to specify where to retrieve additional cross certificates associated with the issuer of a presented certificate. Typically, a certificate will have a cross-certificate URL encoded in the certificate, but in some cases, you may need to specify additional URLs.

To add the additional URLs

1. Open a blank MMC console.

2. On the File menu, click the Add/Remove snap-in.

3. In the Add/Remove snap-in dialog box, click Add.

4. In the Add Standalone Snap-in dialog box, select Certificates, and then click Add.

5. In the Certificates snap-in dialog box, select either My user account, Service account, or computer account, based on whether the certificate that must chain using a cross certificate is issued to the computer, a service, or to your user account, and then click Finish.

| **Note** |
| --- |
| If you are not an Administrator of the local computer, you will automatically load the Certificates console focused on My user account. |

6. In the console tree, expand Certificates – Current User, expand Personal, and then click Certificates.

7. In the details pane, right-click the certificate that must be cross-certified, and then click Properties.

8. In the Certificate Properties dialog box, click the Cross-Certificates tab.

9. In the Cross-Certificates tab (Figure 46), select the Specify additional Cross-Certificate download locations check box. In addition, you can now do the following:

**Figure 46: Defining Manual Cross-Certificate Download Locations**

- Define the Cross-Certificate download interval. The default is every eight hours.
- Add URLs for Cross-Certificate download locations. The URL can be an LDAP, HTTP, FTP, or FILE location.

**Completing Cross-Certification**

The cross-certification must be performed in the opposite direction to ensure that all certificates issued in both organizations are trusted. This requires that the same process be performed at F2CA using the F1Root certificate.

**Completing the Cross-Certification When a Bridge CA Is Implemented**

An additional process must be performed when a Bridge CA is used. The certificates that are issued by the BridgeCA must be published in all forests that are connected to the BridgeCA to allow all certificates to be recognized by the organizations using the bridge.

1. From the BridgeCA, copy all issued CrossCA certificates to a common share point.
2. At the first forest connected to the bridge, run **Certutil –dspublish –f cert1.crt CrossCA** (where *cert1.crt* is the first crossCA cert).
3. Repeat the process for all certificates issued by the Cross CA, at all forests connected to the Bridge CA.

# Appendix B – CAPolicy.inf

Updated: May 15, 2013

Applies To: Windows Server 2003 with SP1

The CAPolicy.inf contains settings that can be used to modify the default installation of the Certification Authority role of Active Directory Certification Service (AD CS). The file is also used when renewing the CA certificate. A CAPolicy.inf file is not required to install AD CS or renew a CA certificate. The file is only needed to modify default settings.

Once you have created your CAPolicy.inf file, you must copy it into the %windir% folder (such as the C:\Windows) of your server before you install AD CS or renew the CA certificate.

**CAPolicy.inf**

The following code illustrates the text of a sample CAPolicy.inf. You can create and save such a file with any text editor, such as Notepad.exe. Ensure that you save the file with the .inf file extension and not .txt or some other file extension. The name of the file must be CAPolicy.inf and must be in the %windir% folder, or it will not work.

# Planning and Implementing Federated Forests in Windows Server 2003

Updated: July 31, 2004

Applies To: Windows Server 2003 with SP1

This paper describes basic concepts that involve forest trusts, common scenarios where you can deploy forest trusts, and the technologies that are included with Windows Server 2003 that enable multiple forest deployments.

**In This White Paper**

Introduction

Scope

Overview

Scope

Multiple Forest Deployment Scenarios

Technologies for Federating Multiple Forests

Considerations for Deploying Forest Trust

Enabling Multiple Forest Scenarios in Windows Server 2003

Walkthroughs

Appendix A: List of Ports

Appendix B: Terms That Are Used in this White Paper

# Introduction

Updated: July 31, 2004

Applies To: Windows Server 2003 with SP1

The concept of the Active Directory forest was introduced in versions of Microsoft Windows 2000, and it was presumed that most organizations would deploy a single forest that spanned the entire organization. However, many organizations deploy multiple forests. In addition, collaboration might be required across forests in different organizations. When this occurs, establishing an external trust relationship requires an enormous amount of management and does not use the newest technological advances.

The concept of the forest trust is introduced in Windows Server 2003 to make multiple forest deployments easier. The forest trust allows administrators to federate two Active Directory forests with a single trust relationship to provide a seamless authentication and authorization experience across the forests. In this white paper, common scenarios where you can deploy forest trusts, basic concepts that involve forest trusts, and the technologies that are included with Windows Server 2003 that enable these multiple forest deployments are described.

| **Note** |
| --- |
| This document refers to features that are included with Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition. These features are not included on computers that are running the Windows Server 2003, Web Edition operating system. |

# Scope

Updated: July 31, 2004

Applies To: Windows Server 2003 with SP1

The scope of this white paper is restricted to concepts about authentication, authorization, and trust management across multiple forests. Although the basic reasons why you may want to deploy multiple forests are explained, this white paper is not intended to be a multiple forest deployment decision guide. Also, this white paper does not discuss how to synchronize Microsoft Outlook address book contacts or Microsoft Exchange Server public folders. This paper does, however, provide information about other technologies, such as Microsoft Metadirectory Services (MMS) and Exchange Server public folder replication tools.

# Overview

Updated: July 31, 2004

Applies To: Windows Server 2003 with SP1

In Windows 2000, the concept of an Active Directory forest that integrates traditional Windows NT Server 4.0 domains is introduced. This integration allows you to enable rich collaboration between domains in the forest. Applications can also use this collaboration. For example, users can search Exchange Server global address lists to locate other users in the forest so that the users can send mail that is based on a variety of attributes.

When this integration was introduced, many of the Windows NT Server 4.0 boundaries disappeared. Domains were no longer completely isolated from one another. They became interdependent of each other, and moving to a single forest required a certain level of consent and trust between the administrators of different domains.

Where this level of trust cannot be achieved, multiple forests must be deployed. In addition, there are scenarios (such as mergers and acquisitions or collaboration across enterprises), where multiple forest deployment already exists. Because of this, a move to a single forest environment is not possible due to the complexity or a lack of trust between organizations.

Windows 2000 Server does not completely address the multiple forest deployment scenario. To enable authentication, administrators must set up trusts between every domain in one forest to every other domain in the other forest. This could lead to so many trusts that they may be difficult to manage. Also, the trust across forests is unlimited, which means that you can either trust every user in the other forest or you can decide to not trust any user. A more limited approach is needed in the scenario across enterprises, where you may want to allow only a specific set of users to authenticate from the other corporation. Trusts across enterprises most likely also have to span firewalls. Windows 2000 trusts have limited support for spanning firewalls.

In the Windows Server 2003 family, the concept of the forest trust is introduced. This concept enables trust between two forests, so that all of the domains in each forest are part of the trust. The problem of unlimited trust is solved by using the **Selective Authentication** option, which allows only specific users or sets of users to authenticate across the trust. Managing trust across network firewalls is also easier because the administrators can control the specific remote procedure call (RPC) ports that need to be open for the trust to work.

# Multiple Forest Deployment Scenarios

Updated: July 31, 2004

Applies To: Windows Server 2003 with SP1

You may need multiple forests for various reasons. You may need to have different schemas, political divisions between resource owners, lack of trust in another organization's administrative infrastructure, mergers and acquisitions, geographically distributed business units, and so on.

There are two generic reasons why you may need to deploy multiple forests.

- You may need to deploy multiple forests for administrative autonomy. Separate departments do not trust each others administrators (for political or security reasons) or cannot agree on a common change control policy (for directory schema and configuration).

  **-and-**

- You may need to deploy multiple forests for asset isolation. Governmental agencies and business units that have become conglomerated through mergers and acquisitions sometimes maintain completely separate computing infrastructures for security or budgetary reasons; application service providers create separate infrastructures for outsourcing large business customers. The "Design Considerations for Delegation of Administration in Active Directory" white paper provides the following reason for why you may want to use multiple forests:

  Because data stored in Active Directory and on computers joined to Active Directory cannot be isolated from the service administrators of the directory, the only way for an organization to achieve complete data isolation is to create a separate forest.

  You can view the Microsoft TechNet "Design Considerations for Delegation of Administration in Active Directory" white paper at http://go.microsoft.com/fwlink/?LinkID=91034.

**Multiple Forests in the Same Corporation**

In a single corporation, the preferred approach is to deploy a single forest. However, for the reasons that are listed in the previous section, you may need to deploy multiple forests. In most scenarios, the forests should be connected by using dedicated leased lines or virtual private networks (VPNs), which allow the necessary data traffic to flow between the forests. If there are packet filters or firewalls, they usually have an "allow all, deny explicit" approach. The administrators for the two forests may be the same people, or they may be different people, but they may want to treat users from the other forest in the same way that they treat users from their own forests.

Consider the following example. There are three forests in the Contoso, Inc. Corporation: contoso.com, plant.contoso.com, and hr.contoso.com. The Human Resources (HR) department has its own forest because it has a program that requires schema changes. The IT department of the HR organization wants to retain control over these changes without going through the central IT department. In addition, the hr.contoso.com forest has a test domain that the contoso.com forest wants to exclude from the trust relationships.

The Fabrikam manufacturing plant also needs to run a program that uses Active Directory. In this scenario, they needed a separate forest because the domain controllers have to be placed on the floor at the manufacturing plant; everyone in the plant will have physical access to the domain controllers.

**Figure 1: Multiple Forests in the Same Corporation**

**Multiple Forests in Different Corporations**

Each organization will have its own forests. However, in a business-to-business (B2B) scenario, collaboration between a forest in one organization and a forest in another organization is necessary. In this scenario, trust also needs to be established between these two forests. However, the administrators in the each forest want only the users in the other forest to have access to a limited set of resources. The two forests might be connected through dedicated leased lines or through VPN connections, but only limited traffic is allowed between the two forests. Because of this, the firewalls typically have rules that deny all traffic and allow only the traffic that is explicitly allowed.

In this scenario, Contoso.com and Fabrikam.com have partnered together to jointly market their toothpaste and toothbrush combination product. However, they would like to restrict access to each others project files to the marketing teams from the other side because much of the collaboration is related to marketing. To keep employees aware of the general progress, both companies want to open their internal news Web site to all of the employees in the other corporation.

**Figure 2: Multiple Forests in Different Corporations**

**Perimeter Network Scenario**

An organization might need to publish resources in the perimeter network (also known as DMZ, demilitarized zone, and screened subnet) and run programs that need Active Directory. However, deploying a separate domain of the internal forest on the perimeter network is not recommended, because it becomes an easy staging point from which to compromise the entire internal forest if the external domain is compromised. Because of this, you must deploy a separate forest in the perimeter network if someone wants all of the administrative and security benefits of managing the perimeter network servers in a domain.

In this scenario, the administrators of contoso.com want to have a separate forest, called dmz.contoso.com. They have a Web application that is running in the perimeter network that uses Windows Live ID authentication so that users can gain access to a portal. The administrators also want to allow users in the internal forest to publish resources to the perimeter network forest. Because of this, the users in the internal forest need to be able to gain access to the resources that are in the perimeter network by using their internal forest accounts.

**Figure 3: Perimeter Network Scenario**

# Technologies for Federating Multiple Forests

Updated: July 8, 2014

Applies To: Windows 7, Windows 8, Windows 8.1, Windows Server 2003 with SP1, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2, Windows Vista, Windows XP

This section describes the technologies that are included in Windows Server (beginning with Windows Server 2003) that address the problems that are associated with multiple forest deployments.

**Forest Trust**

A forest trust makes federated forests possible in Windows Server. A forest trust enables a transitive trust between all of the domains in two forests. Microsoft recommends a forest trust be created between forests rather than an external trust. A forest trust ensures that Kerberos is used whenever possible. Kerberos provides better security and scalability over NTLM.

A forest trust is established between the root domain of both forests. Forest trusts can be one-way or two-way trusts. In Figure 4, Forest A and Forest B have a bidirectional trust between each other. Because of this, users in Forest A can authenticate to resources in Forest B and users in Forest B can authenticate to resources in Forest A. In addition to authentication, the trust enables authorization so that the resource owners in each forest can add principals from the other forest to discretionary access control lists (DACLs) and groups.

**Figure 4: Forest Trust**

**Forest Trust Requirements**

Before you can create a forest trust, you need to verify that all domain controllers in both forests are running Windows Server 2003. You also need to verify that you have the correct Domain Name System (DNS) infrastructure in place and that you have established the appropriate functionality level for Active Directory. This means that the forest has to be raised to the Windows Server 2003 functional level and you cannot add any more Windows 2000 or Windows NT Server 4.0 domain controllers to the forest.

To create a forest trust, the person who will create the trust in Fabrikam and Contoso must have Enterprise Admin privileges in the corresponding forest. Each trust is assigned a password that the administrators in both forests must know. An administrator who has Enterprise Admin privileges in both forests can create the trusts in both Fabrikam and Contoso at one time and, in this scenario, a password that is cryptographically random is automatically generated and written for both forests.

Both Windows NT Server 4.0 and Windows 2000 clients can use the forest trust for authentication. However, Windows NT Server 4.0 clients support only NTLM and they do not support user principal names (UPNs) for logging on to the network.

**External Trusts vs. Forest Trusts**

External trusts are used to enable trusts between two domains that are in different forests. A forest trust is similar to an external trust between the root domains of both forests, but it takes the trust one step further to encompass all of the domains. The basic trust information (for both external trust and forest trust) is represented by a trusted domain object (TDO). The TDO for an external trust contains the name of the other domain with which the trust is established, its domain security identifier (SID), the trust direction, the type of trust, and some other attributes.

When there is a forest trust, the trust is marked as "Forest." The TDO also contains an additional **Forest Trust Information** attribute. The **Forest Trust Information** attribute contains information about all of the domains in the remote forest, the tree names, and any alternate name suffixes. This information is used to route authentication and lookups to the remote forest when needed. This information is propagated to the global catalogs so that any domain controller can look it up. The TDOs are stored in the Domain container that is in Active Directory.

The tree names and alternate name suffixes are stored in TopLevelName (or TLN) records. The DNS name, network basic

input/output system (NetBIOS) name, and SID for every domain is stored in DomainInfo records. Because of this, the forest trust contains enough information to reasonably determine which services or users can reside in the other forest.

The following table shows the key differences between both external and forest trusts.

**Table 1 External vs. Forest Trusts**

| | **External trust** | **Forest trust** |
|---|---|---|
| **TDO** | Yes | Yes |
| **Top level names** | No | Yes |
| **DomainInfo (for every domain)** | No | Yes |
| **Kerberos V5 support** | The following prerequisites must be in place to allow Kerberos to function over an external trust:<br>• The trust has to be created using the fully qualified domain name (FQDN). Kerberos referral fails if the FQDN is missing from the TDO. Windows Server 2003 **Add Trust** wizard does not create trusts with Windows 2000 and newer domains without DNS name resolution. For more information see, DNS and NetBIOS Name Resolution to Create External, Realm, and Forest Trusts (http://go.microsoft.com/fwlink/?LinkID=198352)<br>• User name syntax is UPN and the UPN suffix is resolvable to a DC in DNS (implicit UPN)<br>• UDP 389, UDP/TCP 88, and UDP/TCP 464 (password change requests) ports are open for the domain controllers in the user domain.<br>• The server name in the trusting resource domain has to be the FQDN, and the domain suffix of the server name has to match the AD DS domain's DNS FQDN.<br>• Applications building Service Principal Names need to build three-part SPNs using the service/server@realm syntax<br>• Since it is an external trust, the cross-forest targets only cover the domains that have *direct* trusts. Only these DCs should be used to target Kerberos requests or Kerberos Forest Searches.<br>• There may be additional scenarios, unknown today, where Kerberos over an external trust may fail. As mentioned, Microsoft recommends forest trusts where possible. Forest trusts ensure that Kerberos is used whenever possible. Kerberos provides better security and scalability over NTLM. | Yes |
| **Object picker browsing** | Yes | Yes |
| **NTLM support** | Yes<br>**Note**<br>Interactive logon across external trusts will attempt Kerberos. On Windows XP and Windows Server 2003, NTLM will be tried if Kerberos fails. Windows Vista and newer operating systems will not allow fallback to NTLM for interactive logon over external trusts. | Yes |

| | | |
|---|---|---|
| **UPN logons** | Implicit and explicit UPNs where the suffix matches the AD DS DNS domain name.<br>**Note**<br>Certificate logons may fail if the UPN suffix in the certificate does not match the AD DS domain name. | Implicit and explicit UPNs |

**Routing of Kerberos Authentication**

After you establish the forest trust, Kerberos and NTLM authentication are routed accordingly to the other forest so that they can validate user credentials.

With Kerberos, users receive a Ticket Granting Ticket (TGT) when they log on to the computer. When users need to be authenticated to a resource, the TGT is presented to their domain controller, and then the domain controller returns a service ticket to authenticate. This is accomplished through a Kerberos ticket granting service (TGS) request. If the resource is in another domain, the users' domain controller cannot issue the service ticket. Instead, the domain controller issues a referral for the user to contact the resource domain controller if it has a direct trust to it. If there is no direct trust, the domain controller issues a referral to the next domain controller that is in the trust chain. The final resource domain controller then issues the service ticket to the user. If the resource is in the same forest, the user's domain controller can determine if the resource is in the same forest by querying the global catalog.

If a resource is in another forest that is connected by a forest trust, the global catalog does not have information about all of the resources that are in the other forest. However, the global catalog can determine which forest contains this resource by searching the forest trust information for all of the forest TDOs. After the information is determined, the referrals are issued so that the user reaches the local forest root. The local forest root then refers the user to the root of the trusting forest. After the referrals reach the trusting forest, the user is then authoritatively referred to the resource domain controller to obtain the service ticket.

If a user from a trusted forest is logging onto a computer in the trusting forest, the Kerberos Authentication Service (AS) requests are routed in a similar manner. However, when this occurs, the user does not have to traverse all of the domains that are in the trust path; the user is instead directly referred to the root domains and then to a domain controller that contains the users account that is in the other forest.

**Figure 5: Authentication Process to Another Forest**

Figure 5 shows how the client uses Kerberos to authenticate to a service in the other forest:

1. Clients contacts the domain controller (DC1) to request a service ticket to use the service.

2. The domain controller cannot find the service in its domain, so the domain controller queries a global catalog. After examining the forest trust information, the global catalog sends a hint that the service is probably in the other forest, and the domain controller issues a referral to its parent.

3. The client then contacts the parent root domain controller (DC2) to request a service ticket to use the service. The root domain controller (DC2) sends the client a referral to the root domain controller (DC3) for the other forest.

4. The client then contacts the root domain controller (DC3) that is in the other forest to request a service ticket to use the service. In this example, the root domain controller (DC3) determines that the service is in its own forest after querying the global catalog in its forest, and then the root domain controller (DC3) refers the client to the next domain controller

(DC4) in the trust path.

5. The client then contacts the next domain controller (DC4) to which it is referred (the service domain controller) to request a service ticket. Because this domain controller determines that the service is in its domains, it issues a service ticket to the client.

6. The client then presents this service ticket to the server in a Kerberos KERB_AP_REQ message. The server responds, which establishes a secure communication channel.

**How the Object Picker Tool Works**

You can use the Object Picker command-line tool to add users or groups to DACLs on resources and as members of other groups. For example, if the administrator in the trusting forest needs to add a user from the trusted forest to a group in the trusting forest, the administrator opens the Active Directory Users and Computers Microsoft Management Console (MMC) Snap-in, clicks the desired group, and then clicks **Add members**. The Object Picker tool then prompts the administrator to type the name of the remote forest user. First, Object Picker tries to locate the domain in which the user is located. Because the user is from another forest, the local global catalog cannot find the user name in its forest. The global catalog then examines the forest trust information to determine if the requested object might be in a different forest. If it is possible that the object might be in a different forest, a referral is sent to Object Picker to contact a global catalog in the other forest. The Object Picker tool then contacts the global catalog in the remote forest to authoritatively determine which remote forest domain holds the queried object. After this is determined, Object Picker connects to a domain controller in that domain, and then performs a Lightweight Directory Access Protocol (LDAP) search to retrieve certain attributes of the object, such as its security identifier (SID). After this information is obtained, you can set the DACL or modify group membership.

Object Picker support for selecting objects from a trusted forest is available on computers that are running the Microsoft Windows XP operating system or an operating system that was released later than Windows XP. Note that you have to type the full UPN of the user or group when you use Object Picker to select objects from a trusted forest. Object Picker browsing, which allows you to use wildcard characters in searches, is available on computers that are running Windows Server 2003.

Note that you must have credentials in the remote forest if you want to look up a user from a remote forest. If there is a two-way trust, then the remote forest also trusts the local forest and the default local forest credentials are used. If the local forest trusts only the remote forest, the user in the local forest is prompted for credentials in the remote forest by the Object Picker tool.

| **Note** |
| --- |
| Group membership rules prevent both Universal and Global groups from containing members from another forest. |

A best practice for Active Directory is to have a global group in each domain that contains users in that domain and to add these global groups to a domain local group that is in the resource domain.

**SID Filtering**

When authentication requests come from a trusted forest, you trust that forest to have properly validated the users' credentials. However, you also receive authorization information in the form of a list of security identifiers (SIDs), along with the authentication request. If any of the SIDs correspond to the Enterprise Administrator's SID (or to a similar privileged group or user SID) of the trusting forest, then the user from the trusted forest receives elevated rights to resources. To protect against the possibility of the trusted forest assigning counterfeit SIDs, the operating system always filters the SIDs to verify that they are relative to one of the domain SIDs in the trusted forest. This procedure ensures that the trusted forest issues authorization information only for domains for which it is authoritative. For example, when the domain controller of the root domain of the fabrikam.com forest receives the request from the client, it filters the SIDs in the request to verify that the client is not passing any unauthorized SIDs (see step 4 in Figure 5). SID filtering is automatically enabled across all trust relationships.

SID filtering on forest trusts breaks SID history across forests. If a user from the fabrikam.com forest migrates to the contoso.com forest, the SID history of the users contoso.com account contains the SID of the user's user account in the fabrikam.com forest. When the user tries to gain access to resources that are in the fabrikam.com forest by using the user's contoso.com account, the fabrikam.com account SID is presented with the SIDs from contoso.com. The fabrikam.com root domain domain controller determines that the fabrikam.com account SID that is presented by the user is not authorized to be presented by a user account in the contoso.com forest and filters it out. This breaks SID history because the user does not have access to the user's previous resources.

If the trusted forest administrator can be trusted not to spoof unauthorized SIDs, you can allow SID History to traverse the forest trust. To do this, use the **netdom** command-line tool (Netdom.exe) with the **/enablesidhistory:yes** option. To allow users to access shared resources in their original domain over an external trust, ensure that SID filter quarantining is disabled.

To do this, use the **netdom** tool with the **/quarantine:no** option. The Netdom tool is included with the Windows Server 2003 support tools. You can install Windows Server 2003 support tools from the Support\Tools folder on the Windows Server 2003 CD. To do this, right-click the Suptools.msi file in the Support\Tools folder, and then click **Install**. As an alternative, you can install support tools from the Microsoft Download Center. To download the support tools, see Windows Server 2003 Service Pack 2 32-bit Support Tools (http://go.microsoft.com/fwlink/?LinkId=100114).

For more information about SID filtering and SID spoofing, see Microsoft Help and Support (http://go.microsoft.com/fwlink/?LinkID=69288).

#### Selective Authentication

The **Selective Authentication** option is conceptually similar to the network firewall in the way that it works. In the same way that a network firewall allows only certain network access requests through the firewall, the **Selective Authentication** option allows only specific authentication requests. For more information about how to enable the **Selective Authentication** option, see the "Walkthroughs" section in this document.

#### The Problem of Authenticating Users from a Trusted Forest

When users authenticate from a trusted forest, they receive the Authenticated Users SID in their token. Many of the default rights for users in a forest are granted through the Authenticated Users SID. Because the Authenticated Users group is a computed group and its SID is added on the server to which the user authenticates, you cannot change the membership of the group. Because of this, the users from the other forest receive some default rights to all of the resources that are in the trusting forest that are accessible by the Authenticated Users group after you set up a forest trust. You may not want to do this if the trust is set up only to allow access to a small subset of users who are in the trusted forest.

#### The Solution

The **Selective Authentication** option provides a method that you can use to grant limited rights for authentication requests that come across a trust. When you enable the **Selective Authentication** option, all authentication is examined on the service domain controller. The service domain controller verifies that the user is explicitly allowed to authenticate to the resource before allowing the authentication request through. Because of this, you need to specify which users who come across the trust can authenticate to which resources in the domain when you enable the **Selective Authentication** option across a trust. You can do this if you set up the "Allowed to Authenticate" control access right on an object for that particular user or group from the other forest or domain. When a user authenticates across a trust with the **Selective Authentication** option enabled, a special "Other Organization" SID is added to the users authorization data. The presence of this SID triggers a verification on the service domain to ensure that the user is allowed to authenticate to the particular service. After the user is authenticated, the server to which the user authenticates adds another SID, the "This Organization" SID. (The "This Organization" SID is added if the "Other Organization" SID is not already present.) For example, if the user did not authenticate across a trust with the **Selective Authentication** option enabled, only then is the "This Organization" token present. Because of this, only one of these special SIDs can be present in an authenticated user's context.

#### Trust Port Configurations

Trusts need to be deployed across various network boundaries. Because of this, the trusts may have to span one or more firewalls. When this is required, you can either tunnel the traffic across a firewall or open specific ports in the firewall to allow the trust traffic to pass through. In Windows Server 2003, this procedure is simplified through configurable remote procedure call (RPC) ports for the main trust services. The two main configurable RPC ports are:

- The Local Security Authority (LSA) RPC port. This port is used for trust creation and other access to the LSA policy database: **TCP/IPPort** entry in the **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters** registry key.

  **-and-**

- The Netlogon RPC port. This port is used for NTLM and secure channel: **DCTcpipPort** entry in the **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters** registry key.

  To view a full description of the ports that you can open for different scenarios, see the "List of Ports" section in Appendix A in this document.

# Considerations for Deploying Forest Trust

Updated: July 31, 2004

Applies To: Windows Server 2003 with SP1

This section discusses the various considerations and best practices to keep in mind when you deploy forest trusts.

**UPN Considerations**
When you deploy forest trusts, you can use explicit UPN suffixes across multiple forests. You could not use explicit UPN suffixes across multiple forests with external trusts. Administrators who want to use explicit UPN suffixes should carefully plan their UPN structure across forests. UPN suffixes across forests should be unique and should not overlap.

You can use overlapping UPN suffixes, such as plant.contoso.com and contoso.com, but you must also use TopLevelName exclusion (TLNEx) records. This is because the TopLevelName record for contoso.com (UPN suffixes and tree names of trusted or trusting forests are stored as TopLevelName records in the local forests) claims all of the namespaces that are under contoso.com, including plant.contoso.com. Because of this, there is a conflict about where to route a request for a name, such as server.plant.contoso.com. To ensure that this request is sent to the correct forest, all of the forests that have a trust to contoso.com should add a TopLevelName exclusion record for plant.contoso.com to that trust. The TopLevelName exclusion records specify that requests for names that are under plant.contoso.com should not be routed to that forest. TopLevelName exclusion records add an additional level of complexity, so it is recommended that administrators choose UPN suffixes that do not overlap.

Shared UPN suffixes, such as two forests that both claim contoso.com, are not permitted when you use forest trusts. Administrators who want to use shared UPN suffixes only for logons in their forest (users can use the UPN suffix only to logon to the same forest that their account is in) have to remove the definition of the suffix across the forest and define only the UPN attribute on the user object. This means that you cannot set the UPN suffix on the User object through the Active Directory Users and Computers MMC Snap-in user interface (UI). Because of this, you have to programmatically write the attribute to the user object. When you remove the definition of the UPN suffix across the forest by using the Active Directory Users and Computers MMC Snap-in, the UPN suffix is not propagated to another forest that shares the suffix and, therefore, does not result in a collision. (Note that a collision is when two forests clam the same TLN.) If a collision does occur, the forest trust is disabled. Note that you cannot set an exclusion record if both forests claim the same namespace (for example, if two forests both claim contoso.com). With this approach, you cannot log on across forests with the shared UPN. Because of this, you should use this approach only when the occurrence of logons to computers that are in another forest (a forest other than the forest in which the user account is located) are minimal. Note that you can seamlessly gain access to resources in another forest after you log onto a computer in the forest to which you are a member by using the shared UPN suffix.

**Considerations for Restricting the Scope of a Forest Trust**
There are two methods that you can use to restrict which users are permitted to gain access to the forest from the trusted forest:

- You can disable the corresponding DomainInfo record for the domain or the TopLevelName record for the tree in the UI. This method is useful when only a small part of the other forest is not trusted. Note that only authentication requests from users in that domain are disabled when you disable a DomainInfo record. When you disable a DomainInfo record, authentication requests are not disabled if those authentication requests are received from users who are in the local forest if those users want to gain access to resources that are in the disabled domain.

  **-or-**

- You can use the **Selective Authentication** option. This option is useful only when you want to allow access to a small number of users. If there is a large number of users who want to gain access to a large set of resources, it can be difficult to manage the requests to grant the Allowed to Authenticate right to users. Note that only users who have Write_DAC permissions to the resource object in Active Directory can set this permission. This permission is restricted to both the Domain Admins and delegated administrators who created the object. Note that when a user joins a computer to the domain by using the Add workstation to domain privilege, the user does not receive the Write_DAC permission and, because of this, the user cannot grant users who are in other forests the Allowed to Authenticate right on the computer that the user joined.

**Smart Card Logon Considerations**
For smart card logons to work across forests, users must have a public key infrastructure (PKI) trust and a forest trust. This means that the forest to which the user is logging on must trust the Certification Authority (CA) that issued the users smart

card certificate for smart card logon. In addition, the computer to which the user is logging on must trust the computer certificate for the domain controller of the users domain for server authentication. You can do this by either making the CA a trusted root CA, or by qualified subordination.

**User Experience Changes in Moving to Forest Trusts from External Trusts**

There may be certain changes in the user experience after the move to forest trusts. To minimize these changes and ensure that there is a consistent experience, you may want to upgrade to the latest service pack on computers that are running Windows XP, Windows 2000, or Windows NT Server 4.0; you may also want to deploy the appropriate hotfixes. The following list describes the impact of the service packs and hotfixes:

- Windows logons and authentication: When users log on to computers that are joined to a forest other than the forest where their user account is located, they do not see their account domain listed in the logon dialog box. The user has to type their user principal name (UPN) in the dialog box. This could be the implicit UPN suffix (*user_ID@DNS_domain_name.com*) or a UPN suffix that is explicitly defined by the administrator, such as someone@fabrikam.com. If you want to log on with the Windows NT Server 4.0 style name, you should apply the corresponding hotfix to the computer. Note that domains that are in other forests are not displayed in the logon box; you have to type the name as *domain\user* in the logon box. If your users are not currently using UPNs to log on, have them use the Windows NT Server 4.0 style so that the user logon experience is consistent.

- Authorization: On computers that are not running either Windows Server 2003 or Windows XP Service Pack 2 (SP2), you cannot browse principals in another forest to add them to DACLs and groups. Instead, you can type the UPN or Windows NT Server 4.0 name for the principal that is in the other forest. On computers that are running either Windows Server 2003 or Windows XP SP2, you can browse and search principals that are in the other forest. You must run either Windows 2000 Service Pack 4 (or the hotfix that is specified below) or Windows XP to resolve principals in the Object Picker tool that are in the other forest by using UPN names or Windows NT Server 4.0 names. On computers that are running Windows NT Server 4.0, you can type the Windows NT Server 4.0 style name for the user who is in the other forest. On computers that are running Windows 95, Windows 98, or Windows Millennium Edition (Me), you can choose the domain from which you want to browse for users, and then you can select the user. Microsoft Exchange Server 5.5 administrators and Microsoft SQL Server 2000 administrators have to explicitly type the Windows NT Server 4.0 style name when they want to select Windows users so that they can add the users, associate the users with a mailbox, and then enable SQL server logon. Note that you cannot browse for the users who are in the other forest.

The following tables describe the general user experience when they move to forest trust from external trust.

**Logons and Authentication**

| | **Windows 95, Windows 98, Windows Me** | **Windows NT Server 4.0** | **Windows 2000** | **Windows XP** | **Windows Server 2003** |
|---|---|---|---|---|---|
| **Logon box** | No change | Add the hotfix that enables the Windows NT Server 4.0 style name | Logon with the UPN name and add the hotfix that enables the Windows NT Server 4.0 style name | Logon with the UPN name and add the hotfix that enables the Windows NT Server 4.0 style name | Logon with the UPN name and add the hotfix that enables the Windows NT Server 4.0 style name |

# Enabling Multiple Forest Scenarios in Windows Server 2003

Updated: July 31, 2004

Applies To: Windows Server 2003 with SP1

The Windows Server 2003 technologies that are discussed in the previous section each help to enable a specific functionality across multiple forests. Note that these technologies are limited to trust management, authentication, and authorization problems.

You must use other technologies and tools to address other parts of the problem, such as synchronization of address books, user migration, DNS configuration, and so on. The following section describes how you can use each of the technologies that are discussed in this paper to enable the scenarios for multiple forests that were discussed earlier in this document. It also provides pointers to the other tools that you must use to solve the other parts of the problem.

**Multiple Forests That Are in the Same Corporation**

The first step that you should use when you want to deploy multiple forests in the same corporation is to ensure that you can perform DNS lookups from one forest to look up the domain controllers that are in the other forest. If the forests already use the same DNS infrastructure, then you do not need to perform any of the additional work. If the forests do not use the same DNS infrastructure, you can either merge the DNS infrastructures or you can use conditional forwarding.

After you configure DNS, set up a bidirectional forest trust between the contoso.com and hr.contoso.com forests. Because plant.contoso.com does not contain any user accounts that need to gain access to resources that are in the other forest, a trust that is one way is set up by the administrator to each of the other forests. You should not enable the **Selective Authentication** option in this scenario because there are a considerable number of users in each of the forests who need to gain access to resources that are in the other forests, and because the administrators for each forest feel more comfortable treating the users who are in the other forest as authenticated users. In addition, the users who are in the contoso.com forest should be able to look up users who are in the hr.contoso.com forest when they use the Exchange Server address books for sending e-mail messages. You can do this by using Microsoft Metadirectory Services (MMS) to synchronize the address books for both forests.

Because the hr.contoso.com forest trusts the plant.contoso.com forest for the plant.contoso.com TopLevelName and because the hr.contoso.com forest also trusts the contoso.com forest for the contoso.com TopLevelName, there is a namespace collision because the TopLevelName record for contoso.com also includes plant.contoso.com. To remove this collision, you must exclude the plant.contoso.com namespace from the contoso.com forest trust. You can do this by setting a TopLevelName exclusion record in the FTInfo record for the hr.contoso.com forest for its trust to contoso.com. Similarly, you must set up another exclusion record in the plant.contoso.com forest to exclude the hr.contoso.com namespace from the trust to the contoso.com forest. However, you do not need to set up an exclusion record in contoso.com because the plant.contoso.com and hr.contoso.com namespaces do not overlap.

In addition, the administrator for the contoso.com forest also does not want to trust the test.hr.contoso.com domain, which is a test domain in the hr.contoso.com forest. Because of this, the administrator can disable the DomainInfo record for the test.hr.contoso.com domain that is in the trust record for hr.contoso.com. When you do this, you ensure that the authentication that is performed by the test.hr.contoso.com domain is not accepted by contoso.com. Note that it is easier for you to use the **Explicit Deny** option that is in the forest trust, instead of the **Selective Authentication** option that is in this scenario because you want to prevent authentication for all principals that are in a specific domain that is in a trusted forest to any resource that is in the trusting forest. Note also that you disable authentication requests that are from users in a domain when you disable the DomainInfo record for a particular domain that is in a trusted forest. When you do this, authentication to resources that are in that domain are not disabled.

**Figure 6: Multiple Forests That Are in the Same Corporation Deployment**

**Multiple Forests That Are in Different Corporations**

Unique challenges are presented when you want to deploy multiple forests that are in different corporations. Not only do the trusts have to traverse firewalls, but you have to ensure that all of the resources are well managed so that users from another forest do not accidentally gain access to resources that they are not supposed to see.

In this scenario, Fabrikam and Contoso establish a forest trust. Each company also enables the **Selective Authentication** option. When the administrators enable the **Selective Authentication** option, the authentications that occur across the trust do not work automatically. The administrators must explicitly enable authentications across the trust. The administrator for the Contoso forest then sets a DACL on the marketing group's file server computer account so that members of the marketing group who are in the Fabrikam forest can authenticate to it. After this procedure, the administrator sets another DACL on the service account for the Web server so that all users who have the Authenticated Users SID can authenticate to it. The administrator of the Contoso forest configures the contoso.com forest in the same way that the Fabrikam administrator configured fabrikam.com. Note that one of these forests may be an extranet forest.

The administrators for both Contoso and Fabrikam create the trust independently by using the Netdom tool (Netdom.exe). After the administrators create the trusts, they try to validate the trust so that the Netlogon fixed port and the RPC Endpointmapper port can be opened (between the domain controllers in each domain) for this operation. The administrators can close the ports after the trust is validated. The administrators for both Contoso and Fabrikam then create the following firewall rules.

| Rule name | Port | Source | Destination |
|---|---|---|---|
| **Kerberos authentication inbound** | 88 (UDP, TCPinbound) | Other corporation's subnet | This corporation's domain controllers |
| **Kerberos authentication outbound** | 88 (UDP,TCPoutbound) | This corporation's subnet | Other corporation's domain controllers |
| **Inbound DACL lookups** | 88 (UDPinbound), 389 (TCP,UDPinbound), 135 (TCPinbound), NTDS fixed port (TCPinbound), Netlogon fixed port (TCPinbound) | Other corporation's subnet | This corporation's domain controllers |
| **Outbound DACL lookups** | 88 (UDPoutbound), 389 (TCP,UDPoutbound), 135 (TCPoutbound), NTDS fixed port (TCPoutbound), Netlogon fixed port (TCPoutbound) | This corporation's subnet | Other corporation's domain controllers |

Firewall rules enable authentication and lookups to work between both the corporations. Note that the administrators can also choose to have an Internet Protocol Security (IPSec) tunnel for the traffic that is described in the previous table by opening only the ports for IPSec. Most of the default Windows services use the negotiate package which first uses Kerberos for authentication and then uses NTLM when certain authentications do not work. If you also need NTLM authentication, you need to open the appropriate ports. These ports are specified in the "List of Ports" section in Appendix A in this document.

**Figure 7: Multiple Forests That Are in Different CorporationsDeployment**

**Perimeter Network Scenario**

In a perimeter network (also known as a DMZ, demilitarized zone, and screened subnet) forest, a trust that is one way from the perimeter network forest to the contoso.com corporate forest is established. This allows the users in the internal forest to be able to gain access to the resources in the perimeter network forest with their internal forest accounts. In this scenario, a two-way trust is not recommended, because compromise of the perimeter network forest will then provide a malicious user with an entry point into the corporate forest. Because of this, the administrator creates the following firewall rules.

| Rule name | Port | Source | Destination |
|---|---|---|---|
| **Trust creation** | 88 (UDP,TCPoutbound), 389 (UDP, TCPoutbound), 445 (TCPoutbound) | Other corporation's subnet | This corporation's domain controllers |
| **Kerberos authentication outbound** | 88 (UDP,TCPoutbound) | This corporation's subnet | Perimeter network domain controllers |
| **Inbound DACL lookups** | 88 (UDP,TCPinbound), 389 (TCP,UDPinbound), 135 (TCPinbound)<br><br>NTDS fixed port (TCPinbound), Netlogon fixed port (TCPinbound) | Perimeter network subnet | Internal domain controllers |

In this table:

- The "trust creation" rule needs to be applied by the administrator only when the trust is initially created. This rule allows trust creation for both domains from the internal forest and is immediately disabled after you create the trust.
- The "Kerberos authentication outbound rule" is always applied by the administrator to allow internal users to authenticate to the perimeter network forest.
- The "inbound DACL lookups" rule is applied by the administrator only when there needs to a change to the domain local groups in the perimeter network to add either global or universal groups from the internal forest. These changes should be minimal.

**Figure 8: Perimeter Network ScenarioDeployment**

# Walkthroughs

Updated: July 31, 2004

Applies To: Windows Server 2003 with SP1

The following sections provided the detailed implementation steps that you can use to set up federated forests.

**Walkthrough Setup**
The structure of the forests that are described in this walkthrough are detailed in the following figure.

**Figure 9: Walkthrough Infrastructure**

Each domain has one domain controller and the names of the domain controllers are CORP-DC-01, NW-DC-01, and MARKETING-DC-01. Both the CORP-DC-01 and NW-DC-01 domain controllers host the Active Directory-integrated DNS server for their respective forests.

**Creating a Forest Trust**
Before you begin this process, ensure that all of the domain controllers are running Windows Server 2003. To create a forest trust, use the methods in this section to perform the following tasks:

- Prepare both forests for the trust
    - Configure DNS
    - Raise the forest and all of the domains to the Windows Server 2003 functional level
- Create the forest trust on contoso.com
- Create the forest trust on nwtrader.com

**Configure DNS**
This section provides the steps that you can use to configure DNS for a forest trust.

**Scenario**
The administrators for both the Northwind Traders and Contoso corporations want to establish network connectivity between the two forests by configuring DNS. The Active Directory-integrated DNS zones for each forest are located in the respective root domains.

To configure DNS:

1. Log on to the corp.contoso.com domain with administrative privileges.
2. Configure DNS:
    - Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **DNS**.
    - Right-click **CORP-DC-01** and then click **Properties**.

- Click **New** on the **Forwarders** tab, type **nwtraders.com**, and then click **OK**.
- Type the IP address of the Northwind Traders DNS server (for example, type **10.1.1.2**), and then click **Add**.

3. Verify connectivity:

   - Click **Start**, click **Run**, type **cmd** in the **Open** box, and then press ENTER.
   - Type **ping nwtraders.com** at a command prompt, and then press ENTER.
   - You receive a reply.

**Raise All of the Domains and Forests to the Windows Server 2003 Functional Level**

This section describes how to raise the forest functional level to Windows Server 2003, which is required for forest trust to be established. To do this, you must first raise the domain functional level for each domain that is in the forest to the Windows Server 2003 functional level. After you raise all of the domains in the forest to the Windows Server 2003 functional level, you can raise the forest to the Windows Server 2003 functional level.

**Scenario**

The administrators for the Northwind Traders and Contoso corporations want to raise their forests to the Windows Server 2003 functional level to establish a forest trust.

To raise all of the domains and the forest to the Windows Server 2003 functional level:

**On the domain controller in the corp.contoso.com domain:**

1. Set the corp.contoso.com domain functional level to Windows Server 2003 by using the Active Directory Domains and Trusts MMC Snap-in:

   - Log on to the corp.contoso.com domain with administrative privileges.
   - Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Domains and Trusts**.
   - Right-click **corp.contoso.com** and then click **Raise Domain Functional Level**.
   - In the **Select an available domain functionality** list, click **Windows Server 2003**, click **Raise**, click **OK**, and then click **OK**.

2. Set the forest functional level to Windows Server 2003 by using the Active Directory Domains and Trusts MMC Snap-in:

   - Log on to the corp.contoso.com domain with administrative privileges.
   - Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Domains and Trusts**.
   - Right-click **marketing.contoso.com**.
   - Click **Raise Domain Functional Level**.
   - In the **Select an available domain functionality** list, click **Windows Server 2003**, click **Raise**, click **OK**, and then click **OK**.

3. Set the forest functional level to Windows Server 2003 by using the Active Directory Domains and Trusts MMC Snap-in:

- Log on to the corp.contoso.com domain with administrative privileges.
- Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Domains and Trusts**.
- Right-click **Active Directory Domains and Trusts** and then click **Raise Forest Functional Level**.
- In the **Select an available domain functionality** list, click **Windows Server 2003**, click **Raise**, click **OK**, and then click **OK**.

**On a domain controller in the nwtraders.com domain:**

1. Set the nwtraders.com domain functional level to Windows Server 2003 by using the Active Directory Domains and Trusts MMC Snap-in:

   - Log on to the nwtraders.com domain with administrative privileges.
   - Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Domains and Trusts**.
   - Right-click **Nwtraders.com** and then click **Raise Domain Functional Level**.
   - In the **Select an available domain functionality** list, click **Windows Server 2003**, click **Raise**, click **OK**, and then click **OK**.

2. Set the forest functional level to Windows Server 2003 by using the Active Directory Domains and Trusts MMC Snap-in:

   - Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Domains and Trusts**.
   - Right-click **Active Directory Domains and Trusts** and then click **Raise Forest Functional Level**.
   - In the **Select an available domain functionality** list, click **Windows Server 2003**, click **Raise**, click **OK**, and then click **OK**.

**Implementing Trusts Across Forests**

This section describes how to implement forest trusts.

**Enabling Authentication and Authorization Across the Forest**

The administrators for both the Northwind Traders and Contoso corporations want to enable authentication and authorization across both forests. Both of the companies want users in their forest to be able to seamlessly gain access to resources in the other forest, without having to type a new user name and password. Because of this, the companies must establish a two-way trust across the forest.

To enable authentication and authorization across the forest:

- Verify connectivity to the Nwtraders.com domain:

  - Log on to the corp.contoso.com domain.
  - Click **Start**, click **Run**, type **cmd** in the **Open** box, and then press ENTER.
  - Type **ping nwtraders.com** at a command prompt, and then press ENTER.
  - You receive a reply.

- Create the forest trust:
    - Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Domains and Trusts**.
    - Right-click **corp.contoso.com** and then click **Properties**.
    - Click the **Trusts** tab, click **New Trust**, and then click **Next** in the Trust Creation Wizard.
    - In the **Name** box, type the name of the forest to which you want to configure the trust (in this sample scenario, type **nwtraders.com**), and then click **Next**.
    - Click **Forest Trust**, and then click **Next**. If **Forest Trust** is not an option, verify that you raised the forest functional level to Windows Server 2003 by reviewing the steps in the previous section.
    - Click **Two Way**, and then click **Next**.
    - Click both the **This Domain** domain and the **Specified Domain** domain, and then click **Next**.
    - In the credentials dialog box for the nwtraders.com domain, type both the user name (**administrator**) and password (**nwtraders**), and then click **Next**.

      Note that you must have trust-creation privileges in the domain to create the trust.
    - Click **Allow authentication for all resources in the local forest**, and then click **Next**.
    - Click **Allow authentication for all resources in the Nwtraders.com forest**, and then click **Next**.

      Note that the **Selective Authentication** option for both sides of the trust is disabled when you do this. You will enable the **Selective Authentication** option in the next section.
    - Review the changes that are listed, and then click **Next** to approve the changes.
    - Click **Yes, confirm outgoing trust**, and then click **Next**.
    - Click **Yes, confirm outgoing trust**, and then click **Next**.
    - When the dialog box that lists the name suffixes that you want to route is displayed, do not make any changes. Click **Next**, click **Finish**, and then click **OK**.
- Create a file share in the Marketing.contoso.com domain, and then assign permissions to the share:
    - On the Marketing-DC-01 server, create a folder named Marketingshare, create a Sampletext.txt file with some text by using a text editor (such as Notepad), and then save the Sampletext.txt file in the C:\Marketingshare folder.
    - Right-click the **MarketingShare** folder and then click **Sharing and Security**.
    - Click **Share this folder**, and then click **Permissions**.
    - Click **Add** in the **Group or user names** box, type **administrator@nwtraders.com**, and then click **OK**.
    - Click **administrator@nwtraders.com** in the **Group or user names** box, and then click to select all of the check boxes in both the **Change** and **Read** boxes.
    - Click **Everyone** in the **Group or user names** box, and then click **Remove**.

Note that you cannot grant permissions by adding the user directly to the DACL file share when you use this procedure; however, you can create a domain local group to grant permission to the share and add the remote forest groups to this domain local group. You will directly add the users to the DACL in this section. More information about group membership rules is provided in the following section.

- Verify that you can gain access to the Marketing-DC-01 domain and the SampleText.txt file that you created:
  - Log on to the NW-DC-01 server with administrative privileges.
  - Click **Start**, click **Run**, type **\\Marketing-DC-01\Marketingshare** in the **Open** box, and then press ENTER.
  - Double-click the **Sampletext.txt** file to confirm that you can open and read the file. If you cannot open the file, verify that the permissions are properly assigned.
  - Create a Sampletext2.txt file in a text editor, such as Notepad, and then save the file to the \\Marketing-DC-01\Marketingshare folder to verify that you can save a file to the share.

**Adding an Alternate Name Suffix**

The administrators for the contoso.com forest want to add an alternate name suffix that corresponds to the users e-mail names. This allows the users to log on to the network with their e-mail names, such as user@e-mail.contoso.com. The suffix must be recognized in the other forest for the users to be able to use it.

Use the following steps to add an alternate name suffix, to add the name suffix to the user's UPN name, and then to enable routing to the alternate name suffix:

- Add an alternate name suffix to the corp.contoso.com domain:
  - Click **Start**, point to **All Programs**, and then click **Administrative Tools**.
  - Right-click **Active Directory Domains and Trusts** and then click **Properties**.
  - Type **e-mail.contoso.com** in the **Alternative UPN suffixes** box, and then click **Add**.
- Add the alternate name suffix to a users UPN in the corp.contoso.com domain:
  - Create a user with a **testuser** user login name in the corp.contoso.com domain. For more information about how to do this, see the Windows 2000 Server home page (http://go.microsoft.com/fwlink/?LinkId=145492).
  - In the Active Directory Users and Computers tool, right-click **testuser**, and then click **Properties**.
  - Click the **Account** tab, type **testuser** in **User logon name** box, and then click **e-mail.contoso.com** in the **Domain** box.
- Enable routing to the alternate name suffix in the nwtraders domain:
  - Log on to the nwtraders.com domain with administrative privileges.
  - Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Domains and Trusts**.
  - Right-click **nwtraders.com** in the left pane, and then click **Properties**.
  - Click the **Trusts** tab, click **corp.contoso.com** in the **Domains trusted by this domain (outgoing trusts)** box, and then click **Properties**.
  - Click the **Name Suffix Routing** tab, click ***.e-mail.contoso.com** in the **Name Suffixes** box that is in the corp.contoso.com forest.

- Click **Enable**, click **OK**, and then click **OK**.

**Excluding a Domain from a Trust Relationship**

The administrators for the nwtraders.com forest no longer want a trust relationship with the marketing.contoso.com subdomain, so the administrators want to exclude that domain from the trust relationship.

To exclude a domain from a trust relationship:

- Create a file share in the nwtraders.com domain:
    - Log on to the nwtraders.com domain with administrative privileges.
    - Click **Start**, point to **All Programs**, point to **Accessories**, and then click **Windows Explorer**.
    - Click the %SystemRoot% folder (the folder where Windows is installed) in the left pane, right-click an empty space in the right pane, point to **New**, click **Folder**, and then type **nwshare** for the folder name.
    - Right-click the **Nwshare** folder that you created in the right pane, and then click **Sharing and Security**.
    - Click **Share this folder**, click **Permissions**, and then click **Add**.
    - Type **administrator@marketing.contoso.com** in the **Enter the object names to select** box, and then click **OK**.
    - Click **Administrator@marketing.contoso.com** in the **Group or user names** box, click **Change** in the **Allow** column in the **Permissions for Administrator@marketing.contoso.com** box, click **Read** in the **Allow** column in the **Permissions for Administrator@marketing.contoso.com** box, and then click **OK**.
    - Click **Everyone** in the **Group or user names** box, click **Remove**, and then click **OK**.
    - Confirm that you can gain access the Nwshare folder from the marketing.contoso.com share while you are logged on to the computer with administrative privileges. To do this, Click **Start**, click **Run**, type **\\NW-DC-01\Nwshare** in the **Open** box, and then press ENTER.
- Disable the DomainInfo record for marketing.contoso.com in the nwtraders.com domain:
    - Log on to the nwtraders.com domain with administrative privileges.
    - Click **Start**, point to **All Programs**, point to **Administrator Tools**, and then click **Active Directory Domains and Trusts**.
    - Right-click **nwtraders.com** in the left pane, and then click **Properties**.
    - Click the **Trusts** tab, click **corp.contoso.com** in the **Domains trusted by this domain (outgoing trusts)** box, and then click **Properties**.
    - Click the **Name Suffix Routing** tab, click **marketing.contoso.com**, and then click **Disable**.

**Setting Up a TopLevelName Exclusion Record**

The administrators for the contoso.com forest want to set up a trust relationship with the nwtraders.com forest for all of the namespaces that are in nwtraders.com, except for plant.nwtraders.com. Note that the plant.nwtraders.com forest is a hypothetical forest that is not used in this sample scenario because it is in a different location and because the administrators for the contoso.com forest want to set up a trust relationship with it.

To set up a TopLevelName exclusion record:

- Log on to the corp.contoso.com domain controller with administrative privileges.
- Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Domains and Trusts**.
- Right-click **corp.contoso.com** in the left pane, and then click **Properties**.
- Click the **Trust** tab, right-click **Nwtraders.com** in the **Domains trusted by this domain (outgoing trusts)** box, and then click **Properties**.
- Click the **Name Suffixes to exclude from routing to nwtraders.com** tab, click **Add**, type ***.plant.nwtraders.com**, click **OK**, and then click **OK**.

**The Selective Authentication Option**

The administrators for the Contoso company have decided that they cannot allow every user in the Northwind Traders forest to authenticate in their forest because of security constraints. The Contoso company administrators want to allow only members of the Enterprise Admins group from the other forest to be able to authenticate, but only to the marketing.contoso.com domain.

To enable the Selective Authentication option:

- Turn on the **Selective Authentication** option in corp.contoso.com to enable only selective authentication from nwtraders.com
    - Confirm that you are logged on to the corp.contoso.com domain with administrative privileges.
    - Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Domains and Trusts**.
    - Right-click **corp.contoso.com** in the left pane, and then click **Properties**.
    - Click the **Trusts** tab, right-click **Nwtraders.com** in the **Domains trusted by this domain (outgoing trusts)** box, and then click **Properties**.
    - Click the **Authentication** tab, click **Allow authentication only to selected resources in the local forest**, click **OK**, and then click **OK**.
- Create a file share in the marketing.contoso.com domain, and then assign permissions to the share:
    - On the Marketing-DC-01 computer, click **Start**, point to **All Programs**, point to **Accessories**, and then click **Windows Explorer**.
    - Click **Local Disk (C:)** in the left pane, right-click a blank area in the right pane, point to **New**, click **Folder**, and then type **Testfolder** for the name of the new folder.
    - Double-click the new **Testfolder** folder in the right pane to open the folder, right-click a blank area, point to **New**, click **Text Document**, and then type **Testdoc.txt** for the name of the document.
    - Right-click the **Testfolder** folder in the left pane, and then click **Sharing and Security**.
    - Click **Share this folder**, click **Permissions**, click **Add**, and then type **administrator@nwtraders.com**.
    - Click **Administrator@nwtraders.com** in the **Group or user names** box, click **Change** in the **Allow** column in the **Permissions for Administrator@ nwtraders.com** box, click **Read** in the **Allow** column in the **Permissions for Administrator@ nwtraders.com** box, and then click **OK**.
    - Click **Everyone** in the **Group or user names** box, and then click **Remove**.

- Verify that you cannot gain access to Marketing.contoso.com from Nwtraders.com:
    - Log on to the NW-DC-01 computer with administrative privileges.
    - Click **Start**, click **Run**, type **\\marketing-dc-01\marketingshare** in the **Open** box, and then press ENTER.

      You should not be able to gain access to the share because you enabled the **Selective Authentication** option. If you can gain access to the share, verify that the permissions are properly configured.
- Enable the **Selective Authentication** for Marketing-DC-01:
    - Log on to the marketing.contoso.com computer with administrative privileges.
    - Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
    - Click **Advanced Features** on the **View** menu, and then click **Domain Controllers** in the left pane.
    - Right-click **MARKETING-DC-01** in the right pane, and then click **Properties**.
    - Click the **Security** tab, click **Add**, type **administrator@nwtraders.com**, and then click **OK**.
    - Click **Administrator@nwtraders.com** in the **Group or user names** box, and then click to select the **Allowed to Authenticate** check box in the **Allow** column that is in the **Permissions for Administrator@nwtraders.com** box.

      After you do this, the administrator@nwtraders.com user can authenticate to the NW-DC-01 computer.
- Verify that you can gain access to marketing.contoso.com from nwtraders.com:
    - Log on to the NW-DC-01 computer with administrative privileges.
    - Click **Start**, click **Run**, type **\\marketing-dc-01\marketingshare** in the **Open** box, and then press ENTER.

      You can now gain access to the share.

**Configuring ISA Server 2000 to Enable Forest Trust Across Firewalls**

This section describes how to configure Microsoft Internet Security and Acceleration (ISA) Server 2000 to enable trust and authentication across the firewall.

**Setting Up the Trust**

It is recommended that you set up the trust for both forests from the internal computer because this method requires connections from only the internal network of the firewall to the outside when you set up the trust. To do this, start the ISA Server Firewall client to allow traffic from the internal domain controller to the external domain controller on both the LDAP (389 UDP and TCP) and Microsoft SMB (445 TCP) ports. You need to do this only to set up the forest trusts, so you can close the ISA Server Firewall client after you set up the trust relationship. You also need to add another rule to allow Kerberos (88 UDP) traffic. You must keep this rule so that authentication requests can pass through the firewall. To use this procedure on the ISA Server SP1 Firewall client:

1. Click **Start**, point to **All Programs**, point to **Microsoft ISA Server**, and then click **ISA Management**.
2. In the console pane, click to expand **Servers and Arrays**, click to expand your server, click to expand **Access Policy**, click **Protocol Rules**, and then, in the results pane, click **Create a Protocol Rule**.
3. Type a name for the rules, such as **allow xforest setup**, and then click **Next**.

4. Click **Allow**, and then click **Next**.

5. In the **Apply this rule to list** box, click **Selected protocols**, click to clear the **Show only selected protocols** check box, click to select the **Kerberos-Sec(UDP)** check box, and then click to select the **LDAP** check box, and then click **Next**.

6. In the **Use this schedule** box, click **Always**, and then click **Next**.

7. In the **Apply this rule to requests from** box, click **Any request**, click **Next**, and then click **Finish**.

8. Create protocol definitions for both Microsoft-DS and LDAP UDP, which are not defined by default:

    - After you create the new rule in step 1 through step 7, double-click the rule in the results pane, click the **Protocol** tab, and then click **New**.

    - In the **Properties** dialog box for the rule, type a name for your rules, such as **LDAP UDP**.

    - In the **Port number** box, type **389**.

    - In the **Protocol type** box, click **UDP**.

    - In the **Direction** box, click **Receive Send**, and then click **OK**.

9. Add a protocol definition for Microsoft-DS:

    - In the results pane, double-click the rule that you created in step 1 through step 7, click the **Protocol** tab, and then click **New**.

    - Type a name for your rules, such as **microsoft-ds outbound**.

    - In the **Port number** box, type **445**.

    - In the **Protocol type** box, click **TCP**.

    - In the **Direction** box, click **Outbound**, click **OK**, and then click **OK**.

10. After you create the rule, restart the firewall service to start the rule:

    - In the ISA Management Console, click to expand **Servers and Arrays**, click your server, and then click **Monitoring**, and then click **Services**.

    - In the results pane, click the **Firewall** service, click **Stop a Service**, and then click **Yes**.

    - In the results pane, click the **Firewall** service, click **Start a Service**, and then click **Yes**.

11. Set up the trust across the forest from the internal computer by following the steps that are in the "Implementing Trusts Across Forests" section earlier in this document.

12. Remove the trust setup rules because you no longer need them.

13. In the console tree, click to expand **Servers and Arrays**, click your server, click **Access policy**, and then click **Protocol rules**.

14. Double-click **Allow xforest setup**, and then click to clear the **Enable** check box.

15. Use the procedure in step 8 to restart the firewall service so that the rule is removed.

**Trust Validation and Network Logons**

If you want trust validation and network logons to shares on the external computer, you must open up certain ports. In protocol rules, you must open the LDAP UDP, Kerberos sec UDP, Any RPC server, DCE endpoint resolution outbound, and Microsoft-DS outbound ports. In addition, you must also publish both the LDAP UDP and Any RPC server ports on the internal forest domain controller. To do this:

1. Click **Start**, point to **All Programs**, point to **Microsoft ISA Server**, and then click **ISA Management**.

2. In the console tree, click to expand **Servers and Arrays**, click to expand your server, click to expand **Access policy**, and then click **Protocol rules**.

3. Click **Create a Protocol Rule**.

4. Type a name for the rules (such as **allow xforest validation**), click **Next**, click **Allow**, and then click **Next**.

5. In the **Apply this rule to** list, click **Selected protocols**, and then click to clear the **Show only selected protocols** check box.

6. Click to select all of the following check boxes:

   - **Any RPC server**
   - **Kerberos-Sec(UDP)**
   - **LDAP UDP**
   - **MS-DS outbound**

7. Confirm that the check boxes for the four definitions that you created (DCE Endpoint resolution, LDAP TCP inbound, LDAP UDP inbound, and Kerberos UDP inbound) are selected, confirm that the remaining check boxes are cleared, and then click **Next**.

8. Choose a schedule for your rule, and then click **Next**.

9. Choose to either make this rule applicable to only a specific client set or applicable to all of the clients, click **Next**, and then click **Finish**.

10. The protocol definitions for DCE endpoint resolution, LDAP TCP inbound, LDAP UDP inbound, and Kerberos UDP inbound are not available by default, so you must create them. Note that both LDAP UDP inbound and Kerberos UDP inbound are used only in the next section. To create the protocol definitions:

    - Add a protocol definition for DCE Endpoint resolution:

      In the results pane, double-click the rule, click the **Protocol** tab, and then click **New**.

      Type a name for your rules, such as **dce endpoint resolution outbound**.

      In the **Port number** box, type **135**.

      In the **Protocol type** box, click **TCP**.

      In the **Direction** box, click **Outbound**, and then click **OK**.

- Add a protocol definition for LDAP TCP inbound:

  In the results pane, double-click the rule, click the **Protocol** tab, and then click **New**.

  Type a name for your rules, such as **LDAP TCP inbound**.

  In the **Port number** box, type **389**.

  In the **Protocol type** box, click **TCP**

  In the **Direction** box, click **Inbound**, and then click **OK**.

- Add a protocol definition for LDAP UDP inbound:

  In the results pane, double-click the rule, click the **Protocol** tab, and then click **New**.

  Type a name for your rules, such as **LDAP UDP inbound**.

  In the **Port number** box, type **389**

  In the **Protocol type** box, click **UDP**.

  In the **Direction** box, click **Receive Send**, and then click **OK**.

- Add a protocol definition for Kerberos UDP inbound:

  In the results pane, double-click the rule, click the **Protocol** tab, and then click **New**.

  Type a name for your rules, such as **kerberos UDP inbound**.

  In the **Port number** box, type **88**

  In the **Protocol type** box, click **UDP**.

  In the **Direction** box, click **Receive Send**, and then click **OK**.

11. Publish the ports for the inbound connection:

- In the console tree, click to expand **Publishing**, and then click **Server Publishing Rules**.

- Click **Publish a Server**, type a name for the server (such as **LDAP UDP**), and then click **Next**.

- Type the IP address for the server that you want to publish, type the IP address for the external interface through which the external server will contact the internal server, and then click **Next**.

- Click the appropriate protocol (such as **LDAP UDP inbound**), and then click **Next**.

- Click **Specific computers**, and then click **Next**.

- Click **Add**, add a client set for the IP address for the external server, and then click **OK**.

- Click the client set, click **OK**, click **Next**, and then click **Finish**.

  Repeat above steps to publish the server for the "Any RPC server" rule.

**Object Picker: Allowing a Service Administrator to Set Up DACLs**
For Object Picker to work, you must publish Any RPC server, LDAP UDP inbound, LDAP TCP inbound, and Kerberos UDP inbound. When you do this, you can look up and add objects in the internal forest to DACLs that are in the external forest.

**Separately Setting Up the Trust in the Forests**
This method is not recommended and is only advisable if you cannot create the trust in both forests from the internal server. This involves publishing ports on the internal domain controller to allow the forest to make connections to it. You can create the trust on the forest that is on the internal side of the firewall by using the procedures that are in the previous section (set up the trust in both forests). To create the trust on the forest on the external side of the firewall, publish the following ports on the internal server domain controllers:

- Microsoft-DS (port 445)
- LDAP TCP (port 389)
- LDAP UDP (port 389)
- Kerberos-sec UDP (port 88)
- You can publish a server for each of these ports if you use the steps that are in the previous section.

Note that because the local Direct Host SMB service uses port 445 on the firewall by default, you must disable the service first. To do this, either set or create the registry key DWORD value to zero (0) in the following registry key, and then restart the computer:

**HKEY_LOCAL_MACHINE\SYSTEM\CCS\Services\NetBT\Parameters\SMBDeviceEnabled**

After you do this, the ISA Server firewall client can bind to port 445 and forward packets to the internal server.

**Error Messages**
You may receive the following error messages when you try to set up trusts across firewalls:

- **Specified domain is not a Windows domain name.**

  You may receive this error message if one domain controller cannot locate the other domain controller. DNS is not properly set up.

- **Parameter is invalid.**

  The LDAP UDP port is not open.

- **Access Denied.**

  The Kerberos port is not open, or the remote password is incorrect.

- **RPC server unavailable.**

  The Microsoft-DS port is not open.

- **Cannot query the forest functionality level. The forest is not operational.**

  The LDAP TCP port is not open.

- **The Endpointmapper does not have any more end points.**

  Either the NTDS or Netlogon port is not open.

  The Kerberos port is not open or the remote password is incorrect.

- **Unspecified error.**

Verify that the Endpointmapper port is open.

**Removing the Forest Trust**

The administrators for the Contoso company no longer need the trust across the forest.

In this scenario, you will remove the forest trusts. To remove the forest trusts:

1. Log on to the corp.contoso.com domain with administrative privileges.

2. Click **Start**, point to **All Programs**, point to **Administrative Tools**, and then click **Active Directory Domains and Trusts**.

3. Right-click **corp.contoso.com** in the left pane, and then click **Properties**.

4. Click the **Trusts** tab, right-click **nwtraders.com** in the **Domains trusted by this domain (outgoing trusts)** box, and then click **Remove**.

5. Click **Yes, remove the trust from the local domain and the other domain**.

6. Type **Administrator** in the **User name** box, and then type the password in the **Password** box.

7. Click **Yes**, and then choose the option to remove the trust.

Repeat step 4 through step 7 to remove the incoming trust in the **Domains that trust this domain (incoming trusts)** box.

# Appendix A: List of Ports

Updated: July 31, 2004

Applies To: Windows Server 2003 with SP1

The following tables shows the list of ports that you must open before you set up trusts.

| Scenario | Outbound Ports | Inbound Ports | From - To |
|---|---|---|---|
| Trust setup on both sides from the internal forest | LDAP (389 UDP and TCP)<br>Microsoft SMB (445 TCP)<br>Kerberos (88 UDP)<br>Endpoint resolution portmapper (135 TCP) Netlogon fixed port | | Internal domain domain controllers External domain domain controllers (all ports) |
| Trust validation from the internal forest domain controller to the external forest domain controller (outgoing trust only) | LDAP (389 UDP)<br>Microsoft SMB (445 TCP)<br>Endpoint resolution portmapper (135 TCP) Netlogon fixed port | | Internal domain domain controllers External domain domain controllers (all ports) |
| Object picker on the external forest to add objects that are in internal forest to groups and DACLs | | LDAP (389 UDP and TCP)<br>Windows NT Server 4.0 directory service fixed port<br>Netlogon fixed port<br>Kerberos (88 UDP)<br>Endpoint resolution portmapper (135 TCP) | External server Internal domain PDCs (Kerberos)<br>External domain domain controllers Internal domain domain controllers (Netlogon) |
| Setup trust on the external forest from the external forest | | LDAP (389 UDP and TCP)<br>Microsoft SMB (445 TCP)<br>Kerberos (88 UDP) | External domain domain controllers Internal domain domain controllers (all ports) |
| Kerberos authentication (internal forest client to external forest) | Kerberos (88 UDP) | | Internal client External domain domain controllers (all ports) |
| NTLM authentication (internal forest client to external forest) | | Endpoint resolution portmapper (135 TCP) Netlogon fixed port | External domain domain controllers Internal domain domain controllers (all ports) |

| | | | |
|---|---|---|---|
| Domain join from internal computer to external domain | LDAP (389 UDP and TCP)<br><br>Microsoft SMB (445 TCP)<br><br>Kerberos (88 UDP)<br><br>Endpoint resolution portmapper (135 TCP) Netlogon fixed port<br><br>Windows NT Server 4.0 directory service fixed port | | Internal client External domain domain controllers (all ports) |

Configure the following keys to specify the services that you want to run on a fixed port:

1. LSA(Local Security Authority) RPC port (same as NTDS fixed port) used for trust creation and other access to the LSA Policy database TCP/IPPortentry in the **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters** registry key.

2. Netlogon RPC port used for NTLM, Trust channel DCTcpipPort entry in the **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters** registry key.

# Appendix B: Terms That Are Used in this White Paper

Updated: July 31, 2004

Applies To: Windows Server 2003 with SP1

The following terms are used in this white paper:

- **External trust**: A single trust link between two domains that are in separate forests. The external trust establishes nontransitive trust from domain to the other. These trusts have to be explicitly created and maintained by the administrator. The trusts can be one-way or two-way trusts.

- **Internal Trust**: A single trust link between two domains in the same forest. The internal trust establishes transitive trust between the two domains. For example, if Domain A trusts Domain B and Domain B trusts Domain C, then Domain A trusts Domain C. These trusts are created automatically when a new domain is added to the forest and are required for the forest to work. These trusts are always two-way trusts.

- **Forest trust**: A single trust link between the root domains of two forests. The forest trust establishes transitive trust between all of the domains in each forest. For example, if Forest A trusts Forest B, then all of the domains in Forest A trust all of the domains in Forest B through the forest trust. However, this trust is not transitive across forests. For example, if Forest A trusts Forest B and Forest B trusts Forest C, then Forest A does not automatically trust Forest C. These trusts can be one-way or two-way trusts.

- **Trusted domain object (TDO)**: An object present in Active Directory that represents the trust between two domains or forests.

- **Forest TDO**: An existing trust definition object that has a bit that is set to indicate forest trust.

- **Namespace**: A grouping of related names in which names can be used to symbolically represent another type of information (for example, security principals) and for which specific rules are established to determine which names belong in that namespaces. For example, a namespace might be "all names ending with contoso.com except for the names that end with a.contoso.com or b.contoso.com." Forests manage many namespaces that frequently look similar but are used to identify different types of objects, such as user principal names (UPNs), service principal names (SPNs), and domain names.

- **Top-level name (TLN)**: A name that is used to identify a namespace. For example, corp.fabrikam.com is the TLN that identifies the namespace that contains all of the names under corp.fabrikam.com, such as server.corp.fabrikam.com, server1.corp.fabrikam.com, server2.corp.fabrikam.com, and so on.

- **Top-level name exclusion (TLNEx)**: A record that excludes a part of the namespace. For example, a TLNEx of test.fabrikam.com on the fabrikam.com TLN specifies that the namespace consists of all of the names that are under fabrikam.com except for the names that are under test.fabrikam.com.

- **Forest trust information (FTInfo)**: The set of namespaces (identified by their TLNs) that a trusted forest claims to manage, annotated with a field that indicates whether each claim is actually trusted by the trusting forest. FTInfo is stored on the forest TDO and is used for routing authentication and authorization requests to trusted forests.

- **User principal name (UPN)**: A variation of a users name that looks like an e-mail name, but can be used for logon. The syntax is *user_name@string*.

- **Implicit UPN**: The implicit UPN is always of the *user_id@DNS_domain_name.com* form. This UPN is always associated with the users account, even if an explicit UPN is not defined.

- **Explicit UPN**: The explicit UPN is always of the *string@any_string* form, where both *string* and *any_string* are explicitly defined by the administrator.

- **UPN suffix**: A string that indicates the namespace from which a UPN is derived. A UPN suffix includes everything on the

right side of the at sign (@) in the full UPN. Everything on the left side of the at sign is considered part of the user name, even if the text contains another at sign. UPN suffixes can be either flat or hierarchical in structure, although they are typically used to identify flat namespaces.

- **Service principal name (SPN)**: A multicomponent name that is used to identify a service that is associated with a computer account. SPNs are typically used to request Kerberos service tickets. The syntax is *service_type/instance_name* [:*port_number*] [/*service_name* [@*domain*] ]. For example, host/server.contoso.com, MSSQLSvc/server.contoso.com:1433.

- **SPN suffix**: A string that indicates the namespace from which a component of an SPN is derived. An SPN suffix may consist of the trailing substring of the *instance_name* or *service_name* component. It may include all of the *domain* component, except for the at sign (@).

- **Security identifier (SID)**: A unique identifier that is associated with every security principal, such as S-1-5-123232343434-544. The SID consists of a domain identifier and a relative identifier (RID).

# ADFS Design Guide

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

Active Directory Federation Services (ADFS) in the Microsoft® Windows Server® 2003 R2 operating system helps administrators meet federated identity management challenges. It does this by making it possible for organizations to securely share a user's identity information within an organization and across federated organizations—without creating and maintaining external trusts or forest trusts between those organizations. With ADFS, an administrator in an organization can control resources that users in that organization can access—both within that organization and at partner organizations. An administrator can also use ADFS to configure resources that users in other organizations can access. ADFS provides users with a Web-based, single-sign-on (SSO) experience when they access extranet Web sites or sites on the Internet that are accessible through federation partnerships.

For more information about how ADFS works and how to set up ADFS in a test lab, see the following resources:

- Appendix B: Reviewing Key ADFS Concepts
- Overview of Active Directory Federation Services (ADFS) in Windows Server 2003 R2 (http://go.microsoft.com/fwlink/?LinkId=54650)
- Step-by-Step Guide for Active Directory Federation Services (http://go.microsoft.com/fwlink/?LinkId=49531)

**About this guide**

This guide provides recommendations to help you plan a new deployment of ADFS, based on the requirements of your organization and the particular design that you want to create. This guide is intended for use by an infrastructure specialist or system architect. It highlights your main decision points as you plan your ADFS deployment. Before you read this guide, you should have a good understanding of how ADFS works on a functional level. You should also have a good understanding of the organizational requirements that will be reflected in your ADFS design.

This guide describes a set of deployment goals that are based on three primary ADFS designs, and the guide helps you decide the most appropriate design for your environment. You can use these deployment goals to form one of the following comprehensive ADFS designs or a custom design that meets the needs of your environment:

- Federated Web SSO to support business-to-business (B2B) scenarios and to support collaboration between business units with independent forests
- Federated Web SSO with Forest Trust to support business-to-employee (B2E) scenarios
- Web SSO to support customer access to applications in business-to-consumer (B2C) scenarios

For each design, you will find guidelines for gathering required data about your environment. You can then use these guidelines to plan and design your ADFS deployment. After you read this guide and finish gathering, documenting, and mapping your organization's requirements, you will have the information necessary to begin deploying ADFS using the guidance in the ADFS Deployment Guide.

# Understanding the ADFS Design Process

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

The following topics outline the Active Directory Federation Services (ADFS) design process for planning a new ADFS deployment that will meet the needs of your organization.

- Identifying Your ADFS Deployment Goals
- Mapping Your Deployment Goals to an ADFS Design
- Evaluating ADFS Design Examples
- Appendix C: Documenting Your ADFS Design

After you identify your deployment goals and map them to an ADFS design, you can begin documenting your design, based on the processes that are described in the following topics:

- Appendix A: Reviewing ADFS Requirements
- Planning Partner Organization Deployments
- Designing a Federated Application Strategy
- Planning ADFS-Enabled Web Server Placement
- Planning Federation Server Placement
- Planning Federation Server Proxy Placement
- Planning for ADFS Capacity

# Identifying Your ADFS Deployment Goals

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

Correctly identifying your Active Directory Federation Services (ADFS) deployment goals is essential for the success of your ADFS design project. Depending on the size of your organization and the level of involvement that you want to provide for the information technology (IT) staff in any partner organizations, form a project team that can clearly articulate real-world deployment issues in a vision statement. Make sure that the members of this team understand the direction in which your deployment project must move in order to reach your ADFS deployment goals.

When you write your vision statement, identify, clarify, and refine your deployment goals. Prioritize and, possibly, combine your deployment goals so that you can design and deploy ADFS by using an iterative approach. You can take advantage of existing, documented, and predefined ADFS deployment goals that are relevant to the ADFS designs and develop a working solution for your scenarios.

The following table lists the three main tasks for articulating, refining, and subsequently documenting your ADFS deployment goals.

| **Deployment goal tasks** | **Reference links** |
|---|---|
| Evaluate predefined ADFS deployment goals that are provided in this section of the guide, and combine one or more goals to reach your organizational objectives. | • Provide federated access for your employees on the corporate network<br>• Provide federated access for your remote employees on the Internet<br>• Provide federated access for your hosted applications<br>• Provide single-sign-on access for customers to your hosted applications |
| Map one goal or a combination of any of the predefined ADFS deployment goals to an existing ADFS design. | • Mapping Your Deployment Goals to an ADFS Design |
| Document your deployment goals and other important details for your ADFS design. | • Appendix C: Documenting Your ADFS Design |

# Provide federated access for your employees on the corporate network

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

When you are the account partner administrator and you have a deployment goal to provide federated access for employees on the corporate network:

- Employees who are logged on to an Active Directory forest in the corporate network can use single sign-on (SSO) to access multiple applications, which are secured by Active Directory Federation Services (ADFS), when the applications are in a different organization. For more information, see Federated Web SSO design.

  For example, A. Datum Corporation may want corporate network employees to have federated access to applications that are hosted in Trey Research.

- Employees who are logged on to an Active Directory forest in the corporate network can use SSO to access multiple applications, which are secured by ADFS, in the perimeter network in your own organization. For more information, see Federated Web SSO with Forest Trust design.

  For example, A. Datum Corporation may want corporate network employees to have federated access to applications that are hosted in the A. Datum Corporation perimeter network.

- Information in the Active Directory account store can be populated into the employees' ADFS tokens.

The following components are required for this deployment goal:

- **Active Directory:** Active Directory contains the employees' user accounts that are used to generate ADFS tokens. Information, such as groups and attributes, is populated into ADFS tokens as group claims and custom claims. For more information about Active Directory, see Appendix B: Reviewing Key ADFS Concepts.

  | **Note** |
  | --- |
  | Active Directory Application Mode (ADAM) may also be used to contain the identities are used to generate ADFS tokens. However, ADAM is typically used for this purpose to host customer accounts on the perimeter network. |

- **Corporate DNS:** This implementation of Domain Name System (DNS) contains a simple address (A) resource record so that intranet clients can locate the account federation server. It may host other DNS records that are also required in the corporate network. For more information, see Name resolution requirements for federation servers.

- **Account federation server:** The account federation server is joined to a domain in the account partner forest. It authenticates employee user accounts and generates ADFS tokens. The client computer for the employee performs Windows Integrated authentication against the account federation server to generate an ADFS token. For more information, see Review the role of the federation server in the account partner organization.

  The following users can be authenticated by the account federation server:

  - Employees with user accounts in this domain
  - Employees with user accounts anywhere in this forest
  - Employees with user accounts anywhere in forests that are trusted by this forest (through a Windows trust)

- **Employee:** An employee accesses an ADFS-secured Web application through a supported Web browser while he or she is logged on to the corporate network. The employee's client computer on the corporate network communicates directly with the federation server for authentication.

The following illustration shows each of the required components for this ADFS deployment goal.

# Provide federated access for your remote employees on the Internet

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

This deployment goal builds on the deployment goal that is described in Provide federated access for your employees on the corporate network. It also makes it possible for remote employees to obtain Active Directory Federation Services (ADFS) tokens from the account federation server. After it obtains the tokens, the remote employee's client computer can use the ADFS tokens to gain federated access to ADFS-secured applications that are hosted in another organization and allow employees to access resources in their own organization.

For more information, see Federated Web SSO design.

For example, A. Datum Corporation may want remote employees to have federated access to ADFS-secured applications that are hosted in Trey Research, without requiring A. Datum employees to be on the A. Datum corporate network.

In addition to the foundational components that are described in Provide federated access for your employees on the corporate network (which are shaded in the following figure), the following components are required for this deployment goal:

- **Account federation server proxy:** Employees that access the federated application from the Internet can use this ADFS component to perform authentication. By default, this component performs forms authentication, but it can also perform basic authentication. You may also configure this component to perform Secure Sockets Layer (SSL) client authentication if users at your organization have certificates to present. For more information, see Where to place a federation server proxy.

- **Perimeter DNS:** This implementation of Domain Name System (DNS) provides the host names for the perimeter network. For more information about how to configure perimeter DNS for a federation server proxy, see Name resolution requirements for federation server proxies.

- **Remote employee:** The remote employee accesses an ADFS-secured Web application through a supported Web browser, using valid credentials from the corporate network, while the employee is offsite using the Internet. The employee's client computer in the remote location communicates directly with the federation server proxy to generate a token and authenticate to the application.

The following illustration shows each of the required components for this ADFS deployment goal.

# Provide federated access for your hosted applications

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

When you are the resource partner administrator and you have a deployment goal to provide federated access to an application that resides in your organization (the resource partner organization), federated users both in your organization and in organizations that have configured a federation trust to your organization can access the Active Directory Federation Services (ADFS)-secured application that is hosted by your organization. For more information, see Federated Web SSO design and Federated Web SSO with Forest Trust design.

The following components are required for this deployment goal:

- **Active Directory:** The resource federation server must be joined to an Active Directory domain. If Windows NT token–based applications are supported, the domain also serves as the store that contains the resource accounts or resource groups. Claims-aware applications do not require local accounts in Active Directory. For more information about resource accounts and resource groups, see Determine your resource account mapping method.

- **Perimeter DNS:** This implementation of Domain Name System (DNS) contains a simple host (A) resource record so that clients can locate the resource federation server and the ADFS-enabled Web server. The DNS server may host other DNS records that are also required in the perimeter network. For more information, see Name resolution requirements for federation servers and Name resolution requirements for ADFS-enabled Web servers.

- **Resource federation server:** The resource federation server validates ADFS tokens that the account partners send. Account partner discovery is performed through this federation server. For more information, see Review the role of the federation server in the resource partner organization.

- **ADFS-enabled Web server:** The ADFS-enabled Web server can host a claims-aware application or a Windows NT token–based application. (The following illustration shows a claims-aware application.) The ADFS Web Agent confirms that it receives valid ADFS tokens from federated users before it allows access to the protected Web site. For more information, see When to create an ADFS-enabled Web server.

The following illustration shows each of the required components for this ADFS deployment goal.

# Provide single-sign-on access for customers to your hosted applications

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

When your ADFS deployment goal is to provide single-sign-on (SSO) access for customer accounts to hosted applications that are secured by Active Directory Federation Services (ADFS):

- Customers who are logged on to the Active Directory Application Mode (ADAM) account store, which is hosted in your perimeter network, can access multiple ADFS-secured applications, which are also hosted in your perimeter network, by logging on one time from client computers that are located on the Internet.

  In other words, when you host customer accounts to enable access to applications in your perimeter network, customers that you host in an account store can access one or more applications in the perimeter network simply by logging on once to the Federation Service. For more information, see Web SSO design.

- Information in the ADAM account store can be populated into customers' ADFS tokens.

The following components are required for this ADFS deployment goal:

- **Active Directory:** An Active Directory domain is required only for the resource federation server. It is not used to host customer accounts.

- **ADAM:** ADAM is used to contain the customer accounts that will be used to generate ADFS tokens. For more information about Active Directory or ADAM, see Appendix B: Reviewing Key ADFS Concepts.

  | **Note** |
  | --- |
  | Active Directory may also be used to contain customer accounts that will be used to generate ADFS tokens. |

- **Account/resource federation server:** This federation server serves in both the account role and the resource role. The account/resource federation server is configured so that the Federation Service includes values for both an application and an account store—in this case, ADAM—that contains the customer accounts. For more information, see Review the role of the federation server in the account partner organization and Review the role of the federation server in the resource partner organization.

- **ADFS-enabled Web server:** The ADFS-enabled Web server can host a claims-aware application or a Windows NT token–based application. The ADFS Web Agent confirms that it receives valid ADFS tokens from customer accounts before it allows access to the protected Web site. For more information, see When to create an ADFS-enabled Web server.

- **Customer:** While on the Internet, the customer accesses an ADFS-secured Web application through a supported Web browser. The customer client computer on the Internet communicates directly with the federation server for authentication.

The following illustration shows each of the required components for this ADFS deployment goal. In this case, because Active Directory is used only to support the federation server's requirement to be joined to a domain, it is shaded in this illustration.

Active Directory
Account/ resource federation server
Perimeter DNS
ADAM
ADFS-enabled Web server

Internet

# Mapping Your Deployment Goals to an ADFS Design

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

After you finish reviewing the existing Active Directory Federation Services (ADFS) deployment goals and you determine which goals are related to your specific deployment, you can map those goals to a specific ADFS design. For more information about ADFS predefined deployment goals, see Identifying Your ADFS Deployment Goals.

Use the following table to determine which ADFS design maps to the appropriate combination of ADFS deployment goals for your organization. This table refers only to the three primary ADFS designs as described in this guide. However, you can create a hybrid or custom ADFS design by using any combination of the ADFS deployment goals to meet the needs of your organization.

| **ADFS deployment goal** | **Web SSO design** | **Federated Web SSO design** | **Federated Web SSO with Forest Trust design** |
|---|---|---|---|
| Provide federated access for your employees on the corporate network | No | Yes, in the account partner | Yes, in the account partner |
| Provide federated access for your remote employees on the Internet | No | Yes, optional in the account partner | Yes, optional in the account partner |
| Provide single-sign-on access for customers to your hosted applications | Yes | No | No |
| Provide federated access for your hosted applications | No | Yes, in the resource partner | Yes, in the resource partner |

# Web SSO design

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

In the Web Single-Sign-On (SSO) design in Active Directory Federation Services (ADFS), users must authenticate only once to access multiple ADFS-secured applications. In this design all users are external, and no federation trust exists because there are no partners. Typically, you deploy this design when you want to provide customer access to one or more ADFS-secured applications over the Internet, as shown in the following illustration.

With the Web SSO design, an organization that typically hosts an ADFS-secured application in a perimeter network can maintain a separate store of customer accounts in the perimeter network, which makes it easier to isolate customer accounts and employee accounts.

You can manage the local accounts for customers in the perimeter network by using either Active Directory or Active Directory Application Mode (ADAM) as the account store.

This design coincides with the deployment goal to provide SSO access for customers to your hosted applications. For more information, see Provide single-sign-on access for customers to your hosted applications.

To learn more about the flow of ADFS communications in this design, see Web SSO example.

For a list of detailed tasks that you can use to plan and deploy your Web SSO design, see Checklist: Implementing a Web SSO Design.

# Federated Web SSO design

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

The Federated Web Single-Sign-On (SSO) design in Active Directory Federation Services (ADFS) involves secure communication that spans multiple firewalls, perimeter networks, and name resolution servers—in addition to the entire Internet routing infrastructure.

Typically, this design is used when two organizations agree to create a federation trust relationship to allow users in one organization (the account partner organization) to access Web-based applications, which are secured by ADFS, in the other organization (the resource partner organization).

In other words, a federation trust relationship is the embodiment of a business-level agreement or partnership between two organizations. As shown in the following illustration, you can establish a federation trust relationship between two businesses, which results in an end-to-end federation scenario.

The one-way arrow in the illustration signifies the direction of the federation trust, which—like the direction of Windows trusts—always points to the account side of the forest. This means that authentication flows from the account partner organization to the resource partner organization.

In this Federated Web SSO design, two federation servers (one in A. Datum Corporation and the other in Trey Research) route authentication requests from user accounts in A. Datum Corporation to Web-based applications in Trey Research.

| **Note** |
| --- |
| For additional security, you can use federation server proxies to relay requests to federation servers that are not directly accessible from the Internet. |

In this example, A. Datum Corporation is the identity or account provider. The A. Datum Corporation portion of the Federated Web SSO design combines the following ADFS deployment goals:

- Provide federated access for your employees on the corporate network
- Provide federated access for your remote employees on the Internet

Trey Research is the resource provider. The Trey Research portion of the Federated Web SSO design achieves the following ADFS deployment goal:

- Provide federated access for your hosted applications

To learn more about the flow of ADFS communications in this design, see Federated Web SSO example.

For a list of detailed tasks that you can use to plan and deploy the Federated Web SSO design, see Checklist: Implementing a Federated Web SSO Design.

# Federated Web SSO with Forest Trust design

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

The Federated Web Single-Sign-On (SSO) with Forest Trust design in Active Directory Federation Services (ADFS) combines two Active Directory forests in a single organization, as shown in the following illustration.

Typically, you use this design when you want to provide employees on the corporate network and remote employees with federated access to ADFS-secured applications in the perimeter network, while using each employee's standard corporate domain credentials.

The one-way federation trust arrow in the illustration signifies the direction of the trust, which—like the direction of Windows trusts—always points to the account side of the forest. This means that authentication flows from the corporate network to the perimeter network.

Because a forest trust exists between the perimeter network and the corporate network, employee user accounts that are in the corporate network may be used to access the application, which eliminates the need for resource accounts or resource groups. A Windows NT token–based application requires that a user or group exists so that the ADFS token can be mapped into it. However, using Active Directory in the corporate network enables you to deploy the application without user accounts in the perimeter network.

| **Note** |
| --- |
| If a trust is not in place between the corporate network and the perimeter network and the application in the perimeter network is a Windows NT token–based application, resource accounts or groups must exist in the perimeter network. |

In this design, the single A. Datum Corporation organization combines the following ADFS deployment goals:

- Provide federated access for your employees on the corporate network
- Provide federated access for your remote employees on the Internet
- Provide federated access for your hosted applications

To learn more about the flow of ADFS communications in this design, see Federated Web SSO with Forest Trust example.

For a list of detailed tasks that you can use to plan and deploy the Federated Web SSO with Forest Trust design, see Checklist: Implementing a Federated Web SSO with Forest Trust Design.

# Evaluating ADFS Design Examples

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

The following Active Directory Federation Services (ADFS) design examples illustrate how you can use ADFS to enable federated identity and access management. You can use these topics to evaluate how ADFS communications work across all three ADFS designs and to determine which design or combination of predefined ADFS deployment goals best suits the goals of your organization.

- Web SSO example
- Federated Web SSO example
- Federated Web SSO with Forest Trust example

# Web SSO example

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

In this example, the fictitious company Adventure Works is an online retailer. The company sells products directly to customers over the Internet. The perimeter network hosts the Purchasing application and the Customer Service Web application, which are both claims-aware applications. Internet customer accounts and passwords are managed in Active Directory Application Mode (ADAM).

**Message flow for customer remote access**

The ADFS-enabled Web server that hosts the Purchasing and Customer Service applications is located in the perimeter network forest. Customers perform Active Directory Federation Services (ADFS) authentication for these applications by using the resource federation server for the ADFS-enabled Web server.

**Client application request**

The following illustration and corresponding steps provide a detailed description of the client application request process in ADFS using Transport Layer Security / Secure Sockets Layer (TLS/SSL).

1. The customer uses her Web browser to open the application on the ADFS-enabled Web server.

2. The ADFS-enabled Web server refuses the request because there is no ADFS authentication cookie, and the ADFS-enabled Web server redirects the client browser to the logon Web page on the resource federation server.

3. The client browser requests the logon Web page from the resource federation server.

4. The resource federation server redirects the client browser to its logon Web page.

**Authenticating the user**

The following illustration and corresponding steps continue to describe the client application request process in the previous section. Unless it is otherwise noted, all traffic uses TLS/SSL.

1. The Web page of the resource federation server prompts the client for user credentials.

2. The resource federation server does the following:

   - Validates the client's user credentials and retrieves attributes from ADAM using Lightweight Directory Access Protocol (LDAP).

   - Builds the security token for the ADFS-enabled Web server application.

   - Builds the ADFS authentication cookie.

3. The resource federation server redirects the Web browser to send the POST request to the ADFS-enabled Web server:

   - POST with security token in body and Java script to activate.

   - The ADFS authentication cookie is written to the Web browser.

4. The Web browser sends the POST request to the ADFS-enabled Web server.

5. The ADFS-enabled Web server redirects the Web browser to the Uniform Resource Locator (URL) of the application:

   - The ADFS-enabled Web server validates the security token.

   - Builds the new ADFS authentication cookie.

   - The ADFS authentication cookie is written to the Web browser.

6. The Web browser requests the original application URL from the ADFS-enabled Web server with the ADFS authentication cookie.

7. The application authorizes the user’s request, based on attributes from the security token.

The client browser requests additional application URLs from the ADFS-enabled Web server with its ADFS authentication

cookie that is created by the Web server.

# Federated Web SSO example

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

In this scenario, the fictitious company A. Datum Corporation has employees that work at their corporate offices and mobile employees that work at their homes. As with any other company, office supplies must be ordered from other retailers for the A. Datum employees. When users need to be authenticated, the account partner discovery page on the federation server in Trey Research always returns a Uniform Resource Locator (URL) for the external Federation Service Proxy.

| **Note** |
| --- |
| Domain Name System (DNS) servers in the perimeter network must be configured to resolve the host name of the Federation Service URL to the federation server proxy for employees that authenticate from home or on the road. |

As shown in the following illustration, employee sessions may originate from the corporate network for an office employee or from the Internet for a remote employee. Office employees are authenticated transparently to the federation server through their desktop logon sessions. Mobile employees are authenticated through passwords and forms authentication, or if it is configured, through client Secure Sockets Layer (SSL).

All the ADFS-enabled Web servers in the perimeter network of Trey Research are exposed directly to the Internet, without a federation server proxy. They are protected only by a firewall that screens out non-Web traffic. In a production environment, a business like Trey Research would probably deploy proxy servers in front of its Web farm servers. In this example, a proxy is omitted for the sake of clarity because it complicates the message flow with extra steps.

**Message flow for federation through internal access**

The ADFS-enabled Web server that is hosted by the online retailer is located in the perimeter network. When the office employees connect to the ADFS-enabled Web server directly, they are redirected to the default logon URL at the resource federation server proxy. Then, the employees must use home realm discovery to select the Federation Service endpoint URL. Corporate network DNS servers resolve that to the IP address of the internal account federation server.

The office employee authenticates by using his currently logged-on desktop session credentials and integrated authentication at an internal account federation server in the corporate network. The account federation server and Active Directory in the corporate network are used to validate the office employee's credentials and obtain attributes for building a Security Assertion Markup Language (SAML) security token.

**Client application request**

The following illustration and corresponding steps provide a description of the client application request process in ADFS using Transport Layer Security / Secure Sockets Layer (TLS/SSL).

1. The office employee uses his Web browser to open an application on the ADFS-enabled Web server.

2. The ADFS-enabled Web server refuses the request because there is no ADFS authentication cookie. The Web server redirects the client browser to the logon Web page on the resource federation server.

3. The client browser requests to sign-in from the resource federation server.

**Authenticating the user**

The following illustration and corresponding steps provide a description of the authentication process in ADFS. Unless it is otherwise noted, all traffic uses TLS/SSL.

1. The logon Web page on the resource federation server prompts the user for account partner discovery.

2. The resource federation server redirects the client browser to the logon Web page on the account federation server proxy.

3. The client browser requests the logon Web page from the account federation server proxy:

   - Internal DNS servers resolve the account federation server proxy URL to the CNAME of the account federation server.

   - Windows Integrated authentication occurs transparently.

4. The account federation server does the following:

- Validates user credentials and gets attributes from Active Directory in the corporate network forest using Lightweight Directory Access Protocol (LDAP).
- Builds the security token for the resource federation server.
- Builds the ADFS authentication cookie.

5. The account federation server redirects the Web browser to send the POST request to the resource federation server:
   - The POST request includes the security token in the body and Java script to activate.
   - The ADFS authentication cookie is written to the browser.
6. The client browser sends a POST request to the resource federation server.
7. The resource federation server redirects the Web browser to send the POST request to the ADFS-enabled Web server:
   - Builds the security token for the Web application.
   - Builds the new ADFS authentication cookie.
   - The POST request includes the security token in the body and Java script to activate.
   - The ADFS authentication cookie is written to the browser.
8. The Web browser sends the POST request to the ADFS-enabled Web server.
9. The ADFS-enabled Web server redirects the client to its application URL:
   - ADFS validates the security token.
   - Builds the new ADFS authentication cookie.
   - The ADFS authentication cookie is written to the browser.
10. The client browser uses the ADFS authentication cookie to request the original application URL from the ADFS-enabled Web server.
11. The ADFS-enabled Web server application authorizes the user's request based on attributes from the security token.

| **Note** |
| --- |
| If the resource application is an application that uses traditional Windows-based authorization such as a Windows NT token-based application, a resource account or resource group is required. |

The Web browser requests additional application URLs from the ADFS-enabled Web server with its ADFS authentication cookie.

**Message flow for federation through remote access**
When mobile employees connect to the ADFS-enabled Web server directly, they are redirected to the default logon URL at the resource federation server. Then, they must use home realm discovery to select the account Federation Service endpoint URL.

A mobile employee may then enter his credentials through a Web page that is displayed by the browser.

**Client application request**

The following illustration and corresponding steps provide a description of the client application request process in ADFS using TLS/SSL.

1. The remote employee uses the Web browser to open the application on the ADFS-enabled Web server.

2. The ADFS-enabled Web server refuses the request because there is no ADFS authentication cookie. The ADFS-enabled Web server redirects the client browser to sign-in on the resource federation server.

3. The client browser requests the logon Web page from the resource federation server.

4. The Web page on the resource federation server prompts the user for account partner discovery.

5. The resource federation server redirects the client browser to the logon Web page on the account federation server proxy.

6. The Web browser requests the logon Web page from the account federation server proxy.

**Authenticating the user**

The following illustration and corresponding steps provide a description of the user authentication process in ADFS. Unless it is otherwise noted, all traffic uses TLS/SSL.

1. The Web page on the account federation server proxy prompts the client for user credentials.

2. The account federation server proxy requests a security token from the account federation server by using Secure

Hypertext Transfer Protocol (HTTPS).

3. The account federation server does the following:

    - Validates user credentials and gets attributes from Active Directory in the corporate network forest using LDAP.
    - Builds the security token for the resource federation server.
    - Builds the ADFS authentication cookie.

4. The account federation server sends the security token and the ADFS authentication cookie to the account federation server proxy using Web methods and HTTPS.

5. The account federation server proxy redirects the Web browser to send the POST request to the resource federation server:

    - The POST request includes the security token in the body and Java script to activate.
    - The ADFS authentication cookie is written to the browser.

6. The client browser sends the POST request to the resource federation server.

7. The resource federation server redirects the Web browser to send the POST request to the ADFS-enabled Web server:

    - The POST request includes the security token in the body and Java script to activate.
    - Builds the new ADFS authentication cookie
    - The ADFS authentication cookie is written to the browser.

8. The client browser sends the POST request to the ADFS-enabled Web server.

9. The ADFS-enabled Web server redirects the Web browser to its application URL:

    - ADFS validates the security token.
    - Builds the new ADFS authentication cookie.
    - The ADFS authentication cookie is written to the browser.

10. The Web browser requests the original application URL for the ADFS-enabled Web server with the ADFS authentication, ADFS-enabled Web server cookie.

11. The Web application authorizes the user's request, based on attributes in the security token.

| **Note** |
| --- |
| If the resource application is an application that uses traditional Windows-based authorization, a resource account or resource group is required. |

The Web browser uses its ADFS authentication cookie to request additional application URLs from the ADFS-enabled Web

server.

# Federated Web SSO with Forest Trust example

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

In this scenario, the fictitious company Adventure Works is both a retail distributor and a wholesale distributor. The company sells products directly through Adventure Works salesmen, service departments, and sporting goods stores. Adventure Works obtains its entire inventory from other vendors. It does not manufacture the products it sells.

Adventure Works has two separate Active Directory forests. The forest in the perimeter network hosts the online inventory, purchasing, and customer service Web applications. The Inventory application that Adventure Works uses is critical to its operations. Therefore, this application is protected with strong security measures that require Windows impersonation and use access control lists (ACLs). The Purchasing application and the Customer Service application are claims-aware applications.

Traveling salesmen access perimeter network applications by using their employee accounts, which are managed in Active Directory in the corporate network forest.

As shown in the following illustration, a one-way trust from the perimeter network to the forest in the corporate network (an external trust for Microsoft® Windows® 2000 Server or a forest trust for Microsoft Windows Server® 2003) is created. The required ports are open in the firewall between the corporate network and the perimeter network to support trust and authentication as well as Web application traffic.

Because a one-way trust is already in place, Adventure Works decides to take advantage of it to enable applications to create access tokens for employees and have single sign-on (SSO) in the perimeter network.

Employee sessions may originate from the corporate network, for headquarters staff such as the Plant Manager, or from the Internet for mobile staff, such as traveling salesmen. This means that two types of authentication mechanisms are used:

- Intranet employees use integrated authentication.
- Mobile employees use Transport Layer Security / Secure Sockets Layer (TLS/SSL) client authentication or forms authentication.

Regardless of the type of user account or authentication mechanism, Active Directory Federation Services (ADFS) authentication always generates a security token, which is delivered to the application for the purpose of authorizing user requests. Because the inventory application is used only by employees who have Active Directory accounts, the ADFS Web Agent on the ADFS-enabled Web server also creates a Windows NT token for the user and the token can be impersonated by the application.

All the ADFS-enabled Web servers in the perimeter network are exposed directly to the Internet without a proxy server. They are protected only by a firewall that screens out non-Web traffic. In a production environment, Adventure Works would probably deploy proxy servers in front of its Web farm servers. In this example, however, a proxy server is omitted for the sake of clarity because it complicates the flow with extra steps.

**Message flow for traveling salesman remote access**

The ADFS-enabled Web server that hosts the Purchasing application is located in the Active Directory forest in the perimeter network. A traveling salesman authenticates to the application through an account federation server proxy. However, the default Federation Service for the ADFS-enabled Web server is the resource Federation Service. Therefore, when multiple account stores or multiple partners are configured, account partner discovery is required to redirect employees to the account federation server proxy. The account federation server and the corporate network Active Directory service validate the traveling salesman's credentials and obtain attributes for building a security token.

**Client application request**

The following illustration and corresponding steps provide a detailed description of the client application request process in ADFS using TLS/SSL.

1. The traveling salesman uses his Web browser to open the purchasing application on the ADFS-enabled Web server.

2. The ADFS-enabled Web server refuses the request because there is no ADFS authentication cookie. The Web server redirects the client browser to the logon Web page on the resource federation server.

3. The client browser requests the logon Web page from the resource federation server.

4. Depending on whether there are multiple account stores or multiple partners configured, the Web page on the resource federation server prompts the user for account partner discovery.

5. The resource federation server redirects the client browser to the logon Web page on the account federation server proxy.

6. The client browser requests the logon Web page from the account federation server proxy.

**Authenticating the user requesting access to the application**

The following illustration and corresponding steps describe how the traveling salesman is authenticated after requesting access to the Order Entry application. Unless it is otherwise noted, all traffic uses TLS/SSL.

1. The Web page on the account federation server proxy prompts the user for user credentials.

2. The account federation server proxy requests a security token from the account federation server by using Secure Hypertext Transfer Protocol (HTTPS).

3. The account federation server does the following:

    - Maps the user certificate and retrieves any required Lightweight Directory Access Protocol (LDAP) attributes from Active Directory in the corporate network using LDAP.

    - Builds the security token for the Web application.

    - Builds the ADFS authentication cookie.

4. The account federation server sends the authentication cookie and security token to the account federation server proxy using Simple Object Access Protocol (SOAP) and HTTPS.

5. The account federation server proxy redirects the Web browser to send the POST request to the resource federation server:

    - POST with security token in the body and Java script to activate.

    - The ADFS authentication cookie is written to the browser.

6. The client browser sends the POST request to the resource federation server.

7. The resource federation server does the following:

    - Builds the new security token for the Web application.

    - Builds the new ADFS authentication cookie.

The resource federation server redirects the Web browser to send the POST request to the ADFS-enabled Web server so that:

- POST with security token in the body and Java script to activate.
- The ADFS authentication cookie is written to browser.

8. The client browser sends the POST request to the ADFS-enabled Web server.
9. The ADFS-enabled Web server redirects the Web browser to its application Uniform Resource Locator (URL), and then:

    - The ADFS-enabled Web server component validates the security token.
    - Builds the new ADFS authentication cookie.
    - The ADFS authentication cookie is written to the browser.

10. The Web browser requests the original application URL from the ADFS-enabled Web server with the ADFS authentication cookie.
11. The ADFS-enabled Web server application:

    - Builds an impersonation Windows NT token from the security token.
    - Uses this Windows NT token to impersonate and to access check.

The Web browser requests additional application URLs from the ADFS-enabled Web server with its ADFS authentication cookie.

**Message flow for warehouse manager internal access**
The ADFS-enabled Web server that hosts the Inventory application is located in the perimeter network forest. The warehouse manager authenticates by using currently logged on desktop session credentials and integrated authentication at the account federation server in the corporate network. The account federation server and Active Directory in the corporate network validate the credentials and obtain attributes for building a security token.

When corporate network users connect to the ADFS-enabled Web server directly, they are redirected to the resource federation server. Then, as in the case of the traveling salesman, they are redirected through Domain Name System (DNS) servers to the canonical name (CNAME) of the account federation server.

**Client application request**
The following illustration and corresponding steps provide a detailed description of the client application request process in ADFS using TLS/SSL.

1. The warehouse manager uses a Web browser to open the application on the ADFS-enabled Web server.

2. The ADFS-enabled Web server refuses the request because there is an ADFS authentication cookie. The ADFS-enabled Web server redirects the client browser to the logon Web page on the (resource federation server).

3. The client browser requests the logon Web page from the resource federation server.

4. Depending on whether there are multiple account stores or multiple partners configured, the Web page on the resource federation server prompts the user for account partner discovery.

5. The client browser is sent directly to the account federation server.

**Authenticating the user**

The following illustration and corresponding steps provide a detailed description of the client application request process in ADFS. Unless it is otherwise noted, all traffic uses TLS/SSL.

1. The account federation server does the following:

    - Validates user credentials and gets attributes from Active Directory in the corporate network forest using LDAP.
    - Builds the security token for the Web application.
    - Builds the ADFS authentication cookie.

2. The account federation server redirects the Web browser to send the POST request to the resource federation server:

    - POST with security token in body and Java script to activate.
    - The ADFS authentication cookie is written to the browser.

3. The client browser sends the POST request to the resource federation server.

4. The resource federation server:

    - Builds the new security token for the Web application.
    - Builds the new ADFS authentication cookie.

    The resource federation server then redirects the Web browser to send the POST request to the ADFS-enabled Web server.

    - POST with security token in body and Java script to activate.
    - The ADFS authentication cookie is written to the browser.

5. The client browser sends the POST request to the ADFS-enabled Web server.

6. The ADFS-enabled Web server redirects the Web browser to its application URL:

    - ADFS validates the security token.
    - Builds the new ADFS authentication cookie.
    - The ADFS authentication cookie is written to the browser.

7. The client browser requests the original application URL from the ADFS-enabled Web server with the ADFS authentication cookie.

8. The Web application:

    - Builds an impersonation Windows NT token from the security token.
    - Uses this Windows NT token to impersonate and to access check.

The Web browser requests additional application URLs from the ADFS-enabled Web server with its ADFS authentication cookie.

# Planning Partner Organization Deployments

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

When you plan for cross-organizational (federation-based) collaboration using Active Directory Federation Services (ADFS), you first determine if your organization will host a Web resource to be accessed by other organizations across the Internet or if you will provide access to the Web resource for employees in your organization. This determination affects how you deploy ADFS, and it is fundamental in the planning of your ADFS infrastructure.

| **Note** |
| --- |
| Make sure that the role that your organization plays in the federation agreement is clearly understood by all parties. |

For the federation designs Federated Web SSO design and Federated Web SSO with Forest Trust design, ADFS uses terms such as "account partner" and "resource partner" to help differentiate the organization that hosts the accounts (the account partner) from the organization that hosts the Web-based resources (the resource partner).

"Account partner" and "resource partner" terminology is not applicable in the Web SSO design because one federation server acts in both the account partner role and the resource partner role, and there is no identification of two distinct partners in the Federation Service.

The following sections explain some of the ADFS partner organization concepts. They also contain links to topics in the Active Directory Federation Services Deployment Guide that contain information about setting up and configuring account partners and resource partners based on your ADFS deployment goals.

**Planning the account partner deployment**

An account partner represents the organization in the federation trust relationship that physically stores user accounts in either an Active Directory store or an Active Directory Application Mode (ADAM) store. The Federation Service in the account partner organization authenticates local users and creates security tokens that are used by the resource partner in making authorization decisions.

In scenarios in which you need to provide your users with access to multiple federated applications—when each application is hosted by a different organization—you can configure the account Federation Service so that you can deploy multiple resource partners.

For more information about how to set up and configure an account partner organization, see Checklist: Configuring the account partner organization.

**Planning the resource partner deployment**

The resource partner organization represents the organization whose ADFS-enabled Web servers are protected by the resource-side Federation Service. The Federation Service at the resource partner uses the security tokens that are produced by the account partner to make authorization decisions for ADFS-enabled Web servers that are located in the resource partner.

In scenarios in which you need to provide access to federated applications to many different users—when some users reside in different organizations—you can configure the resource Federation Service so that you can deploy multiple account partners.

For more information about how to set up and configure a resource partner in the account Federation Service, see Checklist: Configuring the resource partner organization.

# Review how ADFS may affect privacy

Updated: November 8, 2007

Applies To: Windows Server 2003 R2

Active Directory Federation Services (ADFS) provides Web single-sign-on (SSO) technologies to authenticate a user to multiple Web applications over the life of a single online session. When you build an application using ADFS in Windows Server 2003 R2, your application may affect your end users' privacy.

For example, your application may explicitly collect user contact information, or it may request or send information over the Internet to your Web site or partner Web sites. If you embed Microsoft technology in your application, that technology may have its own behavior that may affect privacy.

**HTTP requests**

**Messages**

Messages contain Security Assertion Markup Language (SAML) tokens that may include application-defined personal data, depending on the claims that an administrator chooses to include in the token. The information that is contained in these SAML tokens is signed by the Federation Service's token-signing certificate, or, in some cases, the information is protected by a Kerberos session key. Messages are secured by the use of Secure Sockets Layer (SSL).

**Communication between the Federation Service and the application**

Although messages between Federation Services and Web applications transmit message routing information and body information, messages are typically secure by default. In addition, although messages contain application-specific data, such as application-defined personal information, this data is secured during transmission by SSL.

**Communication between the user and the application**

Query string parameters in the messages between a user and an application are subject to inspection by the account federation servers and the resource federation servers. Because an account federation server may be in a different organization, we recommend that you use a programming method that helps to ensure user privacy when you build Web applications.

A mitigation for this problem is to program an application to use HTTP POSTs, such as ASP.NET form submits, to communicate information that a user supplies. However, this method may have unreliable results because unauthenticated POSTs to applications that are protected by ADFS lose the POST body during ADFS authentication. (Unauthenticated POSTs include initial POSTs or POSTs that occur immediately after a token expires.) In spite of the potential for unreliable results, using an HTTP POST may prevent sensitive user data from being disclosed.

**Requested URL**

During the process of authenticating a user, the user is redirected to his or her account organization to perform authentication. As part of this request, the Uniform Resource Locator (URL) of the original requested page at the resource organization is included in encoded form. An account organization may decode this value to determine the first page at the resource that is accessed by the user.

**Cookies**

**Authentication**

After a token is verified at a Federation Service or Web application, an authentication cookie is issued to the client browser. Each time that a client must be authenticated, this cookie is used by the Federation Service, and, if the cookie is valid, the user is not required to enter his or her credentials again. The contents of this cookie are encrypted by SSL during transmission.

Application-defined personal information may be contained in this cookie, depending on the claims that an administrator includes in the token, and this personal information may be written to the disk of the Web browser. The contents of authentication cookies are signed, but they are not encrypted when they are written to disk.

All authentication cookies are session cookies that typically exist only in memory. These cookies are removed when the browser session ends or the ADFS sign-out procedure is invoked.

**Home-realm discovery**

During the process of home-realm discovery at a resource Federation Service or Federation Service Proxy, the client is prompted to select its account realm before being redirected to authenticate. After the account provider is selected, a persistent cookie is written to the disk of the Web browser computer that identifies the account provider. This cookie has a configurable lifetime, with a default of 30 days.

**Auditing**

When you enable the **Audit object access** policy setting and you configure ADFS for auditing, ADFS audits authentication

events. This includes the authentication of the user and any evidence, such as tokens, that the user presents. Application-defined personal information may be included in the security log, based on the configuration of the Federation Service that issues the security token. When auditing is enabled, both claim names and values are written to the security log. When the **Limit the auditing of this claim** check box is selected for a specific claim, only the claim's name is written to the security log.

#### Enhanced identity privacy

**Enable enhanced identity privacy** is an optional setting that you can configure for a resource partner in the trust policy. If the **Enable enhanced identity privacy** option is enabled, this setting hashes the user-name portion of outgoing user principal name (UPN) claims and e-mail claims. A random value is substituted for the common name.

The purpose of this feature is to prevent:

- The resource partner from correlating identity claims to personally identifiable user information.
- Collusion between partners in correlating identity claims to personally identifiable user information.
- Simple dictionary attacks to determine identity.

#### How enhanced identity privacy works

If you enable the **Enable enhanced identity privacy** setting, the user's identity is transformed by the account Federation Service before it is sent to the resource realm. The account Federation Service does this by hashing a combination of the privacy key (for salting), the resource partner Uniform Resource Identifier (URI), and the identity claim itself, as well as the privacy key (for salting), which reduces the possibility of dictionary attacks. When these three elements are combined, a unique hash per partner is created so that the resulting transformed identity is the same when the following values are the same:

- Privacy key
- Resource partner URI
- Identity claim (UPN or e-mail)

The hashing algorithm is case sensitive. Therefore, the hashed results are different if the case of the URI or the user-name portion of the UPN claim or e-mail claim is different.

#### The IT pro experience

#### Event logs

By default, ADFS records activities and events that are associated with messages to the event log. Event log entries are written that include data from messages and activities that are associated with those messages. This may include application-defined personal information, depending on the logging level and the claims that an administrator includes in the token.

#### Troubleshooting logs

You may configure ADFS to log messages that pass through the ADFS system, along with the activities and events that are associated with these messages. This feature is turned off by default. When logging is enabled, a log is written to the configured location. The log includes the messages and activities and the events that are associated with those messages. This may include application-defined personal information, depending on the logging level and the claims that an administrator includes in the token.

# Review the role of claims in the account partner organization

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

An account partner issues tokens containing claims to its users. The claims are built from the account store so that users can access Web-based applications in the resource partner. The following table describes the claim options in the account partner.

| **Claim option** | **Description** |
|---|---|
| Claim extractions | Claim extractions map a user or group in an account store to an organization claim. The account store can be either Active Directory or Active Directory Application Mode (ADAM). |
| Organization claims | Organization claims are used by the federation server—in this case, the account federation server. Claims passing through a federation server are mapped into and out of the organization claim set. These claims are then transformed, or mapped, into outgoing claims. This is the core set of claims that the organization uses for mapping. |
| Outgoing claim mappings | Outgoing claim mappings map organization claims to outgoing claims. The claim names that you configure here are determined by an agreement with your resource partner on a common namespace. |
| Outgoing claims | Outgoing claims are included in the security token of a user. They are generated by the account partner, and they are sent to the resource partner. Organization claims on the federation server of the account partner are mapped to outgoing claims that are then sent to the resource federation server. |

# Review the role of claims in the resource partner organization

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

A resource partner receives a token that contains claims, verifies that the token came from a trusted account partner, and makes the claims available to a Web-based application for authorization purposes. The following table describes claim options in the resource partner.

| Claim option | Description |
|---|---|
| Incoming claims | Incoming claims are received by the resource partner. They are generated by the account federation server as outgoing claims. The claim names that you configure here are determined by an agreement with your account partner on a common namespace. |
| Incoming claim mappings | Incoming claim mappings map incoming claims to organization claims. |
| Organization claims | The resource federation server transforms, or maps, incoming claims to organization claims. Organization claims are used by the federation server—in this case, the resource federation server. This is the core set of claims that the organization uses for mapping. |
| Claim transformation modules | You can use the Active Directory Federation Services (ADFS) user interface (UI) on your federation servers to change the name of a claim during the mapping process; for example, Administrators may become Admins. This way, you can share claims with partners and express claims in a common namespace that does not necessarily match the way that you define your own organization claims.<br><br>There may be situations, though, in which simple mapping of claims may not be sufficient for your scenario. In these situations, you can develop a claim transformation module that modifies claim names and values as they pass through the federation server. For example, the claim transformation module might convert a claim containing a monetary value into another currency based on an exchange rate. Or, the module might look into a sales database and determine the discount level for a partner.<br><br>If you determine that building a claim transformation module is necessary for your scenario, see the ADFS software development kit (SDK) on the MSDN Web site for additional information about how the claim transformation module functions. To find the ADFS SDK, search for "ADFS SDK" on the MSDN home page (http://go.microsoft.com/fwlink/?LinkId=16188). |

# Review the role of the federation server in the account partner organization

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

A federation server in the account partner is used to log on local user accounts in either an Active Directory store or an Active Directory Application Mode (ADAM) store. A federation server also issues initial security tokens that the local user accounts can use to access Web-based applications that are hosted in the resource partner. In addition, a federation server in the account partner issues cookies to users to maintain their logon status. These cookies include claims for those users. The cookies enable single-sign-on (SSO) capabilities so that users do not have to enter credentials each time that the users visit different Web-based applications in the resource partner.

| **Note** |
| --- |
| To create a federation server from a computer in the account partner organization, you must first join the computer to any domain in the forest where the federation server will be used to authenticate users from that forest. |

# Review the role of the federation server in the resource partner organization

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

A federation server in the resource partner validates the security tokens that are issued by the federation server in the account partner. A federation server in the resource partner also issues security tokens that are sent to the Web-based applications in the resource partner. In addition, a federation server in the resource partner issues cookies to the user accounts. The cookies come from the account partner. These cookies enable single-sign-on (SSO) capabilities so that users do not have to log on again at the federation server in the account partner when the users attempt to access different Web-based applications in the resource partner.

| **Note** |
| --- |
| To turn a computer into a federation server in the resource partner organization, you must first join the computer to any Active Directory domain in the resource partner organization. However, in scenarios in which the resource partner will use an ADFS-enabled Web server to host a Windows NT token–based application, you must join the federation server to a domain in the same forest as the ADFS-enabled Web server. |

In the Web SSO design, at least one federation server must be installed in the protected network. In the Federated Web SSO design and the Federated Web SSO with Forest Trust design, there must be at least one federation server in the account partner and at least one federation server in the resource partner.

# Review the role of the federation server proxy in the account partner organization

Updated: November 15, 2007

Applies To: Windows Server 2003 R2

The role of the federation server proxy in the perimeter network of the account partner is to collect authentication credentials from a client that logs on over the Internet and to pass those credentials to the federation server, which is located inside the corporate network of the account partner. (The account for the client is stored in the account partner.) The federation server issues a security token to the federation server proxy, which then sends the token to the client. The security token is used to provide access for that client to a specific resource partner.

The federation server proxy uses a default client logon Web form (clientlogon.aspx) to collect password-based credentials through forms-based authentication. However, you can customize this form to accept other supported types of authentication, such as Secure Socket Layer (SSL) client authentication. For more information about how to customize this page, see Customizing Client Logon and Home Realm Discovery Pages (http://go.microsoft.com/fwlink/?LinkId=104275). A federation server proxy does not accept credentials through Windows Integrated authentication.

| **Caution** |
| --- |
| Exposing a federation server proxy on the account partner extranet will make the client logon Web form accessible by anyone with Internet access. This can potentially leave your organization vulnerable to some password-based attacks, such as dictionary or brute force attacks that can trigger account lockouts for those user accounts that are stored in the corporate Active Directory directory service. |

To summarize, a federation server proxy in the account partner acts as a proxy for client logons to a federation server that is located in the corporate network. The federation server proxy also facilitates the distribution of security tokens to Internet clients that are destined for resource partners.

# Review the role of the federation server proxy in the resource partner organization

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

The role of the federation server proxy in the perimeter network of the resource partner is to perform account partner discovery for Internet clients and to redirect security tokens.

- **Account partner discovery.** An Internet client must identify which account partner will authenticate it. The client finds the account partner by using an account partner discovery Web form (discoverclientrealm.aspx), which is stored on the federation server proxy in the resource partner. If more than one account partner is configured in the trust policy in the Active Directory Federation Services snap-in, a drop-down menu appears with all the available account partners that are visible to Internet clients who access the account partner discovery Web form. You can change how the account partner discovery Web form is presented to clients by customizing the discoverclientrealm.aspx file.

- **Redirect security tokens.** The federation server proxy in the account partner sends the security tokens to the resource partner. The resource federation server proxy accepts these tokens and passes them on to the federation server in the resource partner. The resource federation server then issues a security token that is bound for a specific resource Web server. The resource federation server proxy returns the token to the client.

When it is necessary to help reduce the amount of hardware and number of required certificates, the federation server proxy can be located on the same computer as the ADFS-enabled Web server.

To summarize, a resource federation server proxy facilitates the federated logon process by redirecting clients to a federation server that can authenticate the clients. A resource federation server proxy also acts as a proxy for client security tokens to resource federation servers.

# When to enable Windows trusts

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

Active Directory Federation Services (ADFS) has built-in support for federation in organizations where a forest trust or external trust exists between two forests that represent the same organization. External trusts and forest trusts are also known as Windows trusts.

| **Note** |
| --- |
| External trusts and forest trusts are not required for ADFS to function. |

When Windows trusts have been established and you have decided to deploy a Federated Web Single-Sign-On (SSO) with Forest Trust design in your organization, you can configure ADFS to work over Windows trusts.

To successfully implement the Federation Web SSO with Forest Trust design and configure ADFS to support the Windows trust model, do all of the following:

- Verify that a forest trust exists between two Windows Server 2003 forests or that an external trust exists between Windows Server 2003 or Windows 2000 Server domains in each forest (where the resource forest trusts the account forest). For more information about Windows trusts, see Administering Domain and Forest Trusts (http://go.microsoft.com/fwlink/?LinkId=63917).

- Configure the resource Federation Service to enable the **Use Windows trusts relationship** option in the properties of the account partner. For more information, see Configure an account partner to use Windows trust.

- Configure the account Federation Service to enable the **Use Windows trust relationship for this partner** option in the properties of the resource partner. For more information, see Configure a resource partner to use Windows trust.

| **Note** |
| --- |
| Both the resource Federation Service administrator and the account Federation Service administrator must enable the Windows trust option so that the Federated Web SSO with Forest Trust design can function correctly. |

# Prepare client computers for federation

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

The easiest way for an administrator in the account forest to prepare client computers for access to Active Directory Federation Services (ADFS) federated applications is to use Group Policy. Group Policy provides a convenient way for you to push specific certificates and settings that are required for federation down to all the client computers that will be used to access federated applications.

So that your client computers can seamlessly access federated applications without certificate prompts or trusted site–related prompts, we recommend that you first prepare each client computer before you deploy ADFS broadly in your organization. Consider using Group Policy to:

- Configure Internet Explorer on each client computer to trust the account federation server.

  For more information, see Configure client computers to trust the account federation server.

- Install the appropriate account federation server, resource federation server, and ADFS-enabled Web server Secure Sockets Layer (SSL) certificates (or equivalent certificates that chain to a trusted root) on each client computer.

  For more information, see Distribute certificates to client computers using Group Policy.

# Designing a Federated Application Strategy

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

An important part of designing a new Active Directory Federation Services (ADFS) infrastructure is determining the full set of applications that will participate in the federation and which organizational partners will be the recipients of those application resources. Before you design a federated application strategy, consider the following questions:

- Will your organization host the federated application or applications?
- Will you be deploying a claims-aware application or a Windows NT token-based application?
- Will users on the corporate network require access to the federated application through Windows Integrated authentication?
- Are all of the ADFS-enabled Web servers that host federated applications running the Windows Server 2003 R2 operating system and Internet Information Services (IIS) 6.0?
- Who will the federated application provides resources for?
- Will the federated application be used by users in your perimeter network? If so, will Windows Integrated authentication be required?
- Will you use a Public Key Infrastructure (PKI) or the Kerberos authentication protocol to sign and protect tokens?

Answering these questions will help you plan a solid design. It will also assist you in creating a federated application strategy that is cost effective and resource efficient. For more information about designing the most appropriate federated application strategy for your organization, see the following topics:

- Provide federated access for your hosted applications
- Provide federated access for your employees on the corporate network
- Provide federated access for your remote employees on the Internet
- Provide single-sign-on access for customers to your hosted applications
- Review the role of ADFS Web Agents
- Identify the type of federated application to deploy
- When to use Authorization Manager
- Determine your security token protection method
- Determine your resource account mapping method

# Review the role of ADFS Web Agents

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

Active Directory Federation Service (ADFS) Web Agents are Internet Server Application Programming Interface (ISAPI) extensions. They run on Internet Information Services (IIS) 6.0 and Windows Server 2003 R2, and they manage security tokens and authentication cookies for the Web server. An ADFS Web Agent intercepts incoming client Uniform Resource Locator (URL) requests for a protected resource and ensures that a valid authentication token is presented. If no valid authentication token is presented, the ADFS Web Agent redirects the client to the appropriate federation server or federation server proxy to begin the authentication and claims-creation processes.

| **Note** |
| --- |
| Several non-Microsoft Web agents are available that you can use to run federated applications on platforms other than IIS 6.0. These Web agents are based on a collaboratively developed specification for generating and consuming security tokens that fit a prescribed schema. This specification is called the WS-Federation Passive Requestor Interoperability Profile (WS-F PRP). |

If a valid authentication token is presented, the ADFS Web Agent provides the authorization data in the security token to the target application. An ADFS Web Agent can also write Hypertext Transfer Protocol (HTTP) cookies in client browsers to facilitate Web-based single sign-on (SSO).

ADFS Web Agents provide authorization support for two distinct types of Web applications:

- Applications that use Windows NT token–based authorization mechanisms, for example, access control lists (ACLs)
- Claims-aware ASP.NET 2.0 applications that can authorize against claims in the security token, using either ASP.NET roles or Authorization Manager

For more information about these types of federated applications, see Identify the type of federated application to deploy.

An ADFS Web Agent comprises two separate components:

- The ADFS Web Agent Authentication Service
- The ADFS Web Agent ISAPI Extension

The following sections describe these components.

**ADFS Web Agent Authentication Service**

The ADFS Web Agent Authentication Service validates incoming tokens and cookies. For this service to function correctly, the service account must be granted the TrustedComputingBase (TCB) Privilege. By default, this service runs as Local System.

| **Note** |
| --- |
| If you have a farmed Windows NT token-based application and you have configured the option **Domain service account** (with Kerberos) for the applications security token protection method, you must configure the ADFS Web Agent Authentication Service on each ADFS-enabled Web server that participates in the farm to run as the same domain service account that has been granted the TCB privilege. |

The ADFS Web Agent Authentication Service can generate tokens using either Service-for-User (S4U) or the ADFS authentication package. The IIS application pool is not required to run as Local System.

The ADFS Web Agent Authentication Service has remote procedure call (RPC) interfaces that may be called only from the local computer with local remote procedure call (LRPC), not RPC. This service returns a Windows NT access token if it is given an ADFS security token or an ADFS cookie.

**ADFS Web Agent ISAPI Extension**

The ADFS Web Agent ISAPI Extension is an IIS extension that enables ADFS authentication for Windows NT token-based

applications when those applications have had the ADFS Web Agent enabled through IIS.

In IIS Manager you can use the options on the **ADFS Web Agent** tabs on the **Web Sites** folder, **Default Web Site**, or on any additional Web site or virtual directory property pages to enable and configure a Windows NT token–based application for federation.

The ADFS Web Agent properties in the following table are inheritable. These properties are required on an IIS resource if the ISAPI extension is going to support WS-F PRP.

| Properties | Description |
|---|---|
| Federation Service URL | The URL of the Federation Service. This URL is required so that it may be queried for trust information by all the Web sites and federated applications on a Web server where the ADFS Web Agent is enabled. |
| Cookie path | The path that is specified when the authentication cookie is written. The cookie path identifies the location in an IIS Web site virtual directory to which cookies will be sent in response to an application request by an ADFS client.<br><br>If no cookie path is specified, the path defaults to a location that depends on whether a cookie domain is set, as follows:<br><br>• A cookie domain is set: / below the domain that applies for the requested address on the basis of the cookie domain.<br><br>• No cookie domain is set: / below the domain that is specified in the return URL.<br><br>If you specify a cookie path (for example, /test01), the cookie is sent for requests under that path (for example, /test01, /test01/index.html, /test01/test05/, and so on).<br><br>**Note**<br>The cookie path is case sensitive. It must match exactly with the name of the virtual directory that the federated application uses. |
| Cookie domain | The domain for which the cookie is valid. You can use the cookie domain setting to share an application at a higher level than the domain level that is specified in the return URL. In this way, you can expand the scope of requests for which a cookie will be sent.<br><br>If you do not configure a cookie domain, cookies are sent only in response to requests in which the domain that is specified matches the domain in the return URL. For example, if no cookie domain is set and the domain in the return URL is Sales.Adatum.com, cookies are sent only in response to requests in which the request URL matches Sales.Adatum.com. However, if you set Adatum.com as the cookie domain, cookies are sent in response to requests for Sales.Adatum.com plus requests for any other domain with the suffix Adatum.com. For example, cookies are also sent for Northwest.Adatum.com. |
| Return URL | The return URL that the token from the Federation Service comes back to after authentication at the Federation Service. The return URL identifies an application that is authenticated by ADFS to both the ADFS Web Agent and the Federation Service.<br><br>If the return URL for a federated application changes, you must change its value in IIS (for the Windows NT token–based Web Agent) or in the web.config file (for the claims-aware Web Agent).<br><br>**Note**<br>The **return URL** must match the **Application URL** that you configure in the properties of the application in the resource Federation Service. Therefore, if you change one URL, you must change the other. |

# Identify the type of federated application to deploy

Updated: January 10, 2008

Applies To: Windows Server 2003 R2

As part of the process of designing your deployment, identify the type of federated application that will be secured by Active Directory Federation Services (ADFS). All applications that are secured by Windows Server 2003 R2 ADFS Web Agents must be running under Internet Information Services (IIS) 6.0.

| **Note** |
| --- |
| Applications that require special client software or that are used for server-to-server communication are not good candidates for ADFS authentication. |

So that they can use ADFS Web Agents, each application must be at least one of the following application types:

- **Claims-aware application:** Claims-aware applications are Microsoft ASP.NET 2.0 applications that are written so that they can query ADFS security token claims. When a claims-aware application is presented with a valid token, the application can make authorization decisions based on the claims in the token.

- **Windows NT token–based application:** Windows NT token–based applications use Windows-based authorization mechanisms. These applications require Windows NT security tokens to make authorization decisions. ADFS can enable the transition of an ADFS security token to an impersonation-level Windows NT access token.

The following table shows the differences in requirements for each type of federated application.

| **Requirements and other factors** | **Claims-aware application** | **Windows NT token–based application** |
| --- | --- | --- |
| Requires the application to be written using ASP.NET 2.0 | Yes | No |
| Requires a user account in Active Directory | No | Yes |
| Requires a local Active Directory user store (to generate a user context for the application) | No | Yes |
| Requires Windows-based authorization mechanisms (such as access control lists (ACLs)) | No | Yes |
| Requires resource accounts or groups | No | Yes |
| Supported with ASP.NET 1.1 | No | Yes |
| Requires a web.config file | Yes | No |
| Can handle claims within the application code | Yes | No |
| Can use Authorization Manager for access control | Yes | No |

**Claims-aware applications**

When you set up a claims-aware application, all the information about a given identity is contained in the token that is presented by the application. The application may store additional information that links to the identity that is presented in the token, but a user account in Active Directory is not required to access a claims-aware application.

Federated applications that are claims aware should be developed specifically to use the claims that are produced by ADFS. When an application is presented with a valid token, the claims-aware application can make authorization decisions based on

the claims in the token.

For more information about how to deploy a claims-aware application, see Checklist: Installing a claims-aware application.

| Note |
| --- |
| When you configure the Web server to host only claims-aware applications, you do not have to provide values on any of the **ADFS Web Agent** tabs in the property sheets in IIS Manager. |

**Integrating with Authorization Manager**

Claims-aware applications can take advantage of role-based access control applications, such as Authorization Manager. Authorization Manager provides a flexible framework for integrating role–based access control into applications. Administrators who configure claims-aware applications can use Authorization Manager to provide access through assigned user roles that relate to job functions.

Authorization Manager applications maintain authorization policy in the form of authorization stores in Active Directory or XML files. The stores apply authorization policy at run time. For more information about ADFS and Authorization Manager, see When to use Authorization Manager.

**Windows NT token–based applications**

When you set up a Windows NT token–based application, you can map claims in incoming ADFS tokens to either user accounts or groups in the local Active Directory user store in the resource partner. The user accounts or groups are also known as resource accounts or resource groups. The application then uses the resource accounts or groups to perform authorization. For more information about resource accounts, see When to use resource accounts.

Applications that are protected by Windows Integrated authentication can—in some cases—be enabled as Windows NT token–based applications.

For more information about how to deploy a Windows NT token–based application, see Checklist: Installing a Windows NT token-based application.

| Note |
| --- |
| Because the ADFS Web Agent for Windows NT token–based applications implements authentication functions as an Internet Server Application Programming Interface (ISAPI) extension, an application that requires authentication in an ISAPI filter cannot be protected by ADFS. |

**Using SharePoint products as federated applications**

With ADFS in Windows Server 2003 R2, you can use either Microsoft® Windows® SharePoint® Services, Microsoft Office SharePoint Portal Server 2003, or Office SharePoint Server 2007 as supported federated applications. However, the level of support that ADFS provides depends largely on which SharePoint application that you will deploy.

| Important |
| --- |
| Before you deploy a specific SharePoint product for use with ADFS in your production environment, you should first read the following sections and the linked content to determine which SharePoint product best suits the needs of your organization when you use it as a federated application. |

**Using ADFS with previous versions of SharePoint products**

Windows SharePoint Services 2.0 and SharePoint Portal Server 2003 are considered to be Windows NT token–based applications as a result of their reliance on basic Windows-based authorization mechanisms. Because these SharePoint products depend on Windows-based access control, certain functionality will not be available when either Windows SharePoint Services 2.0 or SharePoint Portal Server 2003 are used as federated applications.

For more information about which functionality is supported in previous SharePoint products, see article 912492 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkId=107034).

For more information about how to configure Windows SharePoint Services 2.0 or SharePoint Portal Server 2003 as federated applications in a test lab environment, see the Step-by-Step Guide for Active Directory Federation Services (http://go.microsoft.com/fwlink/?LinkId=49531). This guide also provides instructions for removing unsupported SharePoint functionality that is not provided in the Knowledge Base article.

| Note |
| --- |

Previous versions of SharePoint products require the exclusive use of the default Web site in IIS.

**Using ADFS with current versions of SharePoint products**

Windows SharePoint Services 3.0 and Office SharePoint Server 2007 products can be configured as claims-aware applications as a result of their support for membership and role provider authorization mechanisms. Because these versions of SharePoint products can use membership and role-based access control, they do not require that resource accounts be created or used in the resource partner organization to take advantage of the single-sign-on (SSO) capabilities that are integrated into ADFS. This means that you can configure Windows SharePoint Services 3.0 and Office SharePoint Server 2007 as claims-aware applications for use with ADFS by using the SharePoint site administration page to configure membership and role-based access control permissions directly. However, for ADFS in Windows Server 2003 R2 to work smoothly with these SharePoint products, Service Pack 2 (SP2) must be installed on the ADFS-enabled Web server where the SharePoint product is installed.

For more information, see article 920764 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkId=107036).

For more information about how to configure Office SharePoint Server 2007 as a federated application, see Configure Web SSO authentication by using ADFS (http://go.microsoft.com/fwlink/?LinkID=84805).

**Note**

Although current versions of SharePoint products do not require the exclusive use of the default Web site in IIS, Windows SharePoint Services 3.0 and Office SharePoint Server 2007 do require the exclusive use of port 80. For this reason, installing these SharePoint products will automatically disable the default Web site in IIS. You can, however, enable the default Web site at a later time after you reassign the port number to something other than port 80.

# When to use Authorization Manager

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

Authorization Manager is a component of Windows Server 2003 that provides role-based access control (RBAC) infrastructure for applications. When Authorization Manager is used with Active Directory Federation Services (ADFS), it offers the following advantages:

- **Administrative efficiency:** Administrators can use Authorization Manager to map ADFS claims to specific application roles to more easily control and enforce corporate access policy, rather than have corporate access policy built directly into a claims-aware application.

- **Developer flexibility:** Developers can create claims-aware applications that take advantage of the application authorization framework of Authorization Manager. The applications can then use RBAC policy and claims to make authorization decisions.

Federated claims-aware applications must be written specifically to take advantage of RBAC. For information about how to map ADFS claims to Authorization Manager roles, see Deploying Applications Using Windows Authorization Manager (http://go.microsoft.com/fwlink/?LinkId=77376).

# Determine your security token protection method

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

You can use the Active Directory Federation Services snap-in to modify the way in which a federated application accepts security tokens from a resource federation server. This can be important when you have an application that requires a specific security-token-signing method, such as Public Key Infrastructure (PKI) or the Kerberos authentication protocol.

Security tokens that an ADFS-enabled Web server receives are signed and protected against tampering by resource federation servers using one of the following methods:

- **PKI:** The PKI method signs security tokens with the resource federation server's token-signing certificate. By default, the security-token-protection method in the Active Directory Federation Services snap-in is PKI.

- **Domain service account**: The domain service account method relies on the Kerberos authentication protocol to sign tokens using an assigned service principal name (SPN).

Federated applications that use PKI for token-signing have the following advantages over applications that use the domain service account method:

- PKI does not require the additional administrative overhead that is associated with manual configuration of service accounts for farmed federated applications.

- PKI can be used in scenarios in which you want an ADFS-enabled Web server, which hosts a federated claims-aware application, to not be joined to a domain (in a workgroup) or to be joined to a domain that is in a different domain than the domain that contains the resource federation server.

- PKI can be used to sign tokens in environments where Active Directory is not present, whereas the Kerberos protocol (which the domain service account method uses), relies on the Key Distribution Center (KDC) of Active Directory domain controllers to sign tokens.

Federated applications that use domain service account method (with the Kerberos authentication protocol) for token signing have the following advantages over PKI:

- The Kerberos protocol does not have the problem of certificate expiration because the expiration of Kerberos tickets is handled automatically.

- The Kerberos protocol provides better signing performance because it uses symmetric key operations, which are faster than the PKI asymmetric key operations.

For more information about how to configure either of these methods, see Configure the security token protection method for a federated application.

**PKI method**

The PKI method is the default value in the properties of the application in the Federation Service. This method is applied automatically when you create a new entry for a Windows NT token–based application or a claims-aware application. PKI is the default security-token-protection method because it does not require the additional configuration steps that the domain service account method requires.

When you use PKI as the security-token-protection method, the resource federation server signs only the tokens that are destined for the federated application (using the federation server's PKI-issued token-signing certificate) to protect the application from tampering.

**Domain service account method**

The domain service account security-token-protection method is an optional value in the properties of the application in the Federation Service. This method is identified by a service principal name (SPN). When a token is transferred using this method, the token contains a binary Kerberos V5 signature for the configured service account. This signature protects the token from

tampering.

If you select the domain service account method and you are using a single ADFS-enabled Web server to host your federation application, no additional service account configuration is necessary. This is because the domain service account on ADFS-enabled Web servers defaults to HOST\<*computername*>. For example, if you select the domain service account method in the properties of the application in the Active Directory Federation Services snap-in and the computer name of your ADFS-enabled Web server is ws.treyresearch.net, you type *HOST\ws.treyresearch.net*. Typing HOST\ws is also acceptable, but the full DNS name of the computer is preferred.

However, if you will be using the domain service account method for a federated application that is hosted on an ADFS-enabled Web server farm (where two or more servers run the appropriate Web Agent and they are used to load-balance the same federated application), there are additional considerations. The following section describes those considerations.

**Using the domain service account method in an ADFS-enabled Web server farm environment**
When you farm a federated application across multiple ADFS-enabled Web servers, you configure each ADFS-enabled Web server in the farm so that it points to the same SPN that is configured in the domain service account settings of the resource Federation Service. Complete the following steps to successfully configure your environment for the domain service account security-token-protection method.

**1. Create the service account**
If the domain service account method is selected in the Federation Service, you must type the SPN for a service account in the properties of the application. Before you can enter the SPN for a service account, you must first create a dedicated service account. The Kerberos protocol needs this service account to function properly and to allow pass-through authentication to the ADFS-enabled Web server. This service account is a dedicated account (that is, it should be used only as a service account) that you create in the Active Directory forest in the resource partner organization.

| **Note** |
| --- |
| To ensure that this service account is not interrupted as a result of domain password change requirements, consider configuring the account so that its password never expires. In the properties of the user account, select the **Password never expires** check box. |

**2. Set the SPN for the new service account**
Because the domain service account runs as a domain account, you must configure the SPN for this account in the domain. You configure the SPN with the Setspn command-line tool. Using a computer that is joined to the same domain where the service account resides, install Windows Server 2003 Support Tools to obtain Setspn.exe.

To install the Support Tools, on your Windows Server 2003 CD-ROM, go to the Support\Tools directory, double-click **Suptools.msi**, and follow the setup instructions. After you install the Support Tools, open a command-line prompt, type the following command, and then press ENTER:

**setspn -a <http/<** *farmclusterdnsname* **>** **<** *serviceaccountname* **>**

For example, in the scenario in which all ADFS-enabled Web servers are clustered under the DNS host name http://ws.treyresearch.net and the service account name that is assigned to the domain service account is adfswsfarm, type the following command:

**setspn -a** http/ws.treyresearch.net **adfswsfarm**

You need to complete this task only once for this account.

**3. Configure the Federation Service**
Now you configure the resource Federation Service to use the same ADFS-enabled Web server SPN that you configured previously, but without specifying the service account name. You can configure this SPN value in the **Domain service account** box for the application in the Active Directory Federation Services snap-in.

For example, if you select the domain service account method and your ADFS-enabled Web server has a computer name of ws.treyresearch.net, type the SPN value of http/ws.treyresearch.net. Also, the format host/ws.treyresearch.net is also acceptable in this field.

**4. Configure the service account on the ADFS-enabled Web server**
Now that the Federation Service contains the domain service account value of the ADFS-enabled Web server SPN, configure each ADFS-enabled Web server in the farm to also use the identity of the service account. However, the location where you configure the service account for each ADFS-enabled Web server is different, depending on the type of federated application that you are deploying in the farm. The following table indicates where in the user interface (UI) you specify the service account on each ADFS-enabled Web server, depending on the type of application that you are deploying in the farm.

| Federated application type | Configure the following: |
| --- | --- |
| Claims-aware application | The IIS application pool identity that is used by the federated application |
| Windows NT token–based application | The ADFS Web Agent Authentication Service |

You can use the following steps to configure each of your ADFS-enabled Web servers—based on the type of federated application—to use the service account that is required for Kerberos token-signing in the domain service account security-token-protection method.

**Claims-aware applications**

Complete the following steps on each of the ADFS-enabled Web servers in the farm when you want to use claims-aware applications with the Kerberos authentication protocol:

1. Open IIS Manager.
2. In the console tree, double-click **Application Pools**, right-click the specific **AppPool** that your federated application is using, and then click **Properties**.
3. On the **Identity** tab, click **Configurable**, and then type the service account name and password.
4. Click **OK** to exit the property page.
5. Repeat these steps on each ADFS-enabled Web server in the farm.

**Windows NT token–based applications**

Complete the following prerequisite tasks on each of the ADFS-enabled Web servers in the farm to configure the service account so that it will function correctly with the ADFS Web Agent Authentication Service:

- Grant the service account the TrustedComputingBase (TCB) privilege. For more information about the TCB privilege, see Review the role of ADFS Web Agents.
- Grant the service account the Audit privilege so that you can view all logged security audit events.
- Add the service account to the local IIS_WPG group.

Complete the following steps on each of the ADFS-enabled Web servers in the farm when you want to use Windows NT token–based applications with the Kerberos authentication protocol.

1. Open the Services snap-in.
2. Right-click **ADFS Web Agent Authentication Service**, and then click **Properties**.
3. On the **Log On** tab, click **This account**, and then type the service account name and password.
4. Click **OK** to exit the property page.
5. Repeat these steps on each ADFS-enabled Web server in the farm.

# Determine your resource account mapping method

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

In the past, Windows NT token–based applications could be used only by Windows users from the local forest or in trusting forests, that is, by users who could log on to the computer with Windows authentication techniques. By using Active Directory Federation Services (ADFS) and resource account mapping methods, you can extend access limits for Windows NT token-based applications, even across organizational boundaries in nontrusted forests.

In ADFS, resource account mapping is the act of mapping a federated user or a group of federated users to a security principal in Active Directory in the resource partner organization so that standard Windows authorization mechanisms can be applied to that security principal on the ADFS-enabled Web server. Resource account mapping is required when you federate Windows NT token–based applications because the Windows NT token–based Web Agent must reference an Active Directory security principal in the resource partner forest to build the Windows NT access token and thereby enforce access control permissions on the application.

| **Note** |
| --- |
| Claims-aware applications do not require resource account mapping because they use the ASP.NET membership and roles model, which means that they can inherently consume user principal names (UPNs) and group claims directly from the ADFS security token. |

The federation server in the resource partner organization supports any combination of the following three resource account mapping methods:

- Resource account
- Resource group
- Group-to-UPN mapping

You can use the information in the following table to help you determine which of these resource account mapping methods best suits your administrative needs.

| **Resource account mapping method** | **Description** | **Advantages** | **Disadvantages** |
| --- | --- | --- | --- |
| Resource account | A single security principal—usually a user account—created in Active Directory that is used to map to a single federated user | • Detailed user access control<br>• Verbose auditing results | High administrative overhead. Requires that account provisioning (creation, maintenance, and deletion) in Active Directory in the resource partner be tightly coupled with Active Directory in the account partner |

| | | | |
|---|---|---|---|
| Resource group | A single security group that is created in Active Directory that incoming group claims (ADFS group claims from the account partner) are mapped to. You can create more than one resource group. | • Eliminates the need to create and manage separate resource accounts for each federated user<br>• Uses standard access control lists (ACLs) to control authorization<br>• Highly scalable: one resource group can support an unlimited number of federated users that are mapped to it<br>• Accurate and accountable auditing results: The resource federation server provides a mechanism by which auditing can record events that uniquely identify each federated user. | The resource organization cannot control access to individual users, and it has to trust the account organization regarding group memberships |
| Group-to-UPN mapping | A group of federated users represented by the UPN of a user account that is created in the resource forest | • Eliminates the need to create and manage separate resource accounts for each federated user<br>• Highly scalable: one resource group can support a nearly unlimited number of federated users that are mapped to it | Inaccurate auditing results. Multiple user accounts are mapped to a single resource account that corresponds to a single UPN. Therefore, auditing cannot distinguish between the different accounts that were mapped. |

Because resource accounts, resource groups, and group-to-UPN mappings are all used solely for resource mapping, these methods are not used when the following conditions are true:

- The ADFS-enabled Web server and the resource federation server are joined to a domain in the forest or in a trusting forest where the identity resides.
- A one-way, cross-forest trust exists from the resource partner forest to the account partner forest.

In these situations, the federated user needing access to the Windows NT token–based application can access the resources directly in the resource forest by using the Windows trust.

The following topics are also relevant to resource account mapping methods:

- When to use resource accounts
- Select the optimal resource account option
- When to use resource groups
- When to use group-to-UPN mapping

# When to use resource accounts

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

Resource accounts are simply user accounts that are stored in a resource partner forest. What makes a resource account different from a standard user account is that the sole purpose of a resource account is to represent the security context of a single identity that does not originate from the resource forest or from any trusting forests.

Because a federated identity is not created from the resource forest, it does not have a security identifier (SID) that identifies it as a security principal to standard, Windows-based authorization controls (such as access control lists (ACLs)) on servers in the resource forest. Therefore, the federated identity is prevented from gaining access to any Web-based federated resources in the resource partner, such as Windows NT token–based applications, that use ACLs.

Active Directory Federation Services (ADFS) requires a way for a federated identity to correspond or map to an existing security principal that does, in fact, have a SID that represents the resource forest. ADFS uses resource accounts to map federated identities to existing security principals.

ADFS creates a security token using the resource account. It then presents the SID of the resource account to any access control mechanism in the resource partner forest or a trusting forest. At this point—because there is a one-to-one mapping of the federated identity to the resource account—the federated identity can be treated like any other user account by Web server administrators.

| **Note** |
| --- |
| A federated identity, in ADFS terms, is known as a federated user. |

Consider using the resource account mapping method when:

- You are deploying a Windows NT token–based application as your federated application, and it requires access control settings.

- You want to provide more detailed levels of access to sensitive or private data.

  For example, the user AlanSh must have a different set of rights than the rest of the Information Technology (IT) staff. In this case, the fact that a user account is AlanSh is given preference in terms of access rights over the fact that he is a member of the group that represents IT staff so that he can get the allowed level of privilege.

So that federated users can access Windows NT token–based applications, resource accounts must be security principals in Active Directory. You cannot use Active Directory Application Mode (ADAM) user accounts as resource accounts in the resource partner forest. However, you can use ADAM user accounts in the account partner forest. You can create a corresponding resource account in the resource partner forest to represent each ADAM user account.

| **Note** |
| --- |
| A resource account is not intended to be accessed directly by the federated user whose user account it represents. Therefore, the federated user does not have to know about the resource account because he or she does not have to log on with this account directly. Also, the password for the resource account does not have to match the password of the federated user account. |

**Best practices for using resource accounts**

The following practices are recommended for using resource accounts to map to a federated user:

- As a security best practice, add all resource accounts to a security group. Then, add this group to the **Deny log on locally** and **Deny log on through Terminal Services** user rights in Group Policy.

  | **Note** |
  | --- |
  | If a resource account is disabled, resource account mapping will not function because a Windows NT token cannot be created for that account. |

- Create a single organizational unit (OU)—or perhaps one OU per account partner—where you can place all of the resource accounts for a particular partner so that you can more easily manage or delegate administrative control through Group Policy.

- To prevent possible interruption of service for federated users as a result of password restrictions, configure each account (in the properties of the user account) so that the password never expires. Use the **Password never expires** setting in Group Policy.

- To optimize how resource accounts are processed in the resource Federation Service, review the advantages and disadvantages of various resource account options. For more information, see Select the optimal resource account option.

- To decrease administrative overhead, write your own provisioning software with a claim transformation module to create a resource account automatically, based on the incoming claims. For more information, see Configure a claims transform module.

**Comparing resource accounts to resource groups**

A single resource account has a one-to-one mapping to a federated user—and only that user. A resource group, however, has a one-to-many mapping scheme. You can use a single resource group to map to one or more federated users that are members of a security group in the account partner forest. For more information about resource groups, see When to use resource groups.

Although both resource account mapping methods provide similar functionality, meaning that both methods provide federated users with a means to access resources without possessing their own resource forest SID, a resource group can usually provide a more well-rounded set of benefits than its resource account counterpart. This is mostly attributable to the amount of administrative resources that you can consume by regularly creating, managing, and pruning individual resource accounts.

As shown in the following illustration, the choice of a correct resource account mapping method for your deployment is important, because it can, over time, severely affect the level of administrative overhead in your organization.

**Preparing the resource forest for resource accounts**

If you decide to use the resource account mapping method, you must make some minor changes to Active Directory. You must also make some minor access control changes to the ADFS-enabled Web server. As shown in the following illustration and described in the following steps, these changes include the following:

- Adding the appropriate user principal name (UPN) suffixes to the resource forest

- Creating each resource account using the appropriate UPN suffix

- Assigning the appropriate permissions to the resource accounts in the Windows NT token–based application

| **Note** |
| --- |
| No modifications to the account forest are necessary to configure resource account mapping. |

**1. Add a UPN suffix to the resource forest for each account partner**
The first step in successfully routing authentication requests that are sent from federated users in the forest of the account partner organization to Windows NT token–based applications that are hosted on an ADFS-enabled Web server in the forest of the resource partner organization is to add a UPN suffix to the resource partner forest for each account partner forest that contains federated users. For example, if you have two account forests named Adatum.com and Tailspintoys.com and the resource forest is named Treyresearch.net, you add Adatum.com and Tailspintoys.com as UPN suffixes in the Treyresearch.net forest.

For more information about adding a UPN suffix to a forest, see Add user principal name suffixes (http://go.microsoft.com/fwlink/?LinkId=78171).

**2. Create the resource accounts using the account partner UPN suffix**
After you add a UPN suffix in the resource forest to mirror the UPN suffix of the account forest, you create individual resource accounts and assign the newly added UPN suffix to them. The UPN suffix in the Security Assertion Markup Language (SAML) tokens that are created by the account partner must match the UPN suffix of the associated resource accounts for successful access to federated Windows NT token–based applications. For more information about creating a resource account, see Create a resource account in the resource partner forest.

For example, say that Alan Shen is an employee of A. Datum Corporation. He regularly logs in to the network using his UPN, AlanSh@Adatum.com. The administrator for Trey Research has been given the task of creating a resource account for the AlanSh account. In this example, Adatum.com is the name of the account partner forest, and Treyresearch.net is the name of the resource partner forest. The administrator of Treyresearch.net uses the Active Directory Users and Computers snap-in to create a new user account. In the **New Object - User** dialog box, he types **AlanSh** in the **User logon name** field. He then selects the newly created UPN suffix **@adatum.com** in the drop-down list and creates the user account.

**3. Assign access permissions to the resource accounts**

After you create your resource accounts, you configure your Windows NT token–based application on the ADFS-enabled Web server with the appropriate access permissions for those accounts. Depending on the application, you can configure access permissions using standard ACLs or using the authorization controls that are built directly into some Windows NT token–based applications.

For example, if you want to configure an ADFS-enabled Web server to federate a Microsoft® Windows® SharePoint® Services site across organizations, you assign the resource account permissions using the **Site Settings** link on the Windows SharePoint Services site. For more information about ADFS and Windows SharePoint Services support, see Identify the type of federated application to deploy.

# Select the optimal resource account option

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

Active Directory Federation Services (ADFS) provides controls that the resource administrator—that is, the ADFS administrator in the resource partner forest—can use to define how resource accounts are used for a particular account partner. The following table describes resource account options and the circumstances in which a resource administrator might use them.

| Resource account option | Description | Can be used when the resource administrator wants to: |
|---|---|---|
| **Resource accounts exist for all users** | Specifies that a resource account is configured for each user from the account partner that needs access to the resource. In this case, incoming group claims are not mapped to resource groups even if resource groups are configured. | • Maintain complete control over access that is granted to specific account partner users. This option is most suitable for managing a small number of account partner users. |
| **Resource accounts exist for some users (prefer resource account)** | Specifies that resource groups are used for some user accounts. This means that some users may have individual resource accounts created for them, while other users may be configured to use resource groups.<br><br>When this option is selected, ADFS first looks for resource accounts that match the user principal name (UPN) claim or e-mail claim that is specified in the incoming token. ADFS uses these resource accounts if they exist. Otherwise, if the token has a group claim that is mapped to a resource group, ADFS uses the resource group. | • Prefer a specific set of account partner users. In addition, this option allows the account partner to manage its users through groups.<br><br>• Override the rights of specific users in a group.<br><br>• Provide specific users who belong in a privileged group in the account partner with more-detailed access to the resource. |
| **Resource accounts exist for some users (prefer groups in token)** | This is the default setting. Specifies that ADFS can use its logic to determine if each incoming token maps to a resource group or if it looks for a resource account.<br><br>When this option is selected, ADFS first looks in the token for incoming group claims that it can map to a resource group. If ADFS finds the incoming group claims, it uses the resource group. If there is no incoming group claim, ADFS looks for a resource account to use. | • Prefer delegating account management to an account administrator, including management of a specific set of account partner users.<br><br>• Provide access for specific users who are not in the privileged group in the account organization when they need access to the resource. For example, a resource is accessible only to executives; however, the account administrator needs access to parts of the resource.<br><br>• Move delegation of account management to the account administrator. |
| **No resource accounts exist for this account partner** | Specifies that one or more resource groups will be used for all users in this account partner. This means that every token that is issued from this account partner will be required to contain one or more group claims that map to one or more resource groups in the resource partner forest. | • Completely delegate account management to the account organization. |

For more information about how you can modify these resource account options, see Configure resource account options.

**Comparing resource account options**

Before you select any other option besides the default option, compare the various advantages and disadvantages that can result from using another resource account option, as described in the following table.

| Resource account option | Advantages | Disadvantages |
|---|---|---|
| **Resource accounts exist for all users** | • Access control list (ACL) model—the resource must be assigned permissions for the security identifier (SID) of the resource account or against SIDs for groups that the resource account is a member of. | • Administrative cost—high for large-scale account management at the resource partner. Costs can rise, depending on whether the account partner uses privacy enhancements. |
| **Resource accounts exist for some users (prefer resource account)** | • ACL model—the resource must be assigned permissions for the SID of the existing resource accounts, against SIDs for groups that the resource account is a member of, and also the SIDs of resource groups that correspond to groups in the token.<br>• Administrative cost—scalable, depending on the number of exception cases. | • Performance—slow as a result of account lookup<br>• Administrative cost—costs can rise, depending on whether the account partner uses privacy enhancements. |
| **Resource accounts exist for some users (prefer groups in token)** | • ACL model—the resource must be assigned permissions for the SID of the existing resource accounts, against SIDs for groups that the resource account is a member of, and also the SIDs of resource groups that correspond to groups in the token.<br>• Performance—In most cases, there is better performance. Exceptions are cases in which user account lookup occurs.<br>• Administrative cost—scalable, depending on the number of exception cases. | • Administrative cost—costs can rise, depending on whether the account partner uses privacy enhancements. |
| **No resource accounts exist for this account partner** | • ACL Model—ACL using groups.<br>• Performance—Better.<br>• Administrative cost—significantly less administrative costs are associated with account partners using privacy enhancements. | • Administrative cost—low, depending on the number of exception cases |

# When to use resource groups

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

In its simplest form, a resource group is a security group in the resource partner forest. Depending on the needs of your organization, you can create a resource group in Active Directory as a domain local group, a global group, or a universal group. When it is used with Active Directory Federation Services (ADFS), however, a resource group becomes a highly effective mapping method that administrators can use to easily map multiple federated users to a single security group.

Resource groups are considered to be a low-cost alternative to resource accounts because they do not require the administrative overhead that is associated with creating and maintaining resource accounts. Consider using the resource group mapping method when:

- You must eliminate or reduce the use of resource accounts. For more information, see When to use resource accounts.
- A Windows NT token–based application will be deployed as a federated application, and it requires per-group authorization.

**Mapping federated users to a resource group**

After federated users have been mapped to a resource group, ADFS-enabled Web servers can make authorization decisions to Windows NT token–based applications based on the access permissions that are assigned to the security identifier (SID) for the resource group. Federated users can be mapped to multiple resource groups for role based access control.

Windows NT token–based applications require access control mechanisms that are based on a valid SID that originates from the resource forest. When a Security Assertion Markup Language (SAML) token from an account partner organization is presented to the Federation Service in the resource partner organization, the resource federation server maps the claims in the SAML token to organization claims that are defined in its own organization, and it forms an organizational token. A component of the Federation Service referred to as the mapping module maps claims using the rules that you provide in the properties of the account partner in the resource Federation Service. If the organizational token contains any group claims that are associated with resource groups, the resource group information is also added to the SAML token. When this organizational token is presented to the Web application, the ADFS Web Agent for Windows NT token–based applications has an authentication package that can create tokens for federated users with group memberships as the resource groups in their token.

The following illustration shows the mapping module and how organization claims that have been previously mapped to a resource group carry the SID of the resource group into the new SAML token for the federated user. This illustration also shows how you can map multiple account security groups to a single resource group.

**How resource groups are applied to the SAML token**

The following illustration and corresponding steps show what happens when resource groups are applied to the SAML token.

1. The SAML token is sent by the account partner, and it contains the incoming group claim payload, along with any other claims that are assigned to Nate.

2. The mapping module in the Federation Service extracts Nate's claims from the SAML token and associates those claims with organization claims that reside in the Federation Service.

3. If the administrator has mapped an organization claim in the Federation Service to a resource group, the SID for that

resource group is added to the new SAML token that the resource federation server creates.

4. The new SAML token for Nate, which now includes the SID of the resource group, is then sent to the ADFS-enabled Web server through a client redirect so that the Web server can perform an access check against the access control lists (ACLs) that are associated with the Windows NT token–based application.

**How resource groups provide access control**

The following illustration and corresponding steps show what happens when resource groups provide access control.

1. A separate SAML token is created for each federated user and then sent by an account federation server to the resource federation server. Each token contains incoming group claims along with any other claims that are assigned to that federated user.

2. The mapping module in the Federation Service extracts the claims and maps them to organization claims that reside in the Federation Service.

3. If resource group SIDs are mapped to organization claims that are used by the incoming claims, these SIDs are added to the new SAML token that is created by the resource federation server. These SIDs are then sent in the token to the ADFS-enabled Web server.

4. The SAML token is used by the ADFS-enabled Web server to perform an access check on the Windows NT token–based application.

5. The access check determines whether or not the client has permission to perform the current operation with the application.

6. The ADFS-enabled Web server returns a page to the client, depending on the outcome of the access check.

# When to use group-to-UPN mapping

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

Group-to-UPN (user principal name) claim mapping is one resource account mapping method that you can use in the resource Federation Service when claims are incoming from an account partner. In this context, "group" is the account partner security group and all the incoming claims that come from its federated member accounts; "UPN" represents a single user account in the resource partner forest. Group-to-UPN mappings map the claims of multiple federated user accounts, which are members of a security group in the account partner, to a single UPN that represents a single user account in the resource partner.

You can use the Active Directory Federation Services snap-in to create an ordered list of group-to-UPN claim mappings. The order of the group-to-UPN mappings is specified in the trust policy for the Federation Service. A group-to-UPN mapping list might be as follows:

1. Dev to devuser@adatum.com
2. Test to testuser@adatum.com
3. PM to pmuser@adatum.com

For example, if an incoming claim set contains (Common name=John Smith, Group=[Dev]), the organization claim set contains (Common name=John Smith, UPN=devuser@adatum.com). Because the list is ordered, a claim set of (Common name=John Smith, Group=[Dev,PM]) results in (Common name=John Smith, UPN=devuser@adatum.com).

**Comparing group-to-UPN mappings to resource groups**

When you use group-to-UPN mappings, audits that pertain to any user with a particular group claim contain the same mapped UPN as the user name. This means that the group-to-UPN mapping method cannot produce audits that identify which specific federated user was attempting an auditable action. This auditing limitation makes the group-to-UPN mapping method different from the resource group mapping method.

### Recommendation

Group-to-UPN mappings act in similar ways to resource groups. However, because group-to-UPN mappings lack the capability to record audits in more detail, we recommend that you consider deploying either the resource account mapping method or the resource group mapping method instead. For more information about how to implement a mapping method that records detailed audits, see When to use resource groups.

# Planning ADFS-Enabled Web Server Placement

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

An Active Directory Federation Services (ADFS)–enabled Web server relies on ADFS Web Agents to check if incoming requests need to be authenticated, and if so, the server directs the requests to a resource federation server to perform the actual authentication. The ADFS Web Agents also parse the tokens and cookies that are issued by the federation server to determine if access to the given application should be granted.

You must place at least one ADFS-enabled Web server in the resource partner organization. See the following topics for details about determining when and where to create and place an ADFS-enabled Web server:

- When to create an ADFS-enabled Web server
- Where to place an ADFS-enabled Web server
- When to create an ADFS-enabled Web server farm

| **Note** |
| --- |
| Although this information may help with your placement planning for ADFS-enabled Web servers, it does not explain how to determine the proper number of ADFS-enabled Web servers or the server hardware requirements for each ADFS design. For more information about determining the proper number of ADFS-enabled Web servers for each design, see Planning for ADFS-enabled Web server capacity. |

For examples of where ADFS-enabled Web servers can be placed in any of the three primary ADFS design scenarios, see Mapping Your Deployment Goals to an ADFS Design.

Certificate requirements for ADFS-enabled Web servers
Name resolution requirements for ADFS-enabled Web servers

# When to create an ADFS-enabled Web server

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

Create at least one Active Directory Federation Services (ADFS)–enabled Web server in the resource partner organization when you deploy any of the following ADFS designs:

- Web SSO design
- Federated Web SSO design
- Federated Web SSO with Forest Trust design

The quickest way to get your federated applications up and running is to install and configure them on a single ADFS-enabled Web server. This way, you can set up a small-scale installation without performing the additional steps necessary to set up an ADFS-enabled Web server farm.

For more information about deploying federated applications, see Designing a Federated Application Strategy.

**Why an ADFS-enabled Web server is required**

An ADFS-enabled Web server provides the appropriate Web Agent software (ADFS Web Agents)—either claims-aware Web Agents or Windows NT token–based Web Agents—that are necessary for authenticating and authorizing federated access to locally hosted, Web-based applications. ADFS-enabled Web servers use these Web Agents to consume security tokens and authentication cookies—to either allow or deny a user access to the protected application—taking into consideration application-specific access control settings. Web Agents enforce application-based access control requirements by creating a security context in which the application can make the appropriate authorization decision.

For the ADFS-enabled Web server to know what tokens to accept, it must have a relationship with a federation server. This relationship is necessary so that all security tokens that are presented to the Web Agent (and destined for the application) are signed by that federation server (or any of the federation servers that represent that Federation Service). A signed security token indicates that the federation server has successfully verified the authenticity of the federated user.

To summarize, ADFS-enabled Web servers are a critical component of the ADFS infrastructure. ADFS Web Agents on these servers confirm that the incoming security tokens are signed by a valid federation server before they send federated access requests to the protected application.

# Where to place an ADFS-enabled Web server

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

As is typical with perimeter networks, an intranet-facing firewall is established between the perimeter network and the corporate network, and an Internet-facing firewall is often established between the perimeter network and the Internet. In this situation, an Active Directory Federation Services (ADFS)–enabled Web server is placed between both of these firewalls on the perimeter network so that users coming from the Internet can access it.

In contrast, federation servers are typically placed inside the corporate network for security purposes. In scenarios in which you want to reduce the number of servers or public certificates in your ADFS deployment, you can make your ADFS-enabled Web server a federation server or federation server proxy by installing either the Federation Service or Federation Service Proxy component. However, placing a federation server on the perimeter network exposes that server to Internet clients, and this is not a security best practice. For more information, see Where to place a federation server.

**Configuring your firewall servers for an ADFS-enabled Web server**

So that ADFS-enabled Web servers can communicate directly with federation servers, both the intranet-facing firewall server and the Internet-facing firewall server must be configured to allow Secure Hypertext Transfer Protocol (HTTPS) traffic, usually over port 443. HTTPS configuration is required because ADFS-enabled Web servers communicate with federation servers—and with clients—over HTTPS. ADFS relies on HTTPS to provide channel security.

In addition, intranet-facing and Internet-facing firewall servers, such as servers running Internet Security and Acceleration (ISA) Server, use a process known as server publishing to distribute Internet client requests to the appropriate corporate federation servers and ADFS-enabled Web servers. Consequently, you must manually create a server publishing rule on any intranet and Internet ISA Server computers that publish the ADFS-enabled Web server URL (http://ws.treyresearch.net).

For general information about how to configure ISA Server to publish a server, see Create a secure Web publishing rule (http://go.microsoft.com/fwlink/?LinkId=74605).

**Joining an ADFS-enabled Web server to a domain**

When they host a Windows NT token-based application, ADFS-enabled Web servers must be joined to the same domain that the resource federation server belongs to. Because claims-aware applications do not require a Windows NT token for authorization, servers that host only claims-aware applications do not have to be joined to any domain.

# When to create an ADFS-enabled Web server farm

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

You create an Active Directory Federation Services (ADFS)-enabled Web server farm when you want to balance the load of incoming federated access requests that are made to one or more protected applications. The obvious benefits that can be obtained from a Web server farm are fault tolerance for the hosted applications and a possible increase in client-side browser performance. To client computers, the Web server farm performs like a single Web server servicing a highly scalable federated application.

If you are thinking about creating a Web server farm solely to increase performance, consider whether it might be better to optimize the hardware or software performance of a single Web server before adding the additional costs and administrative overhead that are associated with synchronizing data between two or more Web servers. For more information about how to measure whether your ADFS-enabled Web server is performing optimally, see Planning for ADFS-enabled Web server capacity.

You can use a network load-balancing service, such as the Microsoft Network Load Balancing (NLB) service that is included in Windows Server 2003 operating systems, to create and manage your ADFS-enabled Web server farm. The number of Web servers that is required to support your federated applications is determined largely by the type and complexity of the applications and their client connection state (stateless as opposed to stateful) requirements.

Guidelines for creating server farms for federated applications using NLB are similar to the guidelines for creating server farms for nonfederated Web applications running on Internet Information Services (IIS) 6.0. For more information about using nonfederated Web applications with NLB, see Identifying Applications That Benefit from NLB (http://go.microsoft.com/fwlink/?LinkId=74610).

When they are used together, the recommendations in the NLB deployment documentation and in the topic Planning for ADFS-enabled Web server capacity should provide sufficient data for you to determine whether your federated applications can benefit from the improved scalability and availability that an ADFS-enabled Web server farm environment provides.

**Configuring servers in the farm**

Creating an ADFS-enabled Web server farm involves more than just placing the Web servers in a resource partner organization and then configuring NLB clustering. The following table provides additional guidance for identically configuring each of the ADFS-enabled Web servers in a farm.

| To configure the ... | To ... | See ... |
|---|---|---|
| Claims-aware Web Agent in the web.config file for the protected application | Point to the same Federation Service Uniform Resource Locator (URL) for each ADFS-enabled Web server in the farm | Set the Federation Service URL for a claims-aware application |
| Windows NT token–based Web Agent in the properties of the Web Sites folder in IIS 6.0 | Point to the same Federation Service URL for each ADFS-enabled Web server in the farm | Set the Federation Service URL for a Windows NT token-based application |
| Server authentication certificate | Export the private key so that the same server authentication certificate can be assigned to each ADFS-enabled Web server in the farm<br><br>Most certificates that are issued by certification authorities (CA)s can be used on multiple computers without first exporting them. If this is the case in your scenario, you do not have to perform this procedure.<br><br>**Note**<br>There is no requirement to use the same certificate on all ADFS-enabled Web servers as long as all Web servers in the farm have a certificate that is issued by the same CA and each of the certificates have a matching "subject name" field. | Export the private key portion of a server authentication certificate |

| | | |
|---|---|---|
| Server authentication certificate | Install on the appropriate Web site or virtual directory where your federated application will reside<br><br>(For an example of how to do this using the default Web site, see the following link.) | Import a server authentication certificate to the default Web site |

For additional details about how to configure an ADFS-enabled Web server farm, see Checklist: Installing an ADFS-enabled Web server.

# Certificate requirements for ADFS-enabled Web servers

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

Each Web server that hosts an Active Directory Federation Services (ADFS) Web Agent requires a Secure Sockets Layer (SSL) server authentication certificate to communicate securely with Web clients. Publicly issued certificates are recommended for SSL server authentication certificates. However, if you are deploying the ADFS Web Single Sign-On (SSO) design, using either a public or corporate certification authority (CA) to obtain your server authentication certificate is sufficient.

| **Note** |
| --- |
| Token-signing certificates and SSL client authentication certificates are not necessary for ADFS-enabled Web servers. |

If you will be hosting additional ADFS components, such as the Federation Service or the Federation Service Proxy, on an already established ADFS-enabled Web server, it is not necessary to obtain additional server authentication certificates for each of those components. The ADFS Web Agent, the Federation Service, and the Federation Service Proxy can use a single server authentication certificate simultaneously. For more information about hosting multiple ADFS components on an ADFS-enabled Web server, see Where to place an ADFS-enabled Web server.

You can request and install server authentication certificates through the Microsoft Management Console (MMC) snap-in for Internet Information Services (IIS). For more general information about using SSL certificates, see Configuring Secure Sockets Layer (http://go.microsoft.com/fwlink/?linkid=62785) and Obtaining Server Certificates (http://go.microsoft.com/fwlink/?linkid=62479).

**Certificate requirements for an ADFS-enabled Web server farm**

In an ADFS-enabled Web server farm scenario, Web servers must obtain server authentication certificates in one of the following ways for ADFS to work:

- **Share the same certificate:** Web servers can share the same server authentication certificate across the farm. To share the same certificate across the Web servers, export the private key of that certificate and install it on the appropriate Web site for each Web server.

  For more information, see Export the private key portion of a server authentication certificate and Import a server authentication certificate to the default Web site.

- **Obtain individual certificates:** If you decide to obtain separate server authentication certificates for each Web server in a farm, you must ensure that the subject names for each of the individual server authentication certificates match. The subject name value for a server authentication certificate is used to identify the computer that the certificate represents.

  | **Note** |
  | --- |
  | Certification authorities (CAs) such as Microsoft Certificate Services create the subject name from the common name (CN) of the requestor that is obtained in Active Directory. |

For more information about configuring an ADFS-enable Web server farm, see When to create an ADFS-enabled Web server farm.

# Name resolution requirements for ADFS-enabled Web servers

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

Before a Web browser client can contact an Active Directory Federation Services (ADFS)–enabled Web server over the Internet, the Web browser must first use Domain Name System (DNS) to resolve the Web server's host name to the actual IP address for an ADFS-enabled Web server that is located in a perimeter network. The following standard DNS tree-walking processes accomplish name resolution to federated applications:

1. The browser client contacts a top-level-domain DNS server on the Internet to resolve the fully qualified domain name (FQDN) of the target Web site that was typed into the browser.

2. The top-level-domain DNS server resolves the FQDN by providing the client with the IP address for the DNS server that is authoritative for the DNS domain that is specified in the Web site address.

   | **Note** |
   | --- |
   | In the federated world of ADFS, this DNS server is the DNS server that is located in the perimeter network of the resource partner organization. |

3. Using values that are stored in preconfigured host address (A) resource records, the perimeter DNS server resolves the target FQDN to the IP address of the ADFS-enabled Web server and then provides that information back to the client.

For more information about how the DNS process works, see How DNS Works (http://go.microsoft.com/fwlink/?LinkId=74637).

**Configuring perimeter DNS**

DNS is required for successful name resolution across the Internet to an ADFS-enabled Web server. DNS must be configured for a new host record that will resolve the IP address of the Web server cluster (if the Web servers are farmed) to a single Web server IP address and DNS host name. You configure DNS in the perimeter network of the resource partner.

In the following illustration, you can see how to configure the perimeter DNS so that it contains a single host (A) record for ws (ws.treyresearch.net) and so that it points to the IP address of the ADFS-enabled Web server cluster in the perimeter network. In this scenario, Network Load Balancing (NLB) provides a single, cluster FQDN name and a single, cluster IP address for an existing ADFS-enabled Web server farm.

For more information about how to configure a cluster IP address or a cluster FQDN using Microsoft NLB technology, see Specifying the Cluster Parameters (http://go.microsoft.com/fwlink/?LinkId=74651).

For more information about how to configure perimeter DNS, see Add a host (A) record to perimeter DNS for an ADFS-enabled Web server.

# Planning Federation Server Placement

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

The most critical component of an Active Directory Federation Services (ADFS) deployment is the federation server. Therefore, it is important that you plan your federation server placement strategy carefully, including when and where to deploy federation servers. The information in the following topics can help you determine when and where to create a federation server and whether to use that federation server in either the account partner role, the resource partner role, or both.

- Review the role of the federation server in the account partner organization
- Review the role of the federation server in the resource partner organization
- When to create a federation server
- Where to place a federation server
- When to create a federation server farm
- Certificate requirements for federation servers
- Name resolution requirements for federation servers

| **Note** |
| --- |
| Although this information might help with your placement planning for federation servers, it does not explain how to determine the proper number of federation servers and the hardware requirements for each ADFS design. For more information about determining the proper number of federation servers for each design, see Planning for federation server capacity. |

For examples of how a federation server can be placed in any of the three primary ADFS design scenarios, see Mapping Your Deployment Goals to an ADFS Design.

# When to create a federation server

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

You create federation servers in your organization whenever you want to deploy any of the following Active Directory Federation Services (ADFS) designs:

- Web SSO design
- Federated Web SSO design
- Federated Web SSO with Forest Trust design

When you create a federation server, you provide a means by which your organization can engage in Web single-sign-on (SSO)–based communication with another organization (that also has at least one federation server) and, when necessary, with the employees in your own organization (who need access over the Internet).

The role that a federation server plays in your organization depends on whether you place the federation server in the account partner organization or in the resource partner organization. For example, when a federation server is placed in the corporate network of the account partner, its role is to authenticate the user credentials of browser clients and send security tokens to the clients. When a federation server is placed in the corporate network of the resource partner, its role is to authenticate users, based on a security token that is issued by a federation server in the resource partner organization, or its role is to redirect token requests from configured Web applications to the account partner organization that the client belongs to.

For more information about account partner and resource partner organizations, see Planning Partner Organization Deployments.

| **Note** |
| --- |
| For the Federated Web SSO and Federated Web SSO with Forest Trust designs, there must be at least one federation server in the account partner and at least one federation server in the resource partner. |

If necessary, an organization that deploys a Federated Web SSO or Federated Web SSO with Forest Trust design can configure a single federation server so that it acts in both the account partner role and in the resource partner role. In this case, the federation server may produce Security Assertion Markup Language (SAML) tokens, based on user accounts in its own organization, or reroute token requests to the organization, based on where the users' accounts reside.

In the Web SSO design, where the user account exists in the same organization as the resource, it is not necessary to configure federation servers for either an account partner or a resource partner. The Federation Service, in this case, produces SAML tokens for the user that can be directly used on the resource.

**Differences between federation servers and federation server proxies**

Federation servers can serve out Web pages for sign-in, policy, authentication, and discovery in the same way that a federation server proxy does. The primary differences between a federation server and a federation server proxy have to do with what operations a federation server can perform that a federation server proxy cannot perform.

The following are the operations that only a federation server can perform:

- The federation server performs the cryptographic operations that produce the token. Although federation server proxies cannot produce tokens, they can be used to route or redirect the tokens to clients and, when necessary, back to the federation servers. For more information about using federation server proxies, see When to create a federation server proxy.
- Federation servers support the use of Windows Integrated authentication for clients on the corporate network, where federation server proxies do not. For more information about using Windows Integrated authentication with federation servers, see When to create a federation server farm.

**Concepts**

Review the role of the federation server in the account partner organization
Review the role of the federation server in the resource partner organization

# Where to place a federation server

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

As a security best practice, place federation servers in front of a firewall and connect them to the corporate network to prevent exposure from the Internet. This is important because federation servers have full authorization to grant security tokens. Therefore, they should have the same protection as a domain controller. If a federation server is compromised, a malicious user has the ability to issue full access tokens to all Web applications and federation servers that are protected by Active Directory Federation Services (ADFS) in all resource partner organizations.

| **Note** |
| --- |
| As a security best practice, avoid having your federation servers directly accessible on the Internet. Consider giving your federation servers direct Internet access only when you are setting up a test lab environment or when your organization does not have a perimeter network. |

For typical corporate networks, an intranet-facing firewall is established between the corporate network and the perimeter network, and an Internet-facing firewall is often established between the perimeter network and the Internet. In this situation, the federation server sits inside the corporate network, and it is not directly accessible by Internet clients.

| **Note** |
| --- |
| Clients that are connected to the corporate network can communicate directly with the federation server through Windows Integrated authentication. |

A federation server proxy should be placed in the perimeter network before you configure your firewall servers for use with ADFS. For more information, see Where to place a federation server proxy.

**Configuring your firewall servers for a federation server**

So that the federation servers can communicate directly with federation server proxies, the intranet firewall server must be configured to allow Secure Hypertext Transfer Protocol (HTTPS) traffic from the federation server proxy to the federation server. This is a requirement because the intranet firewall server must publish the federation server using port 443 so that the federation server proxy in the perimeter network can access the federation server.

| **Note** |
| --- |
| All communications to and from clients also occur over HTTPS. |

In addition, the intranet-facing firewall server, such as a server running Internet Security and Acceleration (ISA) Server, uses a process known as server publishing to distribute Internet client requests to the appropriate corporate federation servers. This means that you must manually create a server publishing rule on the intranet server running ISA Server that publishes the clustered federation server Uniform Resource Locator (URL), for example, http://fs.adatum.com.

For more information about how to configure server publishing in a perimeter network, see Where to place a federation server proxy. For information about how to configure ISA Server to publish a server, see Create a Secure Web Publishing Rule (http://go.microsoft.com/fwlink/?LinkId=75182).

If you are using the Federated Web SSO with Forest Trust design, be sure to open the ports that are required for setting up a one-way, forest trust. For more information about network ports that trusts use, see Domain and Forest Trust Tools and Settings (http://go.microsoft.com/fwlink/?LinkId=79059).

# When to create a federation server farm

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

Consider installing additional federation servers when you have a larger Active Directory Federation Services (ADFS) deployment and you want to provide fault tolerance, load balancing, or scalability to your organization's Federation Service. The act of creating two or more federation servers in the same network, configuring each of them to use the same trust policy file, and adding the public key of each server's token-signing certificates (verification certificates) to the trust policy creates a federation server farm.

Before federation servers can be grouped as a farm, they must first be clustered so that requests arriving at a single fully qualified domain name (FQDN) are routed to the various federation servers in the server farm. You can create the server cluster by deploying Network Load Balancing (NLB) inside the corporate network. This guide assumes that NLB has been configured appropriately to cluster each of the federation servers in the farm.

For more information about how to configure a cluster FQDN using Microsoft NLB technology, see Specifying the Cluster Parameters (http://go.microsoft.com/fwlink/?LinkID=74651).

**Best practices for deploying a federation server farm**

The following best practices are recommended for deploying a federation server in a production environment:

- If you will be deploying multiple federation servers at the same time or you know that you will be adding more servers to the farm over time, consider creating a server image of an existing federation server in the farm and then installing from that image when you need to create additional federation servers quickly.

  | **Note** |
  | --- |
  | If you do decide to use the server image method for deploying additional federation servers, you do not need to complete the tasks in Checklist: Installing a federation server every time that you want to add a new server to the farm. |

- Use NLB or some other form of clustering to allocate a single IP address for many federation server computers.

- Reserve a static IP address for each federation server in the farm and, depending on your Domain Name System (DNS) configuration, insert an exclusion for each IP address in Dynamic Host Configuration Protocol (DHCP). Microsoft NLB technology requires that each server that participates in the NLB cluster be assigned a static IP address.

- Avoid editing the trust policy from multiple federation servers at the same time.

**Configuring federation servers for a farm**

The following table describes the tasks that must be completed so that each federation server can participate in a farmed environment.

| Task | Description |
| --- | --- |

| | |
|---|---|
| Store the trust policy file on a protected network shared folder | A federation server farm consists of two or more federation servers that share the same trust policy information and token-signing certificates. If you currently have one federation server and you will be adding additional federation servers, you will have to move the location of the trustpolicy.xml file to a protected network shared folder so that it can be accessed by all new federation servers that participate in the farm.<br><br>**Note**<br>For farmed scenarios, it is important that the trust policy file be shared on a computer that does not also participate as a federation server in that farm. Microsoft NLB does not allow any of the computers that participate in a farm to communicate with one another.<br><br>After the trustpolicy.xml file has been placed in a shared folder, you protect that share with the appropriate permissions. This means that for each new federation server to successfully share a trust policy file, you must provide at least Read-only access permissions to each of the machine accounts on every federation server in the farm. The administrator of the Federation Service will be able to modify the trust policy file even though the machine accounts have Read-only permissions.<br><br>**Note**<br>Ensure that the identity of the ADFSAppPool on every federation server that participates in the farm has Read access to the shared trust policy file. |
| Obtain and share certificates | A single server authentication certificate can be obtained from a public certification authority (CA)—for example, Verisign—and then configured so that all federation servers share the same private key portion of the certificate. For more information about how to share the same certificate, see Checklist: Configuring certificates for a federation server.<br><br>Unique token-signing certificates can be acquired for each federation server or you can obtain one certificate and share it among all other federation servers in the farm. For more information, see Certificate requirements for federation servers. |
| Point to the trust policy file location | The new federation server must point to the same trust policy file that is used by other federation servers in the farm so that the new server can participate in the farm. The federation server uses the values that are specified in the Federation Service endpoint **Uniform Resource Locator (URL)** and Federation Service **Uniform Resource Identifier (URI)** fields, in the trust policy properties, to identify precisely which ADFS instance, or Federation Service, it belongs to.<br><br>**Note**<br>After you point the new federation server to the existing trust policy file location successfully (which is typically done at setup time), you do not have to alter the existing URL and URI values that are specified in the properties of the trust policy because this information is shared and it applies to every federation server in the farm. |
| Add the verification certificate to the trust policy | The public key of the token-signing certificate that is assigned to the new federation server must be added to the trust policy. The public key of the token-signing certificate is also referred to as the verification certificate.<br><br>This certificate is automatically added to the trust policy when you select an existing trust policy during the installation of the Federation Service or when you select a different token-signing certificate using the Active Directory Federation Services snap-in (click **Yes** when you are prompted to add it to the trust policy).<br><br>In this scenario, you do not have to manually add a verification certificate file to the trust policy. |
| Add Common View State Element to the web.config file | Add the `<pages enableViewStateMac="true"/>` element under the `<system.web>` section of the web.config file on each of the federation servers that participate in the farm. You must configure this element in the web.config file to post form data and to prevent view state validation failures.<br><br>For more information about this element, see How to Configure MachineKey in ASP.NET 2.0 (http://go.microsoft.com/fwlink/?LinkId=79067). |

**Enable Windows Integrated authentication in the account partner**

You must complete the following tasks in the account partner organization when you want to allow clients on the corporate

network to authenticate to any of the federation servers in the farm using Windows Integrated authentication:

1. Create a dedicated user/service account in the Active Directory forest that is located in the account partner organization. This account is necessary for the Kerberos authentication protocol to work in a farm scenario and to allow pass-through authentication on each of the federation servers. Use this account only for the purposes of the federation server farm. To ensure that this service account's function is not interrupted as a result of domain password change requirements, configure the account (in the properties of the user account) so that the password never expires. (Select the **Password never expires** check box.)

   | **Note** |
   | --- |
   | Using the Network Service account for this dedicated account will result in random failures when access is attempted through Windows Integrated authentication as a result of Kerberos tickets not validating from one server to another. |

2. On each federation server in the farm, configure the ADFSAppPool to run as the service account. In IIS Manager, navigate to the properties of **ADFSAppPool** (under the **Application Pools** folder), click the **Identity** tab, click **Configurable**, and type the new service account name and password. Repeat this task for each account federation server in the farm.

3. Because the application pool identity for ADFSAppPool is running as a domain user/service account, you must configure the service principal name (SPN) for that account in the domain using the Setspn.exe command-line tool. To obtain Setspn.exe, install the Windows Server 2003 Support Tools on a computer that is joined to the same domain where the user/service account resides. To install Support Tools, use your Windows Server 2003 CD. Navigate to the Support\Tools directory, double-click **Suptools.msi**, and follow the setup instructions. After you install the Support Tools, open a command prompt, and then type the following command:

   **setspn -a <http/<**farmclusterdnsname**> <**serviceaccountname**>**

   For example, in a scenario in which all federation servers are clustered under the DNS host name http://fs.adatum.com and the service account name that is assigned to the ADFSAppPool is named adfsaccountfarm, type the command as follows:

   **setspn -a http:/fs.adatum.com adfsaccountfarm**

   It is necessary to complete this task only once for this account.

4. After the ADFSAppPool identity is changed to the service account, set the access control lists (ACLs) on the trust policy file to allow Read access to this new account so that ADFSAppPool can read the trust policy.

# Certificate requirements for federation servers

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

In any Active Directory Federation Services (ADFS) design, various certificates must be used to secure communication and facilitate user authentications that are made between Internet clients and federation servers. Each federation server is required to have a server authentication certificate and a token-signing certificate before it can participate in ADFS communications. The trust policy requires an associated certificate, known as a verification certificate, which is the public key portion of the token-signing certificate. The following table describes each of these certificate types.

| Certificate type | Description |
|---|---|
| Token-signing certificate | A token-signing certificate is an X509 certificate. Its associated public/private key pair is used by federation servers to digitally sign all security tokens that they produce. |
| Verification certificate | A verification certificate represents the public-key portion of the token-signing certificate. It is stored in the trust policy and used by the federation server in one organization to verify that incoming security tokens have been issued by valid federation servers in this organization's farm and in other organizations. |
| Server authentication certificate | Federation servers use a server authentication certificate to secure Web services traffic for communication with Web clients or with federation server proxies. |

**Note**

Client authentication certificates are not necessary for federation servers.

**Determining your certification authority strategy**

Because the verification certificate represents the public key portion of the token-signing certificate, only the token-signing certificate and the server authentication certificate have to be issued by either a public certification authority (CA)—for example, Verisign—or a corporate CA.

ADFS does not require that token-signing and server authentication certificates be issued by a CA. However, we recommend that you not use self-signed certificates for server authentication certificates.

**Important**

Use of self-signed, Secure Sockets Layer (SSL) certificates in a production environment can allow a malicious user in an account partner to take control of federation servers in a resource partner organization. This security risk exists because self-signed certificates are root certificates. They must be added to the trusted root store of another federation server (for example, the resource federation server), which can leave that server vulnerable to attack.

After you receive a token-signing certificate and server authentication certificate from a CA, make sure that both certificates are imported into the personal certificate store of the local computer. You can import both certificates to the personal store with the Certificates snap-in in Microsoft Management Console (MMC). For more information, see Import a certificate (http://go.microsoft.com/fwlink/?linkid=20040).

As an alternative to using the Certificates snap-in, you can also import the server authentication certificate with the IIS Manager snap-in at the time that you assign the server authentication certificate to the default Web site. For more information, see Import a server authentication certificate to the default Web site.

**Note**

Before you install the Federation Service on the computer that will become the federation server, make sure that both certificates are in the Local Computer personal certificate store and the server authentication certificate is assigned to the default Web site. For more information about the order of the tasks that are required to set up a federation server, see Checklist: Installing a federation server.

Depending on your security and budget requirements, carefully consider which of your certificates will be obtained by a public CA or a corporate CA. The following figure shows the recommended CA issuers for a given certificate type. This recommendation reflects a best practice approach regarding security and cost.

**Token-signing certificates**

Federation servers require the use of token-signing certificates to prevent attackers from altering or counterfeiting security tokens in an attempt to gain unauthorized access to federated resources. Every token-signing certificate contains cryptographic private keys and public keys that are used to digitally sign (by means of the private key) a security token. Later, after they are received by a partner federation server, these keys validate the authenticity (by means of the public key) of the encrypted security token.

Because each security token is digitally signed by the account partner, the resource partner can verify that the security token was in fact issued by the account partner and that it was not modified. Digital signatures are verified with verification certificates. After the signature is verified, the resource federation server generates its own security token for its organization and signs the security token with its own token-signing certificate.

The Web server in the resource partner uses the public key of the token-signing certificate to verify that the security token is signed by the resource federation server. The Web server then allows the appropriate access to the client.

Digital signatures on security tokens are also used in the account partner when there is more than one federation server (for example, in a farm deployment). In this case the digital signatures verify the origin and integrity of the security tokens that are issued by other federation servers in the account partner.

Token-signing certificates must meet the following requirements to work with ADFS:

- The token-signing certificate must include digital signature key usage. Examples of certificate types that include this key usage are server authentication certificates or code-signing certificates. Enhanced key usage (EKU) is not required for token-signing certificates.

- The token-signing chain must be composed of only X509 certificates, and it must chain to a client-accessible, trusted root CA.

- For a token-signing certificate to successfully sign a security token, the token-signing certificate must contain a private key.

1. The ADFSAppPool identity must have access to the token-signing certificate's private key in the personal store of the local computer.

| **Note** |
| --- |
| This is taken care of by Setup. You can also use the Active Directory Federation Services snap-in to ensure this access if you subsequently change the token-signing certificate. |

- The trust policy includes the entire token-signing certificate chain in the trustpolicy.xml file. This operation takes place automatically. You do not have to configure it manually.

| Note |
| --- |
| It is a public key infrastructure (PKI) best practice to not share the private key for multiple purposes. Therefore, do not use the server authentication certificate that you installed on the federation server as the token-signing certificate. |

**Deployment considerations for token-signing certificates**

When you deploy the first federation server in a new ADFS installation, you must obtain a token-signing certificate and install it in the local computer personal certificate store on that federation server. You can obtain a token-signing certificate by requesting one from an enterprise CA or a public CA or by creating a self-signed certificate.

Token-signing certificates are installed differently, depending on how you create the server farm. There are two server farm options that you can consider when you obtain token-signing certificates for your deployment:

- A private key from one token-signing certificate is shared among all the federation servers in a farm.

  In a federation server farm environment, we recommend that all federation servers share (or reuse) the same token-signing certificate. You can install a single token-signing certificate from a CA on a federation server and then export the private key, as long as the issued certificate is marked as exportable.

  As shown in the following figure, the private key from a single token-signing certificate can be shared to all the federation servers in a farm. This option—compared to the following "unique token-signing certificate" option—reduces costs if you plan to obtain a token-signing certificate from a public CA.

- There is a unique token-signing certificate for each federation server in a farm.

  When multiple unique certificates are used throughout your farm, each server in that farm signs tokens with its own unique private key.

  As shown in the following figure, you can obtain a separate token-signing certificate for every single federation server in the farm. This option is more expensive if you plan to obtain your token-signing certificates from a public CA.

For information about installing token-signing certificates when you use Microsoft Certificate Services as your enterprise CA, see Submit an advanced certificate request via the Web to a Windows Server 2003 CA (http://go.microsoft.com/fwlink/?linkid=64020). For information about installing a token-signing certificate from a public CA, contact your public CA. For information about creating self-signed certificates, see Create a self-signed, code-signing certificate (http://go.microsoft.com/fwlink/?linkid=68171).

**Verification certificates**

Verification certificates verify that a security token was issued by a valid federation server and that the token was not modified. Verification certificates are the public-key portion of your own token-signing certificate as well as the certificates of other federation servers that you trust. As shown in the following figure, verification certificates are exported (from the token-signing certificate) and added to a verification certificate list in the trust policy at the time when you first assign a federation server to an existing trust policy. This process takes place automatically during the installation of the Federation Service. You do not have to add the certificate manually.

To verify that a security token was issued by a given federation server and not modified, the federation server must have a verification certificate for the federation server that issued the security token. For example, if fs.adatum.com (a federation server in the account partner) creates and signs a security token and then sends it to fs.treyresearch.net (a federation server in the resource partner), fs.treyresearch.net must see the verification certificate for fs.adatum.com in the verification certificate list that is stored in its own trust policy.

If the certificate has been issued by a CA, we require that:

1. The certificate revocation lists (CRLs) of the certificate be accessible to resource partners and Web agents that trust the federation server.

2. The root CA certificate be trusted by the resource partners and Web agents that trust the federation server.

**Server authentication certificates**

Federation servers require the use of server authentication certificates so that clients can establish the server's identity because the federation server presents the client with a server authentication certificate that discloses its source. In this way, a client can verify that the data that is transmitted is usable only by the organization that is identified by the certificate.

Server authentication certificates must meet the following requirements to work with ADFS:

- The server authentication certificate must include the server authentication EKU extension.

- The CRLs must be accessible for all the certificates in the chain from the server authentication certificate to the root CA certificate. The root CA must also be trusted by any federation server proxies and Web agents that trust this federation

server.

- The subject name that is used in the server authentication certificate must match the Domain Name System (DNS) name of the Federation Service endpoint Uniform Resource Locator (URL) in the trust policy.

**Deployment considerations for server authentication certificates**

Configure server authentication certificates so that all federation servers use the same certificate. If you are deploying either of the two Federated Web SSO designs, we recommend that your server authentication certificate be issued by a public CA. You can request and install these certificates through the Internet Information Services (IIS) snap-in.

You can use self-signed server authentication certificates successfully on federation servers in a test lab environment. However, for a production environment, we recommend that you obtain server authentication certificates from a public CA. The following list provides reasons why you should not use self-signed server authentication certificates for a live deployment:

- A self-signed Secure Sockets Layer (SSL) certificate must be added to the trusted root store on each of the federation servers in the resource partner organization. While this alone does not enable an attacker to compromise a resource federation server, trusting self-signed certificates does increase the attack surface of a computer, and it can lead to security vulnerabilities if the certificate signer is not trustworthy.

- It creates a bad user experience. Clients will receive Security Alert prompts when they try to access federated resources that display the message "The security certificate was issued by a company you have not chosen to trust." This is expected behavior, because the self-signed certificate is not trusted.

  | **Note** |
  | --- |
  | If necessary, you can work around this condition by using Group Policy to manually push down the self-signed certificate to the trusted root store on each client computer that will attempt to access an ADFS-enabled site. |

- CAs provide additional certificate-based features, such as private key archive, renewal, and revocation, that are not provided by self-signed certificates.

**Certificate revocation lists**

If any certificate that you use has CRLs, the server with the configured certificate must be able to contact the server that distributes the CRLs. The type of CRL determines what ports are used.

# Name resolution requirements for federation servers

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

When clients on the corporate network attempt to access an Active Directory Federation Services (ADFS)-secured application, they must first authenticate to a federation server. One way to authenticate is to have the corporate network clients access a local federation server through Windows Integrated authentication.

**Configure corporate DNS**

So that successful name resolution through Windows Integrated authentication on local federation servers can occur, Domain Name System (DNS) in the corporate network of the account partner must be configured for a new host record that will resolve the fully qualified domain name (FQDN) host name of the federation server to the IP address of the federation server cluster.

In the following illustration, you can see how this task is accomplished for a given scenario. In this scenario, Microsoft Network Load Balancing (NLB) provides a single cluster FQDN name and a single cluster IP address for an existing federation server farm.

For information about how to configure a cluster IP address or cluster FQDN using NLB, see Specifying the Cluster Parameters (http://go.microsoft.com/fwlink/?LinkId=75282).

For information about how to configure corporate DNS for a federation server, see Add a host (A) record to corporate DNS for a federation server.

For information about how to configure federation server proxies in the perimeter network, see Name resolution requirements for federation server proxies.

# Planning Federation Server Proxy Placement

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

After you gather all of the information that you will use to design your Active Directory Federation Services (ADFS) infrastructure and after you plan your federation server and Web server strategy, you can plan when and where to place federation server proxies in your new design. The information in the following topics can help you determine when and where to place a federation server proxy and whether to use either the account partner role or the resource partner role.

- When to create a federation server proxy
- Review the role of the federation server proxy in the account partner organization
- Review the role of the federation server proxy in the resource partner organization
- Where to place a federation server proxy
- When to create a federation server proxy farm

| **Note** |
| --- |
| Although this information might help with your placement planning for federation server proxies, it does not explain how to determine the proper number of proxies and the proxy hardware requirements for each ADFS design. For more information about determining the proper number of federation server proxies for each design, see Planning for federation server proxy capacity. |

For examples of how a federation server proxy can be placed in any of the three primary ADFS design scenarios, see Mapping Your Deployment Goals to an ADFS Design.

# When to create a federation server proxy

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

Creating a federation server proxy in your organization adds additional security layers to your Active Directory Federation Services (ADFS) deployment. Consider deploying a federation server proxy in your organization's perimeter network when you want to:

- Prevent external clients from directly accessing your federation servers. By deploying a federation server proxy in your perimeter network, you effectively isolate your federation servers so that they can be accessed only by clients that are logged in to the corporate network and through federation server proxies, which act on behalf of external clients. Federation server proxies do not have access to the keys that are used to produce tokens.

- Provide a convenient way to differentiate the sign-in experience for users who are coming from the Internet as opposed to users who are coming from your corporate network (using Windows Integrated authentication). A federation server proxy collects credentials or home realm details from Internet clients by using the logon (clientlogon.aspx), logout (signout.aspx), and account partner discovery (discoverclientrealm.aspx) pages that are stored on the federation server proxy.

  In contrast, clients coming from the corporate network encounter a different experience, based on the configuration of the federation server. The corporate network federation server is often configured for Windows Integrated authentication, which provides a seamless sign-in experience for users on the corporate network.

The role that a federation server proxy plays in your organization depends on whether you place the federation server proxy in the account partner organization or in the resource partner organization. For example, when a federation server proxy is placed in the perimeter network of the account partner, its role is to collect the user credential information from browser clients. When a federation server proxy is placed in the perimeter network of the resource partner, it relays security token requests to the resource Federation Service and produces organizational security tokens in response to the security tokens that are provided by its account partners.

# Where to place a federation server proxy

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

You place federation server proxies in a perimeter network to provide a protection layer from malicious users coming from the Internet. Federation server proxies are ideal for the perimeter network environment because they do not have access to the keys that are used to create tokens but they can efficiently route incoming requests to federation servers that are authorized to produce those tokens.

| **Note** |
| --- |
| It is not necessary to place a federation server proxy inside the corporate network for either the account partner or the resource partner because clients that are connected to the corporate network can communicate directly with the federation server. In this scenario, the federation server also provides federation server proxy functionality for clients coming from the corporate network. |

As is typical with perimeter networks, an intranet-facing firewall is established between the perimeter network and the corporate network, and an Internet-facing firewall is often established between the perimeter network and the Internet. In this scenario, the federation server proxy sits between both of these firewalls on the perimeter network.

**Configuring your firewall servers for a federation server proxy**

For the federation server proxy redirection process to be successful, all firewall servers must be configured to allow Secure Hypertext Transfer Protocol (HTTPS) traffic. The use of HTTPS is required because the firewall servers must publish the federation server proxy, using port 443, so that the federation server proxy in the perimeter network can access the federation server in the corporate network.

| **Note** |
| --- |
| All communications made to and from clients also occur over HTTPS. |

In addition, the Internet-facing firewall server, such as a computer running Internet Security and Acceleration (ISA) Server, uses a process known as server publishing to distribute Internet client requests to the appropriate perimeter and corporate network servers, such as federation server proxies or federation servers.

Server publishing rules determine how server publishing works—essentially, filtering all incoming and outgoing requests through the ISA Server computer. Server publishing rules map incoming client requests to the appropriate servers behind the ISA Server computer. For information about how to configure ISA Server to publish a server, see Create a Secure Web Publishing Rule (http://go.microsoft.com/fwlink/?LinkId=75182).

In the federated world of Active Directory Federation Services (ADFS), these client requests are typically made to a specific Uniform Resource Locator (URL), for example, a federation server (http://fs.adatum.com). Because these client requests are incoming from the Internet, the Internet-facing firewall server must be configured to publish the federation server URL for each federation server proxy that is deployed in the perimeter network.

**Configuring ISA Server to allow SSL**

To facilitate secure ADFS communications, you must configure ISA Server to allow Secure Sockets Layer (SSL) communications between:

- **Federation server proxies and federation servers.** An SSL channel is required for all communications between federation servers and federation server proxies. Therefore, it is a requirement that you configure ISA Server to allow an SSL connection between the corporate network and the perimeter network.

- **Clients, federation servers, and federation server proxies.** So that communications can occur between clients and federation servers or between clients and federation server proxies, you can place a computer running ISA Server in front of the federation server or federation server proxy.

  If your organization performs SSL client authentication on the federation server or federation server proxy, when you place a computer running ISA Server in front of the federation server or federation server proxy, the server must be configured for pass-through of the SSL connection because the SSL connection must terminate at the federation server or federation server proxy.

If your organization does not perform SSL client authentication on the federation server or federation server proxy, an additional option is to terminate the SSL connection at the computer running ISA Server and then re-establish an SSL connection to the federation server or federation server proxy.

| **Note** |
| --- |
| The federation server or federation server proxy requires that the connection be secured by SSL to protect the contents of the security token. |

# When to create a federation server proxy farm

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

Consider installing additional federation server proxies when you have a large Active Directory Federation Services (ADFS) deployment and you want to provide fault tolerance, load-balancing, and scalability for the Federation Service Proxy. The act of creating two or more federation server proxies in the same perimeter network—configuring each of them to protect the same Federation Service—and then adding each of the servers' client authentication certificates to the trust policy creates a federation server proxy farm.

Before all the federation server proxies can function together as a farm, you must first cluster them under one IP address and one Domain Name System (DNS) fully qualified domain name (FQDN). You can cluster the servers by deploying Network Load Balancing (NLB) inside the perimeter network. The tasks in the following table require NLB to be configured appropriately to cluster the federation server proxies in the farm.

For more information about how to configure an FQDN for a cluster using Microsoft NLB technology, see Specifying the Cluster Parameters (http://go.microsoft.com/fwlink/?linkid=74651).

**Configuring federation server proxies for a farm**

The following table describes the tasks that must be completed so that each federation server proxy can participate in a farm.

| Task | Description |
|---|---|
| Point to the Federation Services Uniform Resource Locator (URL) | When you create the federation server proxies, you must type the same Federation Service DNS host name in the **Federation Services URL** field for all of the federation server proxies that participate in the farm. The federation server proxy uses the URL that makes up this DNS host name to determine which Federation Service it contacts.<br><br>For more information, see Install the Federation Service Proxy component of ADFS. |
| Obtain and share certificates | You can obtain a server authentication certificate from a public certification authority (CA)—for example, Verisign—and then configure the certificate so that all federation server proxies share the same private key portion of the same certificate on the default Web site for each federation server proxy. To share the certificate, you must install the same server authentication certificate on the default Web site for each federation server proxy. For more information, see Import a server authentication certificate to the default Web site.<br><br>When you obtain a client authentication certificate for a federation server proxy, you can share that certificate across all federation server proxies in the farm or you can obtain separate certificates for each of the federation server proxies in the farm.<br><br>**Note**<br>The Trust Policy user interface (UI) in the Active Directory Federation Services snap-in refers to client authentication certificates as **Federation Service Proxy (FSP) certificates**.<br><br>For more information, see Certificate requirements for federation server proxies. |
| Add the federation server proxy certificate to the trust policy | You must add the public key portion of the client authentication certificate for the federation server proxy to the trust policy on a federation server with which the federation server proxy communicates so that the Federation Service can authenticate the federation server proxy.<br><br>For more information, see Add a Federation Service Proxy (FSP) certificate to the trust policy (http://go.microsoft.com/fwlink/?LinkId=76073). |

For more information about adding new federation server proxies to create a federation server proxy farm, see Adding a New Federation Server Proxy (http://go.microsoft.com/fwlink/?LinkId=76068).

# Certificate requirements for federation server proxies

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

Servers that are running the Federation Service Proxy component of Active Directory Federation Services (ADFS) are required to use the following types of certificates:

- **Secure Sockets Layer (SSL) server authentication certificates:** Federation server proxies use SSL server authentication certificates to secure Web server traffic communication with Web clients. Federation server proxies are usually exposed to computers on the Internet that are not included in your enterprise public key infrastructure (PKI). Therefore, use a server authentication certificate that is issued by a public (third-party) certification authority (CA), for example, Verisign.

  When you have a federation server proxy farm, all federation server proxy computers must use the same server authentication certificate. (For more information, see When to create a federation server proxy farm.) It is important to verify that the subject name in the server authentication certificate matches the Domain Name System (DNS) name of the Federation Service endpoint Uniform Resource Locator (URL) in the trust policy.

  For general information about using SSL certificates, see Configuring Secure Sockets Layer (http://go.microsoft.com/fwlink/?linkid=62785) and Obtaining Server Certificates (http://go.microsoft.com/fwlink/?linkid=62479).

- **SSL client authentication certificates:** Each federation server proxy uses a client authentication certificate to authenticate to the Federation Service. You can use any certificate with client authentication extended key usage (EKU) that chains to a trusted root CA on the federation server as a client authentication certificate for the federation server proxy. In addition, you must explicitly add the client authentication certificate to the trust policy. However, only the federation server proxy stores the private key that is associated with the federation server proxy client authentication certificate. You can install a client authentication certificate by connecting to an enterprise CA or by creating a self-signed certificate.

  | **Important** |
  | --- |
  | Do not use a certificate that was issued by your enterprise CA for client authentication of an Active Directory user (especially a domain administrator) because the private key is stored on the federation server proxy. Storing a private key on the federation server proxy allows an administrator or a successful attacker to assume the identity that the certificate represents. |

  For general information about installing client authentication certificates when you use Microsoft Certificate Services as your enterprise CA, see "Submit an advanced certificate request via the Web to a Windows Server 2003 CA" (http://go.microsoft.com/fwlink/?linkid=64020).

| **Note** |
| --- |
| Token-signing certificates do not have to be issued for federation server proxies. |

If any certificate that you use has certificate revocation lists (CRLs), the server with the configured certificate must be able to contact the server that distributes the CRLs. The type of CRL determines what ports are used.

# Name resolution requirements for federation server proxies

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

When Internet clients attempt to access an application that is secured by Active Directory Federation Services, the clients must first authenticate to the federation server. In most cases, the federation server is usually not directly accessible from the Internet. Therefore, Internet clients must be redirected to the federation server proxy instead. You can accomplish successful redirection by adding the appropriate Domain Name System (DNS) records to your DNS zone or zones that face the Internet.

The method that you use to redirect Internet clients to the federation server proxy depends on how you configure the DNS zone in your perimeter network or a DNS zone that you control on the Internet. Federation server proxies are intended for use in a perimeter network. They redirect Internet client requests to federation servers successfully only when DNS has been configured properly in all of the Internet-facing zones that you control. Therefore, the configuration of your Internet-facing zones—whether you have a DNS zone serving only the perimeter network or a DNS zone serving both the perimeter network and internet clients—is important.

This topic describes the steps that you can use to configure name resolution when you place a federation server proxy in your perimeter network. To determine which steps to follow, first determine which of the following DNS scenarios most closely matches the DNS infrastructure in the perimeter network of your organization. Then, follow the steps for that scenario.

**DNS zone serving only the perimeter network**
In this scenario, your organization has one or two DNS zones in the perimeter network, and your organization does not control any DNS zones on the Internet. Successful name resolution for a federation server proxy in the DNS zone serving only the perimeter network scenario depends on the following conditions:

- The federation server proxy must have a setting in the hosts file to resolve the fully qualified domain name (FQDN) of the Federation Server endpoint Uniform Resource Locator (URL) to an IP address of a federation server or federation server cluster.

- DNS in the perimeter network of the account partner must be configured so that the FQDN of the Federation Server endpoint URL resolves to the IP address of the federation server proxy.

The following illustration and corresponding steps shows how each of these conditions is achieved for a given example. In this illustration, Microsoft Network Load Balancing (NLB) technology provides a single cluster FQDN and a single cluster IP address for an existing federation server farm.

For more information about configuring a cluster IP address or a cluster FQDN using NLB, see Specifying the Cluster Parameters (http://go.microsoft.com/fwlink/?LinkId=75282).

**1. Configure the hosts file on the federation server proxy**

Because DNS in the perimeter network is configured to resolve all requests for fs.adatum.com to the account federation server proxy, the account federation server proxy has an entry in its local hosts file to resolve fs.adatum.com to the IP address of the actual account federation server (or cluster DNS name for the federation server farm) that is connected to the corporate network. This makes it possible for the account federation server proxy to resolve the host name fs.adatum.com to the account federation server rather than to itself—as would occur if it attempted to look up fs.adatum.com using perimeter DNS—so that the federation server proxy can communicate with the federation server.

**2. Configure perimeter DNS**

Because there is only a single Federation Service endpoint URL that clients are directed to—whether they are on an intranet or the Internet—clients on the Internet that use the perimeter DNS server must resolve the FQDN for the account federation server (fs.adatum.com) to the IP address of the account federation server proxy on the perimeter network. So that it can forward clients on to the account federation server proxy when they attempt to resolve fs.adatum.com, perimeter DNS contains a limited corp.adatum.com DNS zone with a single host (A) record for fs (fs.adatum.com) and the IP address of the account federation server proxy on the perimeter network.

For more information about how to modify the hosts file of the federation server proxy and configure DNS in the perimeter network, see Configure name resolution for a federation server proxy in a DNS zone serving only the perimeter network.

**DNS zone serving both the perimeter network and Internet clients**

In this scenario, your organization controls the DNS zone in the perimeter network and at least one DNS zone on the Internet. Successful name resolution for a federation server proxy in this scenario depends on the following conditions:

- DNS in the Internet zone of the account partner must be configured so that the FQDN of the Federation Server endpoint URL resolves to the IP address of the federation server proxy in the perimeter network.

- DNS in the perimeter network of the account partner must be configured so that the FQDN of the Federation Server endpoint URL resolves to the IP address of the federation server in the corporate network.

The following illustration and corresponding steps shows how each of these conditions is achieved for a given example.

**1. Configure perimeter DNS**

For this scenario, because it is assumed that you will configure the Internet DNS zone that you control to resolve requests that are made for a specific endpoint URL (that is, fs.adatum.com) to the federation server proxy in the perimeter network, you must also configure the zone in the perimeter DNS to forward these requests to the federation server in the corporate network.

So that clients can be forwarded to the account federation server when they attempt to resolve fs.adatum.com, perimeter DNS is configured with a single host (A) record for fs (fs.adatum.com) and the IP address of the account federation server on the corporate network. This makes it possible for the account federation server proxy to resolve the host name fs.adatum.com to the account federation server rather than to itself—as would occur if it attempted to look up fs.adatum.com using Internet DNS—so that the federation server proxy can communicate with the federation server.

**2. Configure Internet DNS**

For name resolution to be successful in this scenario, all requests from clients on the Internet to fs.adatum.com must be resolved by the Internet DNS zone that you control. Consequently, you must configure your Internet DNS zone to forward client requests for fs.adatum.com to the IP address of the account federation server proxy in the perimeter network.

For more information about how to modify the perimeter network and Internet DNS zones, see Configure name resolution for a federation server proxy in a DNS zone serving both the perimeter network and Internet clients.

# Planning for ADFS Capacity

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

Capacity planning for Active Directory Federation Services (ADFS) is the process of planning for growth and forecasting peak usage periods to meet specific ADFS server role and federated application requirements. It involves analyzing results from extensive performance testing to establish the ideal resource use and transaction throughput for an ADFS server role or federated application under specific load conditions.

This section describes performance and scalability guidelines for specific ADFS server roles: federation server, federation server proxy, and ADFS-enabled Web servers. These guidelines are based on lab testing that was performed by the ADFS product team at Microsoft. The purpose of this section is to help you:

- Closely estimate the hardware needs for your organization's specific ADFS deployment.
- Get recommendations about ADFS server role and federated application capacity based on an analysis of actual test result data.

| **Note** |
| --- |
| Recommendations are identified with a **Recommendations** heading throughout this section so that you can quickly locate them and assess how they may affect your deployment decisions. |

- Understand how capacity requirements and scaling techniques can affect peak load conditions that might be handled by specific ADFS server roles and federated applications.
- Accurately project the expected peak usage for sign-in requests, plan for growth, and ensure that your ADFS deployment is capable of handling that expected peak usage.

This section does not contain formulas for determining the minimal or optimal number of federation servers, federation server proxies, or ADFS-enabled Web servers for a specific ADFS design.

To understand the full ADFS capacity planning story, see the following topics:

- Planning for federation server capacity
- Planning for federation server proxy capacity
- Planning for ADFS-enabled Web server capacity

**Terminology**

The following table describes important terms that are used in this capacity planning section of the Active Directory Federation Services Design Guide.

**Account federation server**

The federation server in the account partner organization. The account federation server issues security tokens to users based on user authentication. The server authenticates the user, pulls the relevant attributes and group membership information out of the account store, and generates and signs a security token to return to the user—either to be used in its own organization or to be sent to a partner organization.

**Federated application**

An application that is ADFS-enabled, meaning that it can be accessed by federated users.

**Resource federation server**

The federation server in the resource partner organization. The resource federation server typically issues security tokens to users based on a security token that is issued by an account federation server. The server receives the security token, verifies the signature, transforms the organizational claims based on its trust policy, generates a new security token based on information in the incoming security token, and signs the new token to return to the user and ultimately to the Web

application.

**Scaling out**
A design approach that adds additional servers to your deployment to more evenly distribute application processing load across multiple computers. Scaling out adds more servers in the anticipation of further growth, and it provides flexibility so that a server that participates in a Web farm can be taken offline for upgrades with relatively little impact on the cluster.

**Scaling up**
A design approach that upgrades an existing system or individual hardware components of a single system, such as CPU or memory, in your deployment. When a system reaches the maximum limit for the number of CPUs (or other hardware components) as it is scaled up, the only scaling option that remains is scaling out.

#### Hardware and software

This section describes the hardware and software that the ADFS product team used to perform its tests. The team used the following computer hardware and software configuration to gather performance and scalability data in tests of the federation server and ADFS-enabled Web server.

- HP Proliant DL560 G1
- Four Intel Xeon CPUs, each CPU running at 2.2 gigahertz (GHz) with hyper-threading enabled
- 4 gigabytes (GB) of memory
- Windows Server 2003 R2, Enterprise Edition

The team used the following computer hardware and software configuration to gather performance and scalability data for the federation server proxy tests.

- Dell Optiplex GX620
- One Intel Pentium 4 CPU, running at 3.4 GHz
- 2 GB of memory
- Windows Server 2003 R2, Enterprise Edition

#### Measuring ADFS server capacity

Typically, the hardware components that affect server performance and scalability are the CPU, memory, the disk, and network adapters. Fortunately, each of the ADFS components requires very little demand on memory and disk space. Network connectivity is an obvious requirement. Therefore, load tests that are performed on federation servers, federation server proxies, and ADFS-enabled Web servers concentrate on three primary areas for measuring server capacity:

- **Sign-in requests per second:** The number of sign-in requests that are processed per second on federation servers. This measurement can help you determine how many simultaneous users can sign in to a given server. You can use this measurement in conjunction with the CPU consumption measurement to understand this measurement's effect on performance.
- **CPU consumption:** The percentage by which CPU capacity is measured. This measurement can help you determine the overall CPU load that occurred based on the number of incoming sign-in requests per second.
- **Application requests per second:** The number of client requests to a federated application that are processed per second on an ADFS-enabled Web server. This measurement can help you measure the performance impact of client requests on both the federated application and the ADFS Web Agent.

# Planning for federation server capacity

Updated: December 15, 2006

Applies To: Windows Server 2003 R2

Capacity planning for federation servers helps you estimate the following:

- The appropriate hardware requirements for each federation server
- The number of federation servers to place in each organization

Federation servers issue security tokens to users. These tokens are presented to a relying party for consumption. Federation servers issue security tokens after authenticating a user or after receiving a security token that was previously issued by a partner Federation Service. A security token is requested from a Federation Service when users initially sign in to federated applications or when their security tokens expire while they are accessing federated applications.

Federation servers are designed to accommodate high-availability server farm configurations that use Microsoft Network Load Balancing (NLB) technology. Federation servers in a farm configuration can service requests independently, without accessing any common farm components for each request. Therefore, there is little overhead involved in scaling out a federation server deployment.

**Recommendations**

- For mission-critical or high-availability deployments, we recommend that you create a small federation server farm in each partner organization, with at least two federation servers per farm, to provide fault tolerance.
- With the need for high availability and the ease of scaling out federation servers, scaling out is the recommended method for handling high numbers of requests per second for a particular Federation Service. Scaling up beyond the base configuration in this guide is unlikely to produce significant capacity handling gains.

**Estimating hardware requirements**

Fortunately, memory and disk space requirements for federation servers are modest, and they are not likely to be a driving factor in hardware decisions. Memory and disk space requirements for federation servers depend largely on the type of entry —such as claims, applications, or partners—that is made to the trust policy and the number of entries for each type of entry.

As the number of claim, application, and partner entries in the trust policy grow, so does the need for more memory. The following table contains general size requirements for each type of trust policy entry as tested by the Microsoft Active Directory Federation Services (ADFS) product team.

**Memory and disk size requirements for trust policy entries**

| Trust policy entry type | Number of entries | Disk size requirements | Memory size requirements |
|---|---|---|---|
| Applications | 10 | 25 kilobytes (KB) | 75 KB |
| Claims | 100 | 13 KB | 40 KB |
| Partners* | 10 | 40 KB | 120 KB |

**Note**

*Each partner in this configuration contained five claim mappings. More claim mappings increase the size of memory that is necessary to represent the partner entry.

These requirements vary based on the configured content of each claim, application, and partner. Consider them to be general guidelines.

It is important to note that, using a minimal trust policy, the memory usage of the federation server is approximately 35 megabytes (MB). Therefore, add all calculated memory requirements on top of this base memory footprint. Whenever the trust policy is changed, a new copy of the trust policy is loaded into memory while the old copy remains active. After the new copy is loaded in its entirety, the old copy is removed. Therefore, when the trust policy is changed, the memory requirements of the service will briefly double.

### Recommendation

- If your ADFS deployment involves a particularly large trust policy, double your calculations of the memory requirements to account for trust policy changes.

#### Example

You decide that your organization needs a trust policy that contains 45,000 organization group claims, 9,000 applications, and 30 account partners with 5 group claim mappings per partner. Based on actual testing by the ADFS product team, the trust policy file size is about 28 MB with this number of entries. Memory usage for this trust policy is approximately 130 MB (adding about 95 MB to the minimum federation server memory footprint of 35 MB). When you change the trust policy, memory usage is approximately 200 MB. A server with 1 GB of RAM should be able to handle this trust policy configuration, in addition to any other operating system requirements.

Capacity recommendations for federation servers can vary considerably, depending on whether the federation server is acting in the account federation server role or resource federation server role.

#### Account federation server capacity considerations

An account federation server issues security tokens to users based on user authentication. The server authenticates a user, pulls the relevant attributes and group membership out of the account store, creates and signs a security token, and then sends the security token to the user. The security token is ultimately consumed by a resource federation server. Account federation server capacity is measured in terms of the peak number of these user sign-ins.

When you estimate the expected peak number of user sign-ins per second, one important factor is the token-caching lifetime. Consider adjusting the default values for the token-caching lifetime in the resource Federation Service for the Web application. A longer token-caching lifetime results in fewer overall sign-ins and token requests at the account federation server. We do not recommend token cache lifetimes that exceed the token expiration time of the account federation server.

For more information about how to adjust values for the token-caching lifetime, see Configuring ADFS Servers for Troubleshooting (http://go.microsoft.com/fwlink/?LinkID=74970).

#### Gathering log data from the resource partner

Determining accurate capacity requirements for account federation servers can be challenging because the applications that require security tokens from an account federation server are often located in another organization.

If your organization does not have access to the application that currently logs application sign-ins, you may have to request estimates or logs from the organization that does have access to the application so that you can more accurately assess your capacity requirements.

After you have all the application logs, analyze them for peak numbers of user sign-ins. Estimate the peak number of sign-ins per second.

#### Determining peak sign-in capacity

The following table shows test lab results for the hardware that was used by the ADFS product team at Microsoft. The table indicates the peak number of sign-in requests that were made to an account federation server, along with their impact on CPU consumption.

**Peak sign-ins per second for the account federation server**

| Scenario | Sign-in requests per second | CPU consumption, percent |
|---|---|---|
| Token issuance with Windows Integrated authentication on the account federation server | 94 | 95.93 |

You can use the numbers in this table to help calculate how many account federation servers you must have to handle the expected peak sign-ins per second. Administrators for most production deployments are interested in lower CPU usage. They can scale out their hardware accordingly.

### Recommendation

- If the expected value for peak sign-in requests per second for each server in your farm exceeds the peak value in the previous table, we recommend that you add additional federation servers until the expected number of peak sign-ins per second is well under this peak value for each server in the farm.

#### Example

Your organization has 36,000 employees that arrive between 8:00 A.M. and 9:00 A.M. on Monday mornings. The employees

typically access a federated Web application to display their 401(k) information soon after arriving to work. It is important to analyze actual logs of the 401(k) application access to determine peak usage. Analysis of the 401(k) application logs indicates peak usage of 200 sign-ins per second between 8:55 A.M. and 9:00 A.M. The account federation server is configured to authenticate employees using Windows Integrated authentication. If 200 sign-ins per second is the peak usage of the overall system, the previous table indicates that a load-balanced federation server farm, containing at least three federation servers with hardware similar to the hardware that was used in the ADFS product team tests, can adequately handle the load and guarantee high availability, while leaving room for future growth in usage.

**Resource federation server capacity considerations**

A resource federation server typically issues security tokens to users based on the security tokens that it receives from an account federation server. After the resource federation server receives a security token, it verifies the signature, maps the claims based on its trust policy, creates a new security token, signs the new security token, and then sends token to the user. Ultimately, the security token is consumed by the federated application.

If your federation server is acting in an account role as well as a resource role, use the capacity planning numbers in the "Account federation server capacity considerations" section because user authentication is more expensive than validating security tokens.

| **Note** |
| --- |
| Information that is provided here about resource federation server capacity applies only to the resource partner side of the Federated Web SSO design. |

**Gathering log data**

To estimate your resource federation server's peak number of sign-ins per second more precisely, gather and analyze the historical logs of the applications to which users will be signing in. After you have all the application logs, analyze them for peak numbers of user sign-ins.

An important factor that influences the peak number of sign-ins is the configuration of token-caching lifetimes at the resource Federation Service and the Web application. Longer token-caching lifetimes result in less sign-ins at the Federation Service. Each time a new browser session is initiated, a new sign-in occurs.

**Determining peak sign-in capacity**

The following table shows test lab results that the ADFS product team used to measure peak capacity of sign-in requests to a resource federation server, along with their impact on CPU consumption.

**Peak resource partner sign-ins per second for the resource federation server**

| Scenario | Sign-in requests per second | CPU consumption, percent |
| --- | --- | --- |
| Token issuance for an account partner security token on the federation server | 112 | 97.56 |

You can use the numbers in this table to help calculate how many resource federation servers you need to handle the expected peak sign-ins per second.

### Recommendation

- If the expected value for peak sign-in requests per second for each server in the farm exceeds the peak value shown in the previous table, we recommend that you add additional federation servers until the expected number of peak sign-ins per second is well under the value in this table for each server in the farm.

**Example**

Your organization hosts three federated Web applications for account partners to access. Before the ADFS deployment, account partner users were required to log in separately to each application. Analysis of the logs indicates that sign-ins peaked at 30, 50, and 60 sign-ins per second at each application, respectively. Further analysis shows that each application experiences its peak usage at the same time each day. The aggregated number of sign-ins per second is 140. While the single sign-on (SSO) that is provided by the Federation Service reduces the sign-ins that users perceive, the Federation Service must still issue a security token for each application. Therefore, 140 sign-ins per second is a safe number to use as an estimate. The data in the previous table indicates that 140 sign-ins per second can be handled easily by a high-availability deployment of a small, load-balanced federation server farm containing at least two federation servers with hardware similar to the hardware that was used in the ADFS product team tests—while leaving room for future growth in usage.

# Planning for federation server proxy capacity
