This format is applicable for implementations of LDAP servers other than Windows Server 2003–based domain controllers and also possible implementations of LDAP directory services that employ Global Catalog servers other than servers running Windows Server 2003.

**_msdcs.domain_name subdomain**
This Microsoft-specific subdomain allows location of domain controllers that have Windows Server 2003–specific roles in the domain, as well as the location by globally unique identifier (GUID) when a domain has been renamed.

To facilitate location of Windows Server 2003–based domain controllers, the Net Logon service in addition to the standard *_Service._Protocol.DnsDomainName* format records , also registers SRV records that identify the well-known server-type pseudonyms "dc" (domain controller), "gc" (Global Catalog), "pdc" (primary domain controller), and "domains" (GUID) as prefixes in the _msdcs.domain_name subdomain. To accommodate locating domain controllers by server type or by GUID (abbreviated "dctype"), Windows Server 2003–based domain controllers register SRV records in the following form in the _msdcs.*domain_name* subdomain:

*_Service._Protocol.DcType.* **_msdcs** *.DnsDomainName*

**_msdcs.forest_root_domain subdomain**
The _msdcs.*forest_root_domain* subdomain stores forest-wide resource records that are of interest to clients and domain controllers from all parts of the forest. For example, all domain controllers in the forest register CNAME and LDAP, Kerberos, and GC SRV resource records in the msdcs.*forest_root_domain* subdomain. The CNAME resource records are used by the replication system to locate replication partners and the GC SRV resource records are used by clients to lookup global catalog servers.

For any two domain controllers to replicate with each other, including two domain controllers from the same domain, they must be able to look up forest-wide locator records. For a newly created domain controller to participate in replication, it must be able to register its forest-wide records in DNS, and other domain controllers must be able to look up these records. Therefore, the DNS servers that are authoritative for the _msdcs.*forest_root_domain* subdomain needs to be available for replication and global catalog lookups.

For this reason, it is recommended that you create a separate _msdcs.*forest_root_domain* zone and define its replication scope so that it is replicated to all DNS servers in the forest. For more information about creating a separate _msdcs.*forest_root_domain* zone, see KB article 817470. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

Some organizations running Windows 2000 Active Directory already created an _msdcs.*forest_root_domain* to help clients locate domain controllers more efficiently. If an _msdcs.*forest_root_domain* already exists in your Windows 2000 environment, then it is recommended that you move the zone to the ForestDnsZones application directory partition after all domain controllers in the forest are running Windows Server 2003. In addition, for each domain in the forest, move the _msdcs.*domain_name* zone to the DomainDnsZones application directory partition for that domain.

Moving the Active Directory–integrated DNS zones into the domain and forest-wide application directory partitions provides the following benefits:

- Because the forest-wide application directory partition can replicate outside a specified domain, and because moving the _msdcs.*forest_root_domain* into the forest-wide application directory partition replicates it to all domain controllers in the forest that are running the DNS service, you do not have to use DNS zone transfer to replicate the zone file information to DNS servers outside the domain.

- Domain-wide replication can be targeted to minimize replication traffic because administrators can specify which of the domain controllers running the DNS service receive the DNS zone data.

- Forest-wide replication can be targeted to minimize replication traffic because DNS data is no longer replicated to the global catalog.

- DNS records located on global catalog servers in the forest are removed, minimizing the amount of information replicated with the global catalog.

For more information about using application directory partitions to store DNS data, see "Use DNS Application Directory Partitions" later in this chapter.

**Intrasite Replication Frequency**

Windows 2000 domain controllers that are upgraded to Windows Server 2003 maintain their default intrasite replication frequency of 300/30. This means that any changes made to Active Directory replicate to all other domain controllers in the same site five minutes (300 seconds) after a change is made, with a 30-second offset before notifying the next domain controller, until the forest functional level is raised to Windows Server 2003. When the forest functional level is raised to Windows Server 2003, the replication frequency of Active Directory is changed to the Windows Server 2003 default setting of 15/3. This means that changes will replicate to all domain controllers in the same site 15 seconds after a change is made, with a 3-second offset before notifying the next domain controller. If you modified the 300/30 default replication frequency setting in Windows 2000, the setting does not change to the 15/3 default setting in Windows Server 2003 after you complete the upgrade. However, a new installation of Windows Server 2003 will always use the 15/3 intrasite replication frequency setting.

**Important**

- Do not modify the default 300/30 intrasite replication frequency on Windows 2000 domain controllers. Instead, upgrade your Windows 2000 domain to Windows Server 2003 and raise the forest functional level to Windows Server 2003 to take advantage of the 15/3 intrasite replication frequency.

**New Groups and New Group Memberships Created After Upgrading the PDC**

After upgrading the Windows 2000–based domain controller holding the role of the PDC emulator in each domain in the forest to Windows Server 2003, several new well-known and built-in groups are created and some new group memberships are established. If you transfer the PDC emulator role to a Windows Server 2003–based domain controller instead of upgrading it, these groups will be created when the role is transferred. The new well-known and built-in groups are:

- Builtin\Remote Desktop Users

- Builtin\Network Configuration Operators

- Performance Monitor Users

- Performance Log Users

- Builtin\Incoming Forest Trust Builders

- Builtin\Performance Monitoring Users

- Builtin\Performance Logging Users

- Builtin\Windows Authorization Access Group

- Builtin\Terminal Service License Server

The newly established group memberships are:

- If the Everyone group is in the Pre-Windows 2000 Compatible Access group, the Anonymous Logon group and Authenticated Users group are also added to the Pre-Windows 2000 Compatible Access group.
- The Network Servers group is added to the Performance Monitoring alias.
- The Enterprise Domain Controllers group is added to the Windows Authorization Access group.

In addition, when upgrading the Windows 2000 domain controller that holds the role of the PDC emulator in the forest root domain, the following additional security principals are created:

- LocalService
- NetworkService
- NTLM Authentication
- Other Organziation
- Remote Interactive Logon
- SChannel Authentication
- This Organization

For more information about new well-known and built-in groups in Windows Server 2003, see "Default groups" in Help and Support Center for Windows Server 2003.

**Security Policy Considerations When Upgrading from Windows 2000 to Windows Server 2003**
Server message block (SMB) packet signing and secure channel signing are security policies enabled by default on Windows Server 2003–based domain controllers. To allow clients running earlier versions of Windows to communicate with domain controllers running Windows Server 2003, you might need to temporarily disable these security policies during the upgrade process.

**SMB packet signing**
SMB packet signing is a security mechanism that protects the data integrity of SMB traffic between client computers and servers, and prevents man-in-the-middle attacks by providing a form of mutual authentication. This is done by placing a digital security signature into each SMB packet, which is then verified by the receiving party. Server-side SMB signing is required by default on Windows Server 2003–based domain controllers, which means that all clients are required to have SMB packet signing enabled.

Clients running Windows NT 4.0 with Service Pack 2 (SP2) or earlier and clients running Microsoft® Windows® 95 without the Directory Service Client Pack do not support SMB packet signing. These clients will not be able to authenticate to a Windows Server 2003–based domain controller. To ensure successful authentication, upgrade these clients to a later version of the operating system or service pack. However, if you cannot upgrade your clients, you can allow them to be authenticated by configuring SMB packet signing on all Windows Server 2003–based domain controllers so that SMB packet signing is allowed but not required.

For more information about SMB packet signing, see "Microsoft network server: Digitally sign communications (always)" in Help and Support Center for Windows Server 2003.

For more information about configuring SMB packet signing on Windows Server 2003–based domain controllers, see "Modify Security Policies" later in this chapter.

**Secure channel signing and encryption**
When a computer becomes a member of a domain, a computer account is created. Each time the computer starts, it uses the computer account password to create a secure channel with a domain controller for its domain. This secure channel is used to ensure secure communications between a domain member and a domain controller for its domain. Secure channel signing is required by default on Windows Server 2003–based domain controllers, which means that all clients must enable secure channel signing and encryption.

Clients running Windows NT 4.0 with Service Pack 3 (SP3) or earlier installed do not support secure channel signing. These clients will not be able to establish communications with a Windows Server 2003–based domain controller. To ensure successful communication, upgrade these clients to a later version of the operating system or service pack. However, if you cannot upgrade your clients, you must disable secure channel signing on all Windows Server 2003–based domain controllers so that the traffic passing through the secure channel is not required to be signed or encrypted.

For more information about configuring secure channel signing on Windows Server 2003–based domain controllers, see "Modify Security Policies" later in this chapter.

For more information about secure channel signing, see "Domain member: Digitally encrypt or sign secure channel data (always)" in Help and Support Center for Windows Server 2003.

# Planning to Upgrade Windows 2000 Domains to Windows Server 2003 Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Planning to upgrade your Windows 2000 environment to Windows Server 2003 Active Directory involves completing the tasks and procedures that are shown in Figure 9.2.

**Figure 9.2 Planning to Upgrade Windows 2000 Domains to Windows Server 2003 Domains**

# Create a Pre-Upgrade Task Checklist

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can create a pre-upgrade task checklist to help organize the tasks necessary to prepare for a successful domain upgrade. In your checklist, include the tasks listed in the sample checklist in Figure 9.3, in addition to any additional tasks specific to your organization.

For a worksheet to assist you in creating your own pre-upgrade task checklist, see "Pre-Upgrade Task Checklist" (DSSUPWN_1.doc) on the *Microsoft® Windows® Server 2003 Deployment Kit* companion CD (or see "Pre-Upgrade Task Checklist" on the Web at http://www.microsoft.com/reskit).

**Figure 9.3 Example of a Pre-Upgrade Task Checklist**

| Pre-Upgrade Task Checklist | | | |
|---|---|---|---|
| Prepared By | Forest Owner | Date | 1/2/03 |
| Forest Name | Concorp.contoso.com | | |

| Task | Method for Completion | Completed By | Date Completed |
|---|---|---|---|
| Gather job aids | Create new job aids or use job aids found on the *Windows Server 2003 Deployment Kit* companion CD or at http://www.microsoft.com/reskit. | | |
| Assign appropriate credentials | Assign Schema Admins and Enterprise Admins credentials to the individual who will prepare the Active Directory forest for upgrade. Assign Domain or Enterprise Admins credentials to the individual who will prepare each Active Directory domain for upgrade. | | |
| Introduce a Windows Server 2003-based member server | Install a Windows Server 2003 based member server into the forest root domain. | | |
| Verify that your upgrade is supported | Review Table 9.2, "Supported Upgrade Paths to Windows Server 2003." | | |
| Assess all current domain controller hardware | Assess your current hardware and review requirements for domain controllers running Windows Server 2003 as specified in "Planning Domain Controller Capacity" in this book. | | |
| Document the name, IP addresses, locations, operations master roles held by each domain controller before and after the upgrade, and the order in which you will upgrade the operating system on each domain controller. | Complete the worksheet "Windows 2000 Domain Controller Documentation" (DSSUPWN_2.doc) on the *Windows Server 2003 Deployment Kit* companion CD. | | |
| Develop a test plan | Create a matrix outlining the tests and tools to be used throughout the domain upgrade process. | | |
| Develop and approve recovery plan | Call team meeting to determine plan for recovery and approve completed recovery plan. | | |

| | | | |
|---|---|---|---|
| Determine required service pack levels | Use the **Repadmin /showattr** command to inventory the operating system and service pack revision level. | | |
| Backup domain data | Back up all data according to the backup plan specified for your organization. | | |
| Resolve upgrade and application compatibility issues | Use the **winnt32 /checkupgradeonly** command to find any upgrade issues. | | |
| Prepare the forest and each domain for Windows Server 2003 Active Directory | Apply hotfixes to resolve schema compatibility issues with Exchange 2000 and Services for UNIX 2.0.<br>Use ADPrep.exe in the forest and in each regional domain. | | |

# Assign Appropriate Credentials

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Assign appropriate credentials to the users who are responsible for preparing the forest and domain for an Active Directory upgrade. The **adprep /forestprep** command requires a user account that is a member of the Schema Admins, Enterprise Admins, and Domain Admins groups. The **adprep /domainprep** command requires a user account that is a member of the Domain Admins group in the targeted domain.

Additionally, the security context can affect the ability of an administrator to complete the upgrade from Windows 2000 to Windows Server 2003. Members of the Builtin\Administrators group can upgrade the operating system and install software on a computer. The following groups are members of the Builtin\Administrators group by default:

- The Enterprise Admins group is a member of Builtin\Administrators in the forest root domain and in each regional domain in the forest.
- The Domain Admins group is a member of Builtin\Administrators in their domain.
- The Domain Admins group is a member of Builtin\Administrators on member servers in their domain.

Table 9.1 shows the credentials that are required to upgrade servers, depending on the domain membership of the servers.

**Table 9.1 Credentials Required to Upgrade Servers to Windows Server 2003**

| Credential | Domain Controller in Forest Root Domain | Member Server in Forest Root Domain | Domain Controller in Regional Domain | Member Server in Regional Domain |
|---|---|---|---|---|
| Enterprise Admins in forest root domain | ● | | ● | |
| Domain Admins in forest root domain | ● | ● | | |
| Builtin\Administrators in forest root domain | ● | | | |
| Domain Admins in regional domain | | | ● | ● |
| Builtin\Administrators in regional domain | | | ● | |

You also need to ensure that the administrator who is upgrading the domain controllers has the following rights:

- Backup files and directories (SE_BACKUP_NAME)
- Modify firmware environment values (SE_SYSTEM_ENVIRONMENT_NAME)
- Restore files and directories (SE_RESTORE_NAME)
- Shut down the system (SE_SHUTDOWN_NAME)

The setup program cannot run properly if these rights are not defined, or if they are disabled by a domain Group Policy setting on the computer.

**To verify if user rights assignments are disabled by a domain Group Policy setting**

1. In the **Run** dialog box, type **mmc**, and then click **OK**.
2. Click **File**, and then click **Add/Remove snap-in**.
3. In the Add/Remove snap-in dialog box, click **Add**.
4. In the Available Standalone snap-ins dialog box, select **Group Policy**, and then click **Add**.
5. At the Welcome to the Group Policy Wizard screen, verify that **Local Computer** appears in the **Group Policy Object** box, and then click **Finish**.
6. Close the Add/Remove snap-in dialog box and the Add Standalone snap-in dialog box.
7. In the Console Root, navigate to the Local Computer Policy\Computer Configuration\Windows Settings\Security Settings\Local Policies\User Rights Assignment folder.
8. In the details pane, verify that the user who will perform the upgrade is a member in one of the groups that has the necessary rights assigned. The policies are named identically to the user rights listed above.

Assign the appropriate credentials in advance to allow both testing and deployment to proceed without unexpected security delays.

# Introduce a Windows Server 2003-Based Member Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you begin the domain upgrade process, introduce a Windows Server 2003–based member server into your environment. Installing Active Directory on a Windows Server 2003–based member server facilitates the domain upgrade process by allowing all existing services to run uninterrupted while you are upgrading to Windows Server 2003 Active Directory.

You can introduce the member server to any domain in the forest; however, if your forest root domain is a dedicated root, it is recommended that you introduce the member server into the forest root domain. Placing the member server into a dedicated root domain has the lowest impact on your environment because users generally do not log on to a dedicated forest root domain; therefore, user authentications are minimal.

After you prepare the Windows 2000 forest and domain by using the Active Directory Preparation tool, install Active Directory on the member server, creating an additional domain controller in the existing domain. The Windows Server 2003–based member server will become the first Windows Server 2003–based domain controller in the forest.

# Determine Supported Software Upgrades

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Identify the versions of Windows 2000 that are running in your environment, and then determine whether you can upgrade the operating system on your computers to Windows Server 2003, or whether you must perform a clean operating system installation.

Table 9.2 lists the Windows 2000 operating system platforms and indicates which platforms can be upgraded directly to each version of Windows Server 2003.

**Table 9.2 Supported Upgrade Paths to Windows Server 2003**

| Platform | Upgrade to Windows Server 2003, Standard Edition | Upgrade to Windows Server 2003, Enterprise Edition | Upgrade to Windows Server 2003, Datacenter Edition |
|---|---|---|---|
| Microsoft® Windows® 2000 Professional | | | |
| Windows 2000 Server | • | • | |
| Microsoft® Windows® 2000 Advanced Server | | • | |
| Microsoft® Windows® 2000 Datacenter Server | | | • |

# Assess Hardware Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Review and document the existing hardware configuration of each domain controller that you plan to upgrade to Windows Server 2003. Use this information to identify the domain controllers in your environment that you can upgrade to Windows Server 2003 and the domain controllers that do not meet the hardware requirements necessary to run Windows Server 2003. You can retain domain controllers that do not meet the necessary hardware requirements to serve as rollback servers in the event that you must roll back your deployment. In most cases, a Windows 2000–based domain controller meets the requirements to be upgraded to Windows Server 2003, as long as it has adequate disk space.

At minimum, a domain controller requires available free disk space for the Active Directory database, Active Directory log files, SYSVOL, and the operating system. Use the following guidelines to determine how much disk space to allot for your Active Directory installation:

- On the drive that will contain the Active Directory database, NTDS.dit, provide 0.4 gigabytes (GB) of storage for each 1,000 users. For example, for a forest with two domains (domain A, domain B), with 10,000 and 5,000 users respectively, provide a minimum of 4 GB of disk space for each domain controller that hosts domain A and a minimum of 2 GB of disk space for each domain controller that hosts domain B. Available space must equal at least 10 percent of your existing database size, or at least 250 megabytes (MB), whichever is greater.

- On the drive containing the Active Directory log files, provide at least 500 MB of available space.

- On the drive containing the SYSVOL shared folder, provide at least 500 MB of available space.

- On the drive containing the Windows Server 2003 operating system files, to run setup, provide at least 1.25 GB to 2 GB of available space.

For more information about assessing the hardware requirements of domain controllers in a Windows Server 2003 domain, see "Planning Domain Controller Capacity" in this book.

# Determine Domain Controller Upgrade Order

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Determine the order in which you will upgrade your domain controllers before beginning the domain upgrade process. Record the name, IP address, the domain in which the domain controller will be located, and the operations master roles held by each domain controller before and after the upgrade. Finally, record the order in which you will upgrade the operating system on each domain controller.

The recommended order for upgrading domain controllers from Windows 2000 to Windows Server 2003 is:

- Install Active Directory on a Windows Server 2003–based member server in the forest root domain by using the Active Directory Installation Wizard. This creates the first Windows Server 2003–based domain controller.
- Upgrade the operating system on the Windows 2000–based domain controller holding the role of domain naming master. If you choose not to upgrade the domain controller, transfer the domain naming master role to a domain controller running Windows Server 2003.
- Upgrade the domain controller that holds the PDC emulator role in each domain, or transfer the roles to Windows Server 2003–based domain controllers.
- Continue upgrading all Windows 2000–based domain controllers to Windows Server 2003 until the domain upgrade is complete.

**Note**

- This order for upgrading or installing Windows Server 2003 domain controllers is a recommendation only. It is safe to upgrade the domain controllers holding the domain naming master and PDC emulator roles at any time in the upgrade process.

Use a domain controller documentation table to document information about each domain controller in the forest. For a worksheet to assist you in documenting your domain controller information, see "Windows 2000 Domain Controller Documentation" (DSSUPWN_2.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Windows 2000 Domain Controller Documentation" on the Web at http://www.microsoft.com/reskit).

Figure 9.4 shows an example of a completed domain controller documentation table for Contoso.

**Figure 9.4 Example of a Windows 2000 Domain Controller Documentation Table**

| Windows 2000 Domain Controller Documentation | | | |
|---|---|---|---|
| Prepared By | Forest Owner | Date | 1/2/03 |

| | |
|---|---|
| Forest Name | Concorp.contoso.com |
| Domain Name | Noam.concorp.contoso.com |

| DC Name | IP Address | Location | Role Before Upgrade | Role After Upgrade | Order |
|---|---|---|---|---|---|
| SEA-CON-DC01 | 172.16.4.2 | Forest Root Domain | Member Server | Domain Controller | 1 |
| SEA-CON-DC02 | 172.16.4.3 | Forest Root Domain | Schema Master, Domain Naming Master | Schema Master, Domain Naming Master | 2 |
| SEA-CON-DC03 | 172.16.4.4 | Forest Root Domain | Infrastructure Master, PDC, RID Master | Infrastructure Master, PDC, RID Master | 3 |
| SEA-NOAM-DC01 | 172.16.4.10 | North America Regional Domain | Domain Controller | Domain Controller | 5 |
| SEA-NOAM-DC02 | 172.16.4.11 | North America Regional Domain | Infrastructure Master, PDC, RID Master | Infrastructure Master, PDC, RID Master | 4 |
| SEA-EMEA-DC01 | 172.16.4.20 | Europe/ Middle East/Asia Regional Domain | Domain Controller | Domain Controller | 7 |
| SEA-EMEA-DC02 | 172.16.4.21 | Europe/ Middle East/Asia Regional Domain | Infrastructure Master, PDC, RID Master | Infrastructure Master, PDC, RID Master | 6 |

# Developing a Test Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is important to develop a plan for testing your domain upgrade procedures throughout the upgrade process. Before you begin, test your existing domain controllers to ensure that they are functioning properly, and continue to test your domain controllers throughout the process to verify that Active Directory replication is consistent and successful.

Many of the tools required to verify your domain upgrade procedures are located in the Support\Tools folder on the Windows Server 2003 operating system CD. Install the Windows Server 2003 support tools on a client computer running Microsoft® Windows® XP Professional or on a Windows Server 2003–based member server.

Table 9.3 lists the tools and log files to use in your test plan.

**Table 9.3 Tools and Logs Used to Test Domain Upgrade Procedures**

| Tool/Log File | Description | Location |
|---|---|---|
| Repadmin.exe | Checks replication consistency and monitors both inbound and outbound replication partners. Displays replication status of inbound replication partners and directory partitions. | Windows Server 2003 operating system CD in the Support\Tools folder. |
| Dcdiag.exe | Diagnoses the state of domain controllers in a forest or enterprise, tests for successful Active Directory connectivity and functionality, and returns the results as passed or failed. | Windows Server 2003 operating system CD in the Support\Tools folder. |
| Netdiag.exe | Diagnoses networking and connectivity problems by performing a series of tests to determine the state of your network client and whether it is functional. | Windows Server 2003 operating system CD in the Support\Tools folder. |
| Nltest.exe | Queries and checks the status of trusts and can forcibly shut down domain controllers. | Windows Server 2003 operating system CD in the Support\Tools folder. |
| Dnscmd.exe | Provides the properties of DNS servers, zones, and resource records. | Windows Server 2003 operating system CD in the Support\Tools folder. |
| Adprep Log | Provides a detailed progress report of the forest and domain preparation process. | %systemroot%\System32\Debug\Adprep folder. |
| Dcpromoui.log and Dcpromo.log | Provides a detailed progress report of the Active Directory installation. Includes information regarding replication and services in addition to applicable error messages. | %systemroot%\Debug folder. |
| Adsiedit.exe | A Microsoft Management Console (MMC) snap-in that acts as a low-level editor for Active Directory and allows you to view, add, delete, and move objects and attributes within the directory. | Windows Server 2003 operating system CD in the Support\Tools folder. |

For more information about Windows Support Tools, in Help and Support Center for Windows Server 2003, click **Tools**, and then click Install Windows Support Tools.

Create a test matrix that meets your needs, based on the services that you require to support your environment. For a worksheet to assist you in documenting your test matrix, see "Windows 2000 Upgrade Test Matrix" (DSSUPWN_3.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Windows 2000 Upgrade Test Matrix" on the Web at http://www.microsoft.com/reskit).

Figure 9.5 shows an example of a completed upgrade test matrix.

**Figure 9.5 Example of a Windows 2000 Upgrade Test Matrix**

# Windows 2000 Upgrade Test Matrix

| Prepared By | Forest Owner | Date | 1/2/03 |
|---|---|---|---|

| | |
|---|---|
| Forest Name | Concorp.contoso.com |
| Domain Name | Noam.concorp.contoso.com |

| Test | Expected Results | Tool | Success/ Fail | Notes |
|---|---|---|---|---|
| Container Creation | After you prepare the forest and domain for upgrade, the CN=ForestUpdates container is present in the Configuration partition.<br>Expand CN=ForestUpdates, and verify that the CN=Windows2003Update container has been created.<br>Expand the DomainUpdates container in Active Directory Users and Computers, and verify that the Windows2003Update container was created. | ADSI Edit for ForestUpdates container<br>Active Directory Users and Computers for DomainUpdates container | | |
| Trusts | All trusts are active. | Nltest.exe and Dcdiag.exe | | |
| New User Creation | Create a user called "testl" to ensure that accounts can be created. | Active Directory Users and Computers | | |
| Replication | Successful replication. | Repadmin.exe | | |
| DNS | Successful DNS registration and configuration. | Dnscmd.exe | | |
| Active Directory | Successful Active Directory connectivity and functionality. | Dcdiag.exe | | |
| Successful logon request | Account is valid, and access is granted. | Login dialog box | | |

# Develop a Recovery Plan for Your Domain Upgrade Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Develop a recovery plan for use in the event that some portion of your domain upgrade process fails. A successful recovery plan includes:

- Step-by-step instructions, so that the upgrade team can restore normal operations to the organization.
- A sign-off process, ensuring that all team members review, agree upon, and sign off on the recovery plan.

For more information about developing a recovery plan, see the Active Directory Disaster Recovery link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Completing Pre-Upgrade Tasks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Prior to upgrading your Windows 2000 environment to Windows Server 2003 Active Directory, you must complete several pre-upgrade tasks.

Figure 9.6 shows the process for completing pre-upgrade tasks.

**Figure 9.6 Completing Pre-Upgrade Tasks**

# Determine Service Pack Levels

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before preparing your infrastructure for upgrade and installing the Windows Server 2003 operating system, all Windows 2000–based domain controllers in the forest must be running Windows 2000 Service Pack 1 (SP1) with hotfix 265089, or Windows 2000 SP2 (or later).

Hotfix 265089 (included in Windows 2000 SP2 and later) is required to prevent potential domain controller corruption. Use the **repadmin /showattr** command to inventory the operating system and service pack revision level on all domain controllers in a particular domain.

**Note**

- When administering Windows 2000–based domain controllers from a computer running Windows XP Professional or Windows Server 2003, you might experience interoperability problems with the Windows Server 2003 administrative tools unless your Windows 2000–based domain controllers are running Windows 2000 SP3 or later. Some Windows Server 2003 Active Directory administrative tools sign and encrypt all LDAP traffic. Computers running Windows 2000 SP3 or later can interpret the signed and encrypted LDAP traffic.

**To determine domain controller operating system and service pack levels**

- For each domain in the forest, type the following command at the command line of a computer that has the Windows Server 2003 support tools installed:

  ```
  repadmin /showattr domain controller in target domain ncobj:domain: /filter:"(&
  (objectcategory=computer)(primaryGroupID=516))" /subtree
  /atts:operatingSystem,operatingSystemVersion,operatingSystemServicePack
  ```

  The following text is sample output from this command:

  ```
  DN: CN=NA-DC-01,OU=Domain Controllers,DC=company,DC=com
      1> operatingSystem: Windows Server 2003
      1> operatingSystemVersion: 5.2 (3663)
  DN: CN=NA-DC-02,OU=Domain Controllers,DC=company,DC=com
      1> operatingSystem: Windows 2000 Server
      1> operatingSystemVersion: 5.0 (2195)
      1> operatingSystemServicePack: Service Pack 3
  ```

  **Note**

  - The **repadmin /showattr** command does not show any hotfixes that might be installed on a domain controller.

Upgrade domain controllers to the appropriate service pack as needed. For more information about recommended hotfixes to use with Service Pack 2, see article 331161, "List of Fixes to Use on Windows 2000 Domain Controllers Before You Run the Adprep/Forestprep Command" in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Back Up Domain Data

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Back up your Windows 2000 domain data before you begin the upgrade. This task varies according to the operations and procedures that already exist in your environment. At minimum, complete the following steps:

- To allow for fault tolerance, ensure successful replication between two domain controllers in each domain.
- Back up two domain controllers in each domain in the forest, including System State data.
    - Test all backup media to ensure that the data can be restored successfully.

**Important**

- Store backup media in a secure off-site location designated by, and accessible to, the upgrade team before you begin the upgrade process.

# Resolve Upgrade and Application Compatibility Problems

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before upgrading a server to Windows Server 2003, use the **Winnt32.exe** command-line tool with the **/checkupgradeonly** parameter to identify potential upgrade problems, such as inadequate hardware resources or compatibility problems.

Two application compatibility problems you might need to resolve include:

- Distributed File System (DFS) root shares are not supported if they are hosted on a file allocation table (FAT) partition.

  In Windows Server 2003, DFS root shares must be located on NTFS partitions with no files or directories under the DFS link.

  For more information about deploying DFS, see "Designing and Deploying File Servers" in *Planning Server Deployments* in this kit.

- Windows 2000–based computers running Remote Installation Services (RIS) might cause errors in a Windows Server 2003 Active Directory domain.

  When using Windows 2000 RIS server in your Windows Server 2003 Active Directory Domain, you might receive the following error when using the Client Installation Wizard (CIW):

  ```
  " Unable to create or Modify Computer account"
  Error: 00004E4F
  ```

  This error occurs because Windows Server 2003 creates machine account objects differently from Windows 2000. To prevent this error from occurring when creating machine accounts, configure the Windows 2000–based RIS servers in your environment to point to a domain controller running Windows 2000. This is done by adding the DefaultServer registry parameter to the Windows 2000 RIS servers.

  For more information about configuring optional registry parameters for the Boot Information Negotiation Layer (BINL) service, see article 235979, "Optional Registry Parameters for the BINL Service" in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

  You must remove the Windows 2000 Administration Tools Pack before upgrading to Windows Server 2003. For more information about Windows 2000 administration tools and upgrade issues, see article 304718, "Administering Windows 2000–Based Computers Using Windows XP Professional–Based Clients," in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**To identify potential upgrade and compatibility problems**

- At the command line, connect to the I386 directory located at your installation source and type the following command:

  ```
  winnt32 /checkupgradeonly
  ```

Resolve any reported problems prior to performing the upgrade.

# Prepare Your Infrastructure for Upgrade

Updated: February 22, 2011

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Preparing your infrastructure for upgrade involves resolving any Active Directory schema compatibility issues, such as issues that might occur with Microsoft® Exchange 2000 and Services for UNIX 2.0, and then running Adprep.exe to prepare the forest and domains for the upgrade. Before you upgrade the first Windows 2000–based domain controller to Windows Server 2003 Active Directory, you must use Adprep.exe to:

- Run **adprep /forestprep** once on the schema master to prepare the forest.
- Run **adprep /domainprep** once on the infrastructure master in each domain in which you plan to place a Windows Server 2003–based domain controller.

  For more information about the changes that adprep /forestprep and adprep /domainprep perform, see Running Adprep.exe (http://go.microsoft.com/fwlink/?LinkId=142597).
- If you are using the version of Adprep.exe that is included with Windows Server 2003 Service Pack 1 (SP1), run **adprep /domainprep /gpprep** on the infrastructure master in each domain in which you plan to place a Windows Server 2003–based domain controller. For more information about this new adprep.exe switch, see Enhancements to Adprep.exe in Windows Server 2003 Service Pack 1.

When you are upgrading the operating system on a Windows 2000–based domain controller to Windows Server 2003, Setup (Winnt32.exe) verifies that the forest and domain have been prepared. If you have not prepared the forest and the domain in which the domain controller will be a member, or if the changes have not fully replicated, Winnt32.exe fails, the upgrade terminates, and you are notified that you must run Adprep.exe /forestprep in the forest and Adprep.exe /domainprep in the target domain.

**Note**

- You can run Adprep.exe multiple times, but it performs actions only once. For example, Adprep.exe does not adjust access control lists (ACLs) each time you run the command.

You must prepare your infrastructure before using the Active Directory Installation Wizard to install Active Directory on a Windows Server 2003–based member server. The Active Directory installation fails if the wizard detects that the forest and domain have not been prepared.

**Caution**

- Adprep.exe is the only supported method of upgrading the Windows 2000 Active Directory schema to Windows Server 2003. Attempting to use any other script or tool for this purpose can cause problems with the schema and is not supported by Microsoft.

To prepare your Windows 2000 Active Directory forest and domain for the upgrade to Windows Server 2003 Active Directory, Adprep.exe performs the following tasks:

- Updates the Active Directory schema.

  **Note**

  - Changes that are made to the global catalog by Adprep.exe do not cause a full synchronization of the global catalog because the partial attribute set is not changed.
- Improves default security descriptors.
- Upgrades display specifiers.

- Adjusts access control lists on Active Directory objects and on files in the SYSVOL shared folder to allow domain controller access.

  In versions of Windows earlier than Windows Server 2003, including the Everyone security identifier (SID) on an ACL or group membership allows authenticated users, guest users, and anyone with an anonymous logon to gain access to many resources. Windows 2000–based domain controllers also use anonymous access to gain control of some Active Directory objects and files. In Windows Server 2003, the Everyone group no longer contains the anonymous users group, thus restricting domain controller access to particular objects. Adprep.exe adjusts the ACLs on these objects so that domain controllers can still access them.

  In the updated version of adprep.exe, this change is performed by the new **adprep /domainprep /gpprep** switch. For more information about this new adprep.exe switch, see Enhancements to Adprep.exe in Windows Server 2003 Service Pack 1.

- Creates new objects that are used by applications such as COM+ and Windows Management Instrumentation (WMI).

- Creates new containers in Active Directory that are used to verify that the preparation was successful.

You can run Adprep.exe only at the command line.

**Enhancements to Adprep.exe in Windows Server 2003 Service Pack 1**

In the original release version of Windows Server 2003, one of the operations that is performed by the **adprep /domainprep** command adds more restrictive security descriptors to all Group Policy objects (GPOs) in the SYSVOL shared resource. When you modify the permissions on all the GPOs in the SYSVOL tree, the NT File Replication Service (NTFRS) on the originating domain controller must send all the GPOs to all the other domain controllers in that domain, which causes an increase in volume of replication. If you have a large number of domain controllers or a large number of GPOs in the SYSVOL tree, you must assess the potential impact that this replication traffic will have on your network. If you determine that your network will be affected negatively, you can use the **adprep /domainprep /gpprep** switch separately from the **adprep /domainprep** switch to modify the permissions in the SYSVOL shared resource during nonpeak hours when network bandwidth is optimal.

The updated version of Adprep.exe supports the following commands and enhancements. These enhancements help administrators upgrade successfully to Windows Server 2003.

- **adprep /forestprep**

  The **adprep /forestprep** command performs the same operations as it does in the original version of Windows Server 2003. The syntax of this command is unchanged. Enhancements include better error message handling in configurations that prevent the **adprep /forestprep** command from running successfully.

- **adprep /domainprep**

  The **adprep /domainprep** command performs the same operations as it does in the original version of Windows Server 2003. However, the updated command does not modify permissions on GPOs unless the new **/gpprep** switch is used.

  After you run the updated **adprep /domainprep** command, you receive the following message:

```
The new cross domain planning functionality for Group Policy, RSOP Planning Mode,
requires file system and Active Directory permissions to be updated for existing
Group Policy Objects (GPOs). You can enable this functionality at any time by
running "adprep.exe /domainprep /gpprep" on the DC that holds the infrastructure
operations master role.
This operation will cause all GPOs located in the policies folder of the SYSVOL to
be replicated once between the domain controllers in this domain. Microsoft
recommends reading KB Q324392, particularly if you have a large number of Group
Policy Objects.
```

- **adprep /domainprep /gpprep**

The functionality of the **adprep domainprep /gpprep** command depends on the state of the domain. If the updated **adprep /domainprep** command has not been run, this command is the functional equivalent of the **adprep /domainprep** command in the original version of Windows Server 2003.

If the updated **adprep /domainprep** command has already been run, the **adprep /domainprep /gpprep** command adds only the inheritable access control entries (ACEs) on GPOs in the SYSVOL shared resource.

| **Note** |
| --- |
| The new cross-domain planning functionality for Group Policy, Resultant Set of Policy (RSOP) Planning Mode, requires file system and Active Directory permissions to be updated for existing GPOs. You can enable this functionality anytime by running **adprep.exe /domainprep /gpprep** on the domain controller that holds the infrastructure operations master role. For more information about RSoP functionality, see "RSoP Overview" on the Microsoft Web site at http://go.microsoft.com/fwlink/?LinkId=48185. |

**Resolve Adprep.exe Compatibility Problems with Exchange 2000**

When you prepare the forest by using the Active Directory Preparation tool in a Windows 2000 forest containing the Exchange 2000 schema, the LDAP display names of the three Windows Server 2003 InetOrgPerson attributes *Secretary, labeledURI, and houseIdentifier* conflict with the non-RFC-compliant versions added by Exchange 2000. On the domain controller that receives the Windows Server 2003 schema updates, the *lDAPDisplayName* attributes for the Exchange 2000 definitions of these attributes are modified to prevent a conflict. When the changes are replicated in Active Directory, however, the additional domain controllers inadvertently detect the changes as a schema collision because duplicate names are present.

When Active Directory detects a duplicate name, it modifies the name of one of the objects by adding "Dup" and some unique characters to the beginning of the name. For example, the *Secretary, labeledURI,* and *houseIdentifier* name collisions appear similar to the following:

```
lDAPDisplayName: DUP-labeledURI-9591bbd3-d2a6-4669-afda-48af7c35507d
lDAPDisplayName: DUP-secretary-c5a1240d-70c0-455c-9906-a4070602f85f
lDAPDisplayName: DUP-houseIdentifier-e7c5d1bd-a422-4b9e-b4db-ecad2b6839cf
```

If you are already running Exchange 2000, you need to run the fixup script found in article 314649, "ADPREP Command Causes Mangled Attributes in Windows 2000 Forests That Contain Exchange 2000 Servers." To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

If you have not yet deployed Exchange 2000 in your environment, you can avoid name collisions by preparing the Active Directory forest by using **adprep /forestprep** to create the initial definition of the *Secretary, labeledURI,* and *houseIdentifier* attributes before installing Exchange 2000. Specifically, you can avoid LDAP display name collision problems by doing one of the following:

- Run the Active Directory Preparation tool in a Windows 2000 forest before you install Exchange 2000.
- Add Exchange 2000 to an existing Windows Server 2003 forest.

For more information about schema collisions between Exchange 2000 and Windows Server 2003, see article 314649, "ADPREP Command Causes Mangled Attributes in Windows 2000 Forests That Contain Exchange 2000 Servers," and article 325379 "How to Upgrade Windows 2000 Domain Controllers to Windows Server 2003" in the Microsoft Knowledge Base. To find these articles, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Resolve Adprep.exe Compatibility Problems with Services for UNIX 2.0**

Adprep.exe prepares the forest or domain with the schema attribute CN=uid, which is compliant with RFC 2307 for use by the Server for Network Information System (NIS) component of Services for UNIX. However, in Services for UNIX 2.0, the Server for NIS component uses a different attribute schema: CN-uid,CN=msSFUName. This discrepancy can cause the upgrade to Windows Server 2003 to fail. To solve this problem, either upgrade to Windows Services for UNIX 3.0 or install the Q293783_sfu_2_x86_en.exe hotfix.

**To resolve Server for NIS compatibility issues with Windows Server 2003**

1. Run Q293783_sfu_2_x86_en.exe on the domain controller that holds schema master role.

2. Review the Hotfix.txt file that is included with the hotfix for installation specifics.

3. Verify end-to-end Active Directory replication of the schema throughout the forest.

For more information about Services for UNIX 2.0 application compatibility issues and the hotfix installation file, see article 293783, "Cannot Upgrade Windows 2000 Server to Windows Server 2003 with Windows Services for UNIX 2.0 Installed" in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Prepare the Forest for the Upgrade**
Before preparing the forest for the upgrade, use your preferred monitoring tool to verify that replication is functioning properly. Changes that are made by Adprep.exe must replicate for the upgrade process to succeed; therefore, if domain controllers are not replicating properly, the upgrade preparation process will fail.

After verifying successful replication, use the **adprep /forestprep** command to prepare the forest for the upgrade.

**To prepare the Active Directory forest for the upgrade**

1. In the forest root domain, log on to the domain controller that holds the schema master role with an account that is a member of the Schema Admins security group.

2. Verify that the schema operations master has performed inbound replication of the schema directory partition by typing the following at a command prompt:

   - **repadmin /showreps**

3. A previous release of this documentation suggested that you take the schema master offline before running adprep /forestprep as a precautionary measure to protect the Active Directory schema from corruption. It has since been determined that this is not necessary and might cause a schema operations master to reject schema changes when it is restarted on a private network.

4. Insert the Windows Server 2003 operating system CD, or connect to the network installation shared folder, and then locate and open the I386 folder. On the schema operations master, type the following command at the command line:

   ```
   adprep /forestprep
   ```

   The following warning appears:

   ```
   ADPREP WARNING:
   Before running adprep, all Windows 2000 domain controllers in the forest should be
   upgraded to Windows 2000 Service Pack 1 (SP1) with QFE 265089, or to Windows 2000
   SP2 (or later).
   QFE 265089 (included in Windows 2000 SP2 and later) is required to prevent
   potential domain controller corruption.
   For more information about preparing your forest and domain see KB article Q331161
   at http://support.microsoft.com.
   [User Action]
   If ALL your existing Windows 2000 domain controllers meet this requirement, type C
   and then press ENTER to continue. Otherwise, type any key and press ENTER to quit.
   ```

   You can either continue with the preparation process or quit and install SP2. It is recommended that you install SP2 or later on all Windows 2000–based domain controllers before continuing.

After **adprep /forestprep** has finished, verify that all operations have completed successfully.

**To verify that the Active Directory Preparation tool has completed all operations successfully**

1. At the command line, type:

1. At the command line, type:

   ```
   adsiedit.msc
   ```

   **Important**

   - Adsiedit.exe is one of the Windows 2000 support tools, which is still installed on the computer at this point in the domain upgrade process. If you have removed the Windows 2000 support tools, you can reinstall them from the Support\Tools folder on the Windows 2000 operating system CD. For more information about Adsiedit.exe, in Help and Support Center for Windows Server 2003, click **Tools**, and then click Install Windows Support Tools.

2. Expand the **Configuration** container and verify that **CN=ForestUpdates** has been created.

3. Expand **CN=ForestUpdates** and verify that **CN=Windows2003Update** is present.

4. Examine the Event Log for any event messages that indicate that the domain controller is not functioning properly.

5. Verify that the changes that Adprep.exe made to the schema operations master are being replicated to all other the domain controllers in the forest.

   Successful replication is necessary when preparing an entire forest for Active Directory upgrade because you can prepare a domain controller by using the **adprep /domainprep** command only if it has received the changes made by the **adprep /forestprep** command. Attempting to upgrade a domain controller that has not received the changes generates an error message. Allow enough time for the changes to replicate to all domains in the forest.

   **Tip**

   - Adprep.exe creates a log file each time it runs that can help you troubleshoot errors. The log file documents each step of the forest preparation process. Each Adprep.exe log file is located in a subfolder in the %systemroot%\System32\Debug\Adprep folder. Each subfolder is stamped with the date and time when Adprep.exe was run.

**Prepare the Domain for Upgrade**

After you prepare the forest for the upgrade, you must also prepare each domain in which you plan to operate a Windows Server 2003–based domain controller.

**To prepare the Active Directory domain for upgrade**

1. Log on to the infrastructure master by using Domain Admins credentials.

2. Insert the Windows Server 2003 operating system CD, or connect to the network installation shared folder, and then locate and open the I386 folder. At the command line, type:

   ```
   adprep /domainprep
   ```

After **adprep /domainprep** has finished, verify that all operations have completed successfully.

If you are upgrading to Windows Server 2003 with SP1 or you have the updated version of adprep.exe, use the **adprep /domainprep /gpprep** switch at the command line to prepare the domain for upgrade. This command will cause a full synchronization of the SYSVOL folder. Therefore, if you are concerned about the impact of the large-scale replication, you can run **adprep /domainprep** to prepare the domain and then run **adprep /domainprep /gpprep** to synchronize the GPOs in the SYSVOL folder at a later time, when network bandwidth permits.

**To verify that the Active Directory Preparation tool has completed all operations successfully**

- Using Adsiedit.exe, expand the **Domain** container, and then go to **DC=*domainname*,DC=com**,**CN=System**,**CN=DomainUpdates**. Verify that **CN=Windows2003Update** is present.

–Or–

In **Active Directory Users and Computers**, from the **View** menu, select **Advanced Features**. Expand the **System** container, go to the **DomainUpdates** container, and then expand it. Verify that the **Windows2003Update** container is present.

If you receive an error message, do one of the following, based on the error message text:

- Run the **adprep /forestprep** command.
- Wait for replication to complete.
- Troubleshoot replication.

# Upgrading Windows 2000 Domains to Windows Server 2003

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can begin the actual domain upgrade process after the forest is prepared, all changes made by the **adprep /forestprep** command have replicated throughout the forest, and all applicable domains have been prepared with **adprep /forestprep**.

Figure 9.7 shows the process for upgrading Windows 2000–based domain controllers to Windows Server 2003 Active Directory.

**Figure 9.7 Upgrading Windows 2000 Domains to Windows Server 2003 Domains**

Windows Server 2003–based domain controllers can be introduced in your environment by either installing Active Directory on a Windows Server 2003–based member server by using the Active Directory Installation Wizard or by upgrading the operating system of an existing Windows 2000–based domain controller. Refer to your domain controller documentation table, and follow the upgrade order determined earlier in the planning process. For more information about the order in which to upgrade your domain controllers, see "Determine Domain Controller Upgrade Order" earlier in this chapter.

**Note**

- Before you attempt to upgrade a domain controller in another domain to Windows Server 2003 Active Directory, remember that you must first run the **adprep /domainprep** command on the infrastructure master role holder in that domain. Run **adprep /forestprep** only once in the forest root domain, and run **adprep /domainprep** once in each domain in the forest in which you plan to locate a Windows Server 2003-based domain controller.

# Install Active Directory on Windows Server 2003-Based Member Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Install Active Directory on a Windows Server 2003–based member server that is located in the forest root domain by using the Active Directory Installation Wizard. When you install Active Directory, the member server becomes a domain controller. You can install Active Directory on any Windows Server 2003–based member server that meets the domain controller hardware requirements. This is the recommended method for introducing Windows Server 2003 into your environment.

The Active Directory Installation Wizard:

- Allows you to create an additional domain controller in the existing domain.
- Configures the local server to host the directory service.
- Creates directory partitions and default domain security principals.
- Allows you to install or configure DNS.

To install Active Directory on a Windows Server 2003–based member server, start the Active Directory Installation Wizard by using one of the following methods:

**To install Active Directory on a Windows Server 2003–based member server**

- At the command line, type:

  ```
  dcpromo
  ```

  – or –

  Open **Administrative Tools**, and then click **Configure Your Server Wizard**. Select **Domain Controller (Active Directory)** to configure your domain controller. After the Configure Your Server Wizard finishes, the Active Directory Installation Wizard begins.

After the first Windows Server 2003–based domain controller has been deployed, you can install Active Directory on additional domain controllers by installing from media, a new installation feature of Windows Server 2003. Installing from media allows you to pre-populate Active Directory with System State data backed up from an existing Windows Server 2003–based domain controller. This backup can be present on local CD, DVD, or hard disk partition. Installing from media drastically reduces the time required to install directory information by reducing the amount of data that is replicated over the network. Installing from media is most beneficial in environments with very large domains or for installing new domain controllers that are connected by a slow network link.

**To install Active Directory on a Windows Server 2003–based member server from media**

- In the **Run** dialog box, **type dcpromo /adv**, and then click **OK**.

The wizard prompts you to choose a network share or a backup as the installation source. If you are installing from backup files, you must identify the location of the files. If the domain controller from which you restored the System State data was a global catalog, you will have the option to make this new domain controller a global catalog. The wizard will then proceed with the installation.

Table 9.4 lists information for installing Active Directory on a Windows Server 2003–based member server, in addition to sample data for installing Active Directory on an additional domain controller in the existing Contoso forest. Contoso will install Active Directory from a Windows Server 2003, Enterprise Edition CD by using the **dcpromo** command.

**Table 9.4 Installing Active Directory on Windows Server 2003–Based Member Servers**

| Wizard Page or Dialog Box | Action | Example |
|---|---|---|
| Domain Controller Type | Select **Additional domain controller for an existing domain**. | |
| Network Credentials | Type the user name and password of an account with sufficient privileges to install Active Directory on this computer, and the fully qualified domain name of the domain in which the computer will become an additional domain controller. | |
| Additional Domain Controller | Type the full DNS name of the forest root domain. | **Concorp.contoso.com** |
| Database and Log Folders | Type the folder locations specified by your design. | Database folder: C:\Windows\NTDS<br><br>Log folder: D:\Logs |
| Shared System Volume | Confirm or type the location specified by your design. | C:\Windows\SYSVOL |
| Directory Service Restore Mode Administration Password | In the **Password and Confirm password** boxes, type any strong password. | |

Verify that all information on the Summary page is accurate, and then click **Finish**. After Active Directory is installed, you will be prompted to restart the computer. The installation will not be complete until the computer restarts.

After you install Active Directory on the Windows 2003–based member server, allow sufficient time for replication to occur and other domain controllers to synchronize with the new domain controller.

For more information about installing and removing Active Directory, see the *Active Directory Collection* of the *Windows Server 2003 Technical Reference* (or see the Active Directory Collection on the Web at http://www.microsoft.com/reskit).

# Upgrade Existing Windows 2000-Based Domain Controllers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you upgrade the operating system on a Windows 2000–based domain controller to Windows Server 2003, the computer immediately assumes the role of domain controller after the final restart of the computer. It is not necessary to install Active Directory by using the Active Directory Installation Wizard. Upgrade the following existing Windows 2000–based domain controllers early in the upgrade process:

- The Windows 2000–based domain controller that holds the role of the domain naming master. This will ensure the creation of application directory partitions that will later be used for DNS. If you choose not to upgrade the domain naming master, you must transfer the role of the domain naming master to a Windows Server 2003 domain controller.

  When a domain controller running the DNS Server service restarts for the first time after the operating system has been upgraded to Windows Server 2003, it will try to subscribe to existing application directory partitions or create them if it does not detect them. If the domain naming master is not a Windows Server 2003–based domain controller, the creation of the application directory partitions will fail and errors will be generated.

- The Windows 2000–based domain controller that holds the PDC emulator role in the forest root domain. This will ensure that additional security principals are created for the forest. For more information about the additional security principals that are created after the PDC emulator in the forest root domain is upgraded, see "Background Information for Upgrading Windows 2000 Domains to Windows Server 2003 Domains" earlier in this chapter.

- All other Windows 2000–based domain controllers that hold the PDC emulator role. This will ensure that all new Windows Server 2003 groups and group memberships are created. If you choose not to upgrade the PDC emulator for each domain, you must transfer the PDC role to a Windows Server 2003–based domain controller.

To initiate the installation of the operating system on a domain controller, insert the Windows Server 2003 operating system CD on the domain controller, or, if the Windows Server 2003 media are shared over the network, run the Winnt32.exe command-line tool.

You can also perform an unattended installation of Windows Server 2003. Instructions for creating an answer file for an Active Directory installation are located in the Deploy.cab file in the Support\Tools folder on the Windows Server 2003 operating system CD. Inside the Deploy.cab file, open Ref.chm to access the Unattend.txt file. Expand **Unattend.txt** in the left pane, and then click **DCInstall**.

# Modify Default Security Policies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To ensure that clients running older versions of the Windows operating system will be able to access domain resources in the new Windows Server 2003 domain, you might have to modify default security policies.

**Important**

- Be aware that by modifying these policies you are weakening the default security policies in your environment. However, this is necessary to ensure that some clients running earlier versions of Windows will be able to access domain resources. After all clients in your environment are running versions of Windows that support SMB packet and secure channel signing, you can re-enable these security policies to increase security. It is recommended that you upgrade your Windows–based clients as soon as possible.

In order to increase security, Windows Server 2003–based domain controllers require by default that clients attempting to authenticate to them use SMB packet and secure channel signing. Clients running Windows 95 or Windows NT 4.0 with Service Pack 2 (SP2) and earlier without the Directory Service Client Pack do not support SMB packet signing and will not be able to log on or access domain resources on the network. Clients running Windows NT 4.0 with Service Pack 3 (SP3) and earlier do not support secure channel signing and will not be able to establish communications with a domain controller in their domain.

The most secure way to enable these clients to logon and access domain resources on the network is to apply the appropriate service pack or the Directory Service Client Pack. If you cannot apply the most recent service pack or the Directory Service Client Pack, configure all Windows Server 2003–based domain controllers to not require SMB packet signing or secure channel signing by disabling the following settings in the Default Domain Controllers Policy:

- **Microsoft network server: Digitally sign communications (always)**
- **Domain member: Digitally encrypt or sign secure channel data (always)**

Back up the Default Domain Controllers Policy Group Policy object before modifying it. Use the Group Policy Management Console (GPMC) to back up the Group Policy object so that it can be restored if necessary. The Group Policy Management Console (GPMC) is a tool that permits you to manage Group Policy for multiple domains and sites in one or more forests. GPMC is the recommended method for managing Group Policy; however this chapter does not assume that you are using GPMC for security policy management and deployment.

GPMC is not included with Windows Server 2003. To obtain GPMC, see the Group Policy Management Console (GPMC) link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**To disable SMB packet and secure channel signing enforcement on Windows Server 2003–based domain controllers**

1. Open **Active Directory Users and Computers**, right-click the **Domain Controllers** container, and then click **Properties**.
2. Click the **Group Policy** tab, and then click **Edit**.
3. Under **Computer Configuration**, go to the Windows Settings\Security Settings\Local Policies\Security Options folder.
4. In the details pane, double-click **Microsoft network server: Digitally sign communications (always)**, and then click **Disabled** to prevent SMB packet signing from being required.
5. Click **OK**.
6. In the details pane, double-click **Domain member: Digitally encrypt or sign secure channel data (always)**,and then click **Disabled** to prevent secure channel signing from being required.
7. Click **OK**.

To apply the Group Policy change immediately, either restart the domain controller, or type **gpupdate /force** at a command line, and then press ENTER.

**Note**

- Modifying these settings in the Domain Controllers container will change the Default Domain Controllers Policy. Policy changes made here will be replicated to all other domain controllers in the domain, so you only need to modify these policies one time to affect the Default Domain Controllers Policy on all domain controllers.

For more information about SMB packet signing and secure channel signing, see "Background Information for Upgrading Windows 2000 Domains to Windows Server 2003 Domains" earlier in this chapter.

For more information about security policies, see "Security Setting Descriptions" on the Microsoft Web site.

For more information about managing and deploying security policies and the Group Policy Management Console (GPMC), see "Deploying Security Policy" in *Designing a Managed Environment* in this kit.

# Update Group Policy Permissions

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Group Policy Modeling is a new feature of the GPMC that simulates the resultant set of policy for a particular configuration. The simulation is performed by a service that runs on Windows Server 2003–based domain controllers. To perform the simulation across domains, the service must have read access to all Group Policy objects (GPOs) in the forest.

In a Windows Server 2003 domain that has been upgraded from Windows 2000 or newly installed, the Enterprise Domain Controllers group is automatically given read access to all newly created GPOs. This ensures that the service can read all GPOs in the forest.

However, if the domain was upgraded from Windows 2000, the Enterprise Domain Controllers group will not have read access to any existing GPOs that were created prior to the upgrade. The Group Policy Management Console detects this when you click a GPO and notifies the user that Enterprise Domain Controllers do not have read access to all GPOs in this domain. To solve this problem, use the sample script that is provided with the Group Policy Management Console, GrantPermissionOnAllGPOs.wsf. This script will update the permissions on all GPOs in the domain. You must be a member of the Domain Admins group or have permissions to modify security on all GPOs in the domain to run this script.

**Note**

- To download the GPMC, see the Group Policy Management Console link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**To update permissions on all GPOs in a domain**

1. At the command line, change to the %programfiles%\Gpmc\Scripts folder.

2. Type the following:

   ```
   GrantPermissionOnAllGPOs.wsf "Enterprise Domain Controllers" /permission:read
   /domain:DNSDomainName /Replace
   ```

   Using the Replace switch removes existing permissions for the group or user before making the change. If a group or user is already granted a permission type higher than the new permission type, and you do not specify Replace, no change is made.

For more information about using GPMC for deploying Group Policy, see "Designing a Group Policy Infrastructure" in *Designing a Managed Environment* in this kit.

For more information about Group Policy Management Console (GPMC) scripting, see the Platform SDK: Group Policy Management Console (http://go.microsoft.com/fwlink?linkid=17912).

# Perform Clean-up Tasks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After upgrading to Windows Server 2003, perform the following clean-up operations:

- After the security descriptor propagator has finished building the single instance store, perform an offline defragmentation of the database on each upgraded domain controller. This reduces the size of Active Directory on the file system by up to 40 percent, reduces the memory footprint, and updates pages in the database to Windows Server 2003 format. For more information about performing an offline defragmentation of the Active Directory database, see the Active Directory link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources. Search under "Administration and Configuration Guides," and then download the *Active Directory Operations Guide*. The procedure for performing an offline defragmentation of the database applies to both Windows 2000 and Windows Server 2003.

- Create a new System State backup for at least two domain controllers in your environment. For more information about backing up Active Directory, see the *Active Directory Operations Guide*. The procedure for backing up System State data applies to both Windows 2000 and Windows Server 2003. Be sure to label all backup tapes with the operating system version that the domain controller is running, including service packs and hotfixes.

# Completing Post-Upgrade Tasks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After upgrading the operating system on all domain controllers in the forest to Windows Server 2003, complete the domain upgrade by raising the domain and forest functional levels to Windows Server 2003, and use newly created application directory partitions to store DNS information. You must then redirect the Users and Computers containers.

Figure 9.8 shows the tasks necessary to complete your upgrade to Windows Server 2003 Active Directory.

**Figure 9.8 Completing the Upgrade to Windows Server 2003 Active Directory**

# Raise the Functional Levels of Domains and Forests

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To enable all Windows Server 2003 Active Directory features, raise the functional level of your forest to Windows Server 2003. This will automatically raise the functional level of all domains to Windows Server 2003.

**Important**

- Raising the domain and forest functional levels to Windows Server 2003 is a nonreversible task and prohibits the addition of Windows NT 4.0–based or Windows 2000–based domain controllers to the environment. Any existing Windows NT 4.0 or Windows 2000–based domain controllers in the environment will no longer function. Before raising functional levels to take advantage of advanced Windows Server 2003 features, ensure that you will never need to install domain controllers running Windows NT 4.0 or Windows 2000 in your environment.

After all domains are operating at the Windows Server 2003 functional level, raise the forest functional level to Windows Server 2003. To do this, right-click **Active Directory Domains and Trusts** in Active Directory Domains and Trusts, and select **Raise Forest Functional Level**. This allows you to take advantage of all Windows Server 2003 forest-level features.

**Note**

- You can only raise the functional level of the forest to Windows Server 2003 if all domains are set to the Windows 2000 native functional level or higher.

For more information about enabling functional levels after upgrading from a Windows 2000 environment and the features available at the Windows Server 2003 domain and forest functional levels, see "Enabling Advanced Windows Server 2003 Active Directory Features" in this book.

# Use DNS Application Directory Partitions

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Use application directory partitions for Active Directory–integrated DNS zones to reduce replication traffic and the amount of data stored in the global catalog.

After completing the upgrade of all Windows 2000–based domain controllers in the forest to Windows Server 2003, move the Active Directory–integrated DNS data on all DNS servers from the domain partition into the newly created DNS application directory partitions. This is done by changing the replication scope of the DNS zones.

Move the DNS zones that you want to replicate to all DNS servers in the forest to the forest-wide DNS application directory partition, ForestDnsZones. For each domain in the forest, move the DNS zones that you want to replicate to all DNS servers in the domain to the domain-wide DNS application directory partition, DomainDnsZones.

**Important**

- Before you attempt to move DNS data to an application directory partition, make sure that the domain naming master is hosted on a Windows Server 2003–based domain controller.

If there is an existing _msdcs.*forest_root_domain* zone on your DNS server, move it to the ForestDnsZones application directory partition.

If the _msdcs.*forest_root_domain* zone is not present as a separate zone on your DNS server, you do not need to perform this procedure because the DNS data that is stored in the _msdcs.*forest_root_domain* is moved with the forest root domain zone to the domain-wide application directory partition, DomainDnsZones.

**Note**

- For more information about DNS and application directory partitions, see "Background Information for Upgrading Windows 2000 Domains to Windows Server 2003 Domains" earlier in this chapter.

**To change the replication scope of the domain-wide DNS zone by using a DNS application directory partition**

1. On a domain controller that hosts a DNS server in the particular domain, open the DNS snap-in, right-click the DNS zone that uses the fully qualified domain name of the Active Directory domain, and then click **Properties**.
2. Click the **Change** button next to **Replication: All domain controllers in the Active Directory domain**.
3. Click **To all DNS servers in the Active Directory domain *domainname***.

**To change the replication scope of the _msdcs.forest_root_domain DNS zone by using a DNS application directory partition**

1. On a domain controller that hosts a DNS server in the forest root domain, open the DNS snap-in, right-click the _msdcs.*forest_root_domain* DNS zone, and then click **Properties**.
2. Click the **Change** button next to **Replication: All domain controllers in the Active Directory domain**.
3. Click **To all DNS servers in the Active Directory forest *forestname***.

For more information about creating, enlisting in, and removing application directory partitions, see Help and Support Center for Windows Server 2003. For more information about creating a DNS design for Active Directory, see "Designing the Active Directory Logical Structure" in this book.

# Redirect Users and Computers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The default CN=Users and CN=Computers containers that are created when Active Directory is installed are not organizational units. Objects in the default containers are more difficult to manage because Group Policy cannot be applied directly to them. New user accounts, computer accounts, and security groups that are created by using earlier versions of user interface and command-line management tools, do not allow administrators to specify a target organizational unit and, therefore, to create these objects in either the CN=Computers container or the CN=User container by default. Examples of these earlier versions include the **net user** and **net computer** commands, the **net group** command, the **netdom add** command where the **/ou** parameter is either not specified or supported, or Windows NT 4.0 tools such as User Manager for Domains.

It is recommended that administrators who upgrade Windows NT 4.0–based and Windows 2000–based domain controllers to Windows Server 2003 redirect the well-known path for the CN=Users and CN=Computers containers to an organizational unit specified by the administrator so that Group Policy can apply to containers hosting newly created objects.

**Important**

- The CN=Users and CN=Computers containers are computer-protected objects. For backward compatibility reasons, you cannot (and must not) remove them. However, you can rename these objects.

In Windows Server 2003 Active Directory, when the domain functional level has been raised to Windows Server 2003, you can redirect the default CN=Users and CN=Computers containers to organizational units that you specify so that each can support Group Policy, making them easier to manage.

**To redirect the Users container**

1. In Active Directory Users and Computers, create an organizational unit container to which you will redirect user created with earlier versions of user interface and command-line management tools.
2. At the command line, change to the System32 folder by typing:

```
cd %systemroot%\system32
```

3. At the %systemroot%\System32 folder, type the following, where *newuserou* is the name of the new user OU and *domainname* is the name of the domain:

```
redirusr ou=
newuserou
,DC=
domainname
,dc=com
```

**To redirect the Computers container**

1. In Active Directory Users and Computers, create an organizational unit container to which you will redirect computer objects created with earlier versions of user interface and command-line management tools.
2. At the command line, change to the System32 folder by typing:

```
cd %systemroot%\system32
```

3. At the %systemroot%\System32 folder, type the following, where *newcomputerou* is the name of the new computer OU and *domainname* is the name of the domain:

```
redircmp ou=
newcomputerou
,DC=
domainname
,dc=com
```

For more information about creating an organizational unit design, see "Designing the Active Directory Logical Structure" in this book.

# Completing the Upgrade

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Complete the following tasks to finalize the process:

- Review, update, and document the domain architecture to reflect any changes that you made during the domain upgrade process.
- Verify that the NETLOGON and SYSVOL shared folders exist and that the File Replication Service (FRS) is functioning without error by checking the Event Viewer.
- Verify that Group Policy is being applied successfully by checking the application log in Event Viewer for Event ID 1704.
- Verify that all SRV, CNAME, and A resource records have been registered in DNS.
- Continuously monitor your domain controllers and Active Directory. Using a monitoring solution such as Microsoft® Operations Manager to monitor the distributed Active Directory service and the services that it relies on helps maintain consistent directory data and a consistent level of service throughout the forest.

After these tasks have been completed successfully, you will have completed the in-place upgrade process.

# Additional Resources for Upgrading from Windows 2000 Domains to Windows Server 2003 Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information and tools related to this chapter.

# Restructuring Windows NT 4.0 Domains to an Active Directory Forest

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Restructuring Microsoft® Windows NT® 4.0 operating system domains to an Active Directory® directory service forest involves migrating the contents of a number of Windows NT 4.0 domains into a smaller number of Active Directory domains. By restructuring your environment to an Active Directory forest, you can take advantage of new and enhanced Active Directory features, while reducing the complexity of your organization and the associated administrative costs.

**In This Chapter**

Overview of Restructuring Windows NT 4.0 Domains to an Active Directory Forest

Planning to Restructure Windows NT 4.0 Domains to an Active Directory Forest

Preparing the Source and Target Domains for Restructuring

Restructuring Account Domains

Restructuring Resource Domains

Additional Resources for Restructuring Windows NT 4.0 Domains

**Related Information**

- For more information about designing the Active Directory logical structure, see "Designing the Active Directory Logical Structure" in this book.
- For more information about designing the Active Directory site topology, see "Designing the Site Topology" in this book.
- For more information about creating an Active Directory forest, see "Deploying the Windows Server 2003 Forest Root Domain" in this book.

# Overview of Restructuring Windows NT 4.0 Domains to an Active Directory Forest

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you are upgrading from Windows NT 4.0 domains to an Active Directory forest, you can consolidate your existing account and resource domains by restructuring them into a smaller number of larger Active Directory domains. You can restructure Windows NT 4.0 domains into Active Directory domains running the Microsoft® Windows® 2000 or Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; or Windows® Server 2003, Datacenter Edition operating systems.

Before you begin to restructure your Windows NT 4.0 domains, ensure that your organization has designed an Active Directory logical structure and a site topology. In a Windows 2000 environment, ensure that any domains that you plan to use as target domains are operating in Windows 2000 native mode. In a Windows Server 2003 environment, ensure that for any domains that you plan to use as target domains, you have raised the Active Directory domain functional level to Windows 2000 native or Windows Server 2003.

For more information about upgrading Windows NT 4.0 domains in-place, see "Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory" in this book.

After the restructuring process is complete, you can take advantage of the features available in Active Directory. By consolidating multiple Windows NT 4.0 account and resource domains into a single or a few Active Directory domains, you can create an Active Directory domain structure that is more efficient than your existing Windows NT 4.0 domain structure.

**Note**

- For a list of the job aids that are available to assist you in restructuring Windows NT 4.0 domains, see "Additional Resources for Restructuring Windows NT 4.0 Domains" later in this chapter.

# Process for Restructuring Windows NT 4.0 Domains to an Active Directory Forest

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Restructuring Windows NT 4.0 domains to an Active Directory forest involves completing the necessary planning and preparation tasks in the appropriate order, and then migrating Windows NT 4.0 accounts and resources to an Active Directory domain or domains.

Figure 10.1 shows the process for restructuring Windows NT 4.0 domains to an Active Directory forest.

**Figure 10.1 Restructuring Windows NT 4.0 Domains to an Active Directory Forest**

# Windows NT 4.0 Domain Migration Background Information

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Restructuring Windows NT 4.0 domains involves migrating user, group, and computer objects from a Windows NT 4.0 account or resource source domain into an Active Directory target domain. The target domain can either be a newly created Active Directory domain, or a Windows NT 4.0 domain that has been upgraded in-place.

After the migration process is complete, clients can log on to the original Windows NT 4.0 domain or the new Active Directory domain for authentication. Clients can also access resources in either the source or the target domain, until the source domain is decommissioned.

To successfully consolidate Windows NT 4.0 account and resource domains into Active Directory domains, it is important to be familiar with the capabilities of both operating systems in the context of restructuring. You must also be familiar with the tools that support object migrations.

The migration process between forests is non-destructive. Because a Windows NT 4.0 domain cannot be part of an Active Directory forest, when objects are migrated from a Windows NT 4.0 domain to an Active Directory domain, they are copied from the source domain to the target domain. The source account primary security identifier (SID) can be maintained in the SID history of the object. You can use the Active Directory Migration Tool (ADMT) version 2 or a third-party restructuring tool to restructure domains.

For more information about domain migration, SIDs, and SID history, see the Domain Migration Cookbook link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Terms and Definitions for Domain Restructure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The following terms apply to the Windows NT 4.0 domain restructure process.

**Domain restructure** A migration process that involves changing the domain structure of a forest. A domain restructure can involve either consolidating or adding domains, and can take place between forests or within a forest.

**Domain consolidation** A restructuring process that involves eliminating Windows NT 4.0 or Active Directory domains by merging their content with that of other domains.

**Migration objects** Domain objects that you plan to migrate to a new domain by using a tool, such as ADMT. These objects can be user accounts, service accounts, groups, or computers.

**Source domain** The domain that contains the objects that you plan to migrate to a new domain.

**Target domain** The domain that receives the migration objects from the source domain. In a Windows 2000 environment, the target domain must be operating in Windows 2000 native mode. In a Windows Server 2003 environment, the target domain must be at the Windows 2000 native or Windows Server 2003 Active Directory domain functional level.

**Built-in groups** Default security groups with common sets of rights and permissions. These rights and permissions are assigned to any accounts or groups that you designate as members of these groups. Built-in account SIDs are identical in every domain, and therefore, built-in groups cannot be migration objects.

**Password export server (PES)** A domain controller in the source domain that is used to securely copy account passwords from the source domain to the target domain. When you are migrating accounts and passwords between domains, one source domain controller must be configured as the PES.

# Active Directory Migration Tool 2.0

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

ADMT enables you to copy objects from Windows NT 4.0 domains to an Active Directory forest. ADMT includes wizards that automate migration tasks such as copying users, groups, and service accounts; moving computers; migrating trusts; and performing security translation.

When you use ADMT to restructure Windows NT 4.0 domains, ADMT copies the accounts that are migrated, so that when the accounts are created in the target domain, they continue to exist in the source domain. The primary security identifiers (SIDs) for the accounts can be migrated to the SID history in the target domain.

ADMT is available on the Windows Server 2003 operating system CD, in the Admigration.msi file in the \i386\admt directory.

You can perform ADMT tasks by using the ADMT console, by using a command-line procedure, or by using a script. When you are running ADMT from the command line, it is often more efficient to use an option file to specify command-line options. You can use the ADMT option file reference in Listing 10.1 to assist you in creating option files.

Listing 10.1 lists all common options that apply to several migration tasks. Each type of migration task has a section that lists options that are specific to that task. The section name corresponds to the task name used when executing the ADMT command-line tool. Items can be commented out with a semicolon. In Listing 10.1, the default values are commented out.

When running ADMT at the command line, you do not need to include an option in your command if you want to accept the default value. In this chapter, however, tables are provided for reference. The tables list the command-line equivalent of each option that is shown in the corresponding ADMT console procedure, including those where you are accepting the default value.

**Listing 10.1 ADMT Option File Reference**

```
 [Migration]
;TestMigration=No
;IntraForest=No
SourceDomain=" source_domain_name"
;SourceOu=" source_ou_path"
TargetDomain=" target_domain_name"
TargetOu=" target_ou_path"
;RenameOption=dont
;RenamePrefixOrSuffix=""
;PasswordOption=Complex
;PasswordServer=""
;PasswordFile=""
;ConflictOptions=Ignore
;ConflictPrefixOrSuffix=""
;UserPropertiesToExclude=""
;InetOrgPersonPropertiesToExclude=""
;GroupPropertiesToExclude=""
;ComputerPropertiesToExclude=""

[User]
;DisableOption=EnableTarget

;MigrateGroups=No
;UpdatePreviouslyMigratedObjects=No
;FixGroupMembership=Yes
;MigrateServiceAccounts=No
;UpdateGroupRights=No

[Group]
MigrateSIDs=Yes
;UpdatePreviouslyMigratedObjects=No
;FixGroupMembership=Yes
;UpdateGroupRights=No
;MigrateMembers=No
;DisableOption=EnableTarget
;SourceExpiration=None
;TranslateRoamingProfile=No
```

```
;MigrateServiceAccounts=No

[Security]
TranslationOption=Add
;TranslateFilesAndFolders=No
;TranslateLocalGroups=No
;TranslatePrinters=No

;TranslateRegistry=No
;TranslateShares=No
;TranslateUserProfiles=No
;TranslateUserRights=No

;SidMappingFile=" SidMappingFile.txt"
```

For a file that contains the ADMT options, see "ADMT Option File Reference" (DSSRENT_3.txt) on the *Microsoft® Windows® Server 2003 Deployment Kit* companion CD (or see "ADMT Option File Reference" on the Web at http://www.microsoft.com/reskit).

When running ADMT from the command line, it is often more efficient to use an include file to list the users, groups, or computers that will be migrated. For example, to migrate a small number of computers, you might type each computer name at the command line, using the /N option as follows:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
"
```

*Computer_name1* and *computer_name2* are the names of computers in the source domain that you are migrating in this batch.

If you have a large number of users, groups, or computers to migrate, you can list them in an include file. For example, to create an include file for a batch of computers, create a plain text file and list the computer names, each name on a separate line. Then specify the include file name with the /F option, as follows:

```
ADMT COMPUTER /F "
includefile_name
" /SD:"
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
"
```

ADMT supports use of ANSI or standard Unicode files for option files and include files.

For a complete list of all available ADMT options and syntax, run ADMT and select **Help** from the menu.

The sample scripts provided in this chapter reference the symbolic constants that are defined in the AdmtConstants.vbs file. Listing 10.2 shows the ADMT constants VBScript file.

**Listing 10.2 ADMT Scripting Constants**

```
Option Explicit
'-----------------------------------------------------------------------------
' ADMT Scripting Constants
'-----------------------------------------------------------------------------
' RenameOption constants
Const admtDoNotRename      = 0

' Report Type
Const admtReportMigratedAccounts  = 0
Const admtReportMigratedComputers = 1
Const admtReportExpiredComputers  = 2
Const admtReportAccountReferences = 3
Const admtReportNameConflicts     = 4

' Option constants
Const admtNone     = 0
Const admtData     = 1
Const admtFile     = 2
Const admtDomain   = 3
Const admtRecurse           = &H0100
Const admtFlattenHierarchy  = &H0000
Const admtMaintainHierarchy = &H0200
```

For a file that contains the ADMT scripting constants, see "ADMT Scripting Constants" (AdmtConstants.vbs) on the *Windows Server 2003 Deployment Kit* companion CD (or see "ADMT Scripting Constants" on the Web at http://www.microsoft.com/reskit).

# Planning to Restructure Windows NT 4.0 Domains to an Active Directory Forest

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Planning your domain restructure involves defining the accounts and resources to be migrated, creating a test plan, and creating a rollback plan for use in the event that the migration fails. You must also plan for user profile migration, establish administrative procedures to ensure that users can continue to log on to the network and access resources during the migration, and create an end-user communication plan.

Figure 10.2 shows the planning steps associated with restructuring Windows NT 4.0 domains to an Active Directory forest.

**Figure 10.2 Planning to Restructure Windows NT 4.0 Domains to an Active Directory Forest**

# Assign Object Locations and Roles

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Large organizations are likely to be migrating thousands of user, group, and resource objects from numerous Windows NT 4.0 domains to Active Directory domains. It is important to keep track of these objects by assigning them roles and locations in the target domain. It is useful to document the assignments for all of the objects that you are migrating in object assignment worksheets. Create one worksheet for account objects, such as users, groups, and service accounts, and one worksheet for resource objects, such as workstations, profiles, and domain controllers. In your worksheets, list the source and target locations for all objects to be migrated. For information about identifying service accounts to be migrated, see "Service Account Identification" later in this chapter.

**Note**

- Built-in accounts (such as Administrators, Users, and Power Users) and well-known accounts (such as Domain Admins and Domain Users) cannot be ADMT migration objects.

For a worksheet to assist you in documenting account object assignments, see "User and Group Object Assignment Table — Windows NT 4.0 Source" (DSSRENT_1.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "User and Group Object Assignment Table — Windows NT 4.0 Source" on the Web at http://www.microsoft.com/reskit).

Figure 10.3 shows an example of a completed user and group object assignment worksheet.

**Figure 10.3 Example of a Completed User and Group Object Assignment Table Worksheet — Windows NT 4.0 Source**

| User and Group Object Assignment Table - Windows NT 4.0 Source | | | |
|---|---|---|---|
| Prepared By | Active Directory Deployment Team | Date | 01/01/03 |
| Source Domain Name | Boston | | |
| Target Domain Name | east.trccorp.treyresearch.net | | |
| Name | Type | Source Location | Target Location |
| Finance | Group | Boston domain | East\Boston Groups OU |
| Accounting | Group | Boston domain | East\Boston Groups OU |
| JBrown | User | Boston domain | East\Boston Users OU |
| MNguyen | User | Boston domain | East\Boston Users OU |
| !Scheduler | Service Account | Boston domain | East\Service Accounts OU |

Creating a resource object assignment worksheet also involves identifying the target organizational unit (OU) for each object and noting the physical location and role in the target domain. For a worksheet to assist you in documenting resource object assignments, see "Resource Object Assignment Table — Windows NT 4.0 Source" (DSSRENT_2.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Resource Object Assignment Table — Windows NT 4.0 Source" on the Web at http://www.microsoft.com/reskit).

Figure 10.4 shows an example of a completed resource object assignment worksheet.

**Figure 10.4 Example of a Completed Resource Object Assignment Table Worksheet — Windows NT 4.0 Source**

| Resource Assignment Table - Windows NT 4.0 Source | | | |
|---|---|---|---|
| Prepared By | Active Directory Deployment Team | Date | 01/01/03 |

| | |
|---|---|
| Source Domain Name | PROD-APPS |
| Target Domain Name | east.trccorp.treyresearch.net |

| Resource Name | Resource Type | Target OU | Physical Location | Role in Target Domain |
|---|---|---|---|---|
| FS01 | Member server (file server) | Member Servers | Boston | Member Server |
| UserWrk01 | Computer account | Workstations | Boston | Computer account |
| UserWrk02 | Computer account | Workstations | Boston | Computer account |
| DC01 | Domain Controller | Domain Controllers | New York | Domain controller |
| DC02 | Domain Controller | Member Servers | Washington DC | Member server |

# Developing a Migration Test Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is important to develop a test plan to assist you in systematically testing the results of the migration, and identifying and correcting any problems that might occur. Testing allows you to ensure that users who are migrated from the source to the target domain are able to log on, to access resources based on group membership or user credentials, and that they have retained their desktop settings. Testing also allows you to ensure that users are able to access the resources that you migrate.

Use the following process to test your account object and resource object migration:

1. Create a test user in the source domain that you include with your migrations.

2. Join that user to the appropriate global groups to enable resource access.

3. Log on to the source domain as the test user and verify that you can access resources as appropriate.

4. After you migrate the user account, translate the user profile, and migrate the workstation of the user, log on to the target domain as the test user and verify that the user has retained all necessary access and functionality. For example, you might test to verify that:

   - The user can log on successfully.

   - The user has access to all appropriate resources, such as file and print shares; access to services such as messaging; and access to line-of-business applications. It is especially important to test access to applications developed internally that access database servers.

   - The user profile was successfully translated, and the user retains desktop settings, desktop appearance, shortcuts, and access to the My Documents folder. Also, verify that applications appear in and start from the Start Menu.

5. After you migrate resources, log on as the test user in the target domain and verify that you can access resources as appropriate.

If any steps in the test process fail, identify the source of the problem and determine whether you can correct the problem before the object needs to be accessible in the target domain. If you cannot correct the problem before access to the object is required, roll back to your original configuration to ensure access to the user or resource object. For more information about creating a rollback plan, see "Creating a MigrationvRollback Plan" later in this chapter.

As part of your test plan, create a migration test matrix. Complete a test matrix for each step that you complete in the migration process. For example, if you migrate 10 batches of users, complete the test matrix 10 times, once for each batch that you migrate. If you migrate 10 member servers, complete the test matrix for each of the 10 servers.

For a worksheet to assist you in creating a test matrix, see "Migration Test Matrix" (DSSREER_3.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migration Test Matrix" on the Web at http://www.microsoft.com/reskit).

Figure 10.5 shows an example of a completed migration test matrix.

**Figure 10.5 Example of a Completed Migration Test Matrix Worksheet**

# Migration Test Matrix

| Prepared By | Active Directory Deployment Team | Date | 01/01/03 |
|---|---|---|---|

| | |
|---|---|
| Source Domain Name | Boston |
| Target Domain Name | east.trccorp.treyresearch.net |

| Test Name | Performed Before Migration | Result After Migration | Notes |
|---|---|---|---|
| Create test user for users in Sales department "batch1" | Yes | Success | |
| Join user to sales group | Yes | Success | |
| Log on to source domain and verify access to required resources | Yes | Success | |
| Log on to target domain | No | Success | |
| Verify access to file and print shares | No | Success | |
| Verify access to customer management application | No | Success | |
| Verify user desktop settings and access to My Documents folder | No | Success | |
| Verify that applications appear and start from the Start menu | No | Success | |

# Creating a MigrationvRollback Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Reduce the risk of disrupting end users in your organization by establishing a rollback plan. In general, it is possible to isolate and resolve any problems that occur during each phase of the migration. However, it is important to analyze potential risks and identify the levels of user impact and downtime that might necessitate rolling back the migration. You might be required to roll back your migration if any of the following occur:

- Users cannot log on to their accounts after migration.
- Users cannot access resources after migration.
- User migration is incomplete; for example, passwords did not migrate.
- User migration was successful, but user workstation migration or local profile translation failed.

If user impact or downtime reaches a level that you have defined as unacceptable in your organization, you can implement your rollback plan and continue to operate in your premigration environment. Because the source domain remains intact when you are restructuring Windows NT 4.0 domains, you can restore the original environment by completing a few steps.

To roll back the migration of Windows NT 4.0 account objects:

1. Enable the user accounts in the source domain (if you disabled the accounts during the migration process).
2. Notify the users to log off of the Active Directory target domain and log on to the source domain.
3. Verify that users are able to access resources.
4. Verify that the logon scripts and user profiles for users work as configured in the source domain.

The rollback process for Windows NT 4.0 resource objects is similar to that for account objects. To roll back the migration of Windows NT 4.0 resource objects:

1. Change the domain membership for the resource object to the source domain.
2. Restart the server or workstation.
3. Log on as a user and verify that you can access the resource.

**Note**

- Before you modify objects such as member servers or domain controllers during the migration, back up all data.

# Planning for User Profile Migration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

User profiles store user data and information about the user's desktop settings. User profiles can either be roaming or local. The migration process is slightly different for local and for roaming profiles.

Profiles are translated during the migration process. Only the primary SID is used to assign a profile to a user; SIDs in SID history are ignored. If you translate profiles in add mode, the user accounts in the target and the source domains have access to the profile. In this way, if you roll the user account back to the source domain, the user account in the source domain can use the profile. If you translate profiles in replace mode, you must retranslate the profile by using a SID mapping file to restore the environment to the premigration state.

**Important**

- In the event that you need to roll back to your original configuration, notify users that profile changes made in the target domain are not reflected in the source domain.

Some organizations might choose not to migrate user profiles. Other organizations might choose to replace users' workstations during the user account migration process, and use a tool such as the User State Migration Tool (USMT) to migrate user data and settings to the users' new computers. Table 10.1 summarizes the migration requirements for user profiles.

Table 10.1 Migration Requirements for User Profiles

| Type | Description | Migration Requirements |
|---|---|---|
| Roaming profiles | User profiles are stored centrally on servers. Profiles are available to the user, regardless of the workstation in use. | Select the profile migration option during the user account migration process. Then migrate local user profiles for a batch of users immediately after migrating those users. |
| Local profiles | User profiles are stored locally on the workstation. When a user logs on to another workstation, a unique local user profile is created. | Migrate as a separate step from the user account migration process. Migrate local user profiles for a batch of users immediately after migrating those users. |
| Profiles not managed | Same as local profiles. | No migration requirements. Users lose their existing profiles when their user accounts are migrated. |
| Hardware refresh | User state information is stored locally on the workstation. | Migrate as a separate step from the user account migration. Migrate the profiles to the user's new computer by means of a tool such as USMT. |

# Establishing Administrative Procedures

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You must define how the objects that you are migrating are to be administered during the restructure process. Establishing administrative procedures for migration objects enables you to preserve the objects both in the source and the target domains, and therefore enables you to fall back to the premigration environment in the event that the restructure process is not successful.

Plan for the administration and management of the following types of account migration objects:

- User accounts, including SIDs
- Global group memberships

**Administering User Accounts**

During the migration process, user accounts exist in both the source and the target domains. Continue to administer the accounts in the source domain while the migration is taking place. Use the **replace conflicting accounts** option in ADMT to remigrate user accounts as often as necessary during the migration process. This ensures that changes made to the account in the source domain are propagated to the account in the target domain. This operation merges the existing account and the new account so that administration of the object can continue in the source domain for the duration of the migration process.

**Administering Global Groups**

Continue to administer the groups in the source domain during the migration process. Remigrate groups as often as necessary by using the **replace conflicting accounts** option in ADMT to ensure that changes made to group membership in the source domain are propagated to the group in the target domain.

# Creating an End-User Communication Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Develop a plan to inform all affected users about the upcoming account migration, to ensure that they understand their responsibilities, the impact of the migration, and who to contact for help and support.

Before you begin the user migration process, send a notice to all users who are scheduled to be migrated. Because you typically migrate users in batches of approximately one hundred users at a time, it is also helpful to send a final notice to the users in each batch two to three days before their batch is scheduled. If your organization maintains an intranet, publish the account migration schedule and the information contained in the user mail on an easily accessible Web page.

Include the following information in your end-user communication.

**General information**
Alert users to the fact that their user account is scheduled to be migrated to a new domain, as part of the upgrade to Windows 2000 or Windows Server 2003. Point users to a Web page or internal resource where they can find additional information and view a migration schedule.

Inform users of their new domain name. Be sure to let them know that their account passwords will not change. Let them know that the original domain account will be disabled immediately following the migration, and the disabled account will be deleted after a specified period of time.

**Impact**
Make sure that users understand that when their account is migrated, it is possible that they could be unable to access some resources, such as Web sites, shared folders, or resources that are not widely used by individuals in their group or division.

Provide information to users about whom to contact for assistance in regaining access to required resources.

**Logon status during migration**
Make sure that users understand that during the migration process, they will be unable to log on to the domain or access e-mail or other resources. Be sure to specify the period of time for which they will be unable to log on.

**Premigration steps**
Alert users to any steps that they need to complete before the migration process begins. For example, they must decrypt files encrypted by means of Encrypting File System (EFS). Failure to decrypt encrypted files will result in loss of access to encrypted files following the migration.

Users must also ensure that their computers are connected to the network when their account is scheduled to be migrated.

**Expected changes**
Describe other changes that users can expect to experience following the migration, such as changes in use of smart cards, secure mail, or instant messaging.

**Scheduling and support information**
Provide information about where users can go to find more information; for example, an internal Web site where you post information about the migration. Also, provide information about who to contact if a user has a conflict with the date scheduled for the migration.

# Preparing the Source and Target Domains for Restructuring

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you restructure your Windows NT 4.0 domains, ensure that your target domains are set to a mode or functional level that supports restructuring. In a Windows 2000 environment, the target domains must be operating in Windows 2000 native mode. In a Windows Server 2003 environment, the target domains must be at the Windows 2000 native or Windows Server 2003 Active Directory domain functional level.

Figure 10.6 shows the steps involved in preparing the source and target domains for restructuring.

**Figure 10.6 Preparing the Source and Target Domains for Restructuring**

# Installation of High Encryption Software

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you are migrating passwords, both the domain controller on which ADMT is installed in the target domain and the PES in the source domain require 128-bit high encryption.

**Note**

- Installing high encryption in a Windows NT 4.0 domain does not affect the ability of domain controllers to replicate, and does not affect the user logon process or users' access to resources.

This encryption is standard on domain controllers running Windows Server 2003 or Windows 2000 Service Pack 3 (SP3) or later. If you plan to install ADMT on a domain controller that is running Windows 2000 SP2 or earlier, install the 128-bit high encryption pack from the Windows 2000 High Encryption Pack link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

For the PES in the Windows NT 4.0 source domain, install the 128-bit high encryption pack from the Windows NT 4.0 Service Pack 6a — High Encryption link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Important**

- The high encryption pack exists for North America Windows NT 4.0 Service Packs. If you need high encryption on an international Windows NT 4.0 domain controller, you need to install Microsoft Internet Explorer 4.1 or later and the high encryption pack for this Internet Explorer version.

# Establishing Required Trusts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you can migrate accounts and resources from a Windows NT 4.0 source domain to an Active Directory target domain, you must ensure that the appropriate external trusts are in place. Trust relationships between the domains enable ADMT to migrate objects and translate local user profiles from the source to the target domains. In addition, depending on how they are configured, trust relationships can enable users in the source domains to access resources in the target domains, and can enable users in the target domains to access resources in source domains that have not yet been migrated.

In order to migrate users and global groups, you must establish a one-way trust between the Windows NT 4.0 source account domain and the target domain, so that the source domain trusts the target domain.

To migrate resources or translate local profiles, you must do one of the following:

- Create a one-way trust between the source resource domain and the target domain, so that the source resource domain trusts the target domain. This enables migrated users in the target domain to access resources in source resource domains that have not yet been migrated.

- Create a two-way trust between the source resource domain and the target domain. A two-way trust also enables any users that have been migrated to the target domain to access resources in the source domain.

# Establishing Migration Accounts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To migrate accounts and resources, you must establish a migration account or accounts and assign the appropriate credentials to those accounts. Because ADMT requires only a limited set of credentials, creating separate migration accounts enables you to simplify administration. If the migration tasks for your organization are distributed across more than one group, it is helpful to create a migration account for each group involved in performing the migration.

Table 10.2 lists the credentials that are required in the source and target domains for different migration objects.

**Table 10.2 Migration Account Credentials**

| Migration Object | Credentials Necessary In Source Domain | Credentials Necessary in Target Domain |
|---|---|---|
| User/Group with SID history | Local administrator or domain administrator | Delegated permission on the user OU or the group OU, extended permission to migrate SID history, and local administrator on the computer on which ADMT is installed. |
| Computer | Domain administrator or administrator in the source domain and on each computer | Delegated permission on the computer OU and local administrator on the computer on which ADMT is installed. |
| Profile | Local administrator or domain administrator | Delegated permission on the user OU and local administrator on the computer on which ADMT is installed. |

The procedures provide examples for creating groups or accounts to migrate accounts and resources. Procedures differ according to whether a one-way trust or a two-way trust exists. The procedure for creating migration groups when a one-way trust exists is more complex than the procedure for creating migration accounts when a two-way trust exists, because you must add the migration group to the local Administrators group on local workstations. The procedure for creating migration groups when a one-way trust exists involves the creation of separate groups for migrating accounts and resources; however, you can combine *acct_migrators* and *res_migrators* into one group, if you do not need to separate them to delegate different sets of permissions.

**To create an account migration group when a one-way trust exists in which the source domain trusts the target domain**

1. In the target domain, create a global group, *acct_migrators*.

2. In the target domain, add the *acct_migrators* group to the Domain Admins group, or delegate administration of OUs that are targets for account migration to this group.

3. If you are migrating SID history, and you did not place the *acct_migrators* group in the Domain Admins group, grant the *acct_migrators* group the extended permission **Migrate SID History** on the target domain object. To do this:

    a. Start Active Directory Users and Computers, right-click the domain object, and then click **Properties**.

    b. Click the **Security** tab, click **Add**, and select **acct_migrators**.

    c. In the **Permissions for acct_migrators** box, click **Allow** for the Migrate SID History permission.

4. In the source domain, add the *acct_migrators* group to the Administrators group.

5. On each computer on which you plan to translate local profiles, add the *acct_migrators* group to the local Administrators group.

**To create the resource migration group when a one-way trust exists in which the source domain trusts the target domain**

1. In the target domain, create a global group, *res_migrators*.

2. In the target domain, add the *res_migrators* group to the Domain Admins group, or delegate administration of OUs that are targets for resource migration to this group.

3. In the source domain, add the *res_migrators* group to the Administrators group.

4. On each computer that you plan to migrate or on which you plan to perform security translation, add the *res_migrators* group to the local Administrators group.

**To create a resource migration account when a two-way trust exists between the source and target domains**

1. In the source domain, create a user account, *res_migrator*.

2. In the source domain, add the *res_migratos* account to the Domain Admins group. (The Domain Admins group is a member of the local Administrators group on every computer in the domain by default; therefore, you do not need to add it to the local Administrators group on every computer.)

3. In the target domain, delegate permissions on OUs that are targets for resource migration to the *res_migrators* account.

# Configuring the Source and Target Domains to Migrate SID History

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In order to migrate SID history, you must ensure that the following conditions are met:

- A local group used to audit SID history operations exists in the source domain.
- TCP/IP client support is enabled on the source domain primary domain controller (PDC).
- Audit policies are enabled in the source and target domains.

You can configure these items manually before beginning the migration, or you can allow ADMT to configure them automatically the first time that it runs. If you want to configure them manually, use the following procedures:

**To create a local group in the source domain to support auditing**

- On the source domain PDC, create a local group *source_domain*$$$, where domain is the name of your source domain; for example, in a domain called Boston, create a local group called boston$$$.

**To enable TCP/IP client support on the source domain PDC**

1. On the source domain PDC, navigate to the following registry subkey:

   **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Control\Lsa**

2. Modify the registry entry **TcpipClientSupport**, of data type REG_DWORD, by setting the value to 1.
3. Restart the computer.

**Caution**

- The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Windows Server 2003 Resource Kit Registry Reference on the *Windows Server 2003 Deployment Kit* companion CD or on the Web at http://www.microsoft.com/reskit.

**To enable auditing in the Active Directory target domain**

1. Log on as an administrator to any domain controller in the target domain.
2. Start Active Directory Users and Computers, expand the domain, and then double-click the **Domain Controllers** OU.
3. On the **Group Policy** tab, click **Default Domain Controllers Policy**, and then click **Edit**.
4. Expand **Computer Configuration**, expand **Windows Settings**, expand **Security Settings**, expand **Local Policies**, and then click **Audit Policy**.
5. Double-click **Audit account management**, click **Define these policy settings**, and then click both **Success** and **Failure**.

**To enable auditing in the Windows NT 4.0 source domain**

1. Log on as an administrator to any domain controller in the source domain.

2. Open **User Manager for Domains**, click **Policies**, and then click **Audit**.

3. For **User and Group Management**, verify that **Audit These Events** is selected and that **Success** and **Failure** are both selected.

# Configure the Target Domain OU Structure for Administration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Active Directory design team designs the OU structure for the target domain. They also define the groups that are responsible for the administration of each OU and the memberships of each group. You can use that information and the following procedures to configure the target domain for administration.

**To configure the target domain OU structure for administration**

1. Log on as an administrator to any domain controller in the target domain.
2. Start Active Directory Users and Computers**,** and then create the OU structure specified by your design team.
3. Create administrative groups and assign users to these groups.
4. Delegate the administration of the OU structure to groups as defined by your design team.

# Installing ADMT

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Install and run ADMT on a domain controller in the target domain. The target domain owner is responsible for the migration of all Windows NT 4.0 accounts and resources into the Active Directory domain.

**To install ADMT in the target domain**

1. Log on to a domain controller in the target domain by using your ADMT migration account.

2. Insert the Windows Server 2003 operating system CD in the drive, and then navigate to \i386\admt.

3. Run admigration.msi.

# Enabling Password Migration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

ADMT version 2 supports interforest password migration. If you intend to migrate passwords when you restructure your Windows NT 4.0 domains, you must enable password migration.

When you migrate passwords by using ADMT, you must use a PES to host password migration support DLLs. The PES can be any domain controller in the source domain that supports 128-bit encryption. Use the following procedures to enable support for password migration.

In the target domain, ensure that the built-in group Pre-Windows 2000 Compatible Access contains the Everyone and Anonymous Logon groups. The groups will not be present if you selected **Permissions compatible only with Windows 2000 or Windows Server 2003 operating systems** when you installed Active Directory in the target domain.

If the groups are not present, ADMT logs an Access Denied error. You must then manually add them to enable support for password migration. To do this, type the following at the command line on a target domain controller:

```
        NET LOCALGROUP "Pre-Windows 2000 Compatible Access" Everyone /ADD
NET LOCALGROUP "Pre-Windows 2000 Compatible Access" "Anonymous Logon" /ADD
```

After this update to the Pre-Windows 2000 Compatible Access group replicates, you must restart the Server service on all domain controllers in the target domain.

**To create an encryption key**

1. Log on to the domain controller in the target domain on which you installed ADMT by using your ADMT migration account.
2. Place a blank, formatted diskette in the floppy drive.
3. Open a command window, navigate to the folder in which ADMT is installed, and then, at the command line, type:

   ```
   ADMT KEY
   Source_DomainFloppy_Drive [password] [*]
   ```

   The *Source_Domain* is the NetBIOS name, not the fully qualified domain name (FQDN). A password, which provides key encryption, is optional. To protect the shared key, type either the password or an asterisk on the command line. The asterisk causes you to be prompted for a password that is not displayed on the screen.

| **Note** |
| --- |
| For security reasons, providing a password is strongly recommended. |

**To enable password migration on the source domain**

1. On the PES, insert the encryption key diskette.
2. Insert the Windows Server 2003 operating system CD in the CD drive.
3. Navigate to the \i386\admt\pwdmig folder, and then run pwdmig.exe. If you set a password during the key generation process on the domain controller in the target domain, the **Key Password Required** dialog box appears.
4. Type the password, and then complete the setup process.
5. Navigate to the following registry subkey on the source domain PES:
   **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Control\LSA**
6. Modify the registry entry **AllowPasswordExport**, of data type REG_DWORD, by setting the value to 1.

| **Caution** |
| --- |

The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the "Registry Reference" on the *Windows Server 2003 Deployment Kit* companion CD or on the Microsoft Web site.

# Initializing ADMT

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Initialize ADMT by running a test migration of a global group with the option to migrate SID history selected. If you did not previously configure the source and target domains to migrate SID history, you will receive an error and a prompt for each item that has not yet been configured. When you accept each prompt, ADMT automatically completes the following tasks, which are required in order to enable SID history migration:

- Creates a local group, *source_domain*$$$, in the source domain, which is used to audit SID history operations. Do not add members to this group; if you do, SID history migration will fail.

- Enables TCP/IP client support on the source domain PDC by setting to 1 the value of the registry entry **TcpipClientSupport**, which is locatedin the following subkey:

  HKEY_LOCAL_MACHINE\System\CurrentControlSet\Control\Lsa

  Setting **TcpipClientSupport** to 1 enables remote procedure calls (RPCs) over the TCP transport while preserving the security of the system.

- Enables audit policies in the source and target domains.

For more information about configuring the source and target domains to migrate SID history, see "Configuring the Source and Target Domains to Migrate SID History" earlier in this chapter.

**To initialize ADMT by running a test migration of a global group**

1. In the Active Directory Migration Tool console, on the **Action** menu, click **Group Account Migration Wizard**.

2. Complete the Group Account Migration Wizard by using the information provided in Table 10.3. Accept default settings when no information is specified.

**Table 10.3 Migrating Global Groups by Using the Group Account Migration Wizard**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Select **Test the migration settings and migrate later?** |
| Domain Selection | In the **Sourcedomain** box, type the source domain name.<br><br>In the **Target domain** box, type the target domain name. |
| Group Selection | Click **Add.**<br><br>In the **Select Groups** dialog box, select a group. |
| Organizational Unit Selection | Click **Browse**.<br><br>In the **Browse for Container** dialog box, navigate to the **Groups** OU. |
| Group Options | Select the **Migrate Group SIDs to target domain** check box.<br><br>Click **Do not rename accounts**. |
| User Account | Type the name and password of the migration account that you created for migrating accounts.<br><br>In the **Domain** box, type the NetBIOS name of the target domain. |

| | |
|---|---|
| Naming Conflicts | Click **Ignore conflicting accounts and don't migrate**. |

3. When the wizard has finished running, click **View Log**, and then review the migration log for any errors.

4. Verify that the test migration configured ADMT properly by ensuring that:

   - A new local group *source_domain$$$* exists in the source domain. This account supports ADMT auditing of SIDhistory migration.

   - The registry entry **TcpipClientSupport** is created, and its value set to 1, in the following subkey on the source domain PDC:

     HKEY_LOCAL_MACHINE\System\CurrentControlSet\Control\Lsa

   - The audit policy for account management is enabled on the source and target domains.

# Service Account Identification

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Identify the member servers and domain controllers that run applications as services by using a service account. A service account is a user account created explicitly to provide a security context for these applications. The service account is a standard user account that is assigned the **Log on as a service** user right.

**Note**

- This step does not migrate the accounts but only identifies them for later migration. To identify service accounts, ADMT dispatches an agent to the server in the source domain that records the services that are running on that server.

ADMT includes these accounts in the list of service accounts identified as not running under Local System account. These accounts must be updated on the computer after the migration of the accounts.

When service accounts are migrated later by means of the User Account Migration Wizard, ADMT makes the proper changes on the member server. If the service account is assigned rights by means of a group membership, you must also run the Security Translation Wizard to update the user rights and group memberships of the service account. For more information about migrating service accounts, see "Transitioning Service Accounts" later in this chapter.

You can identify service accounts by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To identify service accounts by using the ADMT console**

1. On the domain controller on which ADMT is installed, log on by using the ADMT account migration account.
2. Open the Active Directory Migration Tool console, and then select **Service Account Migration Wizard**.
3. Complete the Service Account Migration Wizard by using the information in Table 10.4.

   **Table 10.4 Using the Service Account Migration Wizard**

| Wizard Page | Action |
|---|---|
| Domain Selection | In the **Source domain** box, type or select the NetBIOS name of the source domain.<br>In the **Target domain** box, type or select the NetBIOS or DNS name of the target domain. |
| Update Information | Select **Yes, update the information**. |
| Service Account Selection | Click **Add**.<br>In the **Select Computers** list box, select the names of all servers that have service accounts.<br>Click **OK**, and then click **Next**. |
| Service Account Information | Select any user accounts that do not need to be marked as service accounts in the ADMT database, and click **Skip/Include** to mark them as **Skip**. |

4. When the wizard has finished running on all computers, on the Server List page, click **View Log**. The log contains information about why the wizard did not succeed on any computers. For example, invalid permissions cause the wizard to not succeed.

**To identify service accounts by using the ADMT console**

1. On the domain controller on which ADMT is installed, log on by using the ADMT account migration account.
2. Open the Active Directory Migration Tool console, and then select **Service Account Migration Wizard**.
3. Complete the Service Account Migration Wizard by using the information in Table 10.4.

**Table 10.4 Using the Service Account Migration Wizard**

| Wizard Page | Action |
|---|---|
| Domain Selection | In the **Source domain** box, type or select the NetBIOS name of the source domain.<br>In the **Target domain** box, type or select the NetBIOS or DNS name of the target domain. |
| Update Information | Select **Yes, update the information**. |
| Service Account Selection | Click **Add**.<br>In the **Select Computers** list box, select the names of all servers that have service accounts.<br>Click **OK**, and then click **Next**. |
| Service Account Information | Select any user accounts that do not need to be marked as service accounts in the ADMT database, and click **Skip/Include** to mark them as **Skip**. |

4. When the wizard has finished running on all computers, on the Server List page, click **View Log**. The log contains information about why the wizard did not succeed on any computers. For example, invalid permissions cause the wizard to not succeed.

**To identify service accounts by using the ADMT command-line option**

1. On a domain controller in the target domain on which ADMT installed, log on by using the ADMT account migration account.
2. At the command line, type:

```
ADMT SERVICE /N "
computer_name1
" "
computer_name2
" [
parameters
]
```

*Computer_name1* and*computer_name2* are the names of computers in the source domain that run service accounts. You can append parameters to the command as follows:

```
ADMT SERVICE /N "
computer_name1
" "
computer_name2
" /SD:"
source_domain
" /TD:"
target_domain
"
```

Alternatively, you can include parameters in an options file that is specified on the command line as follows:

```
ADMT SERVICE /N "
computer_name1
" "
```

```
computer_name2
" /O:"
option_file.txt
"
```

Table 10.5 lists the parameters required for the identification of service accounts, along with the command-line parameter and option file equivalents.

**Table 10.5 Parameters Required for Service Account Identification**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:"`*source_domain*`"` | `SourceDomain="`*source_domain*`"` |
| Target domain | `/TD:"`*target_domain*`"` | `TargetDomain="`*target_domain*`"` |

3. Review the results that are displayed on the screen for any errors.

**To identify service accounts by using a script**

- Prepare a script that incorporates ADMT commands and options for identifying service accounts by using the sample script shown in Listing 10.3.

**Listing 10.3 Identifying Service Accounts**

```
<Job id=" IdentifyingServiceAccounts" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit
   Dim objMigration
   Dim objServiceAccountEnumeration
   '
   'Create instance of ADMT migration objects.
   '
   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objServiceAccountEnumeration = _
        objMigration.CreateServiceAccountEnumeration
   '
   'Specify general migration options.
   '
   objMigration.SourceDomain = " source domain"
   '
   'Enumerate service accounts on specified computers.
   '
   objServiceAccountEnumeration.Enumerate admtData, _
  Array(" computer name1" ," computer name2" )
   Set objServiceAccountEnumeration = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a script file to assist you in creating a script to identify service accounts, see "Identifying Service Accounts" (DSSRENT_5.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Identifying Service Accounts" on the Web at http://www.microsoft.com/reskit).

# Restructuring Account Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Restructuring Windows NT 4.0 account domains involves migrating the user, group, and service accounts that exist in the Windows NT 4.0 domain into an Active Directory domain. If account domains include resources, you must also migrate those resources. The Active Directory target domain owner is responsible for the migration of all Windows NT 4.0 accounts. The migration process must be completed for every Windows NT 4.0 source account domain.

Figure 10.7 shows the process for restructuring Windows NT 4.0 account domains.

**Figure 10.7 Restructuring Account Domains**

# Transitioning Service Accounts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Begin the process of migrating objects by transitioning the service accounts that you selected when you identified service accounts. For more information about identifying service accounts, see "Service Account Identification" earlier in this chapter.

To transition service accounts, use ADMT to complete the following tasks:

- Migrate the service accounts from the Windows NT 4.0 source account domain to the target domain.
- Modify the services on each server in the source domain to use the service account in the target domain in place of the service account in the Windows NT 4.0 source account domain.

**Note**

- This process only updates the **Log on as a service** right. If a service account has local rights based on its membership in a local group, then you must update these rights by running the Security Translation Wizard.

You can transition service accounts by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To transition service accounts by using the ADMT console**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.
2. Open the Active Directory Migration Tool console, and select **User Account Migration Wizard**.
3. Complete the User Account Migration Wizard by using the information provided in Table 10.6.

**Table 10.6 Using the User Account Migration to Transition Service Accounts**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type or select the name of the source domain.<br>In the **Target domain** box, type or select the name of the target domain. |
| User Selection | Click **Add.**<br>In the **Select Users** dialog box, select all of the service accounts that were identified by the Service Account Migration Wizard, and then click **Add**.<br>Click **OK**. |
| Organizational Unit Selection | Click **Browse**.<br>In the **Browse for Container** dialog box, navigate to the target domain and select the container for the service accounts, and then click **OK**. |
| Password Options | Click **Complex passwords**. |
| Account Transition Options | Click **Enable target accounts**.<br>Select the **Migrate user SIDs to target domains** check box. |

| | |
|---|---|
| User Account | Type the user name, password, and domain of a user account that has administrative credentials. |
| User Options | Select the **Update user rights** check box.<br>Make sure that **Do Not Rename Accounts** is selected.<br>Ensure that no other settings are selected, including the **Migrate associated user groups** option. |
| Naming Conflicts | Select **Ignore conflicting accounts**. |
| Service Account Information | Select **Migrate all service accounts and update SCM for items marked include**. If you are also migrating other user accounts that are not service accounts, this wizard page tells you that you have selected some accounts that are marked as service accounts in the ADMT database. By default, the accounts are marked as Include. To change the status of the account, select the account, and then click the **Skip/Include** button.<br>Click **Next** to migrate the accounts. |

4. When the wizard has finished running, click **View Log**, and then review the migration log for any errors.
5. Start Active Directory Users and Computers, navigate to the OU that you created for service accounts, and then verify that the service accounts exist in the target domain OU.
6. Confirm that each application for which the service account was relocated continues to function correctly.

**To transition service accounts by using the ADMT command-line option**

1. On a domain controller in the target domain on which ADMT installed, log on by using the ADMT account migration account.
2. At the command line, type:

```
ADMT USER /N "
user_name1
" "
user _name2
" [
parameters
]
```

You can append parameters to the command as follows:

```
ADMT USER /N "
user _name1
" "
user _name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
" /MSS:
YES
/UUR:YES
```

Alternatively, you can include parameters in an option file that is specified on the command line as follows:

```
ADMT USER /N "
user_name1
" "
user_name2
" /O:"
option_file.txt
"
```

Table 10.7 lists the parameters required for transitioning service accounts, along with the command-line parameter and option file equivalents.

**Table 10.7 Parameters Required for Transitioning Service Accounts**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:"`*source_domain*`"` | `SourceDomain="`*source_domain*`"` |
| Target domain | `/TD:"`*target_domain*`"` | `TargetDomain="`*target_domain*`"` |
| Target OU location | `/TO:"`*target_OU*`"` | `TargetOU="`*target_OU*`"` |
| Disable accounts | /DOT:ENABLETARGET (default) | DisableOption=ENABLETARGET (default) |
| Migrate password | /PO:COMPLEX (default) | PasswordOption= COMPLEX |
| Migrate user SIDs = YES | /MSS:YES | MigrateSIDs=YES |
| Update user rights=YES | /UUR:YES | UpdateUserRights=YES |
| Do not rename accounts | /RO:DONT (default) | RenameOption=DONT (default) |
| Ignore conflicting accounts | /CO:IGNORE (default) | ConflictOptions=IGNORE (default) |

3. Review the results that are displayed on the screen for any errors.
4. Start Active Directory Users and Computers and navigate to the target service account OU. Verify that the service accounts exist in the target domain OU.
5. Confirm that each application for which the service account was relocated continues to function correctly.

**To transition service accounts by using a script**

- Prepare a script that incorporates ADMT commands and options for transitioning service accounts by using the sample script shown in Listing 10.4.

**Listing 10.4 Transitioning Service Accounts**

```
<Job id=" TransitioningServiceAccountsNTSource" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit
   Dim objMigration
   Dim objUserMigration
   '
```

```
   'Create instance of ADMT migration objects.
   '
   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objUserMigration = objMigration.CreateUserMigration
   '
   'Specify general migration options.
   '
   objMigration.SourceDomain = " source domain"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " target container"
   objMigration.ConflictOptions = admtIgnoreConflicting
   '
   'Specify user migration specific options.
   '
   objUserMigration.DisableOption = admtEnableTarget
   objUserMigration.MigrateSIDs = True
   objUserMigration.UpdateUserRights = True
   objUserMigration.MigrateServiceAccounts = True

   '
   'Migrate specified service accounts.
   '
   objUserMigration.Migrate admtData, _
  Array(" service account name1" ," service account name2" )
   Set objUserMigration = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a script file to assist you in creating a script to transition service accounts, see "Transitioning Service Accounts — Windows NT 4.0 Source" (DSSRENT_6.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Transitioning Service Accounts —Windows NT 4.0 Source" on the Web at http://www.microsoft.com/reskit).

# Migrating Global Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In order to preserve the global group user memberships, you must migrate global groups before you migrate users.

Global group migration involves the following steps:

1. The administrator selects the global group objects in the source domain. ADMT reads the objects in the source domain.
2. A new global group object is created in the target domain. A new primary SID is created for the object in the target domain.
3. To preserve resource access if you are migrating SID history, ADMT adds the SID of the global group in the source domain to the SID history attribute of the new global group in the target domain.

Following the migration, audit events are logged in both the source and the target domain.

**Note**

- If the user account migration process takes place over an extended period of time, then you might need to remigrate global groups from the source to the target domain to propagate membership changes that are made in the source domain before the migration process is complete. For more information about remigrating global groups, see "Remigrating Global Groups" later in this chapter.

You can migrate global groups by using the Active Directory Migration Tool console, by using the ADMT command-line option, or by using a script. For a worksheet to assist you in completing your initial global group migration, see "User and Group Object Assignment Table — Windows NT 4.0 Source" (DSSRENT_1.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "User and Group Object Assignment Table — Windows NT 4.0 Source" on the Web at http://www.microsoft.com/reskit).

**To migrate global groups from a Windows NT 4.0 source domain by using the ADMT console**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.
2. Open the Active Directory Migration Tool console, and then select **Group Account Migration Wizard**.
3. Complete the Group Account Migration Wizard by using the information provided in Table 10.8.

**Table 10.8 Using the Group Account Migration Wizard to Migrate Groups**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Select **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type the NetBIOS name of the source domain or select the name from a list.<br>In the **Target domain** box, type the NetBIOS or DNS name of the target domain.<br>If ADMT includes the names of the source and target domains, ensure that they are correct. |
| Group Selection | Click **Add.**<br>In the **Select Groups** dialog box, select all global groups that you want to migrate (except built-in groups), click **Add**, and then click **OK**. |

| | |
|---|---|
| Organizational Unit Selection | Type in the name of the OU or click **Browse**.<br>In the **Browse for Container** dialog box, find the container in the target domain you want to move the global groups into, and then click **OK**. |
| Group Options | Select **Migrate Group SIDs to target domain**.<br>Select **Do not rename accounts**.<br>Make sure that all other options are not selected. |
| User Account | Enter **User name**, **Password**, and **Domain** of an account that has administrative rights in the source domain. |
| Naming Conflicts | Select **Ignore conflicting accounts and don't migrate**. |

4. When the wizard has finished running, click **View Log**, and then review the migration log for any errors.
5. Start Active Directory Users and Computers, and then navigate to the target OU. Verify that the global groups exist in the target domain OU.

**To migrate global groups from a Windows NT 4.0 source domain by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT is installed, log on using the ADMT account migration account.
2. At the command line, type:

```
ADMT GROUP /N "
group_name1
" "
group_name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
" /MSS:YES
```

Alternatively, you can include parameters in an option file that is specified on the command line as follows:

```
ADMT GROUP /N "
group_name1
" "
group_name2
" /O: "
option_file.txt
"
```

Table 10.9 lists the parameters required for migrating global groups, along with the command-line parameter and option file equivalents.

**Table 10.9 Parameters Required for Global Group Migrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|

| | | |
|---|---|---|
| Source domain | /SD:"*source_domain*" | SourceDomain="*source_domain*" |
| Target domain | /TD:"*target_domain*" | TargetDomain="*target_domain*" |
| Target OU location | /TO:"*target_OU*" | TargetOU="*target_OU*" |
| Migrate GG SIDs | /MSS:YES | MigrateSIDs=YES |
| Do not rename accts | /RO:DONT (default) | RenameOption=DONT |
| Ignore conflicting accts and do not migrate them | /CO:IGNORE (default) | ConflictOptions=IGNORE |

3. Review the results that are displayed on the screen for any errors.
4. Start Active Directory Users and Computers, and then navigate to the target OU. Verify that the global groups exist in the target domain OU.

**To migrate global groups by using a script**

- Prepare a script that incorporates ADMT commands and options for migrating global groups by using the sample script shown in Listing 10.5.

**Listing 10.5 Migrating Global Groups**

```
<Job id=" MigratingGlobalGroupsNTSource" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objGroupMigration

   '
   'Create instance of ADMT migration objects.
   '
   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objGroupMigration = objMigration.CreateGroupMigration

   '
   'Specify general migration options.
   '
   objMigration.SourceDomain = " source domain"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " target container"

   '
   'Specify group migration specific options.
   '
   objGroupMigration.MigrateSIDs = True

   '
   'Migrate specified group objects.
   '
   objGroupMigration.Migrate admtData, Array(" group name1" ," group name2" )

   Set objGroupMigration = Nothing
```

```
   Set objMigration = Nothing
</Script>
</Job>
```

For a script file to assist you in creating a script to migrate global groups, see "Migrating Global Groups — Windows NT 4.0 Source" (DSSRENT_7.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating Global Groups —Windows NT 4.0 Source" on the Web at http://www.microsoft.com/reskit).

# Migrating Users in Batches

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To begin migrating users, first migrate a small number of users as a pilot and test whether they are able to access resources after the migration. Then migrate the remaining users in the source account domain in small batches of up to 100 users per batch. This helps to keep the migration process manageable.

Complete the following steps to migrate user accounts to the target domain:

1. Create test accounts that you can use to verify the success of each batch.
2. Migrate a single batch of users.
3. Translate any local user profiles for user accounts that are included in the batch.
4. Migrate workstations for users that are included in the batch.
5. Remigrate all global groups to update any group membership changes.
6. Notify users in the batch to log on to the target domain.
7. Repeat the steps for the next batch of users, until you have migrated all user accounts.

Until you migrate all user and group accounts, continue to administer global group membership in the Windows NT 4.0 source account domain. To support a rollback strategy, manually synchronize any changes you make to users in the target domain with the existing user accounts in the Windows NT 4.0 source account domain.

Figure 10.8 shows the steps you must complete for each batch of user accounts.

**Figure 10.8 Migrating Users in Batches**

# Migrating User Accounts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The ADMT user account migration process includes the following steps:

1. The administrator selects the source user objects to be migrated.
2. ADMT reads attributes from the source user objects.
3. ADMT creates a new user object in the target domain and a new primary SID for the new user account.
4. If you are migrating SID history, ADMT adds the original SID of the user account to the SID history attribute of the new user account.
5. ADMT migrates the password for the user account.

You cannot migrate every user property when you migrate user accounts. For example, Protected Storage (Pstore) contents for Windows NT 4.0 workstations, including Encrypting File System (EFS) private keys, are not migrated by ADMT when you migrate user accounts. To migrate Pstore contents, you must export and import keys during the migration process.

For clients that are running Windows 2000 or later operating systems, data that is protected by the Data Protection API (DPAPI) is also not migrated. DPAPI helps protect the following items:

- Web page credentials (for example, passwords)
- File share credentials
- Private keys associated with EFS, S/MIME, and other certificates
- Program data that is protected by using the CryptProtectData() function

For this reason, it is important to test user migrations by using your test migration account to identify any properties that did not migrate and update user configurations in the target domain accordingly.

Following the migration, audit events are logged in both the source and the target domains if you are migrating SID history.

Using ADMT to migrate user accounts preserves group memberships. Because global groups can contain only members from the domain in which the group is located, when users are migrated to a new domain, the user accounts in the target domain cannot be members of the global groups in the source domain.

As part of the migration process, ADMT identifies the global groups in the source domain that the user account belongs to, and then determines whether the global groups have been migrated. If ADMT identifies global groups in the target domain that the users belonged to in the source domain, the tool adds the users to the appropriate groups in the target domain.

Using ADMT to migrate user accounts also preserves user passwords. After the user accounts are migrated to and enabled in the target domain, the users can log on to the target domain by using their original passwords. If the user account migration is successful but the password migration process fails, then ADMT creates a new complex password for the user account in the target domain. By default, ADMT stores new complex passwords that are created in the default drive, in Program Files\Active Directory Migration Tool\Logs\Password.txt file.

If you have a Group Policy setting on the target domain that does not allow blank passwords (the **Default Domain Policy/Computer Configuration/Security Settings/Account Policies/Password Policy/Minimum password length** setting is set to any number other than zero), then password migration will fail for any user who has a blank password. ADMT generates a complex password for that user, and writes an error to the error log.

Establish a method for notifying users who have been assigned new passwords. For example, you can create a script to send an e-mail message to users to notify them of their new passwords.

**Important**

- Because only a hash of a user password exists in the source domain, the password filter cannot verify whether the password meets complexity or length requirements. The target domain controller used to set the password can verify the password history because it compares the hash of the password against previous hashes.

You can migrate user accounts by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To migrate the current batch of users by using the ADMT console**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.

2. Open the Active Directory Migration Tool, and then select **User Account Migration Wizard**.

3. Complete the User Account Migration Wizard by using the information provided in Table 10.10.

   **Table 10.10 Using the User Account Migration Wizard to Migrate User Accounts**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type or select the NetBIOS name of the source domain.<br><br>In the **Target domain** box, type or select the NetBIOS or DNS name of the target domain. |
| User Selection | Click **Add.**<br><br>In the **Select Users** dialog box, select the user accounts you want to migrate, and click **Add**.<br><br>Click **OK**. |
| Organizational Unit Selection | ADMT lists an OU here. Ensure that this is the correct target OU. If it is not correct, type in the correct OU or click **Browse**.<br><br>In the **Browse for Container** dialog box, navigate to the target domain and OU, and then click **OK**. |
| Password Options | Select **Migrate Passwords**. |
| Account Transition Options | Select **Enable target accounts**.<br><br>Select **Days Until Source Account Expires** and enter a number of days. A value of 7 is commonly used.<br><br>Select the **Migrate user SIDs to target domains** check box. |
| User Account | Type in the **User name**, **Password**, and **Domain** of a user account that has administrative credentials. |
| User Options | Select the **Translate roaming profiles** check box.<br><br>Select the **Update user rights** check box.<br><br>Clear the **Migrate associated user groups** check box.<br><br>Select the **Fix users' group memberships**.<br><br>Select the **Do not rename accounts** check box. |
| Naming Conflicts | Click **Ignore conflicting accounts and don't migrate**. |

4. When the wizard has finished running, click **View Log** and review the migration log for any errors.

5. Start Active Directory Users and Computers, and then verify that the user accounts exist in the appropriate OU in the

target domain.

**To migrate the current batch of users by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT installed, log on by using the ADMT account migration account.

2. To migrate a set of specified users "*user_name1*" "*user_name2*," at the command line, type:

   ```
   ADMT USER /N "user_name1" "user_name2" [parameters]
   ```

   You can append parameters to the command as follows:

   ```
   ADMT USER /N "user_name1" "user_name2" /SD:"source_domain" /TD:"target_domain"
   /TO:"target_OU" /MSS:YES TRP:YES /UUR:YES
   ```

   Alternatively, you can include parameters in an option file that is specified on the command line as follows:

   ```
   ADMT USER /N "user_name1" "user_name2" /O "option_file.txt"
   ```

   Table 10.11 lists the parameters required for migrating user accounts, along with the command-line parameter and option file equivalents.

   **Table 10.11 Parameters Required for User Migrations**

| Options | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:`"*source_domain*" | `SourceDomain=`"*source_ domain*" |
| Target domain | `/TD:`"*target_domain*" | `TargetDomain=`"*target_ domain*" |
| Target OU location | `/TO:`"*target_OU*" | `TargetOU=`"*target_OU*" |
| Migrate SIDs | `/MSS:YES` | `MigrateSIDs=YES` |
| Password options | `/PO:COPY`<br>`/PS:`"*server name*" | `PasswordOption=COPY`<br>`PasswordServer=`"*server name*" |
| Do not rename accts | `/RO:DONT` (default) | `RenameOption=DONT` |
| Ignore conflicting accts and do not migrate them | `/CO:IGNORE` (default) | `ConflictOptions=IGNORE` |
| Translate Roaming Profile | `/TRP:YES (default)` | `TranslateRoamingProfile=YES` |
| Update User Rights | `/UUR:YES(/UUR:NO is the default)` | `UpdateUserRights=NO` |

3. Review the results that are displayed on the screen for any errors.

4. Start Active Directory Users and Computers, and then navigate to the target OU. Verify that the users exist in the target domain OU.

**To migrate users by using a script**

- Prepare a script that incorporates ADMT commands and options for migrating users by using the sample script shown in Listing 10.6.

  **Listing 10.6 Migrating User Accounts**

```
<Job id=" MigratingUserAccountsNTSource" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objUserMigration

   '
   'Create instance of ADMT migration objects.
   '
   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objUserMigration = objMigration.CreateUserMigration

   '
   'Specify general migration options.
   '
   objMigration.SourceDomain = " source domain"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " target container"
   objMigration.PasswordOption = admtCopyPassword
   objMigration.PasswordServer = " password export server name"
   objMigration.ConflictOptions = admtIgnoreConflicting

   '
   'Specify user migration specific options.
   '
   objUserMigration.MigrateSIDs = True
   objUserMigration.TranslateRoamingProfile = True
   objUserMigration.UpdateUserRights = True
   objUserMigration.FixGroupMembership = True
   objUserMigration.MigrateServiceAccounts = False

   '
   'Migrate specified user objects.
   '

   objUserMigration.Migrate admtData, Array(" user name1" ," user name2" )

   Set objUserMigration = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a sample script file to assist you in creating a script to migrate user accounts, see "Migrating User Accounts — Windows NT 4.0 Source" (DSSRENT_8.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating User Accounts — Windows NT 4.0 Source" on the Web at http://www.microsoft.com/reskit).

# Translating Local User Profiles

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Local profiles contain the desktop state and user data for users in the source account domain. ADMT can migrate local profiles only for workstations running Windows NT 4.0, Windows 2000, and Microsoft® Windows® XP. Migrate local user profiles for a batch of users immediately after migrating the batch of users, and before the users log on to the target domain.

It is important to verify that user profile translation succeeded for each user before that user is allowed to log on. If the user profile translation fails for a user, that user must not log on to the target domain. Roll the user back manually, by disabling the user account in the target domain, and enabling the account in the source domain.

You can migrate roaming user profiles during the user account migration process. However, you still need to translate the local copy of the profile.

**Note**

- Migrate the local user profiles the night before you notify the users to log on by using their new accounts in the target domain. Migrating profiles the night before ensures that the new user profile reflects the most current user settings.

Before you migrate local user profiles, create a list of the workstations in the source domain. You can migrate local user profiles by running the ADMT console, by using the ADMT command-line option, or by using a script.

**To migrate local user profiles by using the ADMT console**

1. For each workstation in the source domain that is running Windows NT 4.0, verify that the ADMT account migration account was added as a member of the local Administrators group.
2. On the domain controller in the target domain on which you installed ADMT, log on by using the ADMT resource migration account.
3. Open the Active Directory Migration Tool, and then run the Security Translation Wizard.
4. Complete the Security Translation Wizard by using the information in Table 10.12.

**Table 10.12 Using the Security Translation Wizard to Migrate Local User Profiles**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Select **Migrate Now?** |
| Security Translation Options | Select **Previously migrated objects**. |
| Domain Selection | In the **Source domain** box, type or select the name of the domain that contains the user accounts.<br>In the **Target domain** box, type or select the name of the target domain. |
| Computer Selection | Click **Add** and add computers from the domain that contains the computer accounts. (Depending on your existing domain structure, this might be a resource domain.) |
| Translate Objects | Select **User Profiles**. |
| Security Translation Options | Select **Replace**. |

After migrating local user profiles, you must verify that the migration process was successful. Complete the following steps to

verify that the user profile migration was successful:

1. Review the status message for each computer for which you migrated the user profile.

2. For computers for which the status is not **Success**, review the message to identify the cause of the failure. For more details about the cause of the failure, click **View Dispatch Log**.

3. For each computer for which the agent completed successfully, select the computer name from the list, and click **Agent Detail**.

4. Click **View Log** and review the log for any errors that occurred during the local profile migration process.

5. For computers to which an agent failed to be dispatched, fix the cause of the problem, and then run the Retry Wizard to dispatch agents to those computers.

6. For any computers for which the agent failed to migrate the local profile, fix the cause of the problem, and then perform the local profile migration again on those computers.

You can use the following procedure to migrate local user profiles by using the ADMT command-line option

**To migrate local user profiles by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.
2. At the command line, type:

```
ADMT SECURITY /N "
computer_name1
" "
computer_name2
" [
parameters
]
```

You can append parameters to the command as follows:

```
ADMT SECURITY /N "
computer_name1
" "
computer_name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TOT:ADD /TUP:YES
```

Alternatively, you can include parameters in an option file that is specified on the command line as follows:

```
ADMT USER /N "
user_name1
" "
user_name2
" /O:"
option_file.txt
"
```

Table 10.13 lists the parameters required for migrating user accounts, along with the command-line parameter and option file equivalents.

**Table 10.13 Parameters Required for Local User Profile Migrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:"`*source_domain*`"` | `SourceDomain="`*source_ domain*`"` |
| Target domain | `/TD:"`*target_domain*`"` | `TargetDomain="`*target_ domain*`"` |
| Translate option | /TOT:REPLACE | TranslateOption=REPLACE |
| Modify local user profile security | /TUP:YES | TranslateUserProfiles=YES |

1. Review the results that are displayed on the screen for any errors.

2. Review the dispatch log to determine whether agents were successfully dispatched to every computer.

3. Review the migration log for errors related to local profiles on workstations.

4. For computers to which the agent failed to be dispatched, fix the cause of the problem, and then run the Retry Wizard to dispatch agents to those computers.

5. For any computers for which the agent failed to migrate the local profile, fix the cause of the problem, and then perform the local profile migration again on those computers.

Note that it is important to verify the success of the local profile migration before users attempt to log on to the target domain.

If a user logs on to the target domain by using their new target account and their local profile did not migrate successfully, then you must do the following:

1. On the computer of the user, delete the following registry subkey, where *SID* is the SID of the user account in the target domain:

   HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\ProfileList*SID*

2. Remigrate the local user profile for that computer.

**Caution**

- The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the "Registry Reference" on the *Windows Server 2003 Deployment Kit* companion CD or on the Microsoft Web site.

**To migrate local user profiles by using a script**

- Prepare a script that incorporates ADMT commands and options for migrating local profiles by using the sample script shown in Listing 10.7. To verify that the local user profile migration was successful, use the verification process listed in steps 3 through 7 of the command-line procedure.

**Listing 10.7 Migrating Local Profiles**

```
<Job id=" MigratingLocalProfilesNTSource" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
```

```
   Dim objSecurityTranslation

   '
   'Create instance of ADMT migration objects.
   '
   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objSecurityTranslation = objMigration.CreateSecurityTranslation

   '
   'Specify general migration options.
   '
   objMigration.SourceDomain = " source domain"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " Computers"

   '
   'Specify security translation specific options.
   '
   objSecurityTranslation.TranslationOption = admtTranslateReplace
   objSecurityTranslation.TranslateUserProfiles = True

   '
   'Perform security translation on specified computer objects.
   '
   objSecurityTranslation.Translate admtData, _
  Array(" computer name1" ," computer name2" )

   Set objSecurityTranslation = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a sample script to assist you in migrating local profiles, see "Migrating Local Profiles — Windows NT 4.0 Source" (DSSRENT_9.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating Local Profiles — Windows NT 4.0 Source" on the Web at http://www.microsoft.com/reskit).

# Migrating User Workstations

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For each batch of user accounts that you migrate, migrate a batch containing those users' workstations, so the user account and the workstation exist in the target domain when the user logs on. When you move workstations between domains, the Security Accounts Manager (SAM) database moves along with them. Accounts located in the local SAM database (such as local groups) that are used to enable access to resources always move with the computer, and therefore do not need to be migrated.

**Note**

- Restart workstations immediately after joining them to the target domain, by selecting a low number (such as 1) for the **RestartDelay** parameter. Resources that are not restarted following migration are in an indeterminate state.

You can migrate workstations by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To migrate workstations by using the ADMT console**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT resource migration account.
2. Open the Active Directory Migration Tool and select **Computer Account Migration Wizard**.
3. Complete the Computer Account Migration Wizard by using the information provided in Table 10.14.

   **Table 10.14 Using the Computer Account Migration Wizard to Migrate Workstations**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Select **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type or select the NetBIOS name of the source domain.<br>In the **Target domain** box, type or select the NetBIOS or DNS name of the target domain. |
| Computer Selection | Click **Add.**<br>In the **Select Computers** dialog box, select the names of all the workstations in the source domain that are being migrated in this batch, click **Add**, and then click **OK**. |
| Organizational Unit Selection | Click **Browse**.<br>In the **Browse for Container** dialog box, find the container in the target domain to which the computers are migrating, and then click **OK**. |
| Translate Objects | Ensure that no boxes are selected. |
| Computer Options | In the **Minutes before computer restart after wizard completion** box, type **1**.<br>Select **Do not rename computers**. |
| Naming Conflicts | Select **Ignore conflicting accounts and don't migrate.** |

4. When the wizard has finished running on all computers, click **View Log** and review the migration log for any errors. If errors are reported, run the Retry Wizard to dispatch agents to workstations for which the migration process failed.
5. Start Active Directory Users and Computers, then and verify that the workstations exist in the appropriate OU in the target domain.

**To migrate workstations by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT installed, log on by using the ADMT resource migration account.
2. At the command line, type:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" [
parameters
]
```

You can append parameters to the command as follows:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
" /RDL:1
```

Alternatively, you can include parameters in an option file that is specified on the command line as follows:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" /O "
option_file.txt
"
```

Table 10.15 lists the parameters required for migrating workstations, along with the command-line parameter and option file equivalents.

**Table 10.15 Parameters Required for Workstation Migrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:`"*source_domain*" | `SourceDomain=`"*source_ domain*" |
| Target domain | `/TD:`"*target_domain*" | `TargetDomain=`"*target_ domain*" |
| Target OU location | `/TO:`"*target_OU*" | `TargetOU=`"*target_OU*" |
| • Restart computer one minute after wizard completes | /RDL:1 | RestartDelay=1 |

| | | |
|---|---|---|
| • Do not rename accounts | /RO:DONT (default) | RenameOption=DONT |
| • Ignore conflicting accounts and do not migrate them | /CO:IGNORE (default) | ConflictOptions=IGNORE |

3. Review the results that are displayed on the screen for any errors.
4. Start Active Directory Users and Computers, and then navigate to the target OU. Verify that the workstations exist in the target OU.

**To migrate workstations by using a script**

- Prepare a script that incorporates ADMT commands and options for migrating workstations by using the sample script shown in Listing 10.8.

**Listing 10.8 Migrating Workstations or Member Servers**

```
<Job id=" MigratingWorkstationsMemberServersNTSource" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objComputerMigration

   '
   'Create instance of ADMT migration objects.
   '
   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objComputerMigration = objMigration.CreateComputerMigration

   '
   'Specify general migration options.
   '
   objMigration.SourceDomain = " source domain"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " Computers"

   '
   'Specify computer migration specific options.
   '
   objComputerMigration.RestartDelay = 1

   '
   'Migrate computer objects on specified computer objects.
   '
   objComputerMigration.Migrate admtData, _
  Array(" computer name1" ," computer name2" )

   Set objComputerMigration = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a sample script file to assist you in migrating workstations, see "Migrating Workstations or Member Servers — Windows NT 4.0 Source" (DSSRENT_10.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating Workstations or Member Servers — Windows NT 4.0 Source" on the Web at http://www.microsoft.com/reskit).

# Remigrating Global Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A large user account migration might take place over an extended period of time. For this reason, you might need to remigrate global groups from the source to the target domain to reflect changes made to the groups in the source domain after the initial global group migration occurred. This procedure updates global group membership without overwriting previously migrated user accounts.

| **Note** |
| --- |
| Do not migrate global groups during peak work hours. The global group migration process consumes a large amount of network resources and resources on the domain controller that is running ADMT. |

You can migrate global groups by using the Active Directory Migration Tool console, by using the ADMT command-line option, or by using a script.

**To remigrate global groups from a Windows NT 4.0 source domain by using the ADMT console**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.
2. Open the Active Directory Migration Tool console, and select **Group Account Migration Wizard**.
3. Complete the Group Account Migration Wizard by using the information provided in Table 10.16.

**Table 10.16 Using the Group Account Migration Wizard to Remigrate Groups**

| Wizard Page | Action |
| --- | --- |
| Test or Make Changes | Select **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type the NetBIOS name of the source domain or select the name from a list.<br>In the **Target domain** box, type the NetBIOS or DNS name of the target domain.<br>If ADMT includes the names of the source and target domains, ensure that they are correct. |
| Group Selection | Click **Add**.<br>In the **Select Groups** dialog box, select all global groups that you want to migrate (except built-in groups), click **Add**, and then click **OK**. |
| Organizational Unit Selection | Type in the name of the OU or click **Browse**.<br>In the **Browse for Container** dialog box, find the container in the target domain you want to move the global groups into, and then click **OK**. |
| Group Options | Select **Update user rights**.<br>Ensure that **Copy group members** is not selected.<br>Ensure that **Update previously migrated objects** is not selected.<br>Select **Fix membership of group**.<br>Select **Migrate Group SIDs to target domain**.<br>Select **Do not rename accounts**. |

| | |
|---|---|
| User Account | Enter **User name**, **Password**, and **Domain** of an account that has administrative rights in the source domain. |
| Naming Conflicts | Select **Replace conflicting accounts**.<br>Select **Remove existing user rights**.<br>Select **Remove existing members of groups being replaced**.<br>Ensure that **Move replaced accounts to specified target Organizational Unit** is not selected. |

4. When the wizard has finished running, click **View Log** and review the migration log for any errors.
5. Start Active Directory Users and Computers, and then navigate to the target OU. Verify that the global groups exist in the target domain OU.

**To remigrate global groups from a Windows NT 4.0 source domain by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT is installed, log on using the ADMT account migration account.
2. At the command line, type:

```
ADMT GROUP /N "
group_name1
" "
group_name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
" /MSS:YES /UGR:YES /MMS:NO
/CO:REPLACE+REMOVEUSERRIGHTS+REMOVEMEMBERS
```

Alternatively, you can include parameters in an option file that is specified on the command line as follows:

```
ADMT GROUP /N "
group_name1
" "
group_name2
" /O: "
option_file.txt
"
```

Table 10.17 lists the parameters required for remigrating global groups, along with the command-line parameter and option file equivalents.

**Table 10.17 Parameters Required for Global Group Remigrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:`"*source_domain*" | `SourceDomain=`"*source_ domain*" |
| Target domain | `/TD:`"*target_domain*" | `TargetDomain=`"*target_ domain*" |
| Target OU location | `/TO:`"*target_OU*" | `TargetOU=`"*target_OU*" |

| | | |
|---|---|---|
| Migrate GG SIDs | /MSS:YES | MigrateSIDs=YES |
| Do not rename accts | /RO:DONT (default) | RenameOption=DONT |
| Update user rights | /UGR:YES | UpdateGroupRights=YES |
| Copy group members | /MMS:NO | MigrateMembers=NO |
| Ignore conflicting accts and do not migrate them | /CO:REPLACE+REMOVEUSER RIGHTS+REMOVEMEMBERS | ConflictOptions=REPLACE+REMOVEUSERRIGHTS+REMOVE MEMBERS |

3. Review the results that are displayed on the screen for any errors.
4. Start Active Directory Users and Computers, and then navigate to the target OU. Verify that the global groups exist in the target domain OU.

**To remigrate global groups by using a script**

- Prepare a script that incorporates ADMT commands and options for remigrating global groups by using the sample script shown in Listing 10.9.

**Listing 10.9 Remigrating Global Groups**

```
<Job id=" RemigratingGlobalGroupsNTSource" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objGroupMigration

   '
   'Create instance of ADMT migration objects.
   '
   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objGroupMigration = objMigration.CreateGroupMigration

   '
   'Specify general migration options.
   '
   objMigration.SourceDomain = " source domain"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " target container"
   objMigration.ConflictOptions = admtReplaceConflicting + _
  admtRemoveExistingUserRights + admtRemoveExistingMembers

   '
   'Specify group migration specific options.
   '
   objGroupMigration.MigrateSIDs = True
   objGroupMigration.UpdateGroupRights = True
   objGroupMigration.UpdatePreviouslyMigratedObjects = False
   objGroupMigration.FixGroupMembership = True
   objGroupMigration.MigrateMembers = False

   '
   'Migrate specified group objects.
   '
```

```
   objGroupMigration.Migrate admtData, Array(" group name1" ," group name2" )

   Set objGroupMigration = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a script file to assist you in creating a script to migrate global groups, see "Remigrating Global Groups — Windows NT 4.0 Source" (DSSRENT_11.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Remigrating Global Groups — Windows NT 4.0 Source" on the Web at http://www.microsoft.com/reskit).

# Completing the Account Migration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you migrate all batches of accounts from the source to the target domain, you can complete the account migration process. This involves the following steps:

- Transferring user and group administration to the target domain by doing the following:
    - Freezing user and group administration in the source domain.
    - Maintaining at least two operational domain controllers in the source domain until the account migration process is complete.
    - Backing up the two domain controllers in the source domain.
    - Beginning administration of user and group accounts in the target domain.
- Decommissioning the Windows NT 4.0 source account domain by doing the following:

  **Note**

    - Ensure that you retain a full system backup of the PDC for each account domain. This enables you to bring the account domain back online.
    - Removing all trust relationships involving the Windows NT 4.0 source account domain.
    - Repurposing any remaining account domain controllers in the source account domain that you did not migrate to the target domain.
    - Disabling all accounts that you created during the migration process, including those accounts to which you assigned administrative credentials.

When you decommission the source account domain, shared local groups and local groups in resource domains that you have not translated by using the Security Translation Wizard display group members as **account unknown** because member names from the source domain do not resolve. Those group memberships still exist, however, and this does not impact users.

**Note**

- Do not delete shared local groups and local groups that display **account unknown** because this disables the access facilitated by SID history. Run the Security Translation Wizard to remove these entries.

# Restructuring Resource Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Restructuring Windows NT 4.0 resource domains into an Active Directory domain involves migrating resources, such as workstation and server computer accounts, and the associated shared local groups to the new environment. The target domain owner is responsible for the migration of all Windows NT 4.0 resources. The migration process must be completed for every Windows NT 4.0 source resource domain.

Figure 10.9 shows the process for restructuring Windows NT 4.0 resource domains.

**Figure 10.9 Restructuring Windows NT 4.0 Resource Domains**

# Migrating Workstations and Member Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Migrate remaining workstations that you did not migrate during the user account migration process, along with member servers, in small batches of up to 100 computers. Workstation account and member server migration is a straightforward process. Workstations and member servers have their own SAM account database. When you move workstations and member servers between domains, the database moves along with them. Accounts located in the local SAM database (such as local groups) that are used to enable access to resources always move with the computer, and therefore do not need to be migrated.

**Note**

- Restart member workstations and servers immediately after joining them to the target domain, by selecting a low number (such as 1) for the RestartDelay parameter. Resources that are not restarted following migration are in an indeterminate state.

You can migrate workstations and member servers by running the ADMT console, by using the ADMT command-line procedure, or by using a script.

**To migrate Windows NT 4.0 workstations and member servers by using the ADMT console**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT resource migration account.
2. Open the Active Directory Migration Tool and select **Computer Account Migration Wizard**.
3. Complete the Computer Account Migration Wizard by using the information provided in Table 10.18.

   **Table 10.18 Using the Computer Account Migration Wizard to Migrate Workstations and Member Servers**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Select **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type or select the NetBIOS name of the source domain.<br>In the **Target domain** box, type or select the NetBIOS or DNS name of the target domain. |
| Computer Selection | Click **Add.**<br>In the **Select Computers** dialog box, select the names of all the workstations and member servers in the source domain, click **Add**, and then click **OK**. |
| Organizational Unit Selection | Click **Browse**.<br>In the **Browse for Container** dialog box, find the container in the target domain to which the computers are migrating, and then click **OK**. |
| Translate Objects | Ensure that no check boxes are selected. |
| Computer Options | In the **Minutes before computer restart after wizard completion** box, type **1**. |
| Naming Conflicts | Select **Ignore conflicting accounts and don't migrate.** |

4. When the wizard has finished running on all computers, click **View Log** and review the migration log for any errors. If errors are reported, run the Retry Wizard to dispatch agents to workstations and member servers for which the migration process failed.
5. Start Active Directory Users and Computers**,** and then verify that the workstations and member servers exist in the

appropriate OU in the target domain.

**To migrate workstations and member servers by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT installed, log on by using the ADMT account migration account.
2. At the command line, type:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" [
parameters
]
```

You can append parameters to the command as follows:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
" /RDL:1
```

Alternatively, you can include parameters in an option file that is specified on the command line as follows:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" /O "
option_file.txt
"
```

Table 10.19 lists the parameters required for migrating workstations and member servers, along with the command-line parameter and option file equivalents.

**Table 10.19 Parameters Required for Workstation and Member Server Migrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:`"*source_domain*" | `SourceDomain=`"*source_ domain*" |
| Target domain | `/TD:`"*target_domain*" | `TargetDomain=`"*target_ domain*" |
| Target OU location | `/TO:`"*target_OU*" | `TargetOU=`"*target_OU*" |

| | | |
|---|---|---|
| • Restart computer one minute after wizard completes | /RDL:1 | RestartDelay=1 |
| • Do not rename accounts | /RO:DONT (default) | RenameOption=DONT |
| • Ignore conflicting accounts and do not migrate them | /CO:IGNORE (default) | ConflictOptions=IGNORE |

3. Review the results that are displayed on the screen for any errors.
4. Start Active Directory Users and Computers, and then navigate to the target OUs. Verify that the workstations and member servers exist in the target OUs.

**To migrate workstations and member servers by using a script**

- Prepare a script that incorporates ADMT commands and options for migrating workstations and member servers.

  For a sample script file to assist you in migrating workstations and member servers, see "Migrating User Workstations" earlier in this chapter and "Migrating Workstations or Member Servers — Windows NT 4.0 Source" (DSSRENT_10.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating Workstations or Member Servers — Windows NT 4.0 Source" on the Web at http://www.microsoft.com/reskit).

# Migrating Domain Controllers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In some domains, domain controllers are dedicated servers used for authentication only. In other domains, resources are located on domain controllers. Shared local groups provide resource permissions to all domain controllers that support a resource.

Migrating domain controllers is a more complicated process than migrating member servers for the following reasons:

- Windows NT 4.0 backup domain controllers (BDCs) cannot be returned to member server status or moved between domains.
- All domain controller access rights are based on shared local groups that must also be migrated.

For this reason, only migrate domain controllers running Windows NT 4.0 when shared resources are located on the domain controller. Decommission any domain controllers that do not have shared resources.

When deciding the order in which to migrate resource domains, consider the following:

- Migrate resource domains that use domain controllers as dedicated domain controllers first, then migrate resource domains that use domain controllers hosting resources.
- Migrate all the backup domain controllers in a domain first and then migrate the PDC.

**Migrating Shared Local Groups**

Migrate the shared local groups from the source domain to the target domain before you upgrade the Windows NT 4.0 domain controllers to Windows 2000 or Windows Server 2003 and move them to the target domain. Note that it is not necessary to change any access control lists (ACLs) as part of this process. The ACLs continue to reference the shared local groups in the source resource domain. Because the shared local groups were migrated to the target domain as domain local groups (and have the original SID in the SID history), users are able to access the resources as before. ADMT retains the membership of the local group during the migration.

**To migrate shared local groups by using the ADMT console**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT resource migration account.
2. Open the Active Directory Migration Tool and select **Group Account Migration Wizard**.
3. Complete the Group Account Migration Wizard by using the information provided in Table 10.20.

**Table 10.20 Using the Group Account Migration Wizard to Migrate Shared Local Groups**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Select **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type the NetBIOS name of the source domain or select the name from a list.<br><br>In the **Target domain** box, type the NetBIOS or DNS name of the target domain. |
| Group Selection | Click **Add.**<br><br>In the **Select Groups** dialog box, select all domain local groups that you need to migrate (except built-in groups), click **Add**, and then click **OK**. |

| | |
|---|---|
| Organizational Unit Selection | Type in the name of the OU or click **Browse**.<br><br>In the **Browse for Container** dialog box, find the container in the target domain to which the local groups are migrating, and then click **OK**. |
| Group Options | Select **Fix membership of group**.<br><br>Select **Migrate Group SIDs to target domain**.<br><br>Select **Do not rename accounts**.<br><br>Ensure that all other options are not selected. |
| User Account | Enter the **User name**, **Password**, and **Domain** of an account that has administrative rights in the source domain. |
| Naming Conflicts | Select **Ignore conflicting accounts and don't migrate**. |

4. When the wizard has finished running, click **View Dispatch Log**. Review the migration log for any errors.

5. Start Active Directory Users and Computers, and then navigate tothe target OU. Verify that the shared local groups exist in the target domain OU.

**Migrating Backup Domain Controllers**

Use the following steps to migrate Windows NT 4.0 BDCs from the source resource domain to the target domain.

**To migrate backup domain controllers**

1. Take the BDC offline, then use Server Manager to promote it to a PDC.

2. Upgrade the PDC to a Windows 2000– or Windows Server 2003–based domain controller.

3. Return the domain controller to stand-alone server status by running the Active Directory Installation Wizard. If you are removing Active Directory from the last domain controller in the domain, select **Domain controller is the last controller in the domain**.

4. Join the stand-alone server to the target domain.

# Completing the Resource Migration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you migrate all the resources from the source to the target domain, complete the restructuring process by doing the following:

- Transferring the administration of user and group accounts from the source to the target domain.
- Ensuring that at least two domain controllers are operational in the source resource domain until the resource migration process is complete.
- Backing up the two domain controllers in the source resource domain.

After completing these steps, you can translate security on the member servers in the target domain and decommission the source resource domain.

# Translating Security on Member Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Translate security on member servers to clean up ACLs. After users and groups are migrated to the target domain, ACLs still contain security IDs from the source domain. The SIDs from the source domain remain in the ACLs, and users can access resources by using SID history while the migration is in progress. However, after the migration is complete, the SIDs from the source domain must be translated to SIDs in the target domain. Use the Security Translation Wizard in ADMT to translate the source domain SIDs to the target domain SIDs that are contained in the ACLs.

**To translate security on member servers**

- Complete the Security Translation Wizard in ADMT by using the information provided in Table 10.21.

**Table 10.21 Using the ADMT Security Translation Wizard**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Select **Migrate Now?** |
| Security Translation Options | Select **Previously migrated objects**. |
| Domain Selection | In the **Source domain** box, type or select the name of the domain that contains the user accounts.<br><br>In the **Target domain** box, type or select the name of the target domain. |
| Translate Objects | Clear the **User Profiles** check box.<br><br>Select all other options. |
| Security Translation Options | Select **Add**. |

# Decommissioning the Source Resource Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you complete the resource migration, decommission the Windows NT 4.0 source resource domains.

**Note**

- Ensure that you retain a full system backup of the PDC for each resource domain. This enables you to bring the resource domain back online.

To decommission the Windows NT 4.0 source resource domain:

1. Remove all trust relationships between the Windows NT 4.0 source resource domain and the Active Directory target domain.

2. Repurpose any remaining domain controllers in the source resource domain that you did not migrate to the target domain.

3. Disable all accounts that you created during the migration process, including those accounts to which you assigned administrative permissions.

# Additional Resources for Restructuring Windows NT 4.0 Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

# Restructuring Active Directory Domains Between Forests

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Restructuring Active Directory® directory service domains between forests involves relocating objects from source domains in one forest to target domains in another forest. If you are migrating a pilot domain into your production environment, merging with another organization and consolidating the two IT infrastructures, or consolidating resource and account domains that you upgraded in-place from a Microsoft® Windows NT® 4.0 operating system environment, then restructuring Active Directory domains between forests enables you to reduce the complexity of your organization and the associated administrative costs. However, if your Active Directory environment consists of multiple forests, you might also move objects between forests on a regular basis.

**In This Chapter**

Overview of Restructuring Active Directory Domains Between Forests

Active Directory Merger, Acquisition, and Divestiture: Restructuring Limitations

Planning to Restructure Active Directory Domains Between Forests

Preparing the Source and Target Domains

Migrating Accounts

Migrating Resources

Completing the Migration

# Overview of Restructuring Active Directory Domains Between Forests

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Restructuring Microsoft® Windows® 2000, Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; and Windows® Server 2003, Datacenter Edition operating systems domains between forests enables you to reduce the number of domains in your organization and therefore the administrative complexity and associated overhead costs of your Active Directory environment. Restructuring domains involves copying accounts and resources from a Windows 2000 or Windows Server 2003 Active Directory source domain to a target domain in a different Active Directory forest. The target domain must be a Windows 2000 native mode or Windows Server 2003 functional level domain.

If you completed an in-place upgrade of more than one domain from Windows NT 4.0 to multiple Windows 2000 or Windows Server 2003 forests, you might need to restructure your domains between forests to consolidate the objects because the Windows NT 4.0 Security Accounts Manager (SAM) size limits that restrict the number of objects in a domain do not apply to an Active Directory environment. If your organization has recently merged with another organization or IT infrastructure, then restructuring enables you to consolidate accounts and resources between the two infrastructures.

**Note**

- For a list of the job aids that are available to assist in you restructuring Active Directory domains between forests, see "Additional Resources for Retructuring Active Directory Domains Between Forests" later in this chapter.

# Process for Restructuring Active Directory Domains Between Forests

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Restructuring Active Directory domains between forests involves planning and preparing for the domain restructure for your organization and successfully migrating accounts and resources to an Active Directory domain in another forest. Figure 11.1 shows the process for restructuring Active Directory domains between forests.

**Figure 11.1 Restructuring Active Directory Domains Between Forests**

# Background Information for Restructuring Active Directory Domains Between Forests

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The migration of domain objects between forests is a nondestructive process. The source and target domain environments exist simultaneously during the migration; therefore, you have the option to roll back to the source environment if necessary. The Active Directory Migration Tool (ADMT) version 2 enables you to migrate accounts and resources between domains while preserving user and object permissions. During the interforest restructure process, users have continuous access to required resources, and users, groups, and resources can be moved independently of each other.

Before you begin to restructure Active Directory domains between forests, you must be familiar with the account and resource migration process, Windows Server 2003 functional levels, and ADMT.

#### Terms and Definitions

The following terms apply to the Active Directory domain restructure process.

**Migration** The process of moving or copying an object from a source domain to a target domain, while preserving or modifying characteristics of the object to make it accessible in the new domain.

**Domain Restructure** A migration process that involves changing the domain structure of a forest. A domain restructure can involve either consolidating or adding domains, and can take place between forests or within a forest.

**Migration objects** Domain objects that are moved from the source domain to the target domain during the migration process. Migration objects can be user accounts, service accounts, groups, or computers.

**Source domain** The domain from which objects are moved during a migration. When restructuring Active Directory domains between forests, the source domain is an Active Directory domain in a different forest from the target domain.

**Target domain** The domain to which objects are moved during a migration.

**Built-in accounts** Default security groups that have common sets of rights and permissions. You can use built-in accounts to grant permissions to any accounts or groups that you designate as members of these groups. Built-in account security identifiers (SIDs) are identical in every domain and therefore built-in accounts cannot be migration objects.

#### Account Migration Process

Restructuring accounts between Active Directory forests involves the copying of users, groups, and local profiles from the source domain to the target domain, while preserving the access rights and attributes of those objects.

When user accounts are migrated between Active Directory domains in different forests, the original account remains in place in the source domain and a new account is created in the target domain. Because the SID of a security principal (user or group) always contains an identifier for the domain in which the security principal is located, a new SID is created for the user in the target domain. Because ADMT can migrate the SID of the original security principal to the security principal in the target domain, you do not need to perform additional tasks to ensure resource access, unless you are using SID filtering between the forests.

If you are using Microsoft® Exchange Server version 5.5, use the ADMT Exchange Server Migration Wizard to translate security on the mailboxes for migrated users. If you are using Exchange 2000 servers, ADMT does not provide tools for mailbox migration. In this case, plan to migrate mailboxes first by using the Exchange 2000 mailbox migration tool and then migrate user accounts.

If you are using Group Policy to manage folder redirection or software distribution, you need to ensure that these policies continue to apply when you migrate user accounts to a new forest. Also, if you are using a Group Policy object (GPO) to grant or deny remote access in the source domain and not the target domain, then ADMT cannot determine which remote access to assign to the user.

If you are using Group Policy to manage folder redirection, then Offline Files does not work after the user account is migrated to a new forest. Offline Files stores the SID of the user as owner; the SID changes when the user account is migrated. To restore ownership of Offline Files, use the ADMT Security Translation Wizard to replace the permissions on the files and folders on the client computer containing the offline files cache.

To ensure that users continue to have access to Offline Files after you migrate user accounts to the target domain, you can do

the following:

1. Translate security on client computers to update the Offline Files.

2. If the SID history of the user account was not migrated to the target domain, translate security on the server that hosts redirected folders.

If you are using folder redirection, one of the following occurs:

- If the folder redirection path is different in the new environment, then users can access the folder if the SID history of the user account was migrated to the target domain. The folder redirection extension copies the files from the original location in the source domain to the new location in the target domain. SID history enables the user account to access the source folders.

- If the folder redirection path is the same in the new environment, then users cannot access the redirected folder because folder redirection will check ownership of the redirected folder and will fail. You must then translate security on the redirected folder on the server.

Because some software installation (.msi) packages require access to the original source for operations such as repair and remove, if you are using Group Policy to manage software installation, then you need to translate security on the software distribution point after you migrate users to ensure that software installation continues to function properly in the target domain.

**Resource Migration Process**
Active Directory domains include three types of resources:

- Workstation accounts

- Member server accounts

- Resources on member servers

The migration of workstations and member servers is a straightforward process. The local groups that you create to assign permissions to users are located in the local SAM database and are moved when you move the server. You do not have to reconfigure access control lists (ACLs) to enable users to access resources after the migration.

In Active Directory, domain controllers can be migrated between domains. To do this, you must remove Active Directory from the domain controller, migrate it as a member server to the target domain, and then reinstall Active Directory. If you have deployed any domain controllers in the target domain that are running Windows Server 2003, then you can only reinstall Active Directory on the migrated server if the server is running Windows Server 2003 or if the forest and domain are operating at the Windows 2000 functional level.

For more information about functional levels, see "Enabling Advanced Windows Server 2003 Active Directory Features" in this book.

**Functional Levels**
*Functional levels* in Windows Server 2003 identify the level of functionality that the domain controllers running different Windows operating system versions of Active Directory can use, such as schema compatibility and replication functionality. The functional level of a domain or forest defines the set of Windows operating systems that can run on the domain controllers in that domain or forest. The functional level of a domain or forest also defines the additional Windows Server 2003 Active Directory features that are available in that domain or forest.

All target domains to which you migrate objects when restructuring Windows Server 2003 domains between forests must be operating at the Windows 2000 native mode or Windows Server 2003 functional level.

**Active Directory Migration Tool**
ADMT version 2 enables you to copy objects between Active Directory forests. ADMT includes wizards that automate migration tasks such as copying users, groups, service accounts, and computers; migrating trusts; and performing security translation.

When you use the ADMT tool to perform an interforest restructure, ADMT copies the accounts that are migrated, so that when the accounts are created in the target domain, they continue to exist in the source domain. The primary SIDs for the accounts

can be migrated to the SID history in the target domain.

ADMT is available on the Windows Server 2003 operating system CD, in the Admigration.msi file in the \i386\admt directory.

You can perform ADMT tasks by using the ADMT console, by using a command-line procedure, or by using a script. When running ADMT from the command line, it is often more efficient to use an option file to specify command-line options. You can use the ADMT option file reference in Listing 11.1 to assist you in creating option files.

Listing 11.1 lists all common options that apply to several migration tasks. Each type of migration task has a section listing options specific to that task. The section name corresponds to the task name when executing the ADMT command-line tool. Items can be commented out with a semicolon. In the following list, the default values are commented out.

When running ADMT at the command line, you do not need to include an option in your command if you want to accept the default value. In this chapter, however, tables are provided for reference. The tables list the command-line equivalent of each option that is shown in the corresponding ADMT console procedure, including those where you are accepting the default value.

For a file that contains the ADMT options, see "ADMT Option File Reference" (DSSRENT_3.txt) on the *Microsoft® Window® Server 2003 Deployment Kit* companion CD (or see "ADMT Option File Reference" on the Web at http://www.microsoft.com/reskit).

When running ADMT at the command line, it is often more efficient to use an include file to list the users, groups, or computers that will be migrated. For example, to migrate a small number of computers, you might type each computer name at the command line, using the /N option as follows:

**ADMT COMPUTER /N** " *computer_name1* " " *computer_name2* " **/SD:**" *source_domain* " **/TD:**" *target_domain* " **/TO:**" *target_OU* "

*Computer_name1* and *computer_name2* are the names of computers in the source domain that you are migrating in this batch.

If you have a large number of users, groups, or computers to migrate, you can list them in an include file. For example, to create an include file for a batch of computers, create a plain text file and list the computer names, each on a separate line. Then specify the include file name with the /F option, as follows:

**ADMT COMPUTER /F** " *includefile_name* " **/SD:"source_domain" /TD:"target_domain" /TO:"target_OU"**

ADMT supports the use of American National Standards Institute (ANSI) or standard Unicode files for option files and include files.

To specify names of users, groups, or computers, use one of the following conventions:

- The SAM account name. Note that to specify a computer name in this format, you must append a $ to the computer name. For example, to specify a computer with the name Workstation01, use Workstation01$.
- The Windows NT account name. This includes the domain name and the SAM account name. For example, the Windows NT account name of a computer named Workstation01 that is in the Asia domain is Asia\ Workstation01$.
- The relative distinguished name (also known as RDN). For example, cn= Workstation01.
- The canonical name. This can be specified as *DNS domain name/ou_path/object_name*, or *ou_path/object_name*; for example, Asia.trccorp.treyresearch.net/Computers/ Workstation01 or Computers/Workstation01.

For a complete list of all available ADMT options and syntax, run ADMT and select **Help** from the menu.

The sample scripts provided in this chapter reference the symbolic constants that are defined in the AdmtConstants.vbs file. Listing 11.2 shows the ADMT constants VBScript file.

# Active Directory Merger, Acquisition, and Divestiture: Restructuring Limitations

Updated: May 3, 2010

Applies To: Windows SBS 2003, Windows SBS 2008, Windows Server 2000, Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 Foundation, Windows Server 2008 R2

When a company acquires another company, business unit, or product line, the purchasing company may also want to acquire corresponding IT assets from the seller. Specifically, the buyer may want to acquire some or all of the domain controllers that host the user accounts, computer accounts, or security groups that correspond to the business assets that are to be purchased. The only supported methods for the buyer to acquire the IT assets that are stored in the seller's Active Directory forest are as follows:

1. Acquire the only instance of the forest, including all domain controllers and directory data in the seller's entire forest.

2. Migrate the needed directory data from the seller's forest or domains to one or more of the buyer's domains. The target for such a migration may be an entirely new forest or one or more existing domains that are already deployed in the buyer's forest. We recommend that you migrate the directory data without security identifier (SID) history. If you migrate the directory data with SID history, information about the seller's forest will be retained in the new forest of the buyer. For more information about migrating directory data without SID history, see Migrating Accounts Without Using SID History (http://go.microsoft.com/fwlink/?LinkId=113694).

This support limitation exists because:

- Each domain in an Active Directory forest is assigned a unique identity during the creation of the forest. Copying domain controllers from an original domain to a cloned domain compromises the security of both the domains and the forest. Threats to the original domain and the cloned domain include the following

    - Sharing of passwords that can be used to gain access to resources

    - Insight regarding privileged user accounts and groups

    - Mapping of IP addresses to computer names

    - Additions, deletions, and modifications of directory information if domain controllers in a cloned domain ever establish network connectivity with domain controllers from the original domain

- Cloned domains share a common security identity; therefore, trust relationships cannot be established between them, even if one or both of the domains have been renamed.

# Planning to Restructure Active Directory Domains Between Forests

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Completing the necessary planning tasks before you begin your migration enables you to ensure that users can continue to log on to the network and access resources during the migration. Planning includes defining the accounts and resources to be migrated, creating a test plan, and creating a rollback plan for use in the event that the migration fails. It also includes planning for user profile migration, establishing administrative procedures, and creating an end-user communication plan. To prepare for the restructuring process, the Active Directory deployment team must be sure to obtain the necessary design information from the Active Directory design team.

Figure 11.2 shows the steps involved in planning to restructure Windows Server 2003 domains between forests.

**Figure 11.2 Planning to Restructure Active Directory Domains Between Forests**

# Determining Your Account Migration Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

ADMT enables you to use SID history to maintain resource permissions when you migrate accounts. However, if SID filtering is enabled between your source and target domains, and you do not trust the administrators in the source domain, then you cannot disable SID filtering and use SID history to enable access to resources in the source domain. In this case, you must use a different migration process.

You can choose one of the following three methods to migrate accounts between forests while maintaining user rights to access resources in the source domain:

- Migrate user accounts without using SID history for resource access, but translate security for all resources before the migration process to ensure resource access. For more information about migrating accounts without using SID history, see "Migrating Accounts Without Using SID History" later in this chapter.

- Migrate user accounts while using SID history for resource access. With this method, you remove SID filtering on the trusts between the domains to enable users to access resources in the source domain by means of their SID history credentials.

    - If you have a cross-forest trust in place, you remove SID filtering on the cross-forest trust. (You can also override the cross-forest trust by creating an external trust so that the domain that holds the resources trusts the target domain, and then removing SID filtering on the external trust.)

    - If you do not have a cross-forest trust in place, you establish external trusts between the source and target domains. You then need to remove SID filtering on the external trusts if the domain controller used to create the trust is running Windows Server 2003 or Windows 2000 Service Pack 4 (SP4) or later.

  For more information about this process, see "Migrating Accounts While Using SID History" later in this chapter.

- Migrate all users, groups, and resources to the target domain in one step. For more information about this process, see "Migrating Accounts While Using SID History" later in this chapter.

To determine which account migration process is best for your organization, you must first determine if you can disable SID filtering and migrate accounts while using SID history for resource access. You can safely do this if the administrators of the source domain fully trust the administrators of the target domain. You might choose to disable SID filtering if one of the following conditions applies:

- The administrators of the trusting domain are the administrators for the trusted domain.

- The administrators of the trusting domain trust the administrators of the trusted domain and are confident that they have secured the domain appropriately.

If you disable SID filtering, you remove the security boundary between forests, which otherwise provides data and service isolation between the forests. For example, an administrator in the target domain who has service administrator rights or an individual who has physical access to a domain controller can modify the SID history of an account to include the SID of a domain administrator in the source domain. When the user account for which the SID history has been modified logs on to the target domain, it presents valid domain administrator credentials for and can obtain access to resources in the source domain.

For this reason, if you do not trust the administrators in the target domain or do not believe that the domain controllers in the target domain are physically secure, enable SID filtering between your source and target domains, and migrate user accounts without using SID history for resource access.

Figure 11.3 shows the decision process involved in determining which migration process is appropriate for your organization.

**Figure 11.3 Determining Your User Account Migration Process**

Do you fully trust the source domain?
No
Can you migrate users and resources at the same time?
No
Yes
Yes
Do you have a cross-forest trust in place?
No
Establish trusts between source and target domain
Migrate resources at the same time that you migrate users
Yes
Remove SID filtering on cross-forest trust
Remove SID filtering on explicit trust if between Windows Server 2003 or Windows 2000 SP4 or later domain controllers
Proceed with migration without using SID history for resource access
Proceed with migration while using SID history for resource access

# Using SID History to Preserve Resource Access

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The best practice for granting access to resources is to use global groups to group users, and local groups to protect resources. Place global groups into a local group to grant the members of the global group access to the resource. A global group can only contain members from its own domain. When a user is migrated between domains, any global groups to which the user belongs must also be migrated in order for users to continue to have access to resources protected by discretionary access control lists (DACLs) referring to global groups. After migrating an account and maintaining the SID history of the source domain account, when a user logs on to the target domain, both the new SID and the original SID from the SID history attribute are added to the access token of the user and determine the local group memberships of the user. The SIDs of the groups in which the user is a member are then added to the access token, together with the SID history of those groups.

Resources within the source and target domains resolve their ACLs to SIDs and then check for matches between their ACLs and the access token when granting or denying access. If the SID or the SID history matches, access to the resource is granted or denied, according to the access specified in the ACL. If the resource is in the source domain and you have not run security translation, it uses the SID history of the user account to grant access.

You can also preserve the original SID for global groups and universal groups in the SID history of the global group or universal group in the target domain. Because local group memberships are based on SIDs, when you migrate the SID to the SID history of the global group or universal group in the target domain, the local group memberships of the global group or universal group are preserved automatically.

SID history is used for roaming user profile access, certification authority access, and software installation access, as well as resource access. If you are not using SID history for resource access, you still need to migrate SID history to facilitate access to those items.

# Using SID Filtering When Migrating User Accounts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

SID filtering does not allow for the use of SIDs from outside the forest to enable access to any resource within the forest. You can enable the SID of a user in a different forest to access a resource within a forest that has SID filtering enabled by translating security on the resource to include the user SID in the permission list. Because SID filtering does not apply to authentication within a domain, it is also possible to allow access to resources by means of SID history if the resource and the account are in the same domain.

To allow users or groups to access a resource by using SID history, the forest in which the resource is located must trust the forest in which the account is located. SID filtering is applied by default when a forest trust is established between two forest root domains. Also, SID filtering is enabled by default when external trusts are established between domain controllers running Windows Server 2003 or Windows 2000 SP4 or later. This prevents potential security attacks by an administrator in a different forest.

For more information about SID history–based attacks and SID filtering, see Configuring SID Filtering Settings at http://go.microsoft.com/fwlink/?LinkId=73446.

# Assigning Object Locations and Roles

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Assign your migration objects locations and roles in the target domain. It is useful to create object assignment tables in which to document the assignments for all of the objects that you are migrating. Create one table for account objects, such as users, groups, and service accounts, and one table for resource objects, such as workstations, profiles, and domain controllers. In your tables, list the source and target locations for all objects to be migrated.

Before you create your account object assignment table, determine whether the domain organizational unit (OU) structures for the source and target domains are the same. If the OU structures are not the same, you must identify the source and target OU in your object assignment tables.

For a worksheet to assist you in creating an account object assignment table, see "User and Group Object Assignment Table" (DSSREER_1.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "User and Group Object Assignment Table" on the Web at http://www.microsoft.com/reskit).

Figure 11.4 shows an example of an object assignment table for users and groups.

**Figure 11.4 Example of a User and Group Object Assignment Table**

| User and Group Object Assignment Table | | | |
|---|---|---|---|
| Prepared By | Active Directory Deployment Team | Date | 01/01/03 |
| Source Forest Name | Trccorp.treyresearch.net | | |
| Target Forest Name | Concorp.contoso.com | | |
| Source Domain Name | Asia.trccorp.treyresearch.net | | |
| Target Domain Name | Emea.concorp.contoso.com | | |

| Name | Type | Source Location | Target Location |
|---|---|---|---|
| Finance | Group | Asia\Groups OU | EMEA\Groups OU |
| Accounting | Group | Asia\Groups OU | EMEA\Groups OU |
| JBrown | User | Asia\Users OU | EMEA\Users OU |
| MNguyen | User | Asia\Users OU | EMEA\Users OU |
| !Scheduler | Service Account | Asia\Users OU | EMEA\Service Accounts OU |

Creating a resource object assignment table also involves identifying the source and target OU for each object and noting the physical location and role in the target domain. For a worksheet to assist you in creating a resource object assignment table, see "Resource Object Assignment Table" (DSSREER_2.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Resource Object Assignment Table" on the Web at http://www.microsoft.com/reskit).

Figure 11.5 shows an example of a resource object assignment table.

**Figure 11.5 Example of a Resource Object Assignment Table**

| Resource Assignment Table | | | |
|---|---|---|---|
| Prepared By | Active Directory Deployment Team | Date | 01/01/03 |

| | |
|---|---|
| Source Forest Name | Trccorp.treyresearch.net |
| Target Forest Name | Concorp.contoso.com |
| Source Domain Name | Asia.trccorp.treyresearch.net |
| Target Domain Name | Emea.concorp.contoso.com |

| Name | Type | Source OU | Target OU | Physical Location | Role in Target Domain |
|---|---|---|---|---|---|
| FS01 | Member server (file server) | Computers | Member Servers | Hong Kong SAR | Member Server |
| UserWrk01 | Computer account | Default | Wrk | Hong Kong SAR | Computer account |
| UserWrk02 | Computer account | Wrk | Wrk | Boston | Computer account |

| DC02 | Domain Controller | Domain Controllers | Member Servers | Hong Kong SAR | Member server |

# Developing a Test Plan for Your Migration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is important to develop a test plan to assist you in systematically testing each object after it is migrated to the new environment, and identifying and correcting any problems that might occur. Testing to verify that your migration is successful allows you to ensure that users who are migrated from the source to the target domain are able to log on, to access resources based on group membership, and to access resources based on user credentials. Testing also allows you to ensure that users are able to access the resources that you migrate.

Use the following process to test your account object and resource object migration:

1. Create a test user in the source domain. Include this test user with your migrations.

2. Join that user to the appropriate global groups to enable resource access.

3. Log on to the source domain as the test user and verify that you can access resources as appropriate.

4. After you translate the user profile, migrate the workstation of the user, and migrate the user account, log on to the target domain as the test user and verify that the user has retained all necessary access and functionality. For example, you might test to verify that:

   - The user can log on successfully.

   - The user has access to all appropriate resources, such as file and print shares; access to services such as messaging; and access to line of business applications. It is especially important to test access to internally developed applications that access database servers.

   - The user profile was successfully translated, and the user retains desktop settings, desktop appearance, shortcuts, and access to the My Documents folder. Also, verify that applications appear in and start from the **Start** menu.

After you migrate resources, log on as the test user in the target domain and verify that you can access resources as appropriate.

If any steps in the test process fail, identify the source of the problem and determine whether you can correct the problem before the object needs to be accessible in the target domain. If you cannot correct the problem before access to the object is required, roll back to your original configuration to ensure access to the user or resource object. For more information about creating a rollback plan, see "Creating a Rollback Plan" later in this chapter.

As part of your test plan, create a migration test matrix. Complete a test matrix for each step that you complete in the migration process. For example, if you migrate 10 batches of users, complete the test matrix 10 times, once for each batch that you migrate. If you migrate 10 member servers, complete the test matrix for each of the 10 servers.

For a worksheet to assist you in creating a test matrix, see "Migration Test Matrix" (DSSREER_3.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migration Test Matrix" on the Web at http://www.microsoft.com/reskit).

Figure 11.6 shows an example of a completed migration test matrix.

**Figure 11.6 Example of a Completed Migration Test Matrix**

# Migration Test Matrix

| Prepared By | Active Directory Deployment Team | Date | 01/01/03 |
|---|---|---|---|

| | |
|---|---|
| Source Forest Name | Trccorp.treyresearch.net |
| Target Forest Name | Concorp.contoso.com |
| Source Domain Name | Asia.trccorp.treyresearch.net |
| Target Domain Name | Emea.concorp.contoso.com |

| Test Name | Performed Before Migration | Result After Migration | Notes |
|---|---|---|---|
| Create test user for users in Sales department "batch1" | Yes | Success | |
| Join user to sales group | Yes | Success | |
| Log on to source domain and verify access to required resources | Yes | Success | |
| Log on to target domain | No | Success | |
| Verify access to file and print shares | No | Success | |
| Verify access to customer management application | No | Success | |
| Verify user desktop settings and access to My Documents folder | No | Success | |
| Verify that applications appear and start from the Start menu | No | Success | |

# Creating a Rollback Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Reduce the risk of disrupting end users in your organization by establishing a rollback plan. In general, it is possible to isolate and resolve any problems that occur during each phase of the migration. However, it is important to analyze potential risks and identify the levels of user impact and downtime that might necessitate rolling back the migration. You might be required to roll back your migration if any of the following occur:

- Users cannot log on to their accounts after migration.
- Users cannot access resources after migration.
- User migration is incomplete; for example, passwords did not migrate.
- User migration was successful, but user workstation migration or local profile translation failed.

If user impact or downtime reaches a level that you have defined as unacceptable in your organization, you can implement your rollback plan and continue to operate in your premigration environment. Because the source domain remains intact during an interforest restructure, you can restore the original environment by completing a few key steps.

To roll back to the premigration environment after migrating account objects:

1. Enable the user accounts in the source domain (if you disabled the accounts during the migration process).
2. Notify the users to log off of the target domain.
3. Notify the users to log on to the source domain.
4. Verify that users are able to access resources.
5. Verify that the logon scripts and user profiles for users work as configured in the source domain.

The rollback process for resource objects is similar to that for account objects. To roll back to the premigration environment after migrating resource objects:

1. Change the domain membership for the server or workstation to the source domain.
2. Restart the server or workstation.
3. Log on as a user and verify that you can access the resource.

**Note**

- If you need to modify objects such as member servers or domain controllers in order to migrate them to the target domain, back up all the data before making the modifications and performing the migration.

# Planning for a User Profile Migration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

User profiles store user data and information about the desktop settings of the user. User profiles can either be roaming or local. The migration process is different for local and for roaming profiles.

Profile translation is one type of security translation, and profiles are translated during the migration process. If you perform security translation in add mode, the SIDs in the target and the source domains both have access to the profile. Therefore, if you need to roll back to the source environment, the SID in the source domain can use the profile. If you perform security translation in replace mode, you must retranslate the profile by using a SID mapping file (undoing the security translation) to roll back to the source environment.

**Important**

- In the event that you need to roll back to your original configuration, notify users that profile changes made in the target domain are not reflected in the source domain.

Some organizations might choose not to migrate user profiles. Other organizations might choose to replace users' workstations during the user account migration process, and use a tool such as the User State Migration Tool (USMT) to migrate user data and settings to the users' new computers. Table 11.1 summarizes the migration requirements for user profiles.

Table 11.1 Migration Requirements for User Profiles

| Type | Description | Migration Requirements |
|---|---|---|
| Roaming profiles | User profiles are stored centrally on servers. Profiles are available to the user, regardless of the workstation in use. | Migrate local user profiles for a batch of users before migrating those users. Then select the profile migration option during the user account migration process to migrate the roaming profile. |
| Local profiles | User profiles are stored locally on the workstation. When a user logs on to another workstation, a unique local user profile is created. | Migrate as a separate step from the user account migration process. Migrate local user profiles for a batch of users before migrating those users. |
| Profiles not managed | Same as local profiles. | No migration requirements. Users lose their existing profiles when their user accounts are migrated. |
| Hardware refresh | User state information is stored locally on the workstation. | Migrate as a separate step from the user account migration. Migrate the profiles to the user's new computer by means of a tool such as USMT. |

# Creating Administrative Procedures

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You must define how the objects that you are migrating are to be administered during the interforest restructure process. Establishing administrative procedures for migration objects enables you to preserve the objects both in the source and the target domains, and therefore enables you to fall back to the premigration environment in the event that the restructure process is not successful.

Plan for the administration and management of the following types of account migration objects:

- User accounts, including SIDs.
- Global group membership.
- User profiles.

**Administering User Accounts**

During the migration process, user accounts exist in both the source and the target domains. Administer changes to user accounts in the domain in which the user object is active. Continue to administer changes to group memberships in the source domain while the migration is taking place. Use the **Replace conflicting accounts** option in ADMT to remigrate user accounts as often as necessary during the migration process. This ensures that changes made to the account in the source domain are propagated to the account in the target domain. This operation merges the existing account and the new account so that administration of the object can continue in the source domain for the duration of the migration process.

The **Replace conflicting accounts** option applies the following guidelines when an account is migrated:

- If you change an attribute in the target domain and it is not used in the source domain, then it is not overwritten with the NULL value from the source domain.
- If you change an attribute in the target domain and it is used in the source domain, then it is overwritten with the value from the source domain.
- If the user has group memberships, the memberships are merged together from the source memberships and the target memberships.

If this is not the desired behavior, you can configure ADMT to exclude attributes from being migrated so that attributes in the target domain are retained.

For example, if you migrate a user and after you complete the migration you set attributes on the new user object in the target domain, such as a telephone number or office number, and you remigrate the user by using the **Replace conflicting accounts** option in ADMT, the new information is retained in the target domain. If you changed the group memberships for the user in the source domain, the changes are propagated to the target domain when you perform the remigration.

Some attributes are excluded from the migration. These include:

- Attributes that are always excluded by the system
- Attributes that are in the system exclusion list
- Attributes that are configured by the administrator to be excluded

**Attributes that are always excluded by the system**

Some attributes are always excluded from the migration by ADMT and cannot be configured to be migrated. This protects system-owned attributes. These attributes include:

- Object globally unique identifier (GUID)

- SIDs (although SIDs can be added to the SID history of the object in the target domain)
- LegacyExchangeDN

**System attribute exclusion list**
The first time that you run an ADMT user migration, ADMT generates a system attribute exclusion list, which it stores in its database. The system attribute exclusion list contains two attributes by default: **mail** and **proxyAddresses**. ADMT also reads the schema in the target domain, and adds any attributes to the list that are not part of the base schema. Attributes in this list are excluded from migration operations even if the attribute is not specified in the attribute exclusion list. An administrator can change the system attribute exclusion list only by using a script. This protects attributes that are important in order for server-based applications, such as Exchange, to work. If the target domain schema is further extended after ADMT has generated the list, administrators must manually add the new attributes to the list, unless they are certain that copying the values of these attributes from the source domain will not interfere with server-based applications.

**Attribute exclusion list**
Administrators can define a list of attributes that are excluded from each migration. This is called an attribute exclusion list. By default, when using the ADMT console, state information for attributes that are configured to be excluded is stored in the UI and included in the exclusion list for the next migration. Scripting and command-line attributes do not have state information and therefore are not stored in the UI. These attributes must be added to the attribute exclusion list for each migration operation, either by means of the attribute name or by means of an option file.

**Administering Global Groups**
Continue to administer the groups in the source domain during the migration process. Remigrate groups as often as necessary by using the **Replace conflicting accounts** option in ADMT to ensure that changes made to group memberships in the source domain are propagated to the groups in the target domain.

# Creating the End-User Communication Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Develop a plan to inform all affected users about the upcoming account migration, to ensure that they understand their responsibilities, the impact of the migration, and who to contact for help and support.

Before you begin the user migration process, send a notice to all users who are scheduled to be migrated. Because you typically migrate users in batches of approximately one hundred users at a time, it is also helpful to send a final notice to the users in each batch two to three days before their batch is scheduled. If your organization maintains an intranet, publish the account migration schedule and the information contained in the user mail on an easily accessible Web page.

Include the following information in your end-user communication.

**General information**
Alert users to the fact that their user accounts are scheduled to be migrated to a new domain. Point users to a Web page or internal resource where they can find additional information, and view a migration schedule.

Inform users of their new domain name. Be sure to let them know that their account passwords will not change. Let them know that the original domain account will be disabled immediately following the migration, and the disabled account will be deleted after a specified period of time.

**Impact**
Make sure that users understand that when their account is migrated, it is possible that they could be unable to access some resources, such as Web sites, shared folders, or resources that are not widely used by individuals in their group or division.

Provide information to users about who to contact for assistance in regaining access to required resources.

**Logon status during migration**
Make sure that users understand that during the migration process, they will be unable to log on to the domain or access e-mail or other resources. Be sure to specify the period of time for which they will be unable to log on.

**Premigration steps**
Alert users to any steps that they need to complete before the migration process begins. For example, they must decrypt files encrypted by means of Encrypted File System (EFS). Failure to decrypt encrypted files will result in loss of access to encrypted files following the migration.

Users must also ensure that their computers are connected to the network when their account is scheduled to be migrated.

**Expected changes**
Describe other changes that users can expect to experience following the migration, such as changes in use of smart cards, secure mail, or instant messaging, if applicable.

**Scheduling and support information**
Provide information about where users can go to find more information; for example, an internal Web site where you post information about the migration. Also, provide information about who to contact if a user has a conflict with the date scheduled for the migration.

# Preparing the Source and Target Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you begin to migrate your accounts from the source to the target domains, you need to prepare the source and target domains for the migration. Figure 11.7 shows the tasks required to prepare your source and target domains for the interforest domain restructure process.

**Figure 11.7 Preparing the Source and Target Domains**

# Installing 128-Bit High Encryption Software

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The computer on which ADMT is installed requires 128-bit high encryption. This encryption is standard on computers running Windows Server 2003 and Windows 2000 Server SP3 or later. If you plan to install ADMT on a computer that is running Windows 2000 SP2 or earlier, you must install the 128-bit high encryption pack.

You can download the encryption pack from the Windows 2000 High Encryption Pack link on the Web Resources page at http://www.microsoft.com/windows/webresources.

# Establishing Required Trusts for Your Migration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you can migrate accounts and resources from a source domain to a target domain in a different Active Directory forest, you must ensure that the appropriate trusts exist between the forests. Trust relationships between the forests that you are restructuring enables ADMT to migrate users and service accounts and translate local user profiles from the source to the target domains. In addition, trust relationships enable users in the source domains to access resources in the target domains, and users in the target domains to access resources in the source domains that have not yet been migrated.

To migrate users and global groups, you must establish a one-way trust between the source domain and the target domain, so that the source domain trusts the target domain.

To migrate resources or translate local profiles, you must do one of the following:

- Create a one-way trust between the source domain and the target domain.
- Create a two-way trust between source and target domains.

# Establishing Migration Accounts for Your Migration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To migrate accounts and resources between forests, you must establish a migration account or accounts and assign the appropriate credentials to those accounts. ADMT uses the migration accounts to migrate the objects that you identify. Because ADMT requires only a limited set of credentials, creating separate migration accounts enables you to simplify administration. If the migration tasks for your organization are distributed across more than one group, it is helpful to create a migration account for each group involved in performing the migration

To simplify administration, create a single account in the source domain and a single account in the target domain for all objects, with the required credentials to modify the objects, such as users, global groups, and local profiles, to be migrated by that account. For example, a migration account that you use to migrate user accounts along with SID history, global groups along with SID history, computers, and user profiles has local administrator or domain administrator credentials in the source domain, and delegated permission on the user, group, and computer OUs in the target domain, with the extended right to migrate SID history on the user OU. The user needs to be a local administrator on the computer in the target domain on which ADMT is installed. A migration account that you use to migrate workstations and domain controllers must have local administrator or source domain administrator credentials on the workstations or the account must have source domain administrator credentials on the domain controller, or both.

In the target domain, it is necessary to use an account that has delegated permissions on the computer OU and the user OU. You might want to use a separate account for the migration of workstations if this migration process is delegated to administrators that are in the same location as the workstations.

Table 11.2 lists the credentials that are required in the source and target domains for different migration objects.

**Table 11.2 Migration Account Credentials**

| Migration Object | Credentials Necessary in Source Domain | Credentials Necessary in Target Domain |
|---|---|---|
| User/Group without SID history | Delegated **Read all user information** permission on the user OU or group OU. | Delegated **Create user objects** permission on the user OU or group OU and local administrator on the computer on which ADMT is installed. |
| User/Group with SID history | Local administrator or domain administrator | Delegated permission on the user OU or the group OU, extended permission to migrate SID history, and local administrator on the computer on which ADMT is installed. |
| Computer | Domain administrator or administrator in the source domain and on each computer | Delegated permission on the computer OU and local administrator on the computer on which ADMT is installed. |
| Profile | Local administrator or domain administrator | Delegated permission on the user OU and local administrator on the computer on which ADMT is installed. |

The following procedures provide examples for creating groups or accounts to migrate accounts and resources. Procedures differ according to whether a one-way trust or a two-way trust exists The procedure for creating migration groups when a one-way trust exists is more complex than the procedure for creating migration accounts when a two-way trust exists, because you must add the migration group to the local Administrators group on local workstations. The sample procedure for creating migration groups when a one-way trust exists involves the creation of separate groups for migrating accounts and resources; however, you can combine *acct_migrators* and *res_migrators* into one group, if you do not need to separate them to delegate different sets of permissions.

**To create an account migration group when a one-way trust exists in which the source domain trusts the target domain**

1. In the target domain, create a global group, *acct_migrators*.

2. In the target domain, add the *acct_migrators* group to the Domain Admins group, or delegate administration of OUs that are targets for account migration to this group.

3. If you are migrating SID history, and you did not place the *acct_migrators* group in the Domain Admins group, grant the *acct_migrators* group the extended permission **Migrate SID History** on the target domain object. To do this:

    a. Start Active Directory Users and Computers, right-click the domain object, and then click **Properties**.

    b. Click the **Security** tab, click **Add**, and select ***acct_migrators***.

    c. In the **Permissions for acct_migrators** box, click **Allow** for the Migrate SID History permission.

4. In the source domain, add the *acct_migrators* group to the Administrators group.

5. On each computer on which you plan to translate local profiles, add the *acct_migrators* group to the local Administrators group.

**To create the resource migration group when a one-way trust exists in which the source domain trusts the target domain**

1. In the target domain, create a global group, *res_migrators*.

2. In the target domain, add the *res_migrators* group to the Domain Admins group, or delegate administration of OUs that are targets for resource migration to this group.

3. In the source domain, add the *res_migrators* group to the Administrators group.

4. On each computer that you plan to migrate or on which you plan to perform security translation, add the *res_migrators* group to the local Administrators group.

**To create a resource migration account when a two-way trust exists between the source and target domains**

1. In the source domain, create an account, *res_migrator*.

2. In the source domain, add the *res_migrator* account to the Domain Admins group. (The Domain Admins group is a member of the local Administrators group on every computer in the domain by default; therefore, you do not need to add it to the local Administrators group on every computer.)

3. In the target domain, delegate permissions on OUs that are targets for resource migration to the *res_migrator* account.

# Configuring the Source and Target Domains for SID History Migration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To migrate SID history, three conditions must be met:

- A local group used to audit SID history operations exists in the source domain.
- TCP/IP client support must be enabled on the source domain primary domain controller (PDC) emulator.
- Audit policies must be enabled.

You can configure these items manually before beginning the migration, or you can allow ADMT to configure them automatically the first time it runs. If you want to configure them manually, use the following procedures.

**To create a local group in the source domain to support auditing**

- In the source domain, create a local group *source_domain*$$$, where domain is the NetBIOS name of your source domain, for example, boston$$$. Do not add members to this group; if you do, SID history migration will fail.

  **Caution**

  - The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Windows Server 2003 Resource Kit Registry Reference on the *Windows Server 2003 Deployment Kit* companion CD or at http://www.microsoft.com/reskit.

**To enable TCP/IP client support on the source domain PDC emulator**

1. On the domain controller in the source domain that holds the PDC emulator role, use the registry editor to navigate to the following registry subkey:

   **HKEY_LOCAL_MACHINE\System\CurrentControlSet\Control\Lsa**

2. Modify the registry entry **TcpipClientSupport**, of data type REG_DWORD, by setting the value to 1.
3. Restart the computer.

**To enable auditing on the Windows Server 2003 domains**

1. Log on as an administrator to any domain controller in the target domain.
2. Open **Active Directory Users and Computers**, expand the domain, and double-click the **Domain Controllers** OU.
3. On the **Group Policy** tab, click **Default Domain Controllers Policy**.
4. Expand **Computer Configuration**, expand **Windows Settings**, expand **Security Settings**, expand **Local Policies**, and then click **Audit Policy**.
5. Double-click **Audit account management**, and then click both **Success** and **Failure**.
6. Repeat steps 1-5 on the source domain.

**Note**

- To assist you in using the event log to troubleshoot errors in the migration process, be sure to synchronize the time on all computers that are involved in the migration.

# Configuring the Target Domain OU Structure for Administration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Active Directory design team creates the OU structure for the target domain. They also define the groups responsible for the administration of each OU and the membership of each group. You can use that information to configure the target domain for administration. This involves the following steps:

1. Log on as an administrator to any domain controller in the target domain.
2. Open Active Directory Users and Computers and create the OU structure specified by your design team.
3. Create administrative groups and assign users.
4. Delegate the administration of the OU structure to groups as defined in your design.

# Installing ADMT in the Target Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Install and run ADMT on a domain controller in the target domain.

**To install ADMT in the target domain**

1. Log on to a computer in the target domain by using your ADMT migration account.
2. Insert the Windows 2000 or Windows Server 2003 operating system CD in the drive and navigate to \i386\admt.
3. Run admigration.msi.

# Enabling Migration of Passwords

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

ADMT version 2 supports password migration. When you migrate passwords by using ADMT, you must use a password export server (PES) to host password migration support dynamic-link libraries (DLLs). The PES can be any domain controller in the source domain that supports 128-bit encryption.

Passwords are copied from the source domain to the target domain in hash form; therefore, it is not possible for a password filter to verify that the complexity or length of the passwords meet the requirements of the organization. The target domain controller used to set the password can, however, verify password history by comparing the hash of the password against previous hashes.

In the target domain, ensure that the built-in group Pre-Windows 2000 Compatible Access contains the Everyone and Anonymous Logon groups. The groups will not be present if you selected **Permissions compatible only with Windows 2000 or Windows Server 2003 operating systems** when you installed Active Directory in the target domain.

If the groups are not present, ADMT logs an Access Denied error. You must then manually add them to enable support for password migration. To do this, type the following at the command line on a target domain controller:

```
        NET LOCALGROUP "Pre-Windows 2000 Compatible Access" Everyone /ADD
NET LOCALGROUP "Pre-Windows 2000 Compatible Access" "Anonymous Logon" /ADD
```

After this update to the Pre-Windows 2000 Compatible Access group replicates, you must restart the Server service on all domain controllers in the target domain.

Use the following procedures to enable support for password migration.

**To generate an encryption key**

1. Log on to the domain controller in the target domain on which you installed ADMT by using your ADMT migration account.
2. Select the location to which to save the file. The location can be any local drive, including the floppy drive.
3. Open a command window, change to the drive on which ADMT is installed, and at the command line, type:

```
ADMT KEY
Source_Domain Folder
[
password
] [*]
```

The *Source_Domain* can be specified as either the DNS or NetBIOS name. A password, which provides key encryption, is optional. To protect the shared key, type either the password or an asterisk (*) at the command line. The asterisk prompts for a password that is not displayed on the screen.

**To generate an encryption key**

1. Log on to the domain controller in the target domain on which you installed ADMT by using your ADMT migration account.
2. Select the location to which to save the file. The location can be any local drive, including the floppy drive.
3. Open a command window, change to the drive on which ADMT is installed, and at the command line, type:

```
ADMT KEY
Source_Domain Folder
[
password
```

```
] [*]
```

The *Source_Domain* can be specified as either the DNS or NetBIOS name. A password, which provides key encryption, is optional. To protect the shared key, type either the password or an asterisk (*) at the command line. The asterisk prompts for a password that is not displayed on the screen.

| **Note** |
| --- |
| For security reasons, it is strongly recommended that you provide a password. |

**To enable password migration on the source domain**

1. On the PES in the source domain, insert the encryption key disk.
2. Insert the Windows Server 2003 operating system CD in the CD drive.
3. Navigate to the \i386\admt\pwdmig directory, and run pwdmig.exe. If you set a password during the key generation process on the domain controller in the target domain, the Key Password Required dialog box appears.
4. Enter the password and then complete the setup.
5. On the source domain PES, use the registry editor to navigate to the following registry subkey:

   ```
   HKEY_LOCAL_MACHINE\System\CurrentControlSet\Control\LSA
   ```

6. Modify the registry entry **AllowPasswordExport**, of data type REG_DWORD, by setting the value to 1.

| **Caution** |
| --- |
| The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the Windows Server 2003 Resource Kit Registry Reference. |

# Initializing ADMT by Running a Test Migration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Initialize ADMT by running a test migration of a global group with the option to migrate SID history selected. If you did not previously configure the source and target domains to migrate SID history, you will receive an error and a prompt for each item that has not yet been configured. When you accept each prompt, ADMT automatically completes the following tasks, which are required to enable SID history migration:

- Creates a local group, *source_domain*$$$, in the source domain, which is used to audit SID history operations. Do not add members to this group; if you do, SID history migration will fail.

- Enables TCP/IP client support on the source domain PDC emulator by setting to 1 the value of the registry entry **TcpipClientSupport**, which is locatedin the following subkey:

  HKEY_LOCAL_MACHINE\System\CurrentControlSet\Control\Lsa

  Setting **TcpipClientSupport** to 1 enables remote procedure calls (RPCs) over the TCP transport while preserving the security of the system.

- Enables audit policies in the source and target domains.

For more information about configuring the source and target domains to migrate SID history, see "Configuring the Source and Target Domains for SID History Migration" earlier in this chapter.

**To initialize ADMT by running a test migration of a global group**

1. In the Active Directory Migration Tool console, on the **Tools** menu, click **Group Account Migration Wizard**.

2. Complete the Group Account Migration Wizard by using the information provided in Table 11.3. Accept default settings when no information is specified.

**Table 11.3 Migrating Global Groups by Using the Group Account Migration Wizard**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Test the migration settings and migrate later?** |
| Domain Selection | In the **Sourcedomain** box, type the source domain name.<br><br>In the **Target domain** box, type the target domain name. |
| Group Selection | Click **Add**.<br><br>In the **Select Groups** dialog box, select a group. |
| Organizational Unit Selection | Click **Browse**.<br><br>In the **Browse for Container** dialog box, locate the **Groups** OU. |
| Group Options | Select the **Migrate Group SIDs to target domain** check box.<br><br>Click **Do not rename accounts**. |
| User Account | Type the name and password of the migration account that you created for migrating accounts.<br><br>In the **Domain** box, type the NetBIOS name of the target domain. |

| | |
|---|---|
| Naming Conflicts | Click **Ignore conflicting accounts and don't migrate**. |

3. When the wizard has finished running, click **View Log** and review the migration log for any errors.

4. Verify that the test migration configured ADMT properly by ensuring that:

   - A new local group *source_domain*$$$ exists in the source domain. This account supports ADMT internal auditing.

   - The registry entry **TcpipClientSupport** is created as data type REG_DWORD with a value of 1 in the following subkey on the source domain PDC emulator:

   HKEY_LOCAL_MACHINE\System\CCS\Control\Lsa

   - The audit policy for account management is enabled on the target domain.

# Identifying Service Accounts for Your Migration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Identify the member servers and domain controllers in the source domain that run applications in the context of a service account. A service account is a user account created as a means to provide a security context for applications. The service account is a standard user account that is granted permission to log on as a service. ADMT does not migrate services that run in the context of the Local System account because they are migrated when the computer is migrated; however, services that run in the context of a user account must be updated on the computer after you have completed the account migration process. ADMT also cannot migrate the Local Service or Network Service accounts because they are well-known accounts that always exist in Windows Server 2003.

The process of identifying, migrating, and updating services that run in the context of user accounts involves three steps. First, the administrator starts ADMT from the target Active Directory domain controller and runs the Service Account Migration Wizard. The Service Account Migration Wizard sends an agent to a computer that is specified and identifies all services on the computer that are running in the context of a user account. The wizard only identifies service accounts that are running in the context of a user account; it does not actually migrate the accounts. The next step, which can occur later in the migration process, is to migrate the accounts when other user accounts are migrated by means of the User Account Migration Wizard.

The Service Account Migration Wizard scans an administrator-defined list of servers for services that are configured to use a domain account to authenticate. The accounts are then flagged as service accounts in the ADMT database. The password is never migrated when a service account is migrated. Instead, ADMT uses a clear-text representation of the password to configure the services after the service account migration. An encrypted version of the password is then stored in the "password.txt" file in the ADMT installation folder.

An administrator of a workstation or server can install any service and configure the service to use any domain account. If the administrator cannot configure the service to authenticate with the correct password, then the service will be unable to start. After the service account is migrated, ADMT configures the service on the workstation or the server to use the new password and the service will now start under the user account.

It is important to include in the Service Account Migration Wizard only those servers that are managed by trusted administrators. Do not use the Service Account Migration Wizard to detect service accounts on computers that are not managed by trusted administrators, such as workstations.

Dispatch agents to all servers managed by trusted administrators in the domain to ensure that you do not overlook any service accounts. If you miss a service account that shares an account with a service that has already been migrated, it is not possible for ADMT to synchronize them. You must then manually change the password for the service account and then reset the service account password on each server that is running that service.

When the accounts that the Service Account Migration Wizard identifies in the ADMT database as running in the context of a user account are migrated to the target domain, ADMT grants each account the right to log on as a service. If the service account is assigned rights by means of its membership in a group, the Security Translation Wizard updates the account to assign those rights. For more information about running the Security Translation Wizard, see "Transitioning Service Accounts in Your Migration" later in this chapter.

**To identify service accounts by using the ADMT console**

1. On the domain controller on which ADMT is installed, log on by using the ADMT account migration account.
2. Open the Active Directory Migration Tool console and then select **Service Account Migration Wizard**.
3. Complete the Service Account Migration Wizard by using the information in Table 11.4.

**Table 11.4 Using the Service Account Migration Wizard**

| Wizard Page | Action |
|---|---|
| Domain Selection | In the **Source domain** box, type or select the NetBIOS or DNS name of the source domain.<br>In the **Target domain** box, type or select the NetBIOS or DNS name of the target domain. |
| Update Information | Click **Yes, update the information**. |

| | |
|---|---|
| Service Account Selection | Click **Add**.<br>In the **Select Computers** list box, click the names of all servers that are capable of running services in the source domain and in all domains that trust the source domain.<br>Click **OK**, and then click **Next**. |
| Service Account Information | Select any user accounts that do not need to be marked as service accounts in the ADMT database, and then click **Skip/Include** to mark them as **Skip**. |

4. When the wizard has finished running on all computers, on the Server List page, click **View Log**, and review the migration log for any errors.

**To identify service accounts by using the ADMT command-line option**

1. On a domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.
2. At the command line, type:

```
ADMT SERVICE /N "
computer_name1
" "
computer_name2
" /SD:"
source_domain
" /TD:"
target_domain
"
```

*Computer_name1* and*computer_name2* are the names of computers in the source domain that run service accounts.

Alternatively, you can include parameters in an option file that is specified at the command line as follows:

```
ADMT SERVICE /N "
computer_name1
" "
computer_name2
" /O: "
option_file.txt
"
```

Table 11.5 lists the common parameters used for the identification of service accounts, along with the command-line parameter and option file equivalents.

**Table 11.5 Common Parameters Used for Service Account Identification**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:"`*source_domain*`"` | `SourceDomain="`*source_domain*`"` |
| Target domain | `/TD:"`*target_domain*`"` | `TargetDomain="`*target_domain*`"` |

3. Review the results that are displayed on the screen for any errors.

**To identify service accounts by using a script**

- Create a script that incorporates ADMT commands and options for identifying service accounts by using the sample

script shown in Listing 11.3.

**Listing 11.3 Identifying Service Accounts**

```
<Job id=" IdentifyingServiceAccounts" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objServiceAccountEnumeration

   '
   'Create instance of ADMT migration objects.
   '

   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objServiceAccountEnumeration = _
  objMigration.CreateServiceAccountEnumeration

   '
   'Specify general migration options.
   '

   objMigration.SourceDomain = " source domain"

   '
   'Enumerate service accounts on specified computers.
   '

   objServiceAccountEnumeration.Enumerate admtData, _
  Array(" computer name1" ," computer name2" )

   Set objServiceAccountEnumeration = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a script file to assist you in creating a script to identify service accounts, see "Identifying Service Accounts" (DSSRENT_5.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Identifying Service Accounts" on the Web at http://www.microsoft.com/reskit).

# Migrating Accounts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The process of migrating account objects from a source domain to a target domain in another Active Directory forest involves first migrating service accounts, and then migrating global groups. After the groups are in place in the target domain, you can migrate users according to the process that you selected, either while using SID history for resource access, or without using SID history for resource access. When the account object migration process is complete, you can instruct users from the source domain to log on to the target domain. Figure 11.8 shows the process for migrating accounts between domains in different forests.

**Figure 11.8 Migrating Accounts**

# Transitioning Service Accounts in Your Migration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Begin the process of migrating objects by migrating service accounts. For information about identifying service accounts for migration, see "Identifying Service Accounts" earlier in this chapter. To transition service accounts, you must complete the following tasks:

- Migrate the service accounts from the source domain to the target domain.
- Modify the services on each server in the source domain to use the service account in the target domain in place of the service account in the source domain.

You can transition service accounts by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To transition service accounts by using the ADMT console**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.
2. Open the Active Directory Migration Tool console, and then select **User Account Migration Wizard**.
3. Complete the User Account Migration Wizard by using the information in Table 11.6.

**Table 11.6 Using the User Account Migration Wizard to Transition Service Accounts**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type or select the name of the source domain.<br>In the **Target domain** box, type or select the name of the target domain. |
| User Selection | Click **Add**.<br>In the **Select Users** dialog box, select all of the service accounts that were identified by the Service Account Migration Wizard, and then click **Add**.<br>Click **OK**. |
| Organizational Unit Selection | Click **Browse**.<br>In the **Browse for Container** dialog box, locate the source domain, select the container for the service accounts, and then click **OK**. |
| Password Options | Click **Complex passwords**. |
| Account Transition Options | Click **Enable target accounts**.<br>Click the **Migrate user SIDs to target domains** check box. |
| User Account | Type the user name, password, and domain of a user account that has administrative credentials. |

| | |
|---|---|
| User Options | Click the **Update user rights** check box.<br>Make sure that **Do Not Rename Accounts** is selected.<br>Ensure that no other settings are selected, including **Migrate associated user groups**. |
| Naming Conflicts | Click **Ignore conflicting accounts**. |
| Service Account Information | Click **Migrate all service accounts and update SCM for items marked include**. If you are also migrating other user accounts that are not service accounts, this wizard page tells you that you have selected some accounts that are marked as service accounts in the ADMT database. By default, the accounts are marked as Include. To change the status of the account, select the account, and then click **Skip/Include**.<br>Click **Next** to migrate the accounts. |

4. When the wizard has finished running, click **View Log** and review the migration log for any errors.
5. Open the Active Directory Users and Computers console, locate the OU that you created for service accounts, and verify that the service accounts exist in the target domain OU.

**To transition service accounts by using the ADMT command-line option**

1. On a domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.
2. At the command line, type:

```
ADMT USER /N "
user_name1
" "
user_name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
" /MSS:
YES
```

*Server name1* and *Server_name2* are the names of servers in the source domain that run service accounts. Alternatively, you can include parameters in an option file that is specified on the command line as follows:

```
ADMT USER /N "
server_name1
" "
server_name2
" /O:"
option_file.txt
"
```

Table 11.7 lists the common parameters used for transitioning service accounts, along with the command-line parameter and option file equivalents.

**Table 11.7 Common Parameters Used for Transitioning Service Accounts**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:"`*source_domain*`"` | `SourceDomain="`*source_domain*`"` |
| Target domain | `/TD:"`*target_domain*`"` | `TargetDomain="`*target_domain*`"` |
| Target OU location | `/TO:"`*target_OU*`"` | `TargetOU="`*target_OU*`"` |
| Disable accounts | `/DOT:ENABLETARGET` *(default)* | `DisableOption=ENABLETARGET` *(default)* |
| Migrate password | `/PO:COMPLEX` (default) | `PasswordOption=COMPLEX` |
| Migrate user SIDs = YES | `/MSS:YES` | `MigrateSIDs=YES` |
| Update user rights=YES | `/UUR:YES` | `UpdateUserRights=YES` |
| Do not rename accounts | `/RO:DONT` (default) | `RenameOption=DONT` (default) |
| Ignore conflicting accounts | `/CO:IGNORE` (default) | `ConflictOptions=IGNORE` (default) |

3. Review the results that are displayed on the screen for any errors.
4. Open Active Directory Users and Computers and locate the target service account OU. Verify that the service accounts exist in the target domain OU.

**To transition service accounts by using a script**

- Prepare a script that incorporates ADMT commands and options for transitioning service accounts by using the sample script shown in Listing 11.4.

**Listing 11.4 Transitioning Service Accounts Between Forests**

```
<Job id=" TransitioningServiceAccountsBetweenForests" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objUserMigration

   '
   'Create instance of ADMT migration objects.
   '

   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objUserMigration = objMigration.CreateUserMigration

   '
   'Specify general migration options.
   '

   objMigration.SourceDomain = " source domain"
   objMigration.SourceOu = " source container"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " target container"
   objMigration.ConflictOptions = admtIgnoreConflicting

   '
   'Specify user migration specific options.
   '
```

```
   objUserMigration.MigrateSIDs = True
   objUserMigration.UpdateUserRights = True
   objUserMigration.MigrateServiceAccounts = True

   '
   'Migrate specified service accounts.
   '

   objUserMigration.Migrate admtData, _
  Array(" service account name1" ," service account name2" )

   Set objUserMigration = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a script file to assist you in creating a script to transition service accounts, see "Transitioning Service Accounts Between Forests" (DSSREER_4.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Transitioning Service Accounts Between Forests" on the Web at http://www.microsoft.com/reskit).

# Migration of Global Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To preserve the global group user memberships, you must migrate global groups before you migrate users.

| **Note** |
| --- |
| Do not migrate global groups during peak work hours. The global group migration process can consume a large amount of network resources and resources on the domain controller that is running ADMT. |

Global group migration involves the following steps:

1. The administrator selects global group objects in the source domain.
2. A new global group object is created in the target domain. A new primary SID is created for the object in the target domain.
3. To preserve resource access, ADMT adds the SID of the global group in the source domain to the SID history attribute of the new global group in the target domain.

Following the migration, events are logged in both the source and the target domain.

| **Note** |
| --- |
| If the user account migration process takes place over an extended period of time, then you might need to remigrate global groups from the source to the target domain to propagate membership changes that are made in the source domain before the migration process is complete. For more information about remigrating global groups, see "Remigrating All Global Groups After All Batches Are Migrated" later in this chapter. |

You can migrate global groups by using the Active Directory Migration Tool console, by using the ADMT command-line option, or by using a script.

**To migrate global groups by using the ADMT console**

1. On the domain controller in the target domain on which ADMT installed, log on by using the ADMT account migration account.
2. Open the Active Directory Migration Tool, and then select **Group Account Migration Wizard**.
3. Complete the Group Account Migration Wizard by using the information in Table 11.8.

**Table 11.8 Using the Group Account Migration Wizard to Migrate Groups**

| Wizard Page | Action |
| --- | --- |
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type the NetBIOS or DNS name of the source domain or select the name from a list.<br>In the **Target domain** box, type the NetBIOS or DNS name of the target domain.<br>If ADMT includes the names of the source and target domains, ensure that they are correct. |

| | |
|---|---|
| Group Selection | Click **Add**.<br>In the **Select Groups** dialog box, select all the global groups that you want to migrate (except built-in groups), click **Add**, and then click **OK**. |
| Organizational Unit Selection | Type the name of the OU, or click **Browse**.<br>In the **Browse for Container** dialog box, locate the container in the target domain you want to move the global groups into, and then click **OK**. |
| Group Options | Click **Migrate Group SIDs to target domain**.<br>Click **Do not rename accounts**<br>Make sure that all other options are not selected. |
| User Account | Type the user name, password, and domainof an account that has administrative rights in the source domain. |
| Naming Conflicts | Click **Ignore conflicting accounts and don't migrate**. |

4. When the wizard has finished running, click **View Log**, and review the migration log for any errors.
5. Open the Active Directory Users and Computers console and locate the target OU. Verify that the global groups exist in the target domain OU.

**To migrate global groups by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.
2. At the command line, type:

```
ADMT GROUP /N "
group_name1
" "
group_name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
" [
parameters
]
```

Alternatively, you can include parameters in an option file that is specified on the command line as follows:

```
ADMT GROUP /N "
group_name1
" "
group_name2
" /O: "
option_file.txt
"
```

Table 11.9 lists the common parameters used for migrating global groups, along with the command-line parameter and

option file equivalents.

**Table 11.9 Common Parameters Used for Global Group Migrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:"`*source_domain*`"` | `SourceDomain="`*source_domain*`"` |
| Source OU location | `/SO:"`*source_OU*`"` | `SourceOU="`*source_OU*`"` |
| Target domain | `/TD:"`*target_domain*`"` | `TargetDomain="`*target_domain*`"` |
| Target OU location | `/TO:"`*target_OU*`"` | `TargetOU="`*target_OU*`"` |
| Migrate GG SIDs | `/MSS:YES` | `MigrateSIDs=YES` |
| Do not rename accts | `/RO:DONT` *(default)* | `RenameOption=DONT` |
| Ignore conflicting accts and do not migrate them | `/CO:IGNORE` *(default)* | `ConflictOptions=IGNORE` |

3. Review the results that are displayed on the screen for any errors.
4. Open the Active Directory Users and Computers console and locate the target OU. Verify that the global groups exist in the target domain OU.

**To migrate global groups by using a script**

- Prepare a script that incorporates ADMT commands and options for migrating global groups by using the sample script shown in Listing 11.5

**Listing 11.5 Migrating Global Groups Between Forests**

```
<Job id=" MigratingGlobalGroupsBetweenForests" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objGroupMigration

   '
   'Create instance of ADMT migration objects.
   '

   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objGroupMigration = objMigration.CreateGroupMigration

   '
   'Specify general migration options.
   '

   objMigration.SourceDomain = " source domain"
    objMigration.SourceOu = " source container"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " target container"

   '
   'Specify group migration specific options.
   '
```

```
   objGroupMigration.MigrateSIDs = True

   '
   'Migrate specified group objects.
   '

   objGroupMigration.Migrate admtData, Array(" group name1" ," group name2" )

   Set objGroupMigration = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a script file to assist you in creating a script to migrate global groups, see "Migrating Global Groups Between Forests" (DSSREER_5.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating Global Groups Between Forests" on the Web at http://www.microsoft.com/reskit).

# Migrating Accounts While Using SID History

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To migrate accounts while using SID history, first migrate all user accounts, but do not enable them in the target domain, to prepopulate the target domain and allow migration of user profiles. After all user accounts are successfully migrated, begin migrating users in batches by migrating first the user profile, then the workstation, then the user account. Before migrating all user accounts, ensure that you have created test accounts that you can use to verify the success of each batch.

You cannot migrate every user property when you migrate user accounts. For example, Protected Storage (Pstore) contents for Windows NT 4.0 workstations, including Encrypting File System (EFS) private keys, are not migrated by ADMT when you migrate user accounts. To migrate Pstore contents, you must export and import keys during the migration process.

For clients that are running Windows 2000 or later operating systems, data that is protected by the Data Protection API (DPAPI) is also not migrated. DPAPI helps protect the following items:

- Web page credentials (for example, passwords)
- File share credentials
- Private keys associated with EFS, S/MIME, and other certificates
- Program data that is protected by using the CryptProtectData() function

For this reason, it is important to test user migrations by using your test migration account to identify any properties that did not migrate and update user configurations in the target domain accordingly.

Complete the following steps to migrate user accounts to the target domain:

1. Migrate all user accounts with the account enabled in the source domain, disabled in the target domain, with complex password selected, and with no attributes migrated.
2. Translate local user profiles for a batch of users.
3. Migrate workstations in batches that correspond to the user account batches.
4. Before migrating the batch of user accounts, verify that local profile and workstation migration succeeded for all users in the batch. Do not migrate any user account for which profile or workstation migration failed, because this will result in users overwriting their existing profiles when they log on to the target domain.
5. Remigrate user accounts in batches with the account set to expire in the source domain in seven days, the target account enabled, with password migration selected, and all attributes migrated.
6. After each batch, you might want to remigrate all global groups to update any group membership changes.
7. Notify users in the batch to log on to the target domain.
8. After all users are migrated, run a final global group migration to update any group membership changes.

Migrating user accounts in batches enables you to track the accounts that have been migrated and to test the success of each migration step. If the OU structure for the target domain is the same as the OU structure for the source domain, then migrate groups of users based on OU. If the OU structures are not the same, select an alternate way to group users based on the structure of your organization. For example, you might migrate users by business unit or by floor to enable you to consolidate help desk resources.

If you plan to retain your source domain OU structure, migrate the OU along with the users that they contain. For example, if your source domain is a Windows Server 2003 Active Directory environment that has a functional OU structure, and the target

domain does not have an OU structure, migrate OUs from the source domain.

If you created a new OU structure in the target domain, migrate batches of users without the OUs. For example, if your source environment was a Windows NT 4.0 domain that you upgraded to a Windows Server 2003 domain, the source domain might not have an existing OU structure; therefore, you can migrate users without migrating OUs.

For more information about designing an OU structure, see "Designing the Active Directory Logical Structure" in this book.

Until you migrate all user and group accounts, continue to administer global group membership in the source domain. To support a rollback strategy, manually synchronize any changes you make to users in the target domain with the existing user accounts in the source domain. For more information about administering users and groups during the interforest restructure process, see "Creating Administrative Procedures" earlier in this chapter.

If you are migrating OUs when you migrate user accounts, migrate the groups that belong to those OUs to the target domain OU during the user account migration process. When you migrate global groups by using the global group migration process, they are placed in the target OU in the target domain. If you migrate OUs from the source to the target domain, select the option to move the global groups to the target domain at the same time so that the groups are moved from the target OU that they were placed in during the initial global group migration to the OU in which they belong.

Using ADMT to migrate user accounts preserves group memberships. Because global groups can contain only members from the domain in which the group is located, when users are migrated to a new domain, the user accounts in the target domain cannot be members of the global groups in the source domain. As part of the migration process, ADMT identifies the global groups in the source domain that the user accounts belong to, and then determines whether the global groups have been migrated. If ADMT identifies global groups in the target domain that the migrated users belonged to in the source domain, the tool adds the users to the appropriate global groups in the target domain.

Using ADMT to migrate user accounts also preserves user passwords. After the user accounts are migrated to and enabled in the target domain, the users can log on to the target domain by using their original passwords. If the user account migration process is successful but the password migration process fails, ADMT creates a new complex password for the user account in the target domain. By default, ADMT stores new complex passwords in the C:\Program Files\Active Directory Migration Tool\Logs\Password.txt file.

If you have a Group Policy setting on the target domain that does not allow blank passwords (the **Default Domain Policy/Computer Configuration/Security Settings/Account Policies/Password Policy/Minimum password length** setting is set to any number other than zero), then password migration will fail for any user who has a blank password. ADMT generates a complex password for that user, and writes an error to the error log.

Establish a method for notifying users who have been assigned new passwords. For example, you can create a script to send an e-mail message to users to notify them of their new passwords.

Figure 11.9 shows the steps involved in migrating accounts if you are using SID history for resource access.

**Figure 11.9 Migrating Accounts While Using SID History**

# Migrating All User Accounts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Begin the user account migration process by migrating all users. This enables you to translate local profiles and ensure that users continue to have the appropriate resource access following the migration.

**Notes**

- Built-in accounts (such as Administrators, Users, and Power Users cannot be ADMT migration objects. Because built-in account SIDs are identical in every domain, migrating these accounts to a target domain results in duplicate SIDs in a single domain. Every SID in a forest must be unique.
- Well-known accounts (such as Domain Admins and Domain Users) also cannot be ADMT migration objects

The ADMT user account migration process includes the following steps:

1. ADMT reads the attributes of the source user objects.
2. ADMT creates a new user object in the target domain and a new primary SID for the new user account.
3. ADMT adds the original SID of the user account to the SID history attribute of the new user account.
4. ADMT migrates the password for the user account.
5. If ADMT identifies global groups in the target domain that the migrated users belonged to in the source domain, the tool adds the users to the appropriate global groups in the target domain.

During the migration, audit events are logged in both the source and the target domains.

You can migrate user accounts by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To migrate user accounts by using the ADMT console**

1. On the domain controller in the target domain on which you installed ADMT, log on by using the ADMT account migration account.
2. Open the Active Directory Migration Tool, and then select **User Account Migration Wizard**.
3. Complete the User Account Migration Wizard by using the information in Table 11.10.

**Table 11.10 Using the User Account Migration Wizard to Migrate User Accounts**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?**. |
| Domain Selection | In the **Source domain** box, type or select the name of the source domain.<br>In the **Target domain** box, type or select the name of the target domain. |
| User Selection | Click **Add**.<br>In the **Select Users** dialog box, click all the user accounts, and then click **Add**. By default, the wizard migrates the accounts to the Users container. Click **Do Not Migrate Passwords** (use complex passwords).<br>Click **OK**. |

| | |
|---|---|
| Organizational Unit Selection | ADMT lists an OU here. Ensure that this is the correct target OU. If it is not correct, type the correct OU or click **Browse**.<br>In the **Browse for Container** dialog box, locate the target domain and OU, and then click **OK**. |
| Password Options | Click **Do NotMigrate Passwords**.<br>Click **Complex Passwords**. |
| Account Transition Options | Click **Disable target accounts**.<br>Click **Enable source account**.<br>Click the **Migrate user SIDs to target domains** check box. |
| User Account | Type the user name, password, and domainof a user account that has administrative credentials. |
| User Options | Click the **Translate roaming profiles** check box.<br>Click the **Update user rights** check box.<br>Clear the **Migrate associated user groups** check box.<br>Click **Fix users' group memberships**.<br>Click the **Do not rename accounts** check box. |
| Object Property Exclusion | Clear the **Exclude specific object properties from migration** check box. |
| Naming Conflicts | Click **Ignore conflicting accounts and don't migrate**.<br>Clear the **Remove existing user rights** check box.<br>Clear the **Move replaced accounts to specific target Organizational Unit** check box. |

4. When the wizard has finished running, click **View Log** and review the migration log for any errors.
5. Open Active Directory Users and Computers and verify that the user accounts exist in the appropriate OU in the target domain.

**To migrate user accounts by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.
2. At the command line, type:

```
ADMT USER /N "user_name1" "user_name2"  /SD:"source_domain"
/TD:"target_domain"  /TO:"target_OU"  [parameters]
```

You can append parameters to the command as follows:

```
ADMT USER /N "user_name1" "user_name2"  /SD:"source_domain"
/TD:"target_domain"  /TO:"target_OU" /MSS:YES TRP:YES /UUR:YES
```

Alternatively, you can include parameters in an option file that is specified at the command line as follows:

```
ADMT USER /N "user_name1" "user_name2" /O "option_file.txt"
```

Table 11.11 lists the common parameters used for migrating user accounts, along with the command-line parameter and

option file equivalents.

**Table 11.11 Common Parameters Used for User Migrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:"`*source_domain*`"` | `SourceDomain="`*source_domain*`"` |
| Target domain | `/TD:"`*target_domain*`"` | `TargetDomain="`*target_domain*`"` |
| Target OU location | `/TO:"`*target_OU*`"` | `TargetOU="`*target_OU*`"` |
| Migrate SIDs | `/MSS:YES` | `MigrateSIDs=YES` |
| Do not rename accts | `/RO:DONT` *(default)* | `RenameOption=DONT` |
| Ignore conflicting accts and not migrate them | `/CO:IGNORE` *(default)* | `ConflictOptions=IGNORE` |
| Translate Roaming Profile | `/TRP:YES` *(default)* | `TranslateRoamingProfile=YES` |
| Update User Rights | `/UUR:NO` | `UpdateUserRights=NO` |
| Password Options | `/PO:COMPLEX` | `PasswordOption=COMPLEX` |

3. Review the results that are displayed on the screen for any errors.
4. Open Active Directory Users and Computers and locate the target OU. Verify that the users exist in the target OU.

**To migrate user accounts by using a script**

- Prepare a script that incorporates ADMT commands and options for migrating users by using the sample script shown in Listing 11.6.

**Listing 11.6 Migrating All User Accounts Between Forests**

```
<Job id=" MigratingAllUserAccountsBetweenForests" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objUserMigration

   '
   'Create instance of ADMT migration objects.
   '

   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objUserMigration = objMigration.CreateUserMigration

   '
   'Specify general migration options.
   '

   objMigration.SourceDomain = " source domain"
   objMigration.SourceOu = " source container"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " target container"
   objMigration.PasswordOption = admtComplexPassword
   objMigration.ConflictOptions = admtIgnoreConflicting
```

```
    '
    'Specify user migration specific options.
    '

    objUserMigration.MigrateSIDs = True
    objUserMigration.TranslateRoamingProfile = True
    objUserMigration.UpdateUserRights = True
    objUserMigration.FixGroupMembership = True
    objUserMigration.MigrateServiceAccounts = False

    '
    'Migrate specified user objects.
    '

    objUserMigration.Migrate admtData, Array(" user name1" ," user name2" )

    Set objUserMigration = Nothing
    Set objMigration = Nothing
</Script>
</Job>
```

For a sample script file to assist you in creating a script to migrate user accounts, see "Migrating All User Accounts Between Forests" (DSSREER_6.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating All User Accounts Between Forests" on the Web at http://www.microsoft.com/reskit).

# Remigrating User Accounts and Workstations in Batches

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Remigrating user accounts and workstations in batches helps you track the migration process. For each batch of users, first translate local user profiles, and then migrate workstations. Verify that the profile and workstation migration succeeded, and then migrate the user accounts. Remigrate global groups after each batch.

**Translating Local User Profiles**
ADMT only translates profiles for computers running Windows NT 4.0, Windows 2000, Microsoft® Windows® XP, or Windows Server 2003.

User profiles are stored locally on the workstation. When a user logs on to another workstation, he or she must create a new, unique local user profile. Translate the local user profiles immediately after migrating a batch of users.

Local profiles are translated in replace mode because if you perform the profile translation in add mode, certain aspects of software installation that use software deployment Group Policies might not work. Any application that is packaged with Windows Installer version 2.0 (which is included on workstations running Windows 2000 SP3 or later or Windows XP SP1 or later, as well as many common software packages) might not function after the profile is translated. For example, the application executable files might not be removed after the last user removed the application. When the ADMT Security Translation Wizard translates local profiles in replace mode, it reverts to add mode if a profile cannot be loaded because it is already in use by the user or a service using the user account. In some cases, this can cause some aspects of the software deployment Group Policies to fail to function after the profile is translated.

| **Note** |
| --- |
| Translate the local user profiles the night before you notify the users to log on by using their new accounts in the target domain. Migrating profiles the night before ensures that the new user profile reflects the most current user settings. |

You can translate local user profiles by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To translate local user profiles by using the ADMT console**

1. For each workstation in the source domain that is running Windows NT 4.0, Windows 2000, or Windows XP, add the ADMT resource migration account to the local Administrators group.
2. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.
3. Open the Active Directory Migration Tool, and then select **Security Translation Wizard**.
4. Complete the Security Translation Wizard by using the information in Table 11.12.

   **Table 11.12 Using the Security Translation Wizard to Translate Local User Profiles**

   | Wizard Page | Action |
   | --- | --- |
   | Test or Make Changes | Click **Migrate Now?** |
   | Security Translation Options | Click **Previously migrated objects**. |
   | Domain Selection | In the **Source domain** box, type or select the name of the source account domain.<br><br>In the **Target domain** box, type or select the name of the target domain. |
   | Translate Objects | Click **User Profiles**. |
   | Security Translation Options | Click **Replace**. |

5. When the wizard has finished running on all computers, click **View Log** and review the dispatch log for any errors.

**To translate local user profiles by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.
2. At the command line, type:

```
ADMT SECURITY /N "
computer_name1
" "
computer_name2
" [
```

```
parameters
]
```

You can append parameters to the command as follows:

```
ADMT SECURITY /N "
computer_name1
" "
computer_name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TOT:REPLACE /TUP:YES
```

Alternatively, you can include parameters in an option file that is specified at the command line as follows:

```
ADMT SECURITY /N "
computer_name1
" "
computer_name2
" /O "
option_file.txt
"
```

Table 11.13 lists the common parameters used for migrating user accounts, along with the command-line parameter and option file equivalents.

**Table 11.13 Common Parameters Used for Local User Profile Migrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:"`*source_domain*`"` | `SourceDomain="`*source_domain*`"` |
| Target domain | `/TD:"`*target_domain*`"` | `TargetDomain="`*target_domain*`"` |
| Translate option = REPLACE | /TOT:REPLACE | TranslateOption=REPLACE |
| Modify local user profile security | /TUP:YES | TranslateUserProfiles=YES |

3. Review the results that are displayed in the dispatch log for any errors.

**To translate local user profiles by using a script**

- Prepare a script that incorporates ADMT commands and options for translating local user profiles by using the sample script shown in Listing 11.7.

**Listing 11.7 Translating Local User Profiles Between Forests**

```
<Job id=" TranslatingLocalProfilesBetweenForests" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objSecurityTranslation

   '
   'Create instance of ADMT migration objects.
   '

   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objSecurityTranslation = objMigration.CreateSecurityTranslation

   '
```

```
    'Specify general migration options.
    '

    objMigration.SourceDomain = " source domain"
    objMigration.TargetDomain = " target domain"
    objMigration.TargetOu = " Computers"

    '
    'Specify security translation specific options.
    '

    objSecurityTranslation.TranslationOption = admtTranslateReplace
    objSecurityTranslation.TranslateUserProfiles = True

    '
    'Perform security translation on specified computer objects.
    '

    objSecurityTranslation.Translate admtData, _
   Array(" computer name1" ," computer name2" )

    Set objSecurityTranslation = Nothing
    Set objMigration = Nothing
</Script>
</Job>
```

For a sample script to assist you in translating local user profiles, see "Translating Local User Profiles Between Forests" (DSSREER_7.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Translating Local User Profiles Between Forests" on the Web at http://www.microsoft.com/reskit).

**Migrating Workstations in Batches**

After you migrate a batch of local user profiles, migrate the corresponding batch of user workstations. When you move workstations between domains, the SAM database moves along with them. Accounts located in the local SAM database (such as local groups) that are used to enable access to resources always move with the computer, and therefore do not need to be migrated.

**Note**

- Use a low value in the ADMT computer restart option, to restart workstations immediately after joining them to the target domain, or as soon as possible thereafter. Resources that are not restarted following migration are in an indeterminate state.

You can migrate workstations and member servers by using the AMDT console, by using the ADMT command-line option, or by using a script.

**To migrate workstations by using the ADMT console**

1. On the domain controller in the target domain on which you installed ADMT, log on by using the ADMT resource migration account.
2. Open the Active Directory Migration Tool, and then select **Computer Account Migration Wizard**.
3. Complete the Computer Account Migration Wizard by using the information in Table 11.14.

**Table 11.14 Using the Computer Account Migration Wizard to Migrate Workstations**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type or select the name of the source domain.<br><br>In the **Target domain** box, type or select the name of the target domain. |
| Computer Selection | Click **Add**.<br><br>In the **Select Computers** dialog box, select the names of all the workstations and member servers in the source domain, click **Add**, and then click **OK**. |

| | |
|---|---|
| Organizational Unit Selection | Click **Browse**.<br><br>In the **Browse for Container** dialog box, locate the target domain **Computers** container or the appropriate OU, and then click **OK**. |
| Security Translation Options | Click the **Local groups** check box.<br><br>Click the **User rights** check box. |
| Translate Objects | Click **Add**. |
| Computer Options | In the **Minutes before computer restart after wizard completion** box, type **1**. |
| Naming Conflicts | Click **Ignore conflicting accounts and don't migrate.** |

4. When the wizard has finished running on all computers, click **View Log** and review the migration log and dispatch log for any errors.
5. If errors are reported, run the Retry Wizard to dispatch agents to workstations for which the migration process failed.
6. Open Active Directory Users and Computers and verify that the workstations exist in the appropriate OU in the target domain.

**To migrate workstations by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT installed, log on by using the ADMT resource migration account.
2. At the command line, type:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
" [
parameters
]
```

You can append parameters to the command as follows:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
" /RDL:1
```

Alternatively, you can include parameters in an option file that is specified at the command line as follows:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" /O "
option_file.txt
"
```

Table 11.15 lists the common parameters used for workstation migration, along with the command-line parameter and option file equivalents.

**Table 11.15 Common Parameters Used for Workstation Migrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:"`*source_domain*`"` | `SourceDomain="`*source_domain*`"` |
| Source OU location | `/SO:"`*source_OU*`"` | `SourceOU="`*source_OU*`"` |
| Target domain | `/TD:"`*target_domain*`"` | `TargetDomain="`*target_domain*`"` |
| • Target OU location | `/TO:"`*target_OU*`"` | `TargetOU="`*target_OU*`"` |
| • Restart Delay | `/RDL:1` | `RestartDelay=1` |
| • Do not rename accounts | `/RO:DONT` *(default)* | `RenameOption=DONT` |
| • Translate Option | `/TOT:ADD` | `TranslateOption=YES` |
| • Translate Option | `/TUR:YES` | `TranslateOption=ADD` |
| • Translate User Rights | `/TLG:YES` | `TranslateUserRights=YES` |

3. Review the results that are displayed on the screen for any errors.
4. Open Active Directory Users and Computers and locate the target OU. Verify that the workstations and member servers exist in the target OU.

**To migrate workstations by using a script**

- Prepare a script that incorporates ADMT commands and options for migrating workstations by using the sample script shown in Listing 11.8.

**Listing 11.8 Migrating Workstations Between Forests**

```
<Job id=" MigratingWorkstationsBwtweenForest" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objComputerMigration

   '
   'Create instance of ADMT migration objects.
   '

   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objComputerMigration = objMigration.CreateComputerMigration

   '
   'Specify general migration options.
   '

   objMigration.SourceDomain = " source domain"
   objMigration.SourceOu = " Computers"
   objMigration.TargetDomain = " target domain"
```

```
    objMigration.TargetOu = " Computers"

    '
    'Specify computer migration specific options.
    '

    objComputerMigration.RestartDelay = 1
    objComputerMigration.TranslationOption = admtTranslateAdd
    objComputerMigration.TranslateLocalGroups = True
    objComputerMigration.TranslateUserRights = True

    '
    'Migrate computer objects on specified computer objects.
    '

    objComputerMigration.Migrate admtData, _
   Array(" computer name1" ," computer name2" )

    Set objComputerMigration = Nothing
    Set objMigration = Nothing
</Script>
</Job>
```

For a sample script file to assist you in migrating workstations between forests, see "Migrating Workstations Between Forests" (DSSREER_9.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating Workstations Between Forests" on the Web at http://www.microsoft.com/reskit).

**Remigrating User Accounts in Batches**

After you have verified the success of local user profile and user workstation migration for the user batch, migrate the user accounts for that batch. You can migrate user accounts in batches by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To migrate the current batch of user accounts by using the ADMT console**

1. On the domain controller in the target domain on which you installed ADMT, log on by using the ADMT account migration account.
2. Open the Active Directory Migration Tool, and then select **User Account Migration Wizard**.
3. Complete the User Account Migration Wizard by using the information in Table 11.16.

**Table 11.16 Using the User Account Migration Wizard to Migrate User Accounts**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type or select the name of the source domain.<br><br>In the **Target domain** box, type or select the name of the target domain. |
| User Selection | Click **Add**.<br><br>In the **Select Users** dialog box, select the user accounts that you want to migrate, and then click **Add**. By default, the wizard migrates the accounts to the Users OU. If you need to change the OU, click **Location**, and then browse for the appropriate OU.<br><br>Click **Migrate Passwords**.<br><br>Click **OK**. |
| Organizational Unit Selection | Ensure that ADMT lists the correct target OU. If it is not correct, type the correct OU or click **Browse**.<br><br>In the **Browse for Container** dialog box, locate the target domain **Users** container or appropriate OU, and then click **OK**. |
| Password Options | Click **Migrate Passwords**.<br><br>Click **Password migration source DC.** |

| | |
|---|---|
| Account Transition Options | Click **Enable target accounts**.<br><br>Click **Days until source account expires,** and then type **7** in the text box.<br><br>Click the **Migrate user SIDs to target domains** check box. |
| User Account | Type the user name, password, and domainof a user account that has administrative credentials. |
| User Options | Click the **Translate roaming profiles** check box.<br><br>Click the **Update user rights** check box.<br><br>Clear the **Migrate associated user groups** check box<br><br>Click **Fix users' group memberships**.<br><br>Click **Do not rename accounts** check box. |
| Object Property Exclusion | Clear the **Exclude specific object properties from migration** check box. |
| Naming Conflicts | Click **Replace conflicting accounts and don't migrate**.<br><br>Clear the **Remove existing user rights** check box.<br><br>Clear the **Move replaced accounts to specific target Organizational Unit** check box. |

4. When the wizard has finished, click **View Log**, and review the migration log for any errors.
5. Open Active Directory Users and Computers and verify that the user accounts exist in the appropriate OU in the target domain.

**To migrate the current batch of users by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.
2. At the command line, type:

```
ADMT USER /N "user_name1""user_name2" /SD:"source_domain"
/TD:"target_domain"  /TO:"target_OU"  [parameters]
```

You can append parameters to the command as follows:

```
ADMT USER /N "user_name1""user_name2" /SD:"source_domain"
/TD:"target_domain"  /TO:"target_OU"  /MSS:YES TRP:YES /UUR:YES
```

Alternatively, you can include parameters in an option file that is specified at the command line as follows:

```
ADMT USER /N "user_name1""user_name2" /O "option_file.txt"
```

Table 11.17 lists the common parameters used for migrating user accounts, along with the command-line parameter and option file equivalents.

**Table 11.17 Common Parameters Used for User Migrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:"`*source_domain*`"` | `SourceDomain="`*source_domain*`"` |
| Source OU location | `/SO:"`*source_OU*`"` | `SourceOU="`*source_OU*`"` |
| Target domain | `/TD:"`*target_domain*`"` | `TargetDomain="`*target_domain*`"` |
| Target OU location | `/TO:"`*target_OU*`"` | `TargetOU="`*target_OU*`"` |

| | | |
|---|---|---|
| Migrate SIDs | /MSS:YES | MigrateSIDs=YES |
| Do not rename accts | /RO:DONT *(default)* | RenameOption=DONT |
| Ignore conflicting accts and not migrate them | /CO: REPLACE+REMOVEUSERRIGHTS+MOVEREPLACEDACCOUNTS | ConflictOptions=REPLACE+REMOVEUSERRIGHTS+MOVEREPLACEDACCOUNTS |
| Translate Roaming Profile | /TRP:YES *(default)* | TranslateRoamingProfile=YES |
| Update User Rights | /UUR:NO | UpdateUserRights=NO |
| Password Options | /PO:COPY /PS:<name of PES server> | PasswordOption=COPY<br>PasswordServer=<name of server> |
| Expire accounts | /SEP:7 | SourceExpiration=7 |

3. Review the results that are displayed on the screen for any errors.
4. Open Active Directory Users and Computers and locate the target OU. Verify that the users exist in the target OU.

**To migrate the current batch of user accounts by using a script**

- Prepare a script that incorporates ADMT commands and options for migrating users by using the sample script shown in Listing 11.9.

**Listing 11.9 Migrating User Accounts in Batches Between Forests**

```
<Job id=" MigratingUserAccountsInBatchesBetweenForests" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objUserMigration

   '
   'Create instance of ADMT migration objects.
   '

   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objUserMigration = objMigration.CreateUserMigration

   '
   'Specify general migration options.
   '

   objMigration.SourceDomain = " source domain"
   objMigration.SourceOu = " source container"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " target container"
   objMigration.PasswordOption = admtCopyPassword
   objMigration.PasswordServer = " password export server name"
   objMigration.ConflictOptions = admtReplaceConflicting + _
  admtRemoveExistingUserRights + admtMoveReplacedAccounts
   '
   'Specify user migration specific options.
   '
   objUserMigration.SourceExpiration = 7
   objUserMigration.MigrateSIDs = True
```

```
    objUserMigration.TranslateRoamingProfile = True
    objUserMigration.UpdateUserRights = False
    objUserMigration.FixGroupMembership = True
    objUserMigration.MigrateServiceAccounts = False

    '
    'Migrate specified user objects.
    '

    objUserMigration.Migrate admtData, Array(" user name1" ," user name2" )

    Set objUserMigration = Nothing
    Set objMigration = Nothing
</Script>
</Job>
```

For a sample script file to assist you in creating a script to migrate user accounts, see "Migrating User Accounts in Batches Between Forests" (DSSREER_8.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating User Accounts in Batches Between Forests" on the Web at http://www.microsoft.com/reskit).

**Remigrating All Global Groups Following User Account Migration**

A large user account migration might take place over an extended period of time. For this reason, you might need to remigrate global groups from the source to the target domain after you migrate each batch of users, to reflect changes made to the membership of groups in the source domain after the initial global group migration occurred. For more information about and procedures for remigrating global groups, see "Remigrating All Global Groups After All Batches Are Migrated" later in this chapter.

# Remigrating All Global Groups After All Batches Are Migrated

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After all batches have been migrated, perform a final global group remigration to ensure that any late changes made to global group membership in the source domain are reflected in the target domain. You can remigrate global groups by using the Active Directory Migration Tool console, by using the ADMT command-line option, or by using a script.

**To remigrate global groups by using the ADMT console**

1. On the domain controller in the target domain on which ADMT installed, log on by using the ADMT account migration account.
2. Open the Active Directory Migration Tool, and then select **Group Account Migration Wizard**.
3. Complete the Group Account Migration Wizard by using the information in Table 11.18.

   **Table 11.18 Using the Group Account Migration Wizard to Remigrate Global Groups**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type the NetBIOS or DNS name of the source domain or select the name from a list.<br>In the **Target domain** box, type the NetBIOS or DNS name of the target domain.<br>If ADMT includes the names of the source and target domains, ensure that they are correct. |
| Group Selection | Click **Add**.<br>In the **Select Groups** dialog box, select all global groups, click **Add**, and then click **OK**. |
| Organizational Unit Selection | Type the name of the OU, or click **Browse**.<br>In the **Browse for Container** dialog box, locate the container in the target domain you want to move the global groups into, and then click **OK**. |
| Group Options | Click **Update user rights**.<br>Ensure that **Copy group members** is not selected**.**<br>Ensure that **Update previously migrated objects** is not selected.<br>Click **Fix membership of group**.<br>Click **Migrate Group SIDs to target domain**.<br>Click **Do not rename accounts** |
| User Account | Type the user name, password, and domain of an account that has administrative rights in the source domain. |
| Object Property Exclusion | Clear the **Exclude specific object properties from migration** check box. |
| Naming Conflicts | Click **Replace conflicting accounts** (all other options are cleared). |

4. When the wizard has finished running, click **View Log**, and review the migration log for any errors.

5. Open Active Directory Users and Computers and locate the target OU. Verify that the global groups exist in the target domain OU.

**To remigrate global groups by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.
2. At the command line, type:

```
ADMT GROUP /N "
group_name1
" "
group_name2
" [
parameters
]
```

You can append parameters to the command as follows:

```
ADMT GROUP /N "
group_name1
" "
group_name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
" /MSS:YES
```

Alternatively, you can include parameters in an option file that is specified at the command line as follows:

```
ADMT GROUP /N "
group_name1
" "
group_name2
" /O: "
option_file.txt
"
```

Table 11.19 lists the common parameters used for migrating global groups, along with the command-line parameter and option file equivalents.

**Table 11.19 Common Parameters Used for Global Group Migrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:"`*source_domain*`"` | `SourceDomain="`*source_domain*`"` |
| Source OU location | `/SO:"`*source_OU*`"` | `SourceOU="`*source_OU*`"` |
| Target domain | `/TD:"`*target_domain*`"` | `TargetDomain="`*target_domain*`"` |

| | | |
|---|---|---|
| Target OU location | /TO:"*target_OU*" | TargetOU="*target_OU*" |
| Migrate GG SIDs | /MSS:YES | MigrateSIDs=YES |
| Do not rename accts | /RO:DONT *(default)* | RenameOption=DONT |
| Ignore conflicting accts and do not migrate them | /CO:REPLACE | ConflictOptions=REPLACE |

3. Review the results that are displayed on the screen for any errors.
4. Open Active Directory Users and Computers and locate the target OU. Verify that the global groups exist in the target domain OU.

**To remigrate global groups by using a script**

- Prepare a script that incorporates ADMT commands and options for migrating global groups by using the sample script shown in Listing 11.10.

**Listing 11.10 Remigrating Global Groups Between Forests**

```
<Job id=" RemigratingGlobalGroupsBetweenForests" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objGroupMigration

   '
   'Create instance of ADMT migration objects.
   '

   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objGroupMigration = objMigration.CreateGroupMigration

   '
   'Specify general migration options.
   '

   objMigration.SourceDomain = " source domain"
   objMigration.SourceOu = " source container"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " target container"
   objMigration.ConflictOptions = admtReplaceConflicting

   '
   'Specify group migration specific options.
   '

   objGroupMigration.MigrateSIDs = True

   '
   'Migrate specified group objects.
   '

   objGroupMigration.Migrate admtData, Array(" group name1" ," group name2" )

   Set objGroupMigration = Nothing
   Set objMigration = Nothing
```

```
</Script>
</Job>
```

For a script file to assist you in creating a script to migrate global groups, see "Remigrating Global Groups Between Forests" (DSSREER_10.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Remigrating Global Groups Between Forests" on the Web at http://www.microsoft.com/reskit).

# Migrating Accounts Without Using SID History

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you are not using SID history for resource access because SID filter quarantining is in place between your forests, your migration process involves first migrating all user accounts, but not enabling them in the target domain, to prepopulate the target domain and allow migration of user profiles. Then you run security translation on all resources that the users access across forests. The next step is to migrate users in batches by migrating first the user profile, then the workstation, then the user account. Finally, you must remigrate the global groups to apply any changes made to the global groups in the source domain, and translate security in remove mode.

It is still important to migrate SID history although user accounts will not use SID history for resource access. This ensures that operations such as Offline Files continue to function within the forest. Migrating SID history does not present a security risk because SID filter quarantining is in place between the source and target forests. Before migrating all user accounts, ensure that you have created test accounts that you can use to verify the success of each batch.

Complete the following steps to migrate user accounts to the target domain:

1. Migrate all users, and use the **Fix users' group membership** option to have ADMT identify global groups in the target domain that the user belonged to in the source domain and add the user to the appropriate global group in the target domain. For this initial user migration, leave the user account enabled in source domain, and disabled in the target domain.

2. Translate security in add mode for files, shares, printers, local groups, and domain local groups.

3. Translate local user profiles for a batch of users.

4. Migrate workstations in batches that correspond to the user account batches.

5. Before migrating the batch of user accounts, verify that local profile and workstation migration succeeded for all users in the batch. Do not migrate any user account for which profile or workstation migration failed, because this will result in users overwriting their existing profiles when they log onto the target domain.

6. Remigrate user accounts in small batches with the accounts in the source domain set to expire in seven days, the target accounts enabled, password migration selected, and all attributes selected for migration.

7. After each batch, you might want to remigrate all global groups to update any group membership changes.

8. After all users are migrated, run a final global group migration to update any group membership changes

9. Translate security in remove mode for files, shared folders, printers, local groups, and domain local groups.

10. Notify users in the batch to log on to the target domain.

Until you migrate all user and group accounts, continue to administer global group membership in the source domain.

Figure 11.10 shows the steps involved in migrating accounts that are not using SID history for resources access.

**Figure 11.10 Migrating Accounts Without Using SID History**

# Migration of All User Accounts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Begin the user account migration process by migrating all users. This enables you to translate security on all files, printers, shared folders, local groups, and domain local groups to ensure that users continue to have the appropriate resource access following the migration.

**Notes**

- Built-in accounts (such as Administrators, Users, and Power Users) cannot be ADMT migration objects. Because built-in account SIDs are identical in every domain, migrating these accounts to a target domain results in duplicate SIDs in a single domain. Every SID in a forest must be unique.

- Well-known accounts (such as Domain Admins and Domain Users) also cannot be ADMT migration objects.

The ADMT user account migration process includes the following steps:

1. ADMT reads the attributes of the source user objects.

2. ADMT creates a new user object in the target domain and a new primary SID for the new user account.

3. ADMT adds the original SID of the user account to the SID history attribute of the new user account.

4. ADMT migrates the password for the user account.

5. If ADMT identifies global groups in the target domain that the migrated users belonged to in the source domain, the tool adds the users to the appropriate global groups in the target domain.

During the migration, audit events are logged in both the source and the target domains.

You can migrate user accounts by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To migrate user accounts by using the ADMT console**

1. On the domain controller in the target domain on which you installed ADMT, log on by using the ADMT account migration account.
2. Open the Active Directory Migration Tool, and then select **User Account Migration Wizard**.
3. Complete the User Account Migration Wizard by using the information in Table 11.20.

**Table 11.20 Using the User Account Migration Wizard to Migrate User Accounts**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type or select the name of the source domain.<br>In the **Target domain** box, type or select the name of the target domain. |
| User Selection | Click **Add**.<br>In the **Select Users** dialog box, select all user accounts, and then click **Add**. By default, the wizard migrates the accounts to the Users OU. Click **Do Not Migrate Passwords** (use complex passwords).<br>Click **OK**. |

| | |
|---|---|
| Organizational Unit Selection | Ensure that ADMT lists the correct target OU. If it is not correct, type the correct OU or click **Browse**.<br>In the **Browse for Container** dialog box, locate the target domain **Users** container or appropriate OU, and then click **OK**. |
| Password Options | Click **Do NotMigrate Passwords**.<br>Click **Complex Passwords**. |
| Account Transition Options | Click **Disable target accounts**.<br>Click **Enable source account**.<br>Click the **Migrate user SIDs to target domains** check box. |
| User Account | Type the user name, password, and domain of a user account that has administrative credentials. |
| User Options | Click the **Translate roaming profiles** check box.<br>Click the **Update user rights** check box.<br>Clear the **Migrate associated user groups** check box.<br>Click **Fix users' group membership**.<br>Select the **Do not rename accounts** check box. |
| Object Property Exclusion | Clear the **Exclude specific object properties from migration** check box. |

4. When the wizard finishes, click **View Log**, and review the migration log for any errors.
5. Open Active Directory Users and Computers and verify that the user accounts exist in the appropriate OU in the target domain.

**To migrate user accounts by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.
2. At the command line, type:

```
ADMT USER /N "user_name1" "user_name2" /SD:"source_domain"
/TD:"target_domain" /TO:"target_OU"  [parameters]
```

You can append parameters to the command as follows:

```
ADMT USER /N "user_name1" "user_name2" /SD:"source_domain"
/TD:"target_domain" /TO:"target_OU" /MSS:YES TRP:YES /UUR:YES
```

Alternatively, you can include parameters in an option file that is specified at the command line as follows:

```
ADMT USER /N "user_name1" "user_name2" /O "option_file.txt"
```

Table 11.21 lists the common parameters used for migrating user accounts, along with the command-line parameter and option file equivalents.

**Table 11.21 Common Parameters Used for User Migrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|

| | | |
|---|---|---|
| Source domain | /SD:"*source_domain*" | SourceDomain="*source_domain*" |
| Source OU location | /SO:"*source_OU*" | SourceOU="*source_OU*" |
| Target domain | /TD:"*target_domain*" | TargetDomain="*target_domain*" |
| Target OU location | /TO:"*target_OU*" | TargetOU="*target_OU*" |
| Migrate SIDs | /MSS:YES | MigrateSIDs=YES |
| Do not rename accts | /RO:DONT *(default)* | RenameOption=DONT |
| Ignore conflicting accts and not migrate them | /CO:IGNORE *(default)* | ConflictOptions=IGNORE |
| Translate Roaming Profile | /TRP:YES *(default)* | TranslateRoamingProfile=YES |
| Update User Rights | /UUR:YES | UpdateUserRights=YES |
| Password Options | /PO:COMPLEX | PasswordOption=COMPLEX |

3. Review the results that are displayed on the screen for any errors.
4. Open Active Directory Users and Computers and locate the target OU. Verify that the users exist in the target OU.

**To migrate user accounts by using a script**

- Prepare a script that incorporates ADMT commands and options for migrating users.

  For a sample script file to assist you in creating a script to migrate all user accounts, see "Migrating All User Accounts Between Forests" (DSSREER_6.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating All User Accounts Between Forests" on the Web at http://www.microsoft.com/reskit).

# Translating Security in Add Mode

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Translate security on servers to add the SIDs of the user and group accounts in the target domain to the ACLs of the resources. After objects are migrated to the target domain, the objects contain the ACL entries from both the source and the target domains. Use the Security Translation Wizard in ADMT to add the target domain SIDs from the migrated objects. Run the Security Translation Wizard on all files, shares, printers, local groups, and at least one domain controller (to translate security on shared local groups).

You can translate security in add mode on objects by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To translate security in add mode on objects by using the ADMT console**

1. On the domain controller in the target domain on which you installed ADMT, log on by using the ADMT account migration account.

2. Open the Active Directory Migration Tool, and then select **Security Translation Wizard**.

3. Complete the Security Translation Wizard by using the information in Table 11.22.

**Table 11.22 Using the ADMT Security Translation Wizard in Add Mode**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Security Translation Options | Click **Previously migrated objects**. |
| Domain Selection | In the **Source domain** box, type or select the name of the source account domain.<br>In the **Target domain** box, type or select the name of the target domain. |
| Translate Objects | Clear the **User Profiles** check box.<br>Select all other check boxes. |
| Security Translation Options | Click **Add**. |

**To translate security in add mode on objects by using a script**

- Prepare a script that incorporates ADMT commands and options for translating security in add mode on objects by using the sample script shown in Listing 11.11.

**Listing 11.11 Translating Security in Add Mode on Objects Between Forests**

```
<Job id=" TranslatingSecurityInAddModeOnObjectsBetweenForests" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objSecurityTranslation

   '
   'Create instance of ADMT migration objects.
   '
```

```
   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objSecurityTranslation = objMigration.CreateSecurityTranslation

   '
   'Specify general migration options.
   '

   objMigration.SourceDomain = " source domain"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " Computers"

   '
   'Specify security translation specific options.
   '

   objSecurityTranslation.TranslationOption = admtTranslateAdd
   objSecurityTranslation.TranslateFilesAndFolders = True
   objSecurityTranslation.TranslateLocalGroups = True
   objSecurityTranslation.TranslatePrinters = True
   objSecurityTranslation.TranslateRegistry = True
   objSecurityTranslation.TranslateShares = True
   objSecurityTranslation.TranslateUserProfiles = False
   objSecurityTranslation.TranslateUserRights = True

   '
   'Perform security translation on specified computer objects.
   '

   objSecurityTranslation.Translate admtData, _
  Array(" computer name1" ," computer name2" )

   Set objSecurityTranslation = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a sample script file to assist you in creating a script to translate security in add mode on objects, see "Translating Security in Add Mode on Objects Between Forests" (DSSREER_11.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Translating Security in Add Mode on Objects Between Forests" on the Web at http://www.microsoft.com/reskit).

# Remigration of User Accounts and Workstations in Batches

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Remigrating user accounts and workstations in batches helps you track the migration process. For each batch of users, first translate local user profiles, and then migrate workstations. Verify that the profile and workstation migration succeeded, and then migrate the user accounts. Remigrate global groups after each batch.

**Translating Local User Profiles**
ADMT only translates profiles for computers running Windows NT 4.0, Windows 2000, Windows XP, or Windows Server 2003.

Local profiles are translated in replace mode because if you perform the profile translation in add mode, software installation by means of software deployment Group Policies might not work. Any application that is packaged with Windows Installer version 2.0 (which is used on workstations running Windows 2000 SP3 or later, Windows XP SP1 or later, or many common software packages) might not function after the profile is translated. When the ADMT Security Translation Wizard is translating local profiles in replace mode, it reverts to add mode if a profile is locked. This might result in a successful profile translation; however, application installations might not function after the profile is translated.

Before you start the local user profile translation, allow enough time for the workstations to restart after you move them to the target domain. Allow for the ADMT time delay factor (one minute) plus the time required for a restart cycle for your workstations.

| **Note** |
| --- |
| Translate the local user profiles the night before you notify the users to log on by using their new accounts in the target domain. Migrating profiles the night before ensures that the new user profile reflects the most current user settings. |

You can translate local user profiles by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To translate local user profiles by using the ADMT console**

1. For each workstation in the source domain that is running Windows NT 4.0, Windows 2000, or Windows XP, add the ADMT resource migration account to the local Administrators group.
2. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.
3. Open the Active Directory Migration Tool, and then select **Security Translation Wizard**.
4. Complete the Security Translation Wizard by using the information in Table 11.23.

   **Table 11.23 Using the Security Translation Wizard to Translate Local User Profiles**

   | Wizard Page | Action |
   | --- | --- |
   | Test or Make Changes | Click **Migrate Now?** |
   | Security Translation Options | Click **Previously migrated objects**. |
   | Domain Selection | In the **Source domain** box, type or select the name of the source account domain.<br>In the **Target domain** box, type or select the name of the target domain. |
   | Translate Objects | Click **User Profiles**. |
   | Security Translation Options | Click **Replace**. |

5. When the wizard has finished running on all computers, click **View Log** and review the dispatch log for any errors.
6.

**To translate local user profiles by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.
2. At the command line, type:

```
ADMT SECURITY /N "
computer_name1
" "
computer_name2
```

```
" [
parameters
]
```

You can append parameters to the command as follows:

```
ADMT SECURITY /N "
computer_name1
" "
computer_name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TOT:REPLACE /TUP:YES
```

Alternatively, you can include parameters in an option file that is specified at the command line as follows:

```
ADMT SECURITY /N "
computer_name1
" "
computer_name2
" /O:"
option_file.txt
"
```

Table 11.24 lists the common parameters used for migrating user accounts, along with the command-line parameter and option file equivalents.

**Table 11.24 Common Parameters Used for Local User Profile Migrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:"`*source_domain*`"` | `SourceDomain="`*source_domain*`"` |
| Target domain | `/TD:"`*target_domain*`"` | `TargetDomain="`*target_domain*`"` |
| Translate option = REPLACE | `/TOT:REPLACE` | `TranslateOption=REPLACE` |
| Modify local user profile security | `/TUP:YES` | `TranslateUserProfiles=YES` |

3. Review the results that are displayed in the dispatch log for any errors.

**To translate local user profiles by using a script**

- Prepare a script that incorporates ADMT commands and options for translating local user profiles.

  For a sample script to assist you in translating local user profiles, see "Translating Local User Profiles Between Forests" (DSSREER_7.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Translating Local User Profiles Between Forests" on the Web at http://www.microsoft.com/reskit).

**To translate local user profiles by using a script**

**Migrating Workstations in Batches**

After you migrate a batch of local user profiles, migrate the corresponding batch of user workstations. When you move workstations between domains, the SAM database moves along with them. Accounts located in the local SAM database (such as local groups) that are used to enable access to resources always move with the computer, and therefore do not need to be migrated.

**Note**

- Use a low value in the ADMT computer restart option, to restart workstations immediately after joining them to the target domain, or as soon as possible thereafter. Resources that are not restarted following migration are in an indeterminate state.

You can migrate workstations by using the Active Directory Migration Tool console, by using the ADMT command-line option, or by using a script.

**To migrate workstations by using the ADMT console**

1. On the domain controller in the target domain on which you installed ADMT, log on by using the ADMT resource migration account.
2. Open the Active Directory Migration Tool, and then select **Computer Account Migration Wizard**.
3. Complete the Computer Account Migration Wizard by using the information in Table 11.25.

**Table 11.25 Using the Computer Account Migration Wizard to Migrate Workstations**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type or select the name of the source domain.<br><br>In the **Target domain** box, type or select the name of the target domain. |
| Computer Selection | Click **Add**.<br><br>In the **Select Computers** dialog box, select the names of the workstations, click **Add**, and then click **OK**. |
| Organizational Unit Selection | Click **Browse**.<br><br>In the **Browse for Container** dialog box, locate the target domain **Computers** container, and then click **OK**. |
| Security Translation Options | Click the **Local groups** check box.<br><br>Click the **User rights** check box. |
| Translate Objects | Click **Add**. |
| Computer Options | In the **Minutes before computer restart after wizard completion** box, type **1**. |
| Naming Conflicts | Click **Ignore conflicting accounts and don't migrate**. |

4. When the wizard has finished running on all computers, click **View Log** and review the migration log and dispatch log for any errors.
5. If errors are reported, run the Retry Wizard to dispatch agents to workstations for which the migration process failed.
6. Open Active Directory Users and Computers and verify that the workstations exist in the appropriate OU in the target domain.

**To migrate workstations by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT installed, log on by using the ADMT resource migration account.
2. At the command line, type:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
" [
parameters
]
```

You can append parameters to the command as follows:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" /SD:"
```

```
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
" /RDL:1
```

Alternatively, you can include parameters in an option file that is specified at the command line as follows:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" /O "
option_file.txt
"
```

Table 11.26 lists the common parameters used for workstation migration, along with the command-line parameter and option file equivalents.

**Table 11.26 Common Parameters Used for Workstation Migrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:"`*source_domain*`"` | `SourceDomain="`*source_domain*`"` |
| Source OU location | `/SO:"`*source_OU*`"` | `SourceOU="`*source_OU*`"` |
| Target domain | `/TD:"`*target_domain*`"` | `TargetDomain="`*target_domain*`"` |
| Target OU location | `/TO:"`*target_OU*`"` | `TargetOU="`*target_OU*`"` |
| • Restart computer one minute after wizard completes | `/RDL:1` | `RestartDelay=1` |
| • Do not rename accounts | `/RO:DONT` *(default)* | `RenameOption=DONT` |
| • Ignore conflicting accounts and do not migrate them | `/CO:IGNORE` *(default)* | `ConflictOptions=IGNORE` |
| • Translate Option | `/TOT:ADD` | `TranslateOption=YES` |
| • Translate User Rights | `/TUR:YES` | `TranslateUserRights=YES` |
| • Translate Local Groups | `/TLG:YES` | `TranslateLocalGroups=YES` |

3. Review the results that are displayed on the screen for any errors.
4. Open Active Directory Users and Computers and locate the target OU. Verify that the workstations exist in the target OU.

**To migrate workstations by using a script**

- Prepare a script that incorporates ADMT commands and options for migrating workstations.

  For a sample script file to assist you in migrating workstations between forests, see "Migrating Workstations Between Forests" (DSSREER_9.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating Workstations Between Forests" on the Web at http://www.microsoft.com/reskit).

**Remigrating User Accounts in Batches**

After you have verified the success of local user profile and user workstation migration for the user batch, migrate the user accounts for that batch. You can migrate user accounts in batches by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To remigrate the current batch of user accounts by using the ADMT console**

1. On the domain controller in the target domain on which you installed ADMT, log on by using the ADMT account migration account.
2. Open the Active Directory Migration Tool, and then select **User Account Migration Wizard**.
3. Complete the User Account Migration Wizard by using the information in Table 11.27.

**Table 11.27 Using the User Account Migration Wizard to Migrate User Accounts**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type or select the name of the source domain.<br><br>In the **Target domain** box, type or select the name of the target domain. |
| User Selection | Click **Add**.<br><br>In the **Select Users** dialog box, select the user accounts that you want to migrate, and then click **Add**. By default, the wizard migrates the accounts to the Users container. If you need to change the OU, click **Location**, and then find the OU that contains the accounts.<br><br>Click **Migrate Passwords**.<br><br>Click **OK**. |
| Organizational Unit Selection | Ensure that ADMT lists the correct target OU. If it is not correct, type the correct OU or click **Browse**.<br><br>In the **Browse for Container** dialog box, locate the target domain **Users** container or appropriate OU, and then click **OK**. |
| Password Options | Click **Migrate Passwords**.<br><br>Select **Password migration source DC** from the drop-down list box. |
| Account Transition Options | Click **Enable target accounts**.<br><br>Click **Days until source account expires,** and then type **7** in the text box.<br><br>Click the **Migrate user SIDs to target domains** check box. |
| User Account | Type the user name, password, and domain of a user account that has administrative credentials. |
| User Options | Click the **Translate roaming profiles** check box.<br><br>Click the **Update user rights** check box.<br><br>Click the **Migrate associated user groups** check box.<br><br>Click **Fix users' group memberships**.<br><br>Click **Do not rename accounts**. |
| Object Property Exclusion | Clear the **Exclude specific object properties from migration** check box. |

4. When the wizard finishes, click **View Log**, and review the migration log for any errors.
5. Open Active Directory Users and Computers and verify that the user accounts exist in the appropriate OU in the target domain.

**To remigrate the current batch of users by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.
2. At the command line, type:

```
ADMT USER /N "user_name1""user_name2" /SD:"source_domain"
```

```
/TD:"target_domain" /TO:"target_OU"  [parameters]
```

You can append parameters to the command as follows:

```
                ADMT USER /N "user_name1""user_name2" /SD:"source_domain"
/TD:"target_domain"  /TO:"target_OU" /MSS:YES TRP:YES /UUR:YES
```

Alternatively, you can include parameters in an option file that is specified at the command line as follows:

```
                ADMT USER /N "user_name1""user_name2" /O "option_file.txt"
```

Table 11.28 lists the common parameters used for migrating user accounts, along with the command-line parameter and option file equivalents.

**Table 11.28 Common Parameters Used for User Migrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:"`*source_domain*`"` | `SourceDomain="`*source_domain*`"` |
| Source OU location | `/SO:"`*source_OU*`"` | `SourceOU="`*source_OU*`"` |
| Target domain | `/TD:"`*target_domain*`"` | `TargetDomain="`*target_domain*`"` |
| Target OU location | `/TO:"`*target_OU*`"` | `TargetOU="`*target_OU*`"` |
| Migrate SIDs | `/MSS:YES` | `MigrateSIDs=YES` |
| Do not rename accts | `/RO:DONT` *(default)* | `RenameOption=DONT` |
| Ignore conflicting accts and not migrate them | `/CO: REPLACE+REMOVEUSERRIGHTS+MOVEREPLACEDACCOUNTS` | `ConflictOptions=REPLACE+REMOVEUSERRIGHTS+MOVEREPLACEDACCOUNTS` |
| Translate Roaming Profile | `/TRP:YES` *(default)* | `TranslateRoamingProfile=YES` |
| Update User Rights | `/UUR:YES` | `UpdateUserRights=YES` |
| Password Options | `/PO:COPY /PS:`<name of PES server> | `PasswordOption=copy`<br>`PasswordServer=`<name of server> |
| Expire accounts | `/SEP:7` | `SourceExpiration=7` |

3. Review the results that are displayed on the screen for any errors.
4. Open Active Directory Users and Computers and locate the target OU. Verify that the users exist in the target OU.

**To remigrate the current batch of user accounts by using a script**

- Prepare a script that incorporates ADMT commands and options for migrating users by using the sample script shown in Listing 11.12.

**Listing 11.12 Remigrating User Accounts in Batches Between Forests**

```
 <Job id=" RemigratingUserAccountsInBatchesBetweenForests" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit
```

```
    Dim objMigration
    Dim objUserMigration

    '
    'Create instance of ADMT migration objects.
    '

    Set objMigration = CreateObject(" ADMT.Migration" )
    Set objUserMigration = objMigration.CreateUserMigration

    '
    'Specify general migration options.
    '

    objMigration.SourceDomain = " source domain"
    objMigration.SourceOu = " source container"
    objMigration.TargetDomain = " target domain"
    objMigration.TargetOu = " target container"
    objMigration.PasswordOption = admtCopyPassword
    objMigration.PasswordServer = " password export server name"
    objMigration.ConflictOptions = admtReplaceConflicting

    '
    'Specify user migration specific options.
    '
    objUserMigration.SourceExpiration = 7
    objUserMigration.MigrateSIDs = True
    objUserMigration.TranslateRoamingProfile = True
    objUserMigration.UpdateUserRights = True
    objUserMigration.FixGroupMembership = True
    objUserMigration.MigrateServiceAccounts = False

    '
    'Migrate specified user objects.
    '

    objUserMigration.Migrate admtData, Array(" user name1" ," user name2" )

    Set objUserMigration = Nothing
    Set objMigration = Nothing
</Script>
</Job>
```

For a sample script file to assist you in creating a script to migrate user accounts, see "Remigrating User Accounts in Batches Between Forests" (DSSREER_12.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Remigrating User Accounts in Batches Between Forests" on the Web at http://www.microsoft.com/reskit).

**Remigrating All Global Groups Following User Account Migration**

A large user account migration might take place over an extended period of time. For this reason, you might need to remigrate global groups from the source to the target domain after you migrate each batch of users, to reflect changes made to the membership of groups in the source domain after the initial global group migration occurred. For more information about and procedures for remigrating global groups, see "Remigrating All Global Groups After All Batches Are Migrated" later in this chapter.

# Remigration of All Global Groups After All Batches Are Migrated

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Remigrating All Global Groups After All Batches Are Migrated**

After all batches have been migrated, perform a final global group remigration to ensure that any late changes made to global group membership in the source domain are reflected in the target domain. You can remigrate global groups by using the Active Directory Migration Tool console, by using the ADMT command-line option, or by using a script.

**To remigrate global groups by using the ADMT console**

1. On the domain controller in the target domain on which ADMT installed, log on by using the ADMT account migration account.
2. Open the Active Directory Migration Tool, and then select **Group Account Migration Wizard**.
3. Complete the Group Account Migration Wizard by using the information in Table 11.29.

**Table 11.29 Using the Group Account Migration Wizard to Remigrate Global Groups**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type the NetBIOS or DNS name of the source domain or select the name from a list.<br><br>In the **Target domain** box, type the NetBIOS or DNS name of the target domain.<br><br>If ADMT includes the names of the source and target domains, ensure that they are correct. |
| Group Selection | Click **Add**.<br><br>In the **Select Groups** dialog box, select all global groups, click **Add**, and then click **OK**. |
| Organizational Unit Selection | Type the name of the OU or click **Browse**.<br><br>In the **Browse for Container** dialog box, locate the container in the target domain you want to move the global groups into, and then click **OK**. |
| Group Options | Click **Update user rights**.<br><br>Ensure that **Copy group members** is not selected**.**<br><br>Ensure that **Update previously migrated objects** is not selected.<br><br>Click **Fix membership of group**.<br><br>Click **Migrate Group SIDs to target domain**.<br><br>Click **Do not rename accounts** |
| User Account | Type the user name, password, and domain of an account that has administrative rights in the source domain. |
| Object Property Exclusion | Clear **Exclude specific object properties from migration**. |
| Naming Conflicts | Click **Replace conflicting accounts**. Clear all other options. |

4. When the wizard has finished running, click **View Log**, and review the migration log for any errors.

5. Open Active Directory Users and Computers and locate the target OU. Verify that the global groups exist in the target domain OU.

**To remigrate global groups by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT is installed, log on by using the ADMT account migration account.

2. At the command line, type:

```
ADMT GROUP /N "
group_name1
" "
group_name2
" [
parameters
]
```

You can append parameters to the command as follows:

```
ADMT GROUP /N "
group_name1
" "
group_name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
" /MSS:YES
```

Alternatively, you can include parameters in an option file that is specified at the command line as follows:

```
ADMT GROUP /N "
group_name1
" "
group_name2
" /O:"
option_file.txt
"
```

Table 11.30 lists the common parameters used for migrating global groups, along with the command-line parameter and option file equivalents.

**Table 11.30 Common Parameters Used for Global Group Migrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:"`*source_domain*`"` | `SourceDomain="`*source_domain*`"` |
| Target domain | `/TD:"`*target_domain*`"` | `TargetDomain="`*target_domain*`"` |
| Target OU location | `/TO:"`*target_OU*`"` | `TargetOU="`*target_OU*`"` |
| Migrate GG SIDs | `/MSS:YES` | `MigrateSIDs=YES` |

| | | |
|---|---|---|
| Do not rename accts | `/RO:DONT` *(default)* | `RenameOption=DONT` |
| Ignore conflicting accts and do not migrate them | `/CO:REPLACE` | `ConflictOptions=REPLACE` |

3. Review the results that are displayed on the screen for any errors.

4. Open Active Directory Users and Computers and locate the target OU. Verify that the global groups exist in the target domain OU.

**To remigrate global groups by using a script**

- Prepare a script that incorporates ADMT commands and options for migrating global groups.

  For a script file to assist you in creating a script to remigrate global groups, see "Remigrating Global Groups Between Forests" (DSSREER_10.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Remigrating Global Groups Between Forests" on the Web at http://www.microsoft.com/reskit).

# Translating Security in Remove Mode

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Translate security on objects to remove the SIDs of the accounts in the source domain from the ACLs of the migrated objects. Do this only after all of the source accounts are disabled. Run the Security Translation Wizard on all files, shared folders, printers, and local groups, and at least one domain controller (to translate security on shared local groups).

You can translate security in remove mode on objects by using the ADMT console or by using a script.

**To translate security in remove mode on objects by using the ADMT console**

1. On the domain controller in the target domain on which you installed ADMT, log on by using the ADMT account migration account.

2. Open the Active Directory Migration Tool, and then select **Security Translation Wizard**.

3. Complete the Security Translation Wizard by using the information in Table 11.31.

**Table 11.31 Using the ADMT Security Translation Wizard in Remove Mode**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Security Translation Options | Click **Previously migrated objects**. |
| Domain Selection | In the **Source domain** box, type or select the name of the source account domain.<br>In the **Target domain** box, type or select the name of the target domain. |
| Translate Objects | Clear the **User Profiles** check box.<br>Select all the other check boxes. |
| Security Translation Options | Click **Remove**. |

**To translate security in remove mode on objects by using a script**

- Prepare a script that incorporates ADMT commands and options for translating security in remove mode on objects by using the sample script shown in Listing 11.13.

**Listing 11.13 Translating Security in Remove Mode on Objects Between Forests**

```
<Job id=" TranslatingSecurityInRemoveModeOnObjectsBetweenForests" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration

```

For a sample script file to assist you in creating a script to translate security in remove mode on objects, see "Translating Security in Remove Mode on Objects Between Forests" (DSSREER_13.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Translating Security in Remove Mode on Objects Between Forests" on the Web at http://www.microsoft.com/reskit).

# Migrating Resources

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The process of migrating resources between Active Directory domains in different forests involves completing the migration of workstation accounts, member servers, and domain controllers. When you have successfully migrated all resource objects to the target domain, you can decommission the source domain.

Figure 11.11 shows the process for migrating resource objects between Active Directory domains in different forests.

**Figure 11.11 Migrating Resources Between Active Directory Domains in Different Forests**

# Migration of Workstations and Member Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Migrate remaining workstations that you did not migrate during the user account migration process, along with member servers, in small batches of up to 100 computers. Workstation account and member server migration is a straightforward process. Workstations and member servers have their own SAM account database. When you move workstations and member servers between domains, the database moves along with them. Accounts located in the local SAM database (such as local groups) that are used to enable access to resources always move with the computer, and therefore do not need to be migrated. Because the migration requires that workstations and member servers restart, it is important to schedule the migration for a time when the server is not servicing requests.

**Note**

- Use a low value in the ADMT computer restart option, to restart member servers immediately after joining them to the target domain, or as soon as possible thereafter. Resources that are not restarted following migration are in an indeterminate state.

You can migrate member servers by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To migrate workstations and member servers by using the ADMT console**

1. On the domain controller in the target domain on which you installed ADMT, log on by using the ADMT resource migration account.
2. Open the Active Directory Migration Tool, and then select **Computer Account Migration Wizard**.
3. Complete the Computer Account Migration Wizard by using the information in Table 11.32.

**Table 11.32 Using the Computer Account Migration Wizard to Migrate Workstations and Member Servers**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type or select the name of the source domain.<br>In the **Target domain** box, type or select the name of the target domain. |
| Computer Selection | Click **Add**.<br>In the **Select Computers** dialog box, select the names of all of the workstations and member servers in the source domain that you want to migrate, click **Add**, and then click **OK**. |
| Organizational Unit Selection | Click **Browse**.<br>In the **Browsefor Container** dialog box, locate the target domain **Computers** container, or the appropriate OU, and then click **OK**. |
| Security Translation Options | Click the **Local groups** check box.<br>Click the **User rights** check box. |
| Translate Objects | Click **Add**. |
| Computer Options | In the **Minutes before computer restart after wizard completion** box, type **1**. |

| | |
|---|---|
| Naming Conflicts | Click **Ignore conflicting accounts and don't migrate**. |

4. When the wizard has finished running on all computers, click **View Log** and review the migration log and dispatch log for any errors.
5. If errors are reported, run the Retry Wizard to dispatch agents to workstations and member servers for which the migration process failed.
6. Open Active Directory Users and Computers and verify that the workstations and member servers exist in the appropriate OU in the target domain.

**To migrate workstations and member servers by using the ADMT command-line option**

1. On the domain controller in the target domain on which ADMT installed, log on by using the ADMT resource migration account.
2. At the command line, type:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
" [
parameters
]
```

You can append parameters to the command as follows:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" /SD:"
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
" /RDL:1
```

Alternatively, you can include parameters in an option file that is specified at the command line as follows:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" /O "
option_file.txt
"
```

Table 11.33 lists the common parameters used for workstation and member server migration, along with the command-line parameter and option file equivalents.

**Table 11.33 Common Parameters Used for Workstation and Member Server Migrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Source domain | `/SD:"`*source_domain*`"` | `SourceDomain="`*source_domain*`"` |
| Target domain | `/TD:"`*target_domain*`"` | `TargetDomain="`*target_domain*`"` |
| Target OU location | `/TO:"`*target_OU*`"` | `TargetOU="`*target_OU*`"` |
| • Restart computer one minute after wizard completes | `/RDL:1` | `RestartDelay=1` |
| • Do not rename accounts | `/RO:DONT` *(default)* | `RenameOption=DONT` |
| • Ignore conflicting accounts and do not migrate them | `/CO:IGNORE` *(default)* | `ConflictOptions=IGNORE` |
| • Translate Option | `/TOT:ADD` | `TranslateOption=YES` |
| • Translate User Rights | `/TUR:YES` | `TranslateUserRights=YES` |
| • Translate Local Groups | `/TLG:YES` | `TranslateLocalGroups=YES` |

3. Review the results that are displayed on the screen for any errors.
4. Open Active Directory Users and Computers and locate the target OU. Verify that the workstations and member servers exist in the target OU.

**To migrate workstations and member servers by using a script**

- Prepare a script that incorporates ADMT commands and options for migrating workstations and member servers by using the sample script shown in Listing 11.14.

**Listing 11.14 Migrating Workstations or Member Servers Between Forests**

```
<Job id=" MigratingWorkstationsMemberServersBetweenForests" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objComputerMigration

   '
   'Create instance of ADMT migration objects.
   '

   Set objMigration = CreateObject(" ADMT.Migration" )
```

```
   Set objComputerMigration = objMigration.CreateComputerMigration

   '
   'Specify general migration options.
   '

   objMigration.SourceDomain = " source domain"
   objMigration.SourceOu = " Computers"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " Computers"

   '
   'Specify computer migration specific options.
   '
   objComputerMigration.TranslationOption = admtTranslateAdd
   objComputerMigration.TranslateLocalGroups = True
   objComputerMigration.TranslateUserRights = True
   objComputerMigration.RestartDelay = 1

   '
   'Migrate computer objects on specified computer objects.
   '

   objComputerMigration.Migrate admtData, _
  Array(" computer name1" ," computer name2" )

   Set objComputerMigration = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a script file to assist you in creating a script to migrate member servers, see "Migrating Workstations or Member Servers Between Forests" (DSSREER_14.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating Workstations or Member Servers Between Forests" on the Web at http://www.microsoft.com/reskit).

# Migrating Domain and Shared Local Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Shared local groups are local groups in Windows NT 4.0 and Active Directory domains that can be used in ACLs on domain controllers. When a domain is configured to operate either in Windows 2000 native mode or at the Windows Server 2003 domain functional level, shared local groups are automatically changed to domain local groups. These groups can then be used in ACLs on member servers and workstations. If either domain local groups or shared local groups are used in ACLs on either domain controllers or member servers, then they need to be migrated to the target domain before the server is migrated.

Note that it is not necessary to change any ACLs as part of the migration process. The ACLs continue to reference the domain local groups or shared local groups in the source domain. Because the domain local groups or shared local groups can be migrated to the target domain while using SID history, users maintain access to the resources. ADMT retains the membership of the local group during the migration.

You can migrate domain or shared local groups by using the ADMT console or by using a script.

**To migrate domain and shared local groups by using the ADMT console**

1. On the domain controller in the target domain on which you installed ADMT, log on by using the ADMT resource migration account.

2. Open the Active Directory Migration Tool, and then select **Group Account Migration Wizard**.

3. Complete the Group Account Migration Wizard by using the information in Table 11.34.

   **Table 11.34 Using the Group Account Migration Wizard to Migrate Domain and Shared Local Groups**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type the NetBIOS or DNS name of the source domain or select the name from a list.<br><br>In the **Target domain** box, type the NetBIOS or DNS name of the target domain. |
| Group Selection | Click **Add**.<br><br>In the **Select Groups** dialog box, select all domain and shared local groups that you need to migrate (except built-in groups), click **Add**, and then click **OK**. |
| Organizational Unit Selection | Type the name of the OU or click **Browse**.<br><br>In the **Browse for Container** dialog box, locate the container in the target domain to which the local groups are migrating, and then click **OK**. |
| Group Options | Click **Migrate Group SIDs to target domain**.<br><br>Click **Do not rename accounts**<br><br>Ensure that all other options are not selected. |
| User Account | Type the user name, password, and domainof an account that has administrative rights in the source domain. |
| Naming Conflicts | Click **Ignore conflicting accounts and don't migrate**. |

4. When the wizard has finished running, click **View Log**. Review the migration log for any errors.

5. Open Active Directory Users and Computers, locate the target OU, and then verify that the shared local groups exist in

the target domain OU.

**To migrate domain and shared local groups by using a script**

- Prepare a script that incorporates ADMT commands and options for migrating domain and shared local groups by using the sample script shown in Listing 11.15.

**Listing 11.15 Migrating Domain and Shared Local Groups Between Forests**

```
<Job id=" MigratingDomainAndSharedLocalGroupsBetweenForests" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objGroupMigration

   '
   'Create instance of ADMT migration objects.
   '

   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objGroupMigration = objMigration.CreateGroupMigration

   '
   'Specify general migration options.
   '

   objMigration.SourceDomain = " source domain"
   objMigration.SourceOu = " source container"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " target container"

   '
   'Specify group migration specific options.
   '

   objGroupMigration.MigrateSIDs = True

   '
   'Migrate specified group objects.
   '

   objGroupMigration.Migrate admtData, _
  Array(" local group name1" ," local group name2" )

   Set objGroupMigration = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a script file to assist you in creating a script to migrate domain and shared local groups, see "Migrating Domain and Shared Local Groups Between Forests" (DSSREER_15.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating Domain and Shared Local Groups Between Forests" on the Web at http://www.microsoft.com/reskit).

# Migration of Domain Controllers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In Active Directory, domain controllers can be migrated between domains. To do this, you must remove Active Directory from the domain controller, migrate it as a member server to the target domain, and then reinstall Active Directory. Note that if the server is running Windows 2000, you cannot install Active Directory in the target domain if the target domain is already at the Windows Server 2003 functional level. In this case, you must upgrade the server to Windows Server 2003 before installing Active Directory.

# Completing the Migration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you migrate all accounts and resources from the source to the target domain, complete the restructuring process by doing the following:

- Transferring the administration of user and group accounts from the source to the target domain.
- Ensuring that at least two domain controllers continue to operate in the source domain until the resource migration process is complete.
- Backing up the two domain controllers in the source domain.

Figure 11.12 shows the process for completing the migration of Active Directory domains between forests.

**Figure 11.12 Completing the Migration of Active Directory Domains Between Forests**

# Translating Security on Your Member Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Translate security on member servers to clean up the ACLs of the resources. After objects are migrated to the target domain, resources contain the ACL entries of the source domain objects. If you are using SID history to provide access to resources during the migration, the SIDs from the source domain remain in the ACLs to enable users to access resources while the migration is in progress. After the migration is complete, the SIDs from the source domain are no longer needed. Use the Security Translation Wizard in ADMT to replace the source domain SIDs with the target domain SIDs.

You do not need to perform this procedure if you are not using SID history for resource access because you should have already run security translation in remove mode after the user migration.

**To translate security on member servers**

1. On the domain controller in the target domain on which you installed ADMT, log on by using the ADMT account migration account.

2. Open the Active Directory Migration Tool, and then select **Security Translation Wizard**.

3. Complete the Security Translation Wizard by using the information in Table 11.35.

**Table 11.35 Using the ADMT Security Translation Wizard**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Security Translation Options | Click **Previously migrated objects**. |
| Domain Selection | In the **Source domain** box, type or select the name of the source account domain.<br><br>In the **Target domain** box, type or select the name of the target domain. |
| Translate Objects | Clear the **User Profiles** check box.<br><br>Select all other options. |
| Security Translation Options | Click **Replace**. |

**To translate security on member servers by using a script**

- Prepare a script that incorporates ADMT commands and options for translating security on member servers by using the sample script shown in Listing 11.16.

**Listing 11.16 Translating Security on Member Servers Between Forests**

```
<Job id=" TranslatingSecurityOnMemberServersBetweenForests" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objSecurityTranslation

   '
   'Create instance of ADMT migration objects.
   '
```

```
   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objSecurityTranslation = objMigration.CreateSecurityTranslation

   '
   'Specify general migration options.
   '

   objMigration.SourceDomain = " source domain"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " Computers"

   '
   'Specify security translation specific options.
   '

   objSecurityTranslation.TranslationOption = admtTranslateReplace
   objSecurityTranslation.TranslateFilesAndFolders = True
   objSecurityTranslation.TranslateLocalGroups = True
   objSecurityTranslation.TranslatePrinters = True
   objSecurityTranslation.TranslateRegistry = True
   objSecurityTranslation.TranslateShares = True
   objSecurityTranslation.TranslateUserProfiles = False
   objSecurityTranslation.TranslateUserRights = True

   '
   'Perform security translation on specified computer objects.
   '

   objSecurityTranslation.Translate admtData, _
  Array(" computer name1" ," computer name2" )

   Set objSecurityTranslation = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a sample script file to assist you in creating a script to translate security on member servers, see "Translating Security on Member Servers Between Forests" (DSSREER_16.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Translating Security on Member Servers Between Forests" on the Web at http://www.microsoft.com/reskit).

# Decommissioning the Source Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you complete the migration of the accounts and resources in your source domain, decommission the source domain. Ensure that you retain a full system state backup of a domains controller so that you can bring the domain back online at any time.

To decommission the source domain:

1. Remove all trust relationships between the source domain and the target domain.

2. Repurpose any remaining domain controllers in the source domain that you did not migrate to the target domain.

3. Disable all accounts that you created during the migration process, including those accounts to which you assigned administrative permissions.

**Note**

- When you decommission the source domain, shared local groups and local groups that you have not translated by using the Security Translation Wizard display group members as "account unknown" because member names from the source domain do not resolve. Those group memberships still exist, however, and this does not affect users. Do not delete "account unknown" entries because this disables the access facilitated by SID history. Run the Security Translation Wizard to remove these entries.

# Additional Resources for Retructuring Active Directory Domains Between Forests

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information and tools related to this chapter.

**Related Information**

- "Designing the Active Directory Logical Structure" in this book for more information about designing the Active Directory logical structure and designing DNS for Active Directory.
- "Designing the Site Topology" in this book for more information about the Active Directory site topology.
- "Deploying DNS" in *Deploying Network Services* for more information about deploying DNS.
- "Enabling Advanced Windows Server 2003 Active Directory Features" in this book for more information about functional levels.

**Related Tools**

- ADMT

  You can use ADMT version 2 to migrate accounts to restructure your Windows Server 2003 domains. ADMT includes wizards that you can use to migrate objects such as groups, users, computers, and service accounts. These wizards assist you in performing the appropriate migration for each object type.

# Restructuring Active Directory Domains Within a Forest

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Restructuring Active Directory® directory service domains within a forest with the goal of reducing the number of domains allows you to decrease the administrative overhead for your organization by reducing replication traffic, reducing the amount of user and group administration that is required, and simplifying the administration of Group Policy. If users change positions or move between locations, you might also move objects between forests on a regular basis. The process for restructuring Active Directory domains within a forest differs from the process of restructuring Active Directory domains between forests and requires careful planning and testing.

**In This Chapter**

Overview of Restructuring Active Directory Domains Within a Forest

Preparing to Restructure Active Directory Domains Within a Forest

Migrating Domain Objects Between Active Directory Domains

Completing Post-Migration Tasks

Additional Resources for Restructuring Active Directory Domains Within a Forest

# Overview of Restructuring Active Directory Domains Within a Forest

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The most efficient Active Directory design includes the smallest possible number of domains. By minimizing the number of domains running the Microsoft® Windows® Server 2003, Standard Edition; Microsoft® Windows® Server 2003, Enterprise Edition; and Microsoft® Windows® Server 2003, Datacenter Edition operating systems, you can reduce administrative costs and increase the efficiency of your organization.

You might need to restructure domains within your forest if, for example, your organization closes a regional office location, and the regional domain for that location is no longer needed. You might also restructure domains within your forest if you upgrade your network infrastructure, thereby increasing your bandwidth capacity and your replication capacity and enabling you to reduce the size of your Active Directory logical structure.

The process of restructuring Active Directory domains within a forest is similar to the process of migrating accounts between domains. When you migrate accounts and resources between domains, you migrate objects from the source domain to the target domain without decommissioning the source domain. When you restructure Active Directory domains, you eliminate the source domain from the forest after you complete the migration of all domain objects.

Before you begin the process for restructuring Active Directory domains within a forest, ensure that the source and target domains are operating at the Microsoft® Windows® 2000 native or Windows Server 2003 domain functional level. Restructuring source domains that are operating at the Windows 2000 mixed domain functional level, which can include domain controllers that are running Microsoft® Windows NT® 4.0, is not recommended.

After you complete the process for restructuring Active Directory domains within a forest, you can reduce overhead and simplify administration in your organization.

**Note**

- For a list of the job aids that are available to assist you in restructuring Active Directory domains within a forest, see "Additional Resources for Restructuring Active Directory Domains Within a Forest" later in this chapter.

# Process for Restructuring Active Directory Domains Within a Forest

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Restructuring Active Directory domains within a forest requires careful planning and preparation. To maintain user access to resources during the process of restructuring domains, you must perform the migration steps in a specific order. Figure 12.1 shows the process for restructuring Active Directory domains within a forest.

**Figure 12.1 Restructuring Active Directory Domains Within a Forest**

# Background Information for Restructuring Active Directory Domains Within a Forest

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Restructuring Active Directory domains within a forest involves migrating accounts and resources from the source domains to the target domains. Unlike the process for restructuring Active Directory domains between forests, when you restructure domains within a forest, the migrated objects no longer exist in the source domain. Additionally, migrating user accounts, resources, and groups requires special consideration when you restructure Active Directory domains within a forest because of the containment rules that apply to Active Directory groups. For these reasons, the challenge when you restructure Active Directory domains within a forest is to ensure that users have continuous access to resources during the migration process.

**Active Directory Migration Tool**
The Active Directory Migration Tool (ADMT) version 2 allows you to migrate objects within Active Directory forests. ADMT includes wizards that automate migration tasks such as migrating users, groups, service accounts, computers, and trusts, and performing security translation.

ADMT is available in the Admigration.msi file in the \i386\admt directory on the Windows Server 2003 operating system CD.

You can perform ADMT tasks by using the ADMT console, a command line, or a script. When running ADMT at the command line, it is often more efficient to use an option file to specify command-line options. You can use the ADMT option file reference shown in Listing 12.1 to assist you in creating option files. Examples of command-line syntax are provided for each task that you must perform to restructure the domains within the forest.

Listing 12.1 lists common options that apply to several migration tasks. Each type of migration task has a section that lists options that are specific to that task. The section name corresponds to the task name when you run ADMT at the command line. Items can be commented out with a semi-colon. In Listing 12.1, the default values are commented out.

When running ADMT at the command line, you do not need to include an option in your command if you want to accept the default value. In this chapter, however, tables are provided for reference. The tables list the command-line equivalent of each option that is shown in the corresponding ADMT console procedure, including those where you are accepting the default value.

**Listing 12.1 ADMT Option File Reference**

```
 [Migration]
;TestMigration=No
;IntraForest=No
SourceDomain=" source_domain_name"
;SourceOu=" source_ou_path"

TargetDomain=" target_domain_name"
TargetOu=" target_ou_path"
;RenameOption=Dont
;RenamePrefixOrSuffix=""
;PasswordOption=Complex
;PasswordServer=""
;PasswordFile=""
;ConflictOptions=Ignore
;ConflictPrefixOrSuffix=""

;TranslateFilesAndFolders=No
;TranslateLocalGroups=No
;TranslatePrinters=No
;TranslateRegistry=No
;TranslateShares=No
;TranslateUserProfiles=No
;TranslateUserRights=No
;SidMappingFile=" SidMappingFile.txt"
```

For a file that includes common options that are available for ADMT, see "ADMT Option File Reference" (DSSRENT_3.txt) on the *Microsoft® Windows® Server 2003 Deployment Kit* companion CD (or see "ADMT Option File Reference" on the Web at http://www.microsoft.com/reskit).

When running ADMT from the command line, it is often more efficient to use an include file to list the users, groups, or computers that will be migrated. For example, to migrate a small number of computers, you might type each computer name at the command line, using the /N option as follows:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" /IF:YES /SD:"
source_domain
" /TD:"
target_domain
" /TO:"
target_OU
"
```

*Computer_name1* and *computer_name2* are the names of computers in the source domain that you are migrating in this batch.

If you have a large number of users, groups, or computers to migrate, you can list them in an include file. For example, to create an include file for a batch of computers, create a plain text file and list the computer names, each name on a separate line. Then specify the include file name with the /F option, as follows:

```
ADMT COMPUTER /F "includefile_name" /IF:YES /SD:"source_domain"
/TD:"target_domain" /TO:"target_OU"
```

ADMT supports the use of American National Standards Institute (ANSI) or standard Unicode files for option files and include files.

To specify the names of users, groups, or computers, use one of the following conventions:

- The Security Accounts Manager (SAM) account name. Note that to specify a computer name in this format, you must append a $ to the computer name. For example, to specify a computer with the name Workstation01, use Workstation01$.

- The Windows NT 4.0 account name. This includes the domain name and the SAM account name. For example, the Windows NT 4.0 account name of a computer named Workstation01 that is in the Asia domain is Asia\ Workstation01$.

- The relative distinguished name (also known as RDN). For example, cn= Workstation01.

- The canonical name. This can be specified as *DNS domain name/ou_path/object_name*, or *ou_path/object_name*; for example, Asia.trccorp.treyresearch.net/Computers/ Workstation01 or Computers/Workstation01.

For a complete list of all available ADMT options and syntax, run ADMT, and then select **Help** on the menu.

The sample scripts provided in this chapter reference the symbolic constants that are defined in the AdmtConstants.vbs file. Listing 12.2 shows the ADMT constants VBScript file.

**Listing 12.2 ADMT Scripting Constants**

For a script file that includes the constants that are available for ADMT scripts, see "ADMT Scripting Constants" (AdmtConstants.vbs) on the *Windows Server 2003 Deployment Kit* companion CD (or see "ADMT Scripting Constants" on the Web at http://www.microsoft.com/reskit). The constants are also provided on the Windows Server 2003 operating system CD, in the TemplateScript.vbs file in the \i386\admt directory.

**Closed Sets and Open Sets**

When you restructure Active Directory domains within a forest, you must be concerned with two types of closed sets. The first type is users and groups, and the second type is resources and local groups.

The first type of closed set includes user accounts, all the global groups to which the users belong, and all the other members of the global groups. Because global groups are limited to members of the domain where the global group exists, if you migrate a user account to a new domain but do not migrate the global groups to which the user belongs, the user is no longer a valid member of those global groups and cannot access resources that are based on membership in those global groups. Therefore, when you are moving accounts between domains in a forest, it is necessary to move closed sets so that users retain access to their resources.

Built-in accounts (such as Administrators, Users, and Power Users) and well-known accounts (such as Domain Admins and Domain Users) cannot be ADMT migration objects. However, migrating these groups in closed sets is not a common problem because using them in access control lists (ACLs) or membership in domain local groups is not an effective way to assign resource permissions.

When you migrate users, ADMT makes the user a member of the domain users group in the target domain but does not maintain permissions for other built-in groups, such as Server Operators, Backup Operators, or well-known groups, such as Domain Admins. If you have used built-in or well-known groups to assign resource permissions, you must reassign those permissions to a new domain local group before you begin the migration. Reassigning permissions includes the following steps:

1. Create a new domain local group in the source domain.

2. Create a new global group in the source domain that contains users who need access to the resource.

3. Add the new global group to the domain local group.

4. Run security translation by using a SIDmapping file that maps the well-known group to the new domain local group (created in the first step) on all resources that assign permissions using well-known groups. For information about performing a security translation by using a SIDmapping file, see "Translate Security by Using a SID mapping File" later in this chapter.

In small domain environments that have few global groups, you might be able to identify closed sets of users and groups. If you can identify closed sets, you can migrate users and groups at the same time. In a large domain environment, a user can belong to a number of global groups; therefore, it is difficult to identify and migrate only closed sets of users and groups. For this reason, it is best to migrate groups before you migrate user accounts.

For example, User 1 belongs to global groups Global A and Global B and is a member of Domain 1. If an administrator moves User 1 and Global A to Domain 2, these accounts no longer exist in Domain 1; they exist only in Domain 2. Global B group remains in Domain 1. This creates an *open set*, or a set that includes users and groups in more than one domain. Because global groups can only contain members from the domain where the global group exists, the membership of User 1 in Global B is no longer valid, and User 1 can no longer access resources based on membership in Global B. Therefore, it is best to migrate both global groups before you migrate User 1.

If you are migrating an open set of objects in an environment where the functional level for both the source domain and the target domain is Windows 2000 native or higher, ADMT transforms the global group into a universal group so that it can contain users from other domains and retain the group membership. When the set becomes a closed set, ADMT changes the group back to a global group. The benefit of this process is that ADMT ensures that all closed set problems are resolved. However, replication of the global catalog is affected while the groups are universal groups because membership is copied to

the global catalog.

**Note**

- If the functional level of the source domain is Windows 2000 mixed, ADMT cannot transform the global group into a universal group because universal groups cannot exist at that functional level. Even if the target domain is in native mode, however, users in mixed mode domains would not get the SIDs of universal groups in their access tokens, if the groups are from outside the domain. Therefore, ADMT creates a copy of the global group in the target domain and adds all migrated users to the copy of that group. This group has a new security identifier (SID) and no SID history. This method does not preserve access to resources unless you run the ADMT Security Translation Wizard in Add mode to update permissions, which delays and complicates the migration process. For this reason, it is not recommended that you restructure domains that are operating at the Windows 2000 mixed functional level or the Windows Server 2003 interim domain functional level.

The second type of closed set is resources and local groups. In most cases, resources have permissions assigned to computer local groups or domain local groups. Because computer local groups are migrated when you migrate the computer, these groups are a natural closed set. However, domain local groups can be used on multiple computers to assign permissions. In this case, you can either migrate all the computers that use the domain local group at the same time the domain local group is migrated to the target domain, or you can manually change the domain local group to a universal group and then migrate the universal group. Changing the domain local group to a universal group is a manual process because ADMT does not automatically perform this task. Although this change can affect the size of your global catalog, over a limited time period, it is an effective way to migrate resources and domain local groups as a closed set.

#### SID History

SID history enables you to maintain user access to resources during the process of restructuring Active Directory domains. When you migrate an object to another domain, the object is assigned a new SID. Because you assign permissions to objects based on SIDs, when the SID changes, the user loses access to that resource until you can reassign permissions. When you use ADMT to migrate objects between domains, the SID history is automatically retained. In this way, the SID from the source domain remains as an attribute of the object after the object is migrated to the target domain.

For example, an organization that is restructuring its Active Directory domains moves universal and global groups from a source domain to the target domain before moving user accounts. Because this is a migration within a forest and the functional level of the source domain is Windows 2000 native, these groups cease to exist in the source domain and exist only in the target domain. Because the SID history of both users and groups is migrated, the users continue to have access to resources in the source domain based on their membership in a group that exists in the target domain.

#### Resource Assignment to Groups

The most effective way to assign permissions to resources is to assign users to global groups, place global groups within domain local groups, and then assign permissions to the domain local groups. Assigning permissions to resources in this way simplifies the migration process.

#### Terms and Definitions

The following terms apply to the process for restructuring Active Directory domains within a forest.

**Migration** The process of moving an object from a source domain to a target domain, while preserving or modifying characteristics of the object to make it accessible in the new domain.

**Domain Restructure** A migration process that involves changing the domain structure of a forest. A domain restructure can involve either consolidating or adding domains, and can take place between forests or within a forest.

**Domain Consolidation** A restructuring process that involves eliminating Windows NT 4.0 or Active Directory domains by merging their contents with that of other domains.

# Preparing to Restructure Active Directory Domains Within a Forest

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Careful planning is an important part of restructuring Active Directory domains. Completing the necessary preparatory tasks before you restructure Active Directory domains enables you to reduce the effect on users of migrating objects from source to target domains. To prepare for the restructuring process, the Active Directory deployment team must obtain the necessary design information from the Active Directory design team.

Figure 12.2 shows the steps that are involved in preparing to restructure Active Directory domains within a forest.

**Figure 12.2 Preparing to Restructure Active Directory Domains Within a Forest**

# Design the New Active Directory Forest Structure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Evaluate the domain structure of your existing Active Directory forest, and then identify the domains that you want to restructure by consolidating them with other domains.

To design your new Active Directory forest structure, you must identify the source domain that you will migrate objects from and the target domains where you will place those objects. You must also evaluate the structure of the target domain.

**Identify the Target and Source Domains**
The source domain or domains are the domains that you want to migrate objects from and that you plan to decommission. When you restructure Active Directory domains, it is best to migrate the smallest possible number of objects. When you select source domains, identify the domains that have the fewest objects to migrate.

**Evaluate the OU Structure of the Target Domain**
Identify the organizational units (OUs) from the source domain that you need in the target domain, and then determine whether you need to create new OUs in the target domain.

You can migrate the OU structure when you migrate users, groups, or computers if you are using ADMT in command-line or scripting mode. The OUs are always copied between the domains and are not deleted in the source domain. To successfully migrate an OU, a source OU and a target OU must be specified in ADMT and the target OU must exist. All objects in the source OU and all sub-OUs are migrated. The specified source OU itself is not migrated. The migrated objects and sub-OUs are migrated to the target OU.

For more information about creating an OU structure, see "Designing the Active Directory Logical Structure" in this book.

# Assign Domain Object Roles and Locations

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Use a domain object assignment table to document object roles and locations. In the domain object assignment table, include the domain objects that exist in the source domain and their planned roles and locations in the target domain. For a worksheet to assist you in creating a domain object assignment table, see "Domain Object Assignment Table" (DSSRERA_1.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Domain Object Assignment Table" on the Web at http://www.microsoft.com/reskit).

For example, Contoso Corporation plans to migrate their Africa domain objects to their EMEA domain. The design team creates a domain object assignment table that includes every group, user, and computer that needs to be migrated from the Africa domain to the EMEA domain. The completed table permits the organization to assess the amount of work and time that is required to complete the migration of the Africa domain.

Figure 12.3 shows the domain object assignment table that the Contoso design team created.

**Figure 12.3 Example of a Domain Object Assignment Table**

| Domain Object Assignment Table | | | |
|---|---|---|---|
| Prepared By | Design Team | Date | 01/01/03 |
| Forest Name | Concorp.contoso.com | | |
| Source Domain | Africa.concorp.contoso.com | | |
| Target Domain | Emea.concorp.contoso.com | | |

| Name | Type | Source Location | Target Location |
|---|---|---|---|
| Sales | Global Group | Africa\Groups OU | EMEA\Groups OU |
| Marketing | Global Group | Africa\Groups OU | EMEA\Groups OU |
| Engineering | Global Group | Africa\Groups OU | EMEA\Groups OU |
| AFR-AFRICA-DC01 | Domain Controller | Africa\Domain Controllers | EMEA\Domain Controllers |
| AFR-AFRICA-DC02 | Domain Controller | Africa\Domain Controllers | EMEA\Domain Controllers |
| SSmith | User | Africa\Users OU | EMEA\Users OU |
| EJohnson | User | Africa\Users OU | EMEA\Users OU |
| _SQL user | Service Account | Africa\Users OU | EMEA\Users OU |
| AFR-AFRICA-W2P1 | Computer Account | Africa\Wrk OU | EMEA\Wrk OU |
| AFR-AFRICA-W2P2 | Computer Account | Africa\Wrk OU | EMEA\Wrk OU |

# Plan for Group Migration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Unless you can identify closed sets when you are restructuring Active Directory domains within a forest, it is recommended that you migrate groups and users separately to ensure that users continue to have access to required resources.

Table 12.1 lists each type of group and where the group is physically located.

**Table 12.1 Location of Each Group Type**

| Group Type | Location |
|---|---|
| Global Group | Active Directory |
| Universal Group | Active Directory |
| Domain Local Group | Active Directory |
| Computer Local Group | Database of the local computer |

Each type of group is migrated differently based on the group's physical location and its rules for group membership. Global, universal, and domain local groups are migrated by using ADMT and can be transformed into universal groups for the duration of the migration if you are not migrating closed sets. You can update computer local group membership by running security translation.

Each group type has different rules for membership and serves a different purpose. This affects the order that the groups are migrated from the source to the target domains. Table 12.2 summarizes the groups and their membership rules.

**Table 12.2 Groups and Membership Rules**

| Type of Group | Rules and Membership |
|---|---|
| Universal groups | Universal groups can contain members from any domain in the forest and replicate group membership to the global catalog. For this reason, they can be used for administrative groups. When you restructure domains, migrate universal groups first. |
| Global groups | Global groups can include only members from the domain to which they belong. ADMT automatically changes the global group in the source domain to a universal group when it is migrated to the target domain if the functional level of both domains is Windows 2000 native or higher. ADMT automatically changes universal groups back to global groups after all members of the group are migrated to the target domain. |
| Domain local groups | Domain local groups can contain users from any domain. They are used to assign permissions to resources. When you restructure domains, you must migrate domain local groups when you migrate the resources to which they provide access, or you must change the group type to universal group. This minimizes the disruption in user access to resources. |

# Plan for Service Account Transitioning

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Most services run within the context of the Local System account and because of this, they do not need any maintenance when they are migrated to a different domain. Some services, however, run in the context of a user account instead of the Local System account.

Service account transitioning refers to the process of identifying, migrating, and updating services that run in the context of user accounts. This process has three steps. First, start ADMT on a Windows Server 2003–based member server in the target domain, and then run the Service Account Migration Wizard. The Service Account Migration Wizard sends an agent to a computer that you specify in the wizard and identifies all services on the computer that are running in the context of a user account. The wizard only identifies service accounts that are running in the context of a user account and saves the information in the ADMT database; it does not actually migrate the accounts. The next step, which can occur later in the transition process, is to migrate the accounts by using the User Account Migration Wizard when you migrate the other user accounts.

For information about installing and initializing ADMT, see "Install ADMT" later in this chapter.

The Service Account Migration Wizard checks every service on a computer to identify services that run in the context of a user account. It is possible to create a security hole during the migration of service accounts if someone who is not a service administrator enters an account with administrative permissions in the source domain but uses an invalid password on their computer to start the service. The service will not start before the account migration, because the password is not correct, but it will work after migration because ADMT resets the password of the service account and configures all services that are using that service account with the new password.

To eliminate this possible security problem, it is important to include in the Service Account Migration Wizard only those servers that are managed by trusted administrators. Do not use the Service Account Migration Wizard to detect service accounts on computers that are not managed by trusted administrators, such as workstations.

If you do not identify and transition a trusted computer that therefore does not get its service account updated, you will need to manually set the new password created by ADMT. To do this, obtain the password from the Password.txt file, and then manually enter that account and password information for the service on the computer that did not get transitioned.

When the accounts that the Service Account Migration Wizard identifies in the ADMT database as running in the context of a user account are migrated to the target domain, ADMT grants each account the right to log on as a service.

**To run the Service Account Migration Wizard**

1. In ADMT, start the Service Account Migration Wizard.

2. Complete the wizard by using the information in Table 12.3.

**Table 12.3 Using the Service Account Migration Wizard**

| Wizard Page | Action |
|---|---|
| Domain Selection | In the **Source domain** box, type or select the NetBIOS or DNS name of the source domain.<br><br>In the **Target domain** box, type or select the NetBIOS or DNS name of the target domain. |
| Update Information | Click **Yes, update the information**. |
| Service Account Selection | Click **Add**.<br><br>In the **Select Computers** list box, select all servers that have service accounts.<br><br>Click **OK**,and then click **Next.** |
| Service Account Information | Select any user accounts that do not need to be marked as service accounts in the ADMT database, and then click **Skip/Include** to mark the accounts as **Skip**. |

The wizard connects to the selected computers, and then sends an agent to check every service on the remote computers. The Service Account Information page lists the services that are running in the context of a user account and the name of that user account. ADMT notes in its database that these user accounts need to be migrated as service accounts. If you do not want a user account to be migrated as a service account, select the account, and then click **Skip/Include** to change the status from **Include** to **Skip**.

You use **Update SCM** to update the Service Control Manager with the new information. Unless you have a failure in reaching a computer to update the service, the **Update SCM** button is not available. If you have a problem updating a service account after the account was identified and migrated, ensure that the computer that you are trying to reach is available, and then restart the Service Account Migration Wizard. In the wizard, click **Update SCM** to try to update the service. If you ran the Service Account Migration Wizard previously and the **Update SCM** button is not available, examine the ADMT log files to determine the cause of the problem. After you correct the problem and the agent can connect successfully, the **Update SCM** button becomes available.

# Plan for Test Migrations

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can create a pilot for the migration process by migrating users and the global groups of which they are members to the target domain. However, unless you are migrating a closed set of users and groups in your pilot, the global groups will become universal groups and replicate their membership to the global catalog for the duration of the migration process. Use a test lab that simulates your production environment to test your migration process and to resolve any issues before you begin to restructure your Active Directory domains. Continue to test your migration process until you correct as many errors as possible.

Make sure that you test user access to resources after each step of the migration. If users do not have access to resources during the migration process, the migration is not successful.

For more information about setting up a pilot to test migration, see "Restructuring Windows NT 4.0 Domains to an Active Directory Forest" in this book.

# Create a Rollback Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you begin the migration process, you cannot roll back the changes that you make to the Active Directory domains in your forest. Because accounts are moved and not copied from one domain to another when you restructure domains, the changes are not reversible. If your plans change after you begin the migration process, the only way to return your source domain is to remigrate the accounts. Create a rollback plan in case you need to remigrate accounts after you have begun to restructure your domains. To create a rollback plan, select the method that you will use to remigrate accounts.

You can use the ADMT wizards to remigrate accounts from the target domain back to the source domain. In this case, the original target domain becomes the new source domain, and the original source domain becomes the new target domain. Follow the same steps in the wizards that you used earlier to migrate the accounts. If you remigrate the accounts, the objects that have been migrated to the target domain and then remigrated to the source domain will have new SIDs. However, they will have the original SID in their SID history so they will not be identical to the accounts before the migration, but they will have the same functionality.

Another option for remigrating accounts is to use the Undo Wizard in ADMT. The Undo Wizard uses fewer steps than the other ADMT wizards to remigrate accounts back to their original domain. However, the Undo Wizard only remigrates accounts that were originally migrated by using the User Account Migration Wizard, the Group Account Migration Wizard, and the Computer Account Migration Wizard. It does not undo changes that were made by the Service Account Migration Wizard or the Security Translation Wizard. The Undo Wizard only reverses the last operation that was performed.

If you want to reverse a service account migration, you must enumerate the services again, and then remigrate the service accounts by reversing the target and source domains.

If you use scripts to perform the original migration, using scripts to remigrate accounts is the fastest method to roll back the changes. Simply reverse the objects used for the source and target domains in the script to remigrate the objects.

**Note**

- If the functional level of the original source domain is Windows 2000 mixed, you cannot use a rollback method to undo the changes and migrate the accounts back to the source domain. A remigration requires that the original source domain becomes the target domain, and the functional level of the target domain must be Windows 2000 native or Windows Server 2003. For this reason, it is not recommended that you restructure domains that are operating at the Windows 2000 mixed functional level or the Windows Server 2003 interim domain functional level.

After you create your rollback plan, make sure to test it to identify and correct any problems before you begin to restructure your Active Directory domains.

# Create an End-User Communication Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Develop a plan to inform all affected users about the upcoming account migration, to ensure that they understand their responsibilities, the impact of the migration, and who to contact for help and support.

Before you begin the user migration process, send a notice to all users who are scheduled to be migrated. Because you typically migrate users in batches of approximately one hundred users at a time, it is also helpful to send a final notice to the users in each batch 2-3 days before their batch is scheduled. If your organization maintains an intranet, publish the account migration schedule and the information contained in the user mail on an easily accessible Web page.

Include the following information in your end-user communication.

**General information**
Alert users to the fact that their user accounts are scheduled to be migrated to a new domain. Point users to a Web page or internal resource where they can find additional information, and view a migration schedule.

Inform users of their new domain name. Be sure to let them know that their account passwords will not change. Let them know that the original domain account will be disabled immediately following the migration, and the disabled account will be deleted after a specified period of time. This is not needed if users use User Principal Names (UPNs) to log on.

**Impact**
Make sure that users understand that when their account is migrated, it is possible that they could be unable to access some resources, such as Web sites, shared folders, or resources that are not widely used by individuals in their group or division.

Provide information to users about who to contact for assistance in regaining access to required resources.

**Logon status during migration**
Make sure that users understand that during the migration process, they will be unable to log on to the domain or access e-mail or other resources. Be sure to specify the period of time for which they will be unable to log on.

**Premigration steps**
Alert users to any steps that they need to complete before the migration process begins. For example, they must decrypt files encrypted by means of Encrypted File System (EFS). Failure to decrypt encrypted files will result in loss of access to encrypted files following the migration.

**Expected changes**
Describe other changes that users can expect to experience following the migration, such as changes in use of smart cards, secure mail, or instant messaging if applicable.

**Scheduling and support information**
Provide information about where users can go to find more information; for example, an internal Web site where you post information about the migration. Also, provide information about who to contact if a user has a conflict with the date scheduled for the migration.

# Create Migration Account Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To migrate accounts and resources within a forest, you must establish an account migration group and a resource migration group with the appropriate credentials. You must then add the accounts that will be performing the ADMT migrations to the account migration and resource migration groups, as appropriate. Because ADMT requires only a limited set of permissions, creating separate migration groups allows you to simplify administration by creating the groups, assigning the appropriate permissions, and then adding the necessary administrators to those groups. If the migration tasks for your organization are distributed across more than one administrative group, create separate migration groups for each administrative group that performs the migration.

To simplify administration, create a single migration group in the source domain and a single migration group in the target domain for all objects. Assign the required permissions to modify objects such as users, global groups, and local profiles according to Table 12.4. The user who is running ADMT must be an administrator on the computer where ADMT is installed.

In the target domain, use a group with delegated control of the computer OU and the user OU. You might want to use a separate group for the migration of workstations if this migration process is delegated to administrators who are in the same location as the workstations.

Use the information in Table 12.4 to determine the credentials that are required for your migration.

**Table 12.4 Migration Account Group Credentials**

| Migration Object | Credentials Necessary in Source Domain | Credentials Necessary in Target Domain |
|---|---|---|
| User/Group | Local administrator or domain administrator, or delegated rights to delete the objects in the source OU | Delegated control of the user OU or the group OU and local administrator on the computer where ADMT is installed |
| Computer | Domain administrator or delegated rights to delete the objects in the source OU and member of Administrators group on each computer | Delegated control on the computer OU and local administrator on the computer where ADMT is installed |
| Profile (needed for Windows NT 4.0 computers only) | Local administrator or domain administrator | Delegated control on the computer OU and local administrator on the computer where ADMT is installed |

# Install ADMT

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you have not installed and initialized ADMT in your environment, you must install and run ADMT on a member server or domain controller in the target domain or the source domain.

**To install ADMT in the target domain or the source domain**

1. Log on to a member server or domain controller in the domain by using your ADMT migration account.
2. Insert the Windows Server 2003 CD into the CD-ROM drive, and then locate the \i386\admt folder.
3. Double-click **admigration.msi**.

Initialize ADMT by running a test migration of your global groups.

**To initialize ADMT by running a test migration of a global group**

1. In the ADMT console, select the **Group Account Migration Wizard**.
2. Complete the **Group Account Migration Wizard** by using the information provided in Table 12.5. Accept default settings if no information is specified.

   **Table 12.5 Migrating Global Groups by Using the Group Account Migration Wizard**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Test the migration settings and migrate later?** |
| Domain Selection | In the **Sourcedomain** box, type the source domain name.<br>In the **Target domain** box, type the target domain name. |
| Group Selection | Click **Add.**<br>In the **Select Groups** dialog box, select a group. |
| Organizational Unit Selection | Click **Browse**.<br>In the **Browse for Container** dialog box, locate the targetOU. |
| Group Options | Click **Do not rename accounts**. |
| Naming Conflicts | Click **Ignore conflicting accounts and don't migrate**. |

3. After the wizard runs, click **View Log**, and then review the migration log for any errors.

# Example: Preparing to Restructure Active Directory Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Contoso Corporation upgraded its hardware to increase its network bandwidth and the amount of replication traffic that it can support. As a result, the company is consolidating the Africa domain into the EMEA domain.

The Africa domain is the source domain and the EMEA domain is the target domain for the migration. The organization needs to migrate a total of 1,800 users from the Africa domain to the EMEA domain. In addition to the user accounts, they must also migrate resources such as workstations, servers, and groups. Because Contoso Corporation is a large organization with many global groups, closed sets are difficult to identify, so the company decided to migrate global groups as universal groups. They can do this because the infrastructure of the corporation can handle the increased replication of the universal groups and because both the Africa and EMEA domains are operating at the Windows 2000 native functional level. The company created identical OU structures in the Africa and EMEA domains; therefore, they do not need to create a new OU structure or migrate OUs.

Contoso Corporation created a list of computers that run service accounts, so that it can use the Service Account Migration Wizard to identify services that run in the context of user accounts. The company is most concerned about a set of accounts that access a Microsoft® SQL Server™ database. Access to this database is an important part of their business.

The company decides to use ADMT as its migration tool and to use the wizards. The company installs ADMT and creates two account migration groups to use for the migration process. They assign high-level permissions to the first group, and then add the appropriate deployment team members to that group. The centralized deployment team will use this account to migrate users. They assign workstation and local resource permissions to the second group. The deployment team will use the second group to migrate resources at the remote locations.

# Migrating Domain Objects Between Active Directory Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Restructuring Active Directory domains within a forest involves migrating domain objects in a specific order to ensure that users maintain access to resources. Figure 12.4 shows the process for migrating domain objects between Active Directory domains.

**Figure 12.4 Migrating Domain Objects Between Active Directory Domains**

# Migrate Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To protect your system against the problem of open sets when you restructure Active Directory domains within a forest, migrate groups before you migrate the user accounts that are members of those groups. If you only migrate groups when you migrate users, you might not migrate nested groups, thereby creating an open set. Migrate universal groups first, followed by global groups. Migrate domain local groups when you migrate the resources (domain controllers and member servers) on which they are used to assign permissions. Computer local groups migrate with the computer.

# Migrate Universal Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Migrate universal groups, without migrating users who are members of these groups at the same time, from the source domain to the target domain. Migrating universal groups without the users helps to protect against the problem of open sets. SID history allows group members to continue to have access to resources based on universal group membership. When you migrate universal groups to the target domain, they cease to exist in the source domain.

**Note**

- If you are migrating a small number of universal groups, you can migrate universal groups at the same time that you migrate global groups.

You can migrate universal groups by using the Group Account Migration Wizard or by using a script.

**To migrate universal groups without members**

- Complete the Group Account Migration Wizard by using the information provided in Table 12.6.

**Table 12.6 Using the Group Account Migration Wizard to Migrate Universal Groups**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type the NetBIOS or DNS name of the source domain or select the name from a list.<br><br>In the **Target domain** box, type the NetBIOS or DNS name of the target domain.<br><br>If ADMT includes the names of the source and target domains, ensure that they are correct. |
| Group Selection | Click **Add.**<br><br>In the **Select Groups** dialog box, select all universal groups that you want to migrate, click **Add**, and then click **OK**. |
| Organizational Unit Selection | Type the name of the OU, or click **Browse**.<br><br>In the **Browse for Container** dialog box, find the container in the target domain that you want to move the universal groups into, and then click **OK**. |
| Group Options | The **Migrate Group SIDs to target domain** and **Fix Group Membership** check boxes are checked and appear dimmed.<br><br>Click **Do not rename accounts**.<br><br>Ensure that no other options are selected. |
| Naming Conflicts | Click **Ignore conflicting accounts and don't migrate**. |

**To migrate universal groups by using a script**

- Use Listing 12.3 to prepare a script that incorporates ADMT commands and options for migrating groups within a forest.

**Listing 12.3 Migrating Groups Within a Forest**

```
<Job id=" MigratingGroupsWithinForest" >
```

```
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objGroupMigration

   '
   'Create instance of ADMT migration objects.
   '

   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objGroupMigration = objMigration.CreateGroupMigration

   '
   'Specify general migration options.
   '

   objMigration.IntraForest = True
   objMigration.SourceDomain = " source domain"
   objMigration.SourceOu = " source container"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " target container"

   '
   'Migrate specified group objects.
   '

   objGroupMigration.Migrate admtData, Array(" group name1" ," group name2" )

   Set objGroupMigration = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a sample script to assist you in migrating groups, see "Migrating Groups Within a Forest" (DSSRERA_2.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating Groups Within a Forest" on the Web at http://www.microsoft.com/reskit).

# Migrate Global Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Migrate global groups, without members, from the source domain to the target domain to protect against the problem of open sets. After global groups are migrated to the target domain, they cease to exist in the source domain if the source domain has a functional level of Windows 2000 native or higher.

Because global groups only contain members from their own domain, they cannot be migrated from one domain to another. ADMT changes global groups to universal groups when they are migrated. The universal group in the target domain retains the SID history of the global group in the source domain, which enables users to continue to access resources in the source domain after the global groups are migrated. ADMT changes the universal groups back to global groups after all members of the global group are migrated from the source domain to the target domain.

You do not need to include built-in and well-known global groups in your migration. Built-in and well-known groups already exist in the target domain. If a built-in or well-known global group is selected for migration, ADMT does not migrate it; instead, ADMT makes a note in the log and continues to migrate other global groups.

The procedure for using the Group Account Migration Wizard to migrate global groups is the same as that for migrating universal groups. For more information about the procedure for migrating global groups and universal groups, see "Migrate Universal Groups" earlier in this chapter.

After you complete the global group migration process, use Active Directory Users and Computers to verify that the global groups migrated successfully. Verify that the global groups no longer exist in the source domain and that the groups appear in the target domain in the OU that you specified during the migration process. The global groups are listed as universal groups in the target domain if they still have members in the source domain. To view a list of members of the universal group, right-click the group, click **Properties**, and then click the **Members** tab. The original members of the global group are listed. Note, however, that user accounts have not yet been migrated.

You can migrate global groups by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To migrate global groups by using the ADMT console**

1. On the member server in the target domain where ADMT is installed, log on by using a user account that is a member of the ADMT account migration group.
2. Start ADMT, and select **Group Account Migration Wizard**.
3. Complete the Group Account Migration Wizard by using the information provided in Table 12.7.

**Table 12.7 Using the Group Account Migration Wizard to Migrate Groups**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type the NetBIOS or DNS name of the source domain or select the name from a list.<br>In the **Target domain** box, type the NetBIOS or DNS name of the target domain.<br>If ADMT includes the names of the source and target domains, ensure that they are correct. |
| Group Selection | Click **Add**.<br>In the **Select Groups** dialog box, select all global groups that you want to migrate (except built-in and well-known groups), click **Add**, and then click **OK**. |
| Organizational Unit Selection | Type the name of the OU, or click **Browse**.<br>In the **Browse for Container** dialog box, find the container in the target domain that you want to move the global groups into, and then click **OK**. |

| | |
|---|---|
| Group Options | Click **Migrate Group SIDs to target domain**.<br>Click **Do not rename accounts**.<br>Ensure that no other options are selected. |
| Naming Conflicts | Click **Ignore conflicting accounts and don't migrate**. |

4. After the wizard runs, click **View Log**, and review the migration log for any errors.
5. Open Active Directory Users and Computers, and then locate the target domain OU. Verify that the global groups exist in the target domain OU.

**To migrate global groups by using the ADMT command-line option**

1. On the member server in the target domain where ADMT is installed, log on by using a user account that is a member of the ADMT account migration group.
2. At a command line, type:

```
ADMT GROUP /N "
group_name1
" "
group_name2
" /IF:YES /SD:"source_domain" /TD:"target_domain" /TO:"target_OU"
[parameters]
```

Alternatively, you can include parameters in an option file that is specified at the command line as follows:

```
ADMT GROUP /N "
group_name1
" "
group_name2
" /O: "
option_file.txt
"
```

Table 12.8 lists the parameters that are required for migrating global groups, the command-line parameters, and option file equivalents.

**Table 12.8 Parameters Required for Global Group Migrations**

| Parameters | Command-Line Syntax | Option File Syntax |
|---|---|---|
| Intra-Forest | `/IF:YES` | `IntraForest=YES` |
| Target domain | `/TD:`"*target_domain*" | `TargetDomain=`"*target_domain*" |
| Target OU location | `/TO:`"*target_OU*" | `TargetOU=`"*target_OU*" |
| Do not rename accts | `/RO:DONT` (default) | `RenameOption=DONT` |
| Ignore conflicting accts and do not migrate them | `/CO:IGNORE` (default) | `ConflictOptions=IGNORE` |

3. Review the results that are displayed on the screen for any errors.
4. Open Active Directory Users and Computers, and then locate the target domain OU. Verify that the global groups exist in the target domain OU.

**To migrate global groups by using a script**

1. Use a script that incorporates ADMT commands and options for migrating universal groups. For more information about migrating universal groups, see "Migrate Universal Groups" earlier in this chapter.
2. After completing the global group migration by using a script, view the migration log. The migration.log file is stored in the folder where you installed ADMT, typically %Program Files%\Active Directory Migration Tool.

   For a sample script to assist you in migrating groups, see "Migrating Groups Within a Forest" (DSSRERA_2.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating Groups Within a Forest" on the Web at http://www.microsoft.com/reskit).

| **Note** |
| --- |
| Because universal groups are replicated to the global catalog, converting global groups to universal groups can affect replication traffic. When the domain is operating at the Windows Server 2003 functional level, this impact is reduced because only changes to the universal group membership are replicated. However, if the domain is not operating at the Windows Server 2003 functional level, the entire group membership replicates every time universal group membership changes. |

# Migrate Service Accounts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Migrate the service accounts that you identified earlier in the intraforest restructure process by using the Service Account Migration Wizard. This wizard marked the accounts as service accounts in the ADMT database. For more information about using ADMT to identify service accounts that are running in the context of a user account, see "Plan for Service Account Transitioning" earlier in this chapter.

You can migrate service accounts by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To migrate service accounts by using the ADMT console**

- Complete the User Account Migration Wizard by using the information provided in Table 12.9.

**Table 12.9 Using the User Account Migration Wizard to Migrate Service Accounts**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type or select the name of the source domain.<br>In the **Target domain** box, type or select the name of the target domain. |
| User Selection | Click **Add**.<br>In the **Select Users** dialog box, select all the service accounts that were identified by the Service Account Migration Wizard, and then click **Add**. By default, the wizard adds the service accounts to the Users container. If you need to change the OU, click the **Location** button, and then locate the OU that contains the service accounts.<br>Click **OK**. |
| Organizational Unit Selection | Click **Browse**.<br>In the **Browse for Container** dialog box, locate the source domain, select the container for the service accounts, and then click **OK**. |
| User Options | Select the **Update user rights** check box.<br>Ensure that the **Do Not Rename Accounts** check box is selected.<br>Ensure that no other settings are selected, including the **Migrate associated user groups** option. A warning box will appear to inform you that if the global groups to which the user accounts belong are not also migrated, users will lose access to resources. Select **OK** to continue with the migration. |
| Naming Conflicts | Click **Ignore conflicting accounts and don't migrate**. |
| Service Account Information | Click **Migrate all service accounts and update SCM for items marked include**. The wizard will present you with a list of the service accounts that you are migrating (if you are migrating accounts that are not service accounts, they will be migrated but will not be listed). By default, the accounts are marked as **Include**. To change the status of the account, select the account, and then click the **Skip/Include** button.<br>Click **Next** to migrate the accounts. |

A **Migration Progress** dialog box updates you on the status of the migration. During this time, ADMT moves the accounts to the target domain, generates a new password for the accounts, assigns the accounts the right to log on as a service, and

provides this new information to the services that use the accounts. When the status is listed as **Completed** in the **Migration Progress** dialog box, you can continue with the rest of the intraforest migration. Before the migration of the service accounts is completed, users might experience interruptions when they use the services because the service still uses the account that has been migrated until the service is restarted. For any services that continually use credentials, such as search services, manually restart the services to ensure optimal results.

**To migrate service accounts by using the ADMT command-line option**

1. On a member server in the target domain where ADMT is installed, log on by using a user account that is a member of the ADMT account migration group.
2. At the command line, type:

```
ADMT USER /N "
server_name1
" "
server_name2
" /IF:YES /SD:"source_domain" /TD:"target_domain" /TO:"target_OU"
/MSA:YES
```

   *Server_name1* and *Server_name2* are the names of servers in the source domain that run service accounts. Alternatively, you can include parameters in an option file that is specified at the command line as follows:

```
ADMT USER /N "
server_name1
" "
server_name2
" /O: "
option_file.txt
"
```

   Table 12.10 lists the parameters that are required for migrating service accounts, the command-line parameters, and option file equivalents.

   **Table 12.10 Parameters Required for Migrating Service Accounts**

| Parameters | Command Line Syntax | Option File Syntax |
|---|---|---|
| Intra-Forest | `/IF:YES` | `IntraForest=YES` |
| Target domain | `/TD:`"*target_domain*" | `TargetDomain=`"*target_domain*" |
| Target OU location | `/TO:`"*target_OU*" | `TargetOU=`"*target_OU*" |
| Migrate Service Accounts | `/MSA:YES` | `MigrateServiceAccounts=YES` |
| Update user rights | `/UUR:YES` | `UpdateUserRights=YES` |
| Do not rename accounts | `/RO:DONT` *(default)* | `RenameOption=DONT` *(default)* |
| Ignore conflicting accounts | `/CO:IGNORE` *(default)* | `ConflictOptions=IGNORE` *(default)* |

3. Review the results that are displayed on the screen for any errors.
4. Open Active Directory Users and Computers, and locate the target domain OU. Verify that the service accounts exist in the target domain OU.

**To migrate service accounts by using a script**

- Use Listing 12.4 to prepare a script that incorporates ADMT commands and options for migrating service accounts.

**Listing 12.4 Migrating Service Accounts Within a Forest**

```
<Job id=" MigratingServiceAccountsWithinForest" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objUserMigration

   '
   'Create instance of ADMT migration objects.
   '

   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objUserMigration = objMigration.CreateUserMigration

   '
   'Specify general migration options.
   '

   objMigration.IntraForest = True
   objMigration.SourceDomain = " source domain"
   objMigration.SourceOu = " source container"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " target container"

   '
   'Specify user migration specific options.
   '

   objUserMigration.UpdateUserRights = True
   objUserMigration.MigrateServiceAccounts = True

   '
   'Migrate specified service accounts.
   '

   objUserMigration.Migrate admtData, _
  Array(" service account name1" ," service account name2" )

   Set objUserMigration = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a sample script to assist you in migrating service accounts, see "Migrating Service Accounts Within a Forest" (DSSRERA_3.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating Service Accounts Within a Forest" on the Web at http://www.microsoft.com/reskit).

# Migrate User Accounts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Domains can include a large number of user accounts. To make the migration of user accounts manageable, use a technique called *phased transitioning*, by which you place your user accounts into smaller batches and migrate each of the smaller batches individually. You can group the users in any way that you prefer.

You cannot migrate every user property when you migrate user accounts. For example, Protected Storage (Pstore) contents for Windows NT 4.0 workstations, including Encrypting File System (EFS) private keys, are not migrated by ADMT when you migrate user accounts. To migrate Pstore contents, you must export and import keys during the migration process.

For clients that are running Windows 2000 or later operating systems, data that is protected by the Data Protection API (DPAPI) is also not migrated. DPAPI helps protect the following items:

- Web page credentials (for example, passwords)
- File share credentials
- Private keys associated with EFS, S/MIME, and other certificates
- Program data that is protected by using the CryptProtectData() function

For this reason, it is important to test user migrations by using your test migration account to identify any properties that did not migrate and update user configurations in the target domain accordingly.

If you are using Group Policy objects to manage software installation, you need to consider that some software installation (.msi) packages require access to the original source for certain operations, such as repair and uninstall. The administrator must reassign permissions to the software distribution point to provide access to any account.

To retain software distribution access, perform these tasks:

- Migrate users by using ADMT.
- Run the Security Translation Wizard on the software distribution point.

# Migrating OUs and Subtrees of OUs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you want to copy OUs and subtrees of OUs to your target domain, you can use either the command-line or scripting option and substitute the appropriate parameters. You must specify a source OU and a target OU, and the target OU must exist. All objects in the source OU and all sub-OUs are migrated, but the specified source OU itself is not migrated. The migrated objects and sub-OUs are migrated to the target OU.

If you are using the command-line option to migrate your accounts, groups, or computers, and you also want to migrate OUs, modify the command line to use the /D option. Instead of using the /N (/IncludeName) option, you must use the /D (/IncludeDomain) option with RECURSE and MAINTAIN as follows:

```
ADMT /D:RECURSE+MAINTAIN /O "option_file.txt"
```

If you are migrating accounts, groups, or computers by using the scripting option, and you also want to migrate OUs, modify your script to use the admtDomain option. Instead of using the admtData or admtFile option, you must use the admtDomain option with admtRecurse and admtMaintainHierarchy as follows:

```
objUserMigration.Migrate admtDomain + admtRecurse + admtMaintainHierarchy
```

# Migrate Accounts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can migrate each batch of user accounts by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To migrate user accounts by using the ADMT console**

- Complete the User Account Migration Wizard by using the information provided in Table 12.11.

  **Table 12.11 Using the User Account Migration Wizard to Move User Accounts**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type or select the name of the source domain.<br>In the **Target domain** box, type or select the name of the target domain. |
| User Selection | Click **Add**.<br>In the **Select Users** dialog box, select the user accounts that you want to migrate in the current batch, and then click **Add**.<br>Click **OK**. |
| Organizational Unit Selection | Ensure that ADMT lists the correct target OU. If it is not correct, type the correct OU, or click **Browse**.<br>In the **Browse for Container** dialog box, locate the target domain and OU, and then click **OK**. |
| User Options | Click the **Translate roaming profiles** check box.<br>Click the **Update user rights** check box.<br>Clear the **Migrate associated user groups** check box. A warning box appears that states that if the global groups to which the user accounts belong are not also migrated, users will lose access to resources. Click **OK** to continue with the migration. |
| Naming Conflicts | Click **Ignore conflicting accounts and don't migrate**. |

After you click **Finish** in the User Account Migration Wizard, the **Migration Progress** dialog box appears. After the status changes to **Completed**, view the migration log to determine whether any errors occurred in the migration process. In the **Migration Progress** dialog box, click **Close**.

**To migrate the user accounts by using the ADMT command-line option**

1. On the member server in the target domain where ADMT is installed, log on by using a user account that is a member of the ADMT account migration group.
2. At the command line, type:

```
ADMT USER /N "
user_name1
" "
user_name2
" /IF:YES /SD:"source_domain" /TD:"target_domain" /TO:"target_OU"
[parameters]
```

You can append parameters to the command as follows:

```
ADMT USER /N "
user_name
1" "
user_name2
" /IF:YES /SD:"source_domain" /TD:"target_domain" /TO:"target_OU"
TRP:YES /UUR:YES
```

Alternatively, you can include parameters in an option file that is specified on the command line as follows:

```
ADMT USER /N "
user_name1
" "
user_name2
" /O "
option_file
.txt"
```

Table 12.12 lists the parameters that are required for migrating user accounts, the command-line parameters, and option file equivalents.

**Table 12.12 Parameters Required for Migrating User Accounts**

| Parameters | Command Line Syntax | Option File Syntax |
|---|---|---|
| Intra-Forest | `/IF:YES` | `IntraForest=YES` |
| Source domain | `/SD:"`*source_domain*`"` | `SourceDomain="`*source_domain*`"` |
| Source OU location | `/SO:"`*source_OU*`"` | `SourceOU="`*source_OU*`"` |
| Target domain | `/TD:"`*target_domain*`"` | `TargetDomain="`*target_domain*`"` |
| Target OU location | `/TO:"`*target_OU*`"` | `TargetOU="`*target_OU*`"` |
| Do not rename accts | `/RO:DONT` (default) | `RenameOption=DONT` |
| Ignore conflicting accts and not migrate them | `/CO:IGNORE` (default) | `ConflictOptions=IGNORE` |
| Translate Roaming Profile | `/TRP:YES` (default) | `TranslateRoamingProfile=YES` |
| Update User Rights | `/UUR:YES` | `UpdateUserRights=YES` |

3. Review the results that are displayed on the screen for any errors.
4. Open Active Directory Users and Computers, and then locate the target domain OU. Verify that the users exist in the target domain OU.

**To migrate user accounts by using a script**

- Use Listing 12.5 to prepare a script that incorporates ADMT commands and options for migrating user accounts within a forest.

**Listing 12.5 Migrating User Accounts Within a Forest**

```
<Job id=" MigratingUserAccountsWithinForest" >
```

```
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objUserMigration

   '
   'Create instance of ADMT migration objects.
   '

   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objUserMigration = objMigration.CreateUserMigration

   '
   'Specify general migration options.
   '

   objMigration.IntraForest = True
   objMigration.SourceDomain = " source domain"
   objMigration.SourceOu = " source container"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " target container"

   '
   'Specify user migration specific options.
   '

   objUserMigration.TranslateRoamingProfile = True
   objUserMigration.UpdateUserRights = True
   objUserMigration.FixGroupMembership = True
   objUserMigration.MigrateServiceAccounts = False

   '
   'Migrate specified user objects.
   '

   objUserMigration.Migrate admtData, Array(" user name1" ," user name2" )

   Set objUserMigration = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a sample script file to assist you in migrating user accounts, see "Migrating User Accounts Within a Forest" (DSSRERA_4.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating User Accounts Within a Forest" on the Web at http://www.microsoft.com/reskit).

# Translate Local User Profiles

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Translate local user profiles after you migrate the user accounts. You only need to translate local user profiles for Windows NT 4.0 computers. To minimize the disruption to users, translate local user profiles immediately after you migrate a batch of users. If your source domain includes only a small number of pre-Active Directory clients, migrate them as a group, and then translate their user profiles before you migrate the next batch of users.

**Note**

- Because roaming profiles are stored on a server, you do not need to translate them.

Local profiles are translated in replace mode because if you perform the profile translation in add mode, software installation by using software deployment group policies might not work. Any application that is packaged with Microsoft® Windows® Installer version 2.0 (which is used on workstations with Windows 2000 Service Pack 3 (SP3) or later, Microsoft® Windows® XP Service Pack 1 (SP1) or later, and many common software packages) might not function after the profile is translated. When the Security Translation Wizard is translating local profiles in replace mode, it reverts to add mode if a profile is locked. This could result in a successful profile translation, but application installations might not function after the profile is translated.

No action is required to translate a local profile on Windows 2000 or Windows XP clients between domains in the same forest because the globally unique identifier (GUID) of the user remains the same. The local profile can use the SID-to-GUID mapping that it preserves in the registry to reassign the profile of the user, and then reassociate it with the new SID.

For profile translations if a user is using offline files on a client running Windows XP SP1, the user loses access to the files in the offline folder. Although the SID of the user changes, the owner in the access control lists of the files and folders does not change. On Windows XP SP1 clients, users will not have access to content in offline folders unless they are owners of the files and folders. Therefore, to give the user access to the offline file folder, you must run the Security Translation Wizard on the profile folder.

If you are migrating the user account to a domain within the forest, and the path for the local profile is different, the user profile is modified, and a new profile folder is created on the server with the correct ACLs. The administrator must make sure that the user has access to the profile folder.

You can translate local user profiles by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To translate local user profiles by using the ADMT console**

- Complete the Security Translation Wizard by using the information provided in Table 12.13.

  **Table 12.13 Using the Security Translation Wizard to Translate Local User Profiles**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Security Translation Options | Click **Previously migrated objects**. |
| Domain Selection | In the **Source domain** box, type or select the name of the source domain.<br>In the **Target domain** box, type or select the name of the target domain. |
| Translate Objects | Click **User Profiles**. |
| Security Translation Options | Click **Replace**. |

**To translate local user profiles by using the ADMT command-line option**

1. On the member server in the target domain where ADMT is installed, log on by using a user account that is a member of the ADMT account migration group.

2. At the command line, type:

```
ADMT SECURITY /N "
computer_name1
" "
computer_name2
" [
parameters
]
```

You can append parameters to the command as follows:

```
ADMT SECURITY /N "
computer_name1
" "
computer_name2
" /IF:YES /SD:"source_domain" /TD:"target_domain" /TOT:REPLACE
/TUP:YES
```

Alternatively, you can include parameters in an option file that is specified at the command line as follows:

```
ADMT SECURITY /N "
computer_name1
" "
computer_name2
" /O:"
option_file.txt
"
```

Table 12.14 lists the parameters that are required for translating local user profiles, command-line parameters, and option file equivalents.

**Table 12.14 Parameters Required for Migrating Local User Profiles**

| Parameters | Command Line Syntax | Option File Syntax |
|---|---|---|
| IntraForest | /IF:YES | IntraForest=YES |
| Source domain | /SD:"*source_domain*" | SourceDomain="*source_domain*" |
| Target domain | /TD:"*target_domain*" | TargetDomain="*target_domain*" |
| Target domain | /TOT:REPLACE | TranslateOption=REPLACE |
| Modify local user profile security | /TUP:YES | TranslateUserProfiles=YES |

3. Review the results that are displayed in the migration log for any errors.

**To translate local user profiles by using a script**

- Use Listing 12.6 to prepare a script that incorporates ADMT commands and options for translating local user profiles.

**Listing 12.6 Translating Local User Profiles Within a Forest**

```
<Job id=" TranslatingLocalProfilesWithinForest" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
```

```
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objSecurityTranslation

   '
   'Create instance of ADMT migration objects.
   '

   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objSecurityTranslation = objMigration.CreateSecurityTranslation

   '
   'Specify general migration options.
   '

   objMigration.IntraForest = True
   objMigration.SourceDomain = " source domain"
   objMigration.TargetDomain = " target domain"

   '
   'Specify security translation specific options.
   '

   objSecurityTranslation.TranslationOption = admtTranslateReplace
   objSecurityTranslation.TranslateUserProfiles = True

   '
   'Perform security translation on specified computer objects.
   '

   objSecurityTranslation.Translate admtData, _
  Array(" computer name1" ," computer name2" )

   Set objSecurityTranslation = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a sample script to assist you in migrating local user profiles, see "Translating Local Profiles Within a Forest" (DSSRERA_5.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Translating Local Profiles Within a Forest" on the Web at http://www.microsoft.com/reskit).

# Migrate Workstations and Member Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Migrate workstations and member servers from the source domain to the target domain. When you migrate computers, the changes do not take effect until the computer is restarted. Restart the computers that you are migrating as soon as possible to complete the migration process.

Computer accounts are treated differently than user and group accounts during a migration between domains within an Active Directory forest. Computer accounts are copied instead of moved during an intraforest migration, and an account for the computer remains in the source domain after the computer has been successfully migrated to the target domain. It is recommended that you delete the computer account in the source domain seven days after the migration is complete.

You can migrate workstations and member servers by using the ADMT console, by using the ADMT command-line option, or by using a script.

**To migrate workstations and member servers by using the ADMT console**

- Complete the Computer Account Migration Wizard by using the information provided in Table 12.15.

**Table 12.15 Using the Computer Account Migration Wizard to Migrate Workstations and Member Servers**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type or select the name of the source domain.<br>In the **Target domain** box, type or select the name of the target domain. |
| Computer Selection | Click **Add**.<br>In the **Select Computers** dialog box, select the names of the workstations and member servers in the source domain that you want to migrate, click **Add**, and then click **OK**. |
| Organizational Unit Selection | Click **Browse**.<br>In the **Browse for Container** dialog box, locate the OU in the target domain to which the computers are migrating, and then click **OK**. |
| Translate Objects | Click the **Local groups** check box**.**<br>Click the **User rights** check box. |
| Security Translation Options | Click **Add**. |
| Computer Options | In the **Minutes before computer restart after wizard completion** box, type **1**. |
| Naming Conflicts | Click **Ignore conflicting accounts and don't migrate**. |

**To migrate workstations and member servers by using the ADMT command-line option**

1. On the member server in the target domain where ADMT installed, log on by using a user account that is a member of the ADMT resource migration group.
2. At the command line, type:

```
ADMT COMPUTER /N "
computer_name1
"
"
computer_name2
" /IF:YES /SD:"source_domain" /TD:"target_domain" /TO:"target_OU"
[parameters]
```

You can append parameters to the command as follows:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" /IF:YES /SD:"source_domain" /TD:"target_domain" /TO:"target_OU"
/RDL:1
```

Alternatively, you can include parameters in an option file that is specified at the command line as follows:

```
ADMT COMPUTER /N "
computer_name1
" "
computer_name2
" /O "
option_file.txt
"
```

Table 12.16 lists the parameters that are required for workstation and member server migration, the command-line parameters, and option file equivalents.

**Table 12.16 Parameters Required for Workstation and Member Server Migrations**

| Parameters | Command Line Syntax | Option File Syntax |
|---|---|---|
| IntraForest | `/IF:YES` | `IntraForest=YES` |
| Source domain | `/SD:`"*source_domain*" | `SourceDomain=`"*source_domain*" |
| Target domain | `/TD:`"*target_domain*" | `TargetDomain=`"*target_domain*" |
| Target OU location | `/TO:`"*target_OU*" | `TargetOU=`"*target_OU*" |
| • Restart computer one minute after wizard completes | `/RDL:1` | `RestartDelay=1` |
| • Do not rename accounts | `/RO:DONT` (default) | `RenameOption=DONT` |
| • Ignore conflicting accounts and do not migrate them | `/CO:IGNORE` (default) | `ConflictOptions=IGNORE` |
| • Translate Option | `/TOT:ADD` | `TranslateOption=YES` |

| | | |
|---|---|---|
| • Translate User Rights | /TUR:YES | TranslateUserRights=YES |
| • Translate Local Groups | /TLG:YES | TranslateLocalGroups=YES |

3. Review the results that are displayed on the screen for any errors. The migration log lists computers, completion status, and the path to the DCTLog.txt file for each computer. If an error is reported for a computer, you will need to refer to the DCTLog.txt file on that computer to review any problems with local groups.
4. Open Active Directory Users and Computers, and then locate the target domain OU. Verify that the workstations and member servers exist in the target domain OU.

**To migrate workstations and member servers by using a script**

- Use Listing 12.7 to prepare a script that incorporates ADMT commands and options for migrating workstations and member servers within a forest.

**Listing 12.7 Migrating Workstations and Member Servers Within a Forest**

```
<Job id=" MigratingWorkstationsMemberServersWithinForest" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objComputerMigration

   '
   'Create instance of ADMT migration objects.
   '

   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objComputerMigration = objMigration.CreateComputerMigration

   '
   'Specify general migration options.
   '

   objMigration.IntraForest = True
   objMigration.SourceDomain = " source domain"
   objMigration.SourceOu = " Computers"
   objMigration.TargetDomain = " target domain"
   objMigration.TargetOu = " Computers"

   '
   'Specify computer migration specific options.
   '

   objComputerMigration.TranslationOption = admtTranslateAdd
   objComputerMigration.TranslateLocalGroups = True
   objComputerMigration.TranslateUserRights = True
   objComputerMigration.RestartDelay = 1

   '
   'Migrate computer objects on specified computer objects.
   '

   objComputerMigration.Migrate admtData, _
```

```
  Array(" computer name1" ," computer name2" )

   Set objComputerMigration = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a sample script to assist you in migrating workstations and member servers, see "Migrating Workstations and Member Servers Within a Forest" (DSSRERA_6.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating Workstations and Member Servers Within a Forest" on the Web at http://www.microsoft.com/reskit).

# Migrate Domain Local Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Migrate the domain local groups that exist in Active Directory. You can migrate domain local groups by using the ADMT console or by using a script.

**To migrate domain local groups by using the ADMT console**

- Complete the Group Account Migration Wizard by using the information provided in Table 12.17.

**Table 12.17 Using the Group Account Migration Wizard to Migrate Domain Local Groups**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Domain Selection | In the **Source domain** box, type the NetBIOS or DNS name of the source domain, or select the name from a list.<br><br>In the **Target domain** box, type the NetBIOS or DNS name of the target domain. |
| Group Selection | Click **Add**.<br><br>In the **Select Groups** dialog box, select all domain local groups that you need to migrate (except built-in and well-known groups), click **Add**, and then click **OK**. |
| Organizational Unit Selection | Type the name of the OU, or click **Browse**.<br><br>In the **Browse for Container** dialog box, locate the OU in the target domain to which the domain local groups are migrating, and then click **OK**. |
| Group Options | The **Migrate Group SIDs to target domain** and **Fix Group Membership** check boxes are selected and appear dimmed.<br><br>Click **Do not rename accounts**.<br><br>Ensure that no other options are selected. |
| Naming Conflicts | Click **Ignore conflicting accounts and don't migrate**. |

**To migrate domain local groups by using a script**

- Use a script that incorporates ADMT commands and options for migrating universal groups. For more information about migrating universal groups, see "Migrate Universal Groups" earlier in this chapter.

  For a sample script to assist you in migrating groups, see "Migrating Groups Within a Forest" (DSSRERA_2.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Migrating Groups Within a Forest" on the Web at http://www.microsoft.com/reskit).

# Example: Restructuring Active Directory Domains

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Contoso Corporation wants to migrate the Africa domain objects to the EMEA domain. To minimize the impact on users and reduce the time that network traffic is affected, Contoso decided to complete the migration of domain objects in as little time as possible. During the migration, all global groups that are migrated become universal groups until each user who belongs to the group is migrated to the target domain. Because the forest includes domains running at the Windows 2000 functional level, only incremental membership changes to the universal groups are replicated to the global catalog.

Contoso administrators set up an extensive test lab to test the migration process before proceeding. They determined by testing the procedures that they could complete the migration process in two weeks. Global and universal groups will be migrated on Monday and Tuesday of the first week. Service accounts will be migrated and services updated on Wednesday. Thursday, Friday, and Saturday are reserved for migrating user accounts. Servers will be migrated on Sunday of the first week. The second week is reserved for migrating workstations. Domain local groups will be migrated at the end of the second week.

# Completing Post-Migration Tasks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you complete all the migration tasks that are required to restructure your Active Directory domains within a forest, you must verify that the migration occurred as planned and complete a few post-migration tasks. Figure 12.5 shows the process for completing post-migration tasks.

**Figure 12.5 Process for Completing Post-Migration Tasks**

# Examine Migration Logs for Errors

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

ADMT keeps a detailed log of every action that you perform when you migrate resources between Active Directory domains. Errors that occur during the migration process are noted in the migration log, although they might not produce a warning message in ADMT. Examining the migration log after a migration is a good way to verify that all tasks were completed successfully. Because it is important to complete the steps of the migration in a specific order, it is best to check the migration log after each step so that you can discover any failures in time to fix them.

# Verify Group Types

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

ADMT changes global groups to universal groups when you migrate them from the source domain to the target domain. The change occurs automatically because global groups can only contain members of their own domain. Therefore, they cannot continue to be global groups when they are migrated to another domain until the group members are migrated. ADMT changes the universal groups back to global groups when the last member of the group is migrated to the target domain. Because universal groups replicate their membership to the global catalog, it is important to verify that the universal groups correctly changed back to global groups.

Use Active Directory Users and Computers to verify that universal groups migrated successfully. If you manually changed domain local groups into universal groups, make sure that you switch them back to domain local groups when all resources have been migrated.

# Translate Security on Member Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Translate security on member servers to clean up the ACLs of the resources. After objects are migrated to the target domain, resources contain the ACL entries of the source domain objects. Although SID history provides access to resources during the migration, access control lists should be cleaned up after the migration to contain the new primary SID of the migrated groups. Use the Security Translation Wizard in ADMT to replace the source domain SIDs with the target domain SIDs.

**To translate security on member servers by using the ADMT console**

- Complete the Security Translation Wizard by using the information provided in Table 12.18.

**Table 12.18 Using the ADMT Security Translation Wizard**

| Wizard Page | Action |
|---|---|
| Test or Make Changes | Click **Migrate Now?** |
| Security Translation Options | Click **Previously migrated objects**. |
| Domain Selection | In the **Source domain** box, type or select the name of the source domain.<br>In the **Target domain** box, type or select the name of the target domain. |
| Translate Objects | Click **file and folders**, **shares**, **printers**, **user rights**, and **registry**. |
| Security Translation Options | Click **Replace**. |

**To translate security on member servers by using a script**

- Use Listing 12.8 to prepare a script that incorporates ADMT commands and options to translate security on member servers.

**Listing 12.8 Translating Security on Member Servers Within a Forest**

```
<Job id=" TranslatingSecurityOnMemberServersWithinForest" >
<Script language=" VBScript"  src=" AdmtConstants.vbs" />
<Script language=" VBScript" >
   Option Explicit

   Dim objMigration
   Dim objSecurityTranslation

   '
   'Create instance of ADMT migration objects.
   '

   Set objMigration = CreateObject(" ADMT.Migration" )
   Set objSecurityTranslation = objMigration.CreateSecurityTranslation

   '
   'Specify general migration options.
   '

   objMigration.IntraForest = True
   objMigration.SourceDomain = " source domain"
   objMigration.TargetDomain = " target domain"
```

```
   objMigration.TargetOu = " Computers"

   '
   'Specify security translation specific options.
   '

   objSecurityTranslation.TranslationOption = admtTranslateReplace
   objSecurityTranslation.TranslateFilesAndFolders = True
   objSecurityTranslation.TranslateLocalGroups = True
   objSecurityTranslation.TranslatePrinters = True
   objSecurityTranslation.TranslateRegistry = True
   objSecurityTranslation.TranslateShares = True
   objSecurityTranslation.TranslateUserProfiles = False
   objSecurityTranslation.TranslateUserRights = True

   '
   'Perform security translation on specified computer objects.
   '

   objSecurityTranslation.Translate admtData, _
  Array(" computer name1" ," computer name2" )

   Set objSecurityTranslation = Nothing
   Set objMigration = Nothing
</Script>
</Job>
```

For a sample script to assist you in translating security on member servers, see "Translating Security On Member Servers Within a Forest" (DSSRERA_7.wsf) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Translating Security On Member Servers Within a Forest" on the Web at http://www.microsoft.com/reskit).

# Translate Security by Using a SID mapping File

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To translate security so that permissions that are granted to the source account or group are now granted to the target account or group, use a SID mapping file to associate the two accounts. The SID mapping file is a comma-separated-value (CSV) format file that lists pairs of accounts in either a Windows NT account name (domain\name) format or a SID format. The account on the left side of the file is the source account, and the account on the right side of the file is the target account. ADMT security translation translates security from the source account to the target account.

To use a SID mapping file, you must run ADMT from the command line. The parameter is **/SMF**. The full command looks similar to the following:

**ADMT SECURITY /N** " *computer_name* " **/SMF:**" *sid_mapping_file_path* "

A large SID mapping file can take hours to load on the computer that is running ADMT. If the computer that is running ADMT is also an Active Directory domain controller, this problem may affect the performance of that domain controller. For more information and a hotfix to help alleviate this problem, see article 842533 in Microsoft Help and Support at http://go.microsoft.com/fwlink/?LinkId=74264.

# Decommission the Source Domain

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you have migrated all the objects from the source domain to the target domain, including all the computers and member servers, only the domain controllers remain in the source domain. To decommission the source domain, run the Active Directory Installation Wizard to remove Active Directory from the domain controllers in the source domain. Migrate the domain controllers from the source domain to the target domain as member servers. If necessary, depending on the new role that is planned for the servers in the target domain, use the Active Directory Installation Wizard to install Active Directory on the member servers to return them to domain controller status in the target domain. Run security translation on domain controllers if resources reside on the computer that will be used as the new domain controller.

# Example: Completing Post-Migration Tasks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The post-migration team of Contoso Corporation starts the post-migration tasks during the first week of the migration. The team examines the migration log after the first group of migrations is completed on the first day. They analyze the migration log and define the action that is required to migrate any accounts that run into errors so that the migration team can continue with the migration without interruption.

During the second week of the migration process, the deployment team verifies that global groups have returned from universal group to global group status after the migration of users has completed. After the member servers are migrated, the deployment team runs the Security Translation Wizard to remove the source domain SIDs from the ACLs of the member servers. Finally, the deployment team decommissions the Africa domain at the end of the second week by removing Active Directory from the domain controllers in the Africa domain. They then migrate the domain controllers to the EMEA domain as member servers.

# Additional Resources for Restructuring Active Directory Domains Within a Forest

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information and tools related to this chapter.

**Related Information**

- "Designing the Active Directory Logical Structure" in this book for more information about the Active Directory logical structure.
- "Designing the Site Topology" in this book for more information about Active Directory site topology.
- "Restructuring Windows NT 4.0 Domains to an Active Directory Forest" in this book for more information about restructuring Windows NT 4.0 domains to an Active Directory forest.
- "Designing a Resource Authorization Strategy" in this book for more information about creating a security group strategy.

**Related Tools**

- ADMT version 2

  You can use ADMT version 2 to migrate accounts to restructure your Active Directory domains. ADMT includes wizards that you can use to migrate objects such as groups, users, computers, and service accounts. These wizards assist you in performing the appropriate migration for each object type.

# Planning a Secure Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To plan a secure environment, you need a clear and consistent strategy for addressing the many aspects of the Microsoft® Windows® Server 2003 operating system, including security-related issues and features. You can begin by identifying the user-related requirements that impact security, and the other aspects of the network that comprise a secure common infrastructure. You can use this chapter to locate the chapters in this book that can help you address those requirements.

**In This Chapter**

Overview of a Secure Windows Server 2003 Environment

Addressing User-Related Requirements

Establishing a Secure Shared IT Infrastructure

Additional Resources for Planning a Secure Environment

**Related Information**

- For more information about deployment project planning, see "Planning for Deployment" in *Planning, Testing, and Piloting Deployment Projects* in this kit.
- For more information about Active Directory project planning, see "Planning an Active Directory Deployment Project" in this book.
- For more information about Group Policy-related features, see "Planning a Managed Environment" in *Designing a Managed Environment* in this kit.

# Overview of a Secure Windows Server 2003 Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Secure IT environments are the result of careful planning from the time you decide to deploy a new feature or service to the moment when responsibility for those features and services is handed over to those responsible for the day-to-day operation of the network. To ensure a secure IT environment, security must be addressed in every possible area of network design and planning, including such diverse areas as the Active Directory® directory service, networking, and client configuration. Even then, the best security plans and designs in the world cannot protect an organization if security is not an essential part of their operating procedures.

Every organization has its own unique mix of clients, servers, and user requirements that make planning a comprehensive, secure environment a major challenge. Without a consistent approach to security, some areas of the network might benefit from extremely rigorous security while others are only minimally secured.

Fortunately, the Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; Windows® Server 2003, Datacenter Edition; and Windows® Server 2003, Web Edition operating systems, and the Microsoft® Windows® XP Professional operating system provide many features and capabilities that you can use to configure and maintain a secure network operating environment. In fact, there are security capabilities in nearly every area of Windows Server 2003 and Windows XP Professional. Many of these security features and capabilities have been added or enhanced since the introduction of the Microsoft® Windows® 2000 Professional and Windows® 2000 Server operating systems.

This Windows Server 2003 security planning process is based on a high-level view of the security configuration options and capabilities. This security planning process is based on two organizing principles:

- **Users need access to resources.** This access can be very basic, including only desktop logon and the availability of access control lists (ACLs) on resources. This access can also include optional services such as remote network logons, wireless network access, and access for external users, such as business partners or customers.

- **The network requires a secure shared IT infrastructure.** This infrastructure includes security boundaries, secure servers and services, secure networking, and an effective plan for delegating administration.

Together, these building blocks of network operating system security can provide the trust and integrity needed in today's complex operating environments. By analyzing the security requirements of your organization by using a security planning process, you can establish a high-level security framework for your Windows Server 2003 deployment.

**Important**

- This security planning process is not intended to replace a detailed assessment of existing security systems, gaps, and solutions. For more information about designing and deploying a secure Windows Server 2003 environment you need to complete the assessment, design, and planning steps that are described throughout the *Microsoft® Windows® Server 2003 Deployment Kit*. You might also have to assess the non-operating system software, such as messaging, database, and office suite programs, that are used in your environment.

# Addressing User-Related Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

User-related requirements are essential considerations in network design. There are security requirements associated with almost every user-related design decision that you make. For example, who are your users? Do they log on from a computer that is connected to a network? Do they connect to the network while traveling or from home? Are they customers or business partners? Most importantly, how do you verify that your users are who they say they are?

Many chapters in the *Microsoft® Windows® Server 2003 Deployment Kit* require you to assess user and network requirements before you design or plan your implementation of the technologies and capabilities they cover. You should compile and evaluate these requirements across functional lines so that decisions you make in one area do not conflict with your requirements in other areas.

The following items are key security-related user requirements that every organization must address:

- Keyboard logons
- Access to resources

Other user-related requirements are not as universally applicable, though most organizations also implement security-related requirements in the following areas:

- Remote network access
- Wireless network access
- Standard Client configurations
- Encrypting File System (EFS)
- Certificates for secure e-mail and smart card logons
- Extranet access

# Keyboard Logons

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The most fundamental user-related security requirement is authentication of users who log on to the network from computers that are physically connected to the network. Authentication technology in the Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition operating systems allows you to implement a variety of authentication strategies. These strategies can be based on factors such as the complexity of your organization, the quality of a user's credentials, how users access the network, and the clients that they use to gain access.

To plan for the secure use of user and computer accounts based on Windows Server 2003 authentication technologies, use the following guidelines:

- If you have implemented Active Directory in your environment, you can use it to manage users and computers across domains and forests. Deploying Active Directory enables the use of the Kerberos V5 protocol for authentication. This provides the highest level of security and manageability.

- If you are using UNIX, you can use a UNIX Kerberos Key Distribution Center (KDC) to provide authentication services for a realm. Although it is potentially as secure as an Active Directory environment, configuring interoperability with UNIX Kerberos realms is more complex to configure and maintain.

- If you have not upgraded to an Active Directory environment, you can rely on the Security Accounts Manager (SAM) and NTLM to authenticate local users. This option is not as secure as using Active Directory and the Kerberos V5 protocol to authenticate users.

You can also meet differing security needs by varying the strength of credentials that you enforce:

- You can rely on passwords, and define password complexity requirements and password expiration requirements.

- For greater credential strength, you can issue computer- or smart card–based certificates to users and computers. Although these certificates are more difficult to configure and administer, they make it possible to use credentials that are much more complex and secure than any user-conceived password.

For more information about creating a basic authentication framework, see "Designing an Authentication Strategy" in this book. For more information about using certificates to enhance the authentication process, see "Designing a Public Key Infrastructure" in this book. For more information about using smart cards for authentication, see "Planning a Smart Card Deployment" in this book.

# Access to Resources

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

There is little reason to authenticate users and computers unless you also intend to allow them to access resources on the network. Few organizations allow all security principals, no matter how carefully authenticated, to access all resources on the network. Therefore, you need a strategy to manage access to resources.

The first part of this process is identifying your users by workgroup, job function, or a combination of workgroup and job function. You can then identify the different types of resources that users might access, such as departmental or job-specific data. This step allows you to plan for different levels of access. In Windows Server 2003 and Windows XP Professional, there are four basic strategies for controlling access to resources:

- **User/ACL method.** Security principal accounts are added directly to the ACL for a resource. The ACL is then configured to allow the appropriate permissions for each security principal. This option is appropriate only for managing basic access to a limited number of resources for a small number of users. Otherwise, the complexity and administrator time needed to set and maintain the appropriate permissions becomes burdensome.

- **Account group/ACL method.** Security groups, rather than individual security principal accounts, are added to the resource ACL, and the group is given a set of access permissions. The Account group/ACL method is scalable because security groups can be nested if your domain is configured for Windows 2000 or Windows Server 2003 native mode functional levels. If groups from multiple domains or from multiple forests require identical access permissions, they can be grouped together into one all-encompassing security group, and you can add this security group to the resource ACL. However, if different groups require different access permissions, this method requires more administrative effort from the resource owner. In this case, each group must be added to the ACL separately, and access permissions must be granted to each group.

- **Account group/resource group method.** Users with similar access requirements are grouped into account groups, and the account groups are added to a resource group that is granted specific resource access permissions. The Account group/resource group method is often most appropriate for large organizations with many shared resources because it is scalable and can be maintained in all environments and at all domain functional levels. This method can be used in any environment, but it is most useful when you cannot nest groups because, for example, your domains are at Windows 2000 mixed functional levels or you need to share resources with Microsoft® Windows NT® version 4.0 operating system domains. The Account group/resource group method is also preferable if your resources require a stable set of common permissions.

- **Role-based authorization method.** Users with similar roles are authorized to perform predefined sets of tasks based on scripts called authorization rules. This allows you to apply fine-grained control over the mapping between access control and the structure and tasks performed in your organization. To use role-based authorization, however, programs need to be written to take advantage of this capability. Additionally, your environment must be operating at the Windows Server 2003 domain functional level.

For more information about establishing and deploying an access management strategy, see "Designing a Resource Authorization Strategy" in this book. For more information about role-based authorization, see the Microsoft Platform SDK link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources. Your authorization strategy is also a factor in other design and deployment processes, such as server deployments. For more information about deploying file and print servers, see "Designing and Deploying File Servers" and "Designing and Deploying Print Servers" in *Planning Server Deployments* in this kit.

# Remote Network Access

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A growing number of employees require remote network access. Many of these employees are traveling and might have different levels of connectivity from one day to the next. Other employees simply find it efficient to work at a customer location or at home, at least some of the time. Configuring each user's computer for remote network access or relying on users to configure their own computers for remote network access can lead to heavy support responsibilities.

To address this problem, you can use Connection Manager to customize a self-installing service profile for the Connection Manager client. The Connection Manager client allows your users to either connect to your network directly or to create a virtual private network (VPN) connection from a remote location. This solution reduces administration by providing a single connection client for all remote access users. Additionally, it allows you to configure precise client security settings, such as idle timeout time, maximum session time, and encryption strength.

**Note**

- To provide this service, you need to configure remote access to support a dial-up network, a virtual private network (VPN), or a combination of both. For more information about these options, see "Securing Network Traffic" later in this chapter.

For more information about deploying Connection Manager solutions, see "Deploying Remote Access Clients Using Connection Manager" in *Deploying Network Services* in this kit.

# Wireless Network Access

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Direct wire-based connections to the network are not always practical, even within the physical premises of an organization. With a wireless local area network (WLAN), users of portable computers can access their network connections from any facility in which the organization has wireless access points.

However, wireless networks have significant security implications:

- Any person with a compatible wireless network adapter can potentially associate with your wireless access points. To counter this security risk, wireless access points must require authentication and authorization of the wireless client before data can be sent to, and received from, the network that is attached to the wireless access points.

- In some situations, you might want to allow limited unauthenticated wireless access. For example, in a corporate environment, you can grant guest access to visitors, such as consultants, by redirecting them to a specific virtual LAN (VLAN) that provides only limited network access, such as access to the Internet.

- Wireless networking signals use radio waves to send and receive information. Anyone within a certain distance of a wireless access point can detect and receive all data sent to and from the wireless access point. To counter this threat, you can encrypt the data that is sent between the wireless clients and the wireless access points by using Wired Equivalent Privacy (WEP). For increased security, you can use certificate-based encryption, which requires both a public key infrastructure (PKI) and that a certificate be installed on each wireless client.

For more information about designing a wireless LAN, see "Deploying a Wireless LAN" in *Deploying Network Services* in this kit. For information about deploying a public key infrastructure to support a wireless network, see "Designing a Public Key Infrastructure" in this book.

# Standard Client Configurations

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Most IT organizations think of their users as customers of their services. However, users can unintentionally become adversaries of the IT department when they install their own software and then require support for this software, when they tinker with and damage approved software programs, when they inadvertently allow viruses onto their computers and, ultimately, the network, and when they fail to protect their data by performing proper maintenance tasks, such as periodic backups.

For these reasons, many organizations consider establishing and maintaining the Standard Client configurations as one of the most significant security and cost-related challenges that they face. Consider the following questions:

- How do you define and implement secure client and server configurations?
- How do you deploy, update, and repair user programs?
- How do you update server and client operating systems with required service packs and patches?
- How do you ensure that user data is adequately protected against potential hardware failures?
- How do you prevent unauthorized users from viewing user data, even if they gain physical access to the computer?

Windows Server 2003 provides a number of features that you can use to enhance security by implementing and maintaining Standard Client configurations. These include:

- **IntelliMirror user settings management.** This feature can be used to define and implement a wide variety of user security settings.
- **IntelliMirror software installation and maintenance.** This feature can be used to deploy, update, and repair user programs.
- **Software Update Services.** This feature can be used to update the operating system itself with required service packs and patches.
- **IntelliMirror user data management.** This feature can be used to protect user data by storing it on a network server.
- **Encrypting File System.** This feature can be used to prevent unauthorized users from viewing data, even when they have physical access to a computer.

**Defining Secure Configurations**

The way you configure your clients and servers has a critical impact on the protection that you provide for network resources and how vulnerable you are to attacks. Creating secure configurations can be daunting. There are so many security-related options that configuring and applying each individual setting to individual clients and servers is virtually impossible.

To address this issue, Windows 2000 and Windows Server 2003 provide a wide variety of Group Policy–based security policy settings that can be configured once and applied at the same time to hundreds or thousands of servers and clients. These servers and clients must be running Windows Server 2003, Windows 2000, or Windows XP Professional. You can use Group Policy to deploy and manage the following types of security policies:

- **Password policies.** These policies are used to enforce restrictions that relate to password age, length, and complexity.
- **Account lockout policies.** These policies define options for the number of unsuccessful logon attempts that are allowed.
- **Audit policies.** These policies are used to track account logon, object access, and management events.

- **User rights assignments.** These policies are security options that apply to user accounts.
- **Security options.** These policies enable you to set and enforce well-known security-related registry options without editing the registry.
- **Public key policies.** These policies allow you to enable or prevent certificate auto-enrollment and renewal.
- **Encrypting file system policies.** These policies allow you to establish a data recovery agent for files and folders that have been encrypted by using EFS.
- **Software restriction policies.** These policies are used to protect computers from code that is not trusted by identifying and specifying which programs are allowed to run.
- **Internet Protocol security (IPsec) policies.** These policiesare used to configure IPsec services for authenticating or encrypting network traffic. An IPsec policy consists of a set of security rules, and each security rule consists of an IP filter with an action.

Setting and applying security policies to large numbers of computers by using Group Policy is much easier than setting security policy on individual computers. To simplify the task of selecting security policy settings, Windows Server 2003 comes with a number of security policy templates that combine groups of security policy settings for different scenarios. The following server security policy templates are available:

- **Setup Security.inf.** This policy template provides the default security settings that are applied during installation of the operating system, including the file permissions for the root of the system drive.
- **DC Security.inf.** This policy template provides the default security settings for domain controllers.
- **Compatws.inf.** This policy template changes the default file and registry permissions that are granted to users. It also removes all members of the Power Users group.
- **Secure.inf.** This policy template definesenhanced security settings that are least likely to impact application compatibility and restrict anonymous users. This policy template also limits the use of LanManager and NTLM authentication.
- **Hisec.inf.** This policy template includes supersets of the secure templates that impose further restrictions on the levels of encryption and signing required for authentication and for the data that flows over Secure Channels and between SMB clients and servers. It also removes all members of the Power Users group.
- **Rootsec.inf.** This policy template provides system root security, and defines the new permissions that were introduced with Windows XP Professional for the root of the system drive.
- **Notssid.inf.** This policy template removes the Terminal Server user security identifier (SID).

**Note**

- Similar client-specific versions of the Setup, Compatible, Secure, and Highly Secure templates are available for computers that are running Windows XP Professional.

You can apply these templates without modification to servers and clients in your organization. You can also modify a few settings on these templates and then apply the templates, or you can create your own security policy templates that contain only the security policy settings that you want.

Many organizations prefer to use the most secure policy templates that still allow all of their required programs and usage scenarios to succeed. Whichever option you select, you need to test your security policy settings thoroughly to ensure that they meet your security requirements without unduly restricting the ability of your users to complete their tasks.

For more information about selecting and deploying security policy settings and security policy templates that are appropriate

for your organization, see "Deploying Security Policy" in *Designing a Managed Environment* in this kit.

**Managing Application Software**
Many organizations rely on tens or even hundreds of software programs to conduct their business. Software administrators have to ensure that users have continuous, reliable access to these programs, including deploying new programs when they become available, updating them on a timely basis, and removing them when they are no longer needed.

At the same time, most administrators want to prevent users from installing or running unknown or potentially dangerous software. At the most benign level, users might merely be installing games or other software that distracts them from their assigned tasks. However, even games or other "harmless" software can at times corrupt a system or require help desk support. At the most dangerous level, unauthorized programs might release a harmful virus or open a security hole in the network.

To make matters more complex, software management is not a solution that can be configured once for all types of programs and all types of users. Certain programs, such as antivirus and e-mail programs, are needed by every user. Other programs might be needed only by users in certain departments or by users who perform certain tasks. Some users, such as frequent travelers, may only be connected to the network intermittently at varying speeds, and they might want to control when large programs are downloaded.

IntelliMirror software management allows you to address these concerns by doing the following:

- Mandating the installation of certain software on every computer.
- Requiring other programs only on certain computers.
- Making other programs available for installation on an as-needed basis or when the user has an adequate connection and time to complete the installation.
- Automatically repairing or updating programs as needed.

Base your software management options on the requirements, locations, and connectivity that are available to your users. For more information about selecting and configuring appropriate software management options for your organization, see "Deploying a Managed Software Environment" in *Deploying a Managed Environment* in this kit.

**Managing Operating System Updates**
Hostile users are constantly looking for vulnerabilities in operating systems. As new vulnerabilities are exposed and solutions become available, it is up to network administrators to ensure that patches and service packs are installed on a timely basis.

Maintaining operating system software through the deployment of patches and service packs has become an increasingly challenging part of organizational security strategies. Until recently, organizations had to check the Windows Update Web site for operating system patches, and then download, test, and distribute patches manually.

A new Windows Server 2003 feature, Microsoft Software Update Services (SUS), helps you collect, approve, and distribute critical operating system patches to resolve known security vulnerabilities and stability issues. You can use these services on computers that are running Windows 2000, Windows XP Professional, and Windows Server 2003.

As an alternative, you can use Microsoft® Systems Management Server (SMS) with an SUS Feature Pack to deploy and manage software patches.

When you choose whether to use Windows Update, SUS, or SMS, consider the following:

- For home offices and small businesses, manual deployment of operating system patches using Windows Updates remains the recommended solution.
- For medium-size organizations (one or more locations with up to 500 users), SUS is the recommended method for distributing operating system patches and service packs.
- For large organizations, SMS is the recommended software-management solution. However, SUS can also work in these environments if the following circumstances exist:
    - You do not need to support clients that are running Microsoft Windows NT 4.0.
    - You need a deployment method only for patches that are not critical updates.

- The needs of your organization are met by SUS and do not require the more comprehensive reporting tools that are included in SMS.

**User Data Management**

Users typically do not back up their data, so if a user has a computer failure or works on a different computer, his or her data is no longer available. IntelliMirror data management allows you to protect and improve the availability of users' data resources by storing them on a network server, where they can be backed up regularly and made available when a user logs on to any computer on the network.

Typically, users in larger organizations have a wide range of data management needs in addition to the data management needs of the organization itself. Users also typically have user settings that must be available to them wherever they log on to the network. Consider not only the needs of the organization, but also the different work needs of different types of users before you design and deploy services that define the users' computing environment.

To develop a plan for managing users' data and settings, categorize users according to their job types and computer experience. Determine if users need to be able to work from any computer on the network and if they need to retain access to network-based files when disconnected from the network.

When planning a deployment, determine the following:

- The number of users to be accommodated. The allocation of resources, such as disk space and network bandwidth varies depending on the number of users.

- The primary programs and computing services in use in the organization, such as databases and e-mail programs. Databases are stored on network shares and do not move with users. However, user settings typically must be available to users wherever they log on to the network. E-mail programs might store users' e-mail folders on network shares or on the local computer. In either case, these folders must remain available.

- If mobile users switch from one computer to another or each user uses a single portable computer in different locations. A user who switches between computers might benefit from Roaming User Profiles more than a user who works exclusively on a single computer.

- The security requirements of different users, programs, and data files. Security involves both access controls and backup requirements.

For more information about planning and deploying IntelliMirror data management, see "Planning a Managed Environment" in *Deploying a Managed Environment* in this kit.

# Encrypting File System (EFS)

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In many organizations, a high percentage of users travel with portable computers that they use in customer facilities, airports, hotels, and at home. This means that valuable data is often beyond the control of the organization. If the user's computer is stolen, a hostile user can bypass many aspects of the operating system's security and possibly gain access to sensitive data. The same problem can exist even with desktop computers that are shared among multiple users.

One solution to this problem is to encrypt sensitive files by means of EFS, which adds another layer of security. When files are encrypted, user data is protected even if an attacker has full access to the computer's data storage. Users can encrypt files if they have permission to modify the files. To use EFS, all users must have EFS certificates. These certificates can be self-signed or they can be issued and managed by using a PKI. Businesses that have a PKI and use it to deliver EFS certificates to users can significantly simplify the manageability and recovery of data that is encrypted with EFS if the key becomes lost.

If EFS is not appropriate in your environment, or if you have files that you do not want to be encrypted, you can partially or completely disable EFS in various ways. There are also a number of ways in which you can configure EFS to meet the specific needs of your organization.

For more information about deploying EFS, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

# Securing E-mail

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Many organizations place a high priority on implementing more secure mail services that provide confidential communication, data integrity, and nonrepudiation. In today's increasingly interconnected network environments, intruders can monitor mail servers and network traffic to obtain proprietary or sensitive information. You also risk exposure of proprietary and confidential business information when you send mail over the Internet from within your organization. Additionally, on IP networks, anyone can impersonate mail senders by using readily available tools to counterfeit the originating IP address and mail headers. When you use standard Internet mail, you can never be absolutely certain who really sent a message or whether the contents of the message are valid.

Windows Server 2003 allows you to enhance e-mail security by issuing user certificates that prove the sender's identity, the mail's point of origin, and the authenticity of the message. These certificates can also make it possible to encrypt mail to protect the confidentiality of data. However, encryption also results in a greater likelihood that the recipient will not be able to read the document if he or she does not have the needed decryption key.

- To issue e-mail certificates, you either need to contract for this service with an independent certification authority (CA) or configure one or more certification authorities for your own organization by using Certificate Services that are available in Windows Server 2003.

For more information about configuring a network of CAs to issue and manage certificates for secure-e-mail and other programs, see "Designing a Public Key Infrastructure" in this book.

# Securing the Logon Process with Smart Cards

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A growing number of organizations are concerned that conventional password-based logons do not provide sufficient security. They base this concern on potential vulnerabilities posed by:

- Interactive logons by users
- Interactive logons by administrators or other personnel who have access to sensitive systems or data
- Logons by users who are accessing the network from a remote location and computer

Requiring the use of secure encrypted logon credentials that are stored on a smart card can enhance the security of any or all of these scenarios. However, requiring the use of smart cards and smart card readers can impose significant costs and requires substantial administrative support.

Additionally, requiring smart cards for interactive user or administrator logons can be particularly problematic for organizations that are spread across different geographic locations. They can also be problematic for organizations that do not have security personnel in each location to administer and support smart cards.

Another problem that occurs with the use of smart cards for remote access logons is that remote users often own computer hardware and software that does not conform to minimum corporate standards, and therefore might not support smart card use. This complicates your ability to administer and promote the use of smart cards for remote access logons.

Finally, consider that users might experience longer logon times when they use smart cards, especially over slow dial-up connections.

For more information about evaluating and planning for the use of smart cards in your organization, see "Planning a Smart Card Deployment" in this book.

# Setting Up Extranet Access

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A growing number of organizations find it valuable to share some restricted data with business partners, contractors, suppliers, and customers. You can accomplish this by combining the same networking technologies that you use on your public Internet Web sites and internal intranet with a tight security model to form an extranet. In fact, extranets have become a primary means of interaction between companies that contribute to each other's everyday business.

There are many aspects involved in setting up a secure extranet. For many organizations, the two key steps involve:

- Preventing unauthorized users from accessing data that is not intended for them.
- Encrypting all data that is transferred between the client and the Web server.

The authentication methods that you select vary based on the method's ability to protect the users' credentials (user account and password information). To ensure your users' credentials are protected, select the strongest authentication method possible.

The following authentication methods are used for Web site authentication:

- **Anonymous authentication.** This method gives anonymous users the right to log on locally. You can set up different anonymous accounts for different Web sites, virtual directories, directories, and files. This provides a great deal of flexibility and fine control by specifying where specific accounts can be used within the site.
- **Basic authentication.** This authentication method is supported by most Web servers and Web browsers. With Basic authentication, you can restrict access to files on a server that is running Internet Information Services (IIS) 6.0 by using NTFS file system security. Users must enter credentials, which allows you to track access based on the user ID. You can use this method to restrict access to some parts of the Web server when you cannot guarantee that the user's browser supports integrated Windows authentication, and you must authenticate through a proxy server.
- **Digest authentication.** This method does not send the password in clear text, unlike Basic authentication. Additionally, Digest authentication can work through proxy servers, unlike integrated Windows authentication.
- **Advanced Digest authentication.** This method is a newer version of Digest Authentication that was introduced with Windows XP Professional. In Advanced Digest authentication, the client uses a hash of the password, which is the same as the hash of the password that is stored on the server. Older Web browsers do not support Advanced Digest authentication.
- **Integrated Windows authentication.** This method uses either NTLM authentication or Kerberos authentication and the current credentials of the logged on user to authenticate to the Web server. This method is primarily used for intranet situations.
- **Certificate authentication.** This method can be used to allow both servers and clients to authenticate each other. Server certificates usually contain information about your company and the organization that issued the certificate. Client certificates usually contain identifying information about the user and the organization that issued the certificate.

To provide confidential data exchange, you encrypt the data that is transferred between the client and the Web server. Based on the type of client that might access your program, select one of the following methods for encrypting the data:

- **Secure Sockets Layer (SSL).** This method can be used when you are creating an Internet solution, the client computers are not a part of your organization, and you want to avoid installing any files on the client computers.
- **IPsec.** This method can be used when you are creating an intranet or an extranet partner solution, the client computers are a part of your organization or a partner organization, it is acceptable to install certificates on the client computer, and the client computers have high-speed persistent connections to your private network.

- **VPN.** This method can be used when you are creating an intranet or an extranet partner solution, the client computers are a part of your organization or a partner organization, it is acceptable to install certificates on the client computers, and the client computers are connecting over direct or dial-up Internet connections.

For more information about security and IIS, see "Securing Web Sites and Applications" in the *Internet Information Services (IIS) 6.0 Deployment Guide* in this kit (or see "Securing Web Sites and Applications" on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=48683). For more information about designing and deploying IPsec, see "Deploying IPSec" in *Deploying Network Services* in this kit. For more information about designing and deploying VPN, see "Deploying Dial-up and VPN Remote Access Servers" in *Deploying Network Services* in this kit. For more information about designing a public key infrastructure and certificates for use with external clients, see "Designing a Public Key Infrastructure" in this book.

# Establishing a Secure Shared IT Infrastructure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Not all security-related features apply directly to users. Many basic network services and configuration decisions involve creating and defining explicit boundaries, securing network traffic, and securing your servers.

# Creating and Enhancing Security Boundaries

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As networks become more complex, they can become more difficult to manage. Windows NT 4.0 introduced the concept of domains to enhance an administrator's ability to manage the users and computers in a network. The domain concept has been enhanced and expanded considerably in Windows 2000 and Windows Server 2003 to address security concerns of organizations, including the following concerns:

- Organizations that have acquired subsidiaries with significantly different administrative and security requirements.
- International organizations that want to divide up administrative and security responsibilities along national or regional boundaries.
- Rapidly growing organizations that want to unify security and administrative responsibilities across disparate business units.

Active Directory in Microsoft Windows Server 2003 enables organizations to simplify user and resource management; support directory-enabled programs; and create a scalable, secure, and manageable infrastructure. A well-designed Active Directory logical structure provides the following benefits:

- Centralized management of Windows networks that contain large numbers of objects
- A consolidated domain structure and reduced hardware and administration costs
- The supporting framework for Group Policy–based user, data, and software management
- The ability to delegate administrative control over resources
- Integration with services such as Microsoft® Exchange 2000 Server, a PKI, and domain-based distributed file system (DFS)

Achieving these results requires careful planning of the following elements:

- **Domains.** An administrative unit in a computer network that groups a number of capabilities for management convenience, including network-wide user identity, authentication, trust relationships, policy administration, and replication.
- **Forests.** One or more Active Directory domains that share a schema and global catalog. Each forest is a single instance of the directory and defines a security boundary.
- **Organizational units.** Active Directory containers where you can place users, groups, computers, and other organizational units. You can use organizational units to create containers within a domain to represent the hierarchical and logical structures within your organization.

The way that you plan your domains, forests, and organizational units plays a critical role in defining your network's security boundaries. The relationship might sometimes be based on administrative requirements; at other times, the relationship might be defined by operational requirements such as controlling replication. Additionally, if you have multiple forests, you need to plan the logical trust relationships between forests that allows pass-through authentication.

**Domains, Forests, and Organizational Units**

Active Directory is a distributed database that stores and manages information about network resources. The way that you organize Active Directory determines how well you can manage network resources and distribute administrative responsibilities.

Active Directory allows administrators to organize elements of a network (such as users, computers, and devices) into a

hierarchical, tree-like structure based on containers. The top-level Active Directory container is the forest. Forests include domains, and domains include organizational units. Administrative ownership and control in Active Directory containers are organized in the following ways:

- The default administrative owner of a forest is the Domain Admins group of the forest root domain. The Domain Admins group of the forest root controls the membership of the Enterprise Admins and Schema Admins groups. By default, the Enterprise Admins and Schema Admins groups have control over forest-wide configuration settings, which also makes them service administrators.

- The default administrator of a domain is the Domain Admins group of the domain. Because the Domain Admins control domain controllers, they are also service administrators. All non-root Domain Admins in a forest are peers, regardless of their domain's position in the naming hierarchy.

- Control over an organizational unit and the objects within it is determined by the ACLs on the organizational unit and on the objects in the organizational unit. Users and groups that have control over objects in organizational units are data administrators.

To facilitate the management of large numbers of objects, Active Directory supports administrative delegation at the container level. If administrative control is the priority for your organization, base your logical structure design on forests and organizational units. Forests and organizational units are used to control the delegation of authority throughout the directory. Many organizations consolidate divisions into a single forest to enhance their users' ability to collaborate and to reduce costs.

If you choose to organize Active Directory according to geographic location, you must apply a domain model to your logical design. Domains let you control where information is replicated and let you partition data so that it can be stored where it is used most frequently. A well-designed domain model prevents unnecessary replication and promotes more efficient use of available bandwidth between remote locations.

To determine the number of forests that your organization requires, identify the isolation requirements for each division of the organization that will be using the directory service. Consider the following elements:

- Generally, a single forest deployment isolates data from parties outside the organization. If your organization includes more than one IT group, the only way to achieve isolation in a single forest environment is to select one IT group to act as the administrators of the forest, and then make the other IT groups in the organization relinquish control of the directory.

- If divisions of your organization require that you isolate data from the rest of the organization, you must deploy multiple forests. For example, you might need multiple forests if legal or contractual obligations require that your organization guarantees the security of data for a particular project.

- If your organization includes multiple divisions with separate IT groups, each IT group might prefer to manage its own forest; however, your business needs might require resource sharing between divisions. You can deploy multiple forests, each of which is managed by an individual IT group, and then establish external trusts between the forests to facilitate collaboration. In this type of environment, be careful to avoid granting administrative access to users in other forests.

**Trusts**

If your organization includes more than one forest, you must enable the forests to allow authentication and resource sharing. You can do this by establishing trust relationships between some or all of the domains in the forests. The types of trust relationships that you can establish depend on the versions of the operating system that are running in each forest:

- **Authentication between Windows Server 2003 forests.** When all domains in two forests trust each other and must authenticate users, establish a forest trust between the forests. When only some of the domains in two Windows Server 2003 forests trust each other, establish one-way or two-way external trusts between the domains that require interforest authentication.

- **Authentication between Windows Server 2003 and Windows 2000 forests.** It is not possible to establish transitive forest trusts between Windows Server 2003 and Windows 2000 forests. To enable authentication with Windows 2000 forests, establish one-way or two-way external trusts between the domains that need to share resources.

- **Authentication between Windows Server 2003 and Windows NT 4.0 forests.** It is not possible to establish transitive forest trusts between Windows Server 2003 and Windows NT 4.0 domains. Establish one-way or two-way

external trusts between the domains that need to share resources.

For more information about designing Active Directory forests, see "Designing the Active Directory Logical Structure" in this book. For more information about implementing trusts between forests, see "Designing an Authentication Strategy" in this book.

# Public Key Infrastructure (PKI)

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A growing number of organizations are choosing to use digital certificates for programs, including the following:

- Secure e-mail
- Software code signing
- Internet authentication
- IP security
- Smart card logon
- Encrypting File System user and recovery certificates
- Wireless (802.1x) authentication

Before you can enable these programs, you must contract with a third-party authentication service or use Windows Server 2003 to configure one or more CAs as a PKI to issue and manage your digital certificates.

An outside authentication service might be a good option if you plan to use your certificates outside of your own organization, but they can also be expensive and relatively inflexible.

If you plan to use your certificates only within your organization or with a limited number of business partners with whom you share resources, setting up and maintaining an internal PKI can be both less expensive and open to modification as your needs change.

A Windows Server 2003 PKI makes it possible for an organization to perform the following tasks:

- **Publish certificates**. The PKI administrator makes certificate templates available to clients (users, services, programs, and computers) and enables additional CAs to issue certificates.
- **Enroll clients**. To participate in a PKI, users, services, and computers must request and receive certificates from an issuing CA. Typically, enrollment is initiated when a requester provides unique identifying information and a newly generated public key. The CA administrator or enrollment agent uses this unique identifying information to authenticate the identity of the requester before issuing a certificate.
- **Use certificates**. Client certificates are validated while CAs and certificate revocation lists are available to verify or deny their authenticity. If they are validated, a PKI provides an easy way for users to use keys in conjunction with programs that perform public key cryptographic operations. This makes it possible to provide security for e-mail, e-commerce, and networks.
- **Renew or revoke certificates**. A well-designed PKI makes it easy for you to renew or revoke existing certificates and to manage the trust levels that are associated with certificates used by different clients or for different programs.

Because certificates are intended to enhance the quality of a user's or computer's identification, almost every decision you make regarding certificate services — from the number and placement of certification authorities to the specifications for the useful life of each certificate — can have a significant impact on the effectiveness of a PKI as a security solution. For more information about setting up and maintaining a PKI, see "Designing a Public Key Infrastructure" in this book.

# Securing Network Traffic

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Hostile users have become increasingly sophisticated in monitoring and compromising network traffic. The tools that are available to assist them in their activities have also become more powerful every year. At the same time, most organizations want to open up their networks to support new methods of doing business that are enabled by telecommunications. Supporting these business scenarios without compromising security requires the use of very critical networking technologies, including the following:

- Remote access servers
- IPsec
- Internet Authentication Service (IAS)
- Microsoft Internet Security and Acceleration (ISA) Server

A consistent and integrated plan for using these features along with other components of the networking infrastructure can enhance the security of your environment.

**Remote Access Servers**

A growing number of users require access to the network when they are away from the organization's physical premises. However, opening up your network to the outside world poses potential security risks.

To support users who require access to your network from remote locations without compromising security, you can deploy a dial-up network, a virtual private network (VPN), or a combination of both.

- A *dial-up network* enables remote users to dial in directly to a remote access server on your network.
- A *VPN* enables remote users who are connected to the Internet to establish a connection to a VPN server on your network through a VPN connection.

Dial-up connections are inherently more private than a solution that uses a public network such as the Internet. However, with dial-up networking, your organization faces a large initial investment and continuing expenses throughout the life cycle of the solution. These expenses include:

- **Hardware purchase and installation.** Dial-up networking requires an initial investment in modems or other communication hardware, server hardware, and phone line installation.
- **Monthly phone costs.** Each phone line that is used for remote access increases the cost of dial-up networking. If you use toll-free numbers or the callback feature to defray long distance charges for your users, these costs can be substantial. Most businesses can arrange a bulk rate for long distance, which is preferable to reimbursing users individually at their more expensive residential rates.
- **Ongoing support.** The number of remote access users and the complexity of your remote access design significantly affects the ongoing support costs for dial-up networking. Support costs include network support engineers, testing equipment, training, and help desk personnel to support and manage the deployment. These costs represent the largest portion of your organization's investment.

If you use a VPN for remote access, users connect to your corporate network over the Internet. VPNs use a combination of tunneling, authentication, and encryption technologies to create secure connections. VPNs reduce remote access expenses by using the existing Internet infrastructure. You can use a VPN to partially or entirely replace your centralized, in-house, dial-up remote access infrastructure and legacy services.

VPNs offer two primary benefits:

- **Reduced costs.** Using the Internet as a connection medium saves long-distance phone expenses and requires less hardware than a dial-up networking solution.

- **Sufficient security.** Authentication prevents unauthorized users from connecting to your network. Strong encryption methods make it extremely difficult for a hostile party to interpret the data that is sent across a VPN connection.

For more information about deploying dial-up remote access server and VPN solutions, see "Deploying Dial-up and VPN Remote Access Servers" in *Deploying Network Services* in this kit.

**IPsec**

Although business networks typically separate their internal networks from the Internet by using a limited number of security gateways, internal corporate networks have become so complex that it is difficult to know that all critical data is protected at all times from external and internal attackers. Using a firewall to block incoming traffic by port is not always practical because it is difficult to identify all ports that require protection. IPsec provides a much stronger access model based on enforcing trusted communication.

You can use the Windows Server 2003 implementation of IPsec to compensate for the limited protection for network traffic provided by programs, or as a network-layer foundation of a defense-in-depth strategy. While the IPsec features in Windows Server 2003 provide greater security, they are not always compatible with earlier versions of Windows.

The first step in deploying IPsec on your network is to determine which data and which computers you need to secure and at what level of security. Although adding IPsec security can protect your network and data, it can also produce tradeoffs in performance, and some computers might not support the security you require.

For more information about planning and implementing IPsec in your environment, including how to choose between IPsec and other solutions, see "Deploying IPSec" in *Deploying Network Services* in this kit.

**IAS**

Not all users can be directly authenticated by Active Directory. For example, organizations that outsource network access or form joint ventures with other organizations require the authentication of user accounts from outside their private network. In addition, organizations that provide outsourcing services, such as Internet service providers (ISPs), face the increasingly complex challenge of managing all types of network access from a single point of administration, regardless of the type of network access equipment that is used.

IAS allows you to provide authentication and authorization for the following types of network access:

- Dial-up

- VPN

- Wireless

- Switch access

IAS also allows you to apply different types of security policies to different groups based on their mode of access and quality of credentials.

For more information about planning an IAS deployment, see "Deploying IAS" in *Deploying Network Services* in this kit.

**ISA Server**

The Internet is a tremendous source of information for the employees of many organizations. News updates, background information about customers, product research, and other activities are just a few of the business activities that are enhanced by the Internet.

Allowing employees to access the Internet poses significant reliability and security risks:

- **Reliability.** Network bandwidth might be compromised if too many users access the Internet at the same time.

- **Security.** Allowing users to access resources outside the organization's network can create a potential breach in the network's perimeter defenses.

ISA Server allows you to address these concerns with two important capabilities:

- **A multilayer firewall with integrated intrusion detection**. ISA is a complete firewall product that provides packet filtering, stateful packet inspection and application-level awareness for many common protocols, such as Simple Mail Transfer Protocol (SMTP) and Domain Name System (DNS). You can create access policies based on user-level information, IP addresses, or Web content.

- **A caching server.** You can configure ISA Server to cache content that your organization uses frequently or that your Internet clients access.

ISA Server can be configured to perform one or more of these tasks. In addition, it can be configured for the following uses:

- To connect to remote sites

- To secure network perimeters

- To support extranets

For more information about these design and deployment options, see "Deploying ISA Server" in *Deploying Network Services* in this kit.

# Securing Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In general, servers are only as secure as the configuration options that you enable or disable. The security of the configuration options depends on who can access the servers. A secure server configuration for one organization might not be secure for another organization. Whether security is adequate depends on a variety of factors, such as where the server is on the network, what data is stored on the server, what role the server plays, and who administers it. One point is certain, however: securing servers requires painstaking attention to detail based on strict evaluations of what services and configuration options are needed and not needed, and testing to ensure that access control mechanisms perform without preventing the server from performing its legitimate tasks.

The *Windows Server 2003 Deployment Kit* includes detailed information about how to configure and administer servers securely for a variety of specific roles. In addition, you can enhance general server security by doing the following:

- Whenever possible, keep critical servers offline or unavailable to the Internet.
- Require administrators to use smart cards when they access your servers.
- Implement a strategy for auditing all activities on critical servers.
- Create standard server configurations and require their use whenever a server is deployed to fill a similar role, even in remote offices or in subsidiaries.

# Planning for Secure Administration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Just as organizations need to configure and manage access by users to files, shares, and other resources, you also need to delegate administrative tasks in Windows Server 2003 environments. Delegating these tasks allows you to distribute the administrative workload without granting sweeping privileges to each person. From a high-level perspective, your decisions regarding delegation of administration will be based on the following four factors:

- Isolation: The degree to which administrative roles need to be separated.
- Autonomy: The limits that you want to place on the ability of any administrator or group to act unchallenged.
- Service administration: The authority to manage key network services.
- Data administration: The authority to manage key data resources.

For example, you might choose to delegate administration to meet one or more of the following needs:

- **Organizational structure requirements**. Parts of an organization might participate in a shared infrastructure to save costs, but they might also want the ability to operate independently from the rest of the organization. For example, a research division within a large organization might want to maintain control over all of its own research data.
- **Operational requirements**. One part of an organization or a program that leverages Active Directory might place unique constraints on directory service configuration, availability, or security. Examples are found in:
    - Military organizations
    - Hosting scenarios
    - Organizations that maintain a directory that is available both internally and externally (publicly accessible by users on the Internet)
- **Legal requirements**. Some organizations have legal requirements that require them to operate in a specific manner, such as restricting access to certain information. These requirements commonly apply to the following types of organizations:
    - Financial institutions that need to maintain private client financial records
    - Defense contractors working on classified military projects
    - Government organizations that maintain top secret data

For information about delegation of administration, see "Designing the Active Directory Logical Structure" in this book. For information about how to use security groups to delegate administrative tasks, see "Designing a Resource Authorization Strategy" in this book. For information about deploying smart cards for administrative logons, see "Planning a Smart Card Deployment" in this book.

# Additional Resources for Planning a Secure Environment

Updated: March 28, 2003

# Designing an Authentication Strategy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Most organizations need to support seamless access to the network for multiple types of users, such as workers in offices, employees who are traveling, and perhaps even business partners and customers. At the same time, organizations need to protect network resources from potential intruders. A well-designed authentication strategy can help you achieve this complex balance between providing reliable access for users and strong network security for your organization.

# Overview of the Authentication Strategy Design Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

One of the most fundamental elements of an organization's security strategy is verifying the identity of clients and granting them appropriate access to system resources based on their identity. By creating an authentication strategy for your organization, you can prevent attackers and malicious users from accessing and tampering with sensitive information, consuming computing power or other system resources, and impersonating users in order to send misleading or incorrect information.

Authentication technology in the Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; and Windows® Server 2003, Datacenter Edition operating systems allows you to implement a variety of authentication strategies based on the complexity of your organization, the quality of a user's credentials, the means by which users access the network, and the clients they use to gain access. In addition, Windows Server 2003 authentication technology allows you to establish a foundation for more efficient management of users, computers, and services on the network.

**Note**

- For a list of the job aids that are available to assist you in designing an authentication strategy, see "Additional Resources for Designing an Authentication Strategy" later in this chapter.

# Process for Designing an Authentication Strategy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Designing an authentication strategy involves evaluating your existing infrastructure and creating accounts, establishing a means to secure the authentication process, and establishing standards for network authentication and time synchronization. You might also need to extend your authentication model to allow authentication between forests or between other Kerberos realms, and to enable delegated authentication in order to facilitate user access to system resources.

Figure 14.1 shows the process for designing an authentication strategy.

**Figure 14.1 Designing an Authentication Strategy**

# Authentication Background Information

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 authentication technology includes a number of features that provide solutions for a wide variety of business needs.

**Central administration of accounts**
Administrators can create a single account for each user that allows the user to access the appropriate network resources. Users can log on at different desktops, workstations, or notebooks in the domain by using the same user name and a password or smart card.

**Single sign-on environment**
Users are required to enter a user name and password or smart card only when first logging on to a Windows Server 2003–based computer. The Windows Server 2003 operating system automatically authenticates the user to the local computer, to the Active Directory domain, and to any other application or resource server in the forest that requires authentication prior to access.

When users change passwords, the updates are made to the user accounts in Active Directory. The password changes apply automatically to all resources in the domain or forest.

**Computer accounts in Active Directory**
Computer accounts in Active Directory for all of the computers within a domain allow many of the Windows Server 2003 security features that are designed for users to be applied to computers as well.

Computer accounts in Active Directory also allow you to add application servers as member servers within your trusted domains and to demand authentication from the users and other services that access these resource servers.

**Service accounts in Active Directory**
The services running on resource servers are authenticated automatically if the servers are members of a domain that trusts the user's account domain. In Windows Server 2003, all of the domains in a forest automatically have two-way transitive trust. Windows Server 2003 also supports transitive trust relationships between forests. In this way, when organizations add application servers to their domains, only authenticated users and services can access them.

**Smart card support**
Windows Server 2003 supports optional smart card authentication. A smart card contains a processor chip that stores the user's private key and public key certificate. The user inserts the card into a smart card reader attached to the computer. The user then types in a personal identification number (PIN) when requested, to enable access to the keys stored on the smart card. Authentication proceeds when the correct PIN enables access to the private key and the certificate on the card, allowing the Active Directory authentication service to verify the user's identity. In this way, computers that store highly sensitive data can be secured from attack without the need to store them in locked rooms. At the same time, authorized users can access information stored on high-security computers.

**Certification for Microsoft Windows**
Windows Server 2003 authentication interoperates with third-party applications designed according to the Application Specification for Windows 2000. The Application Specification defines the technical requirements for applications to earn the Certified for Microsoft Windows logo.

Applications can carry the Certified for Microsoft Windows logo when they have passed compliance testing and have executed a logo license agreement with Microsoft. To pass compliance testing, a server application must operate within the appropriate security context, reducing the risk posed by successful attacks, and perform Kerberos-based mutual authentication for all client requests, ensuring that clients know that the servers with which they are communicating are the intended parties, and not attackers posing as the server.

**Auditing authentication**
Windows Server 2003 provides security audit information to track attempts to log on to servers and workstations. This gives organizations the ability to detect unauthorized attempts to access the system.

**Kerberos V5 authentication protocol**
When a client attempts to connect to a resource server, the Kerberos Key Distribution Center (KDC), running on a domain controller, provides the client with a ticket to verify the user's identity to the server, and a shared secret key. The ticket allows the server to validate the user immediately and can be used multiple times. The shared secret key is passed to the server in

encrypted form, allowing both computers to use the shared secret key to encrypt any network data they exchange.

The Microsoft implementation of the Kerberos authentication protocol is based on industry standard specifications defined by the Internet Engineering Task Force (IETF). The Kerberos V5 authentication protocol provides the following advantages:

- **Efficient authentication to servers.** Because authentication takes place quickly, users do not lose productive work time. Clients can obtain a ticket for a particular server one time and reuse the ticket for multiple network sessions.

- **Mutual authentication.** By means of the shared secret key, parties at both ends of a network connection can verify each other's identities. This is a change from NTLM, which allows only servers to verify the identities of their clients.

- **Delegated authentication.** A service can impersonate a client when connecting to a network service, such as a database. Delegated authentication is not available in NTLM.

- **Interoperability**. Kerberos authentication in Windows Server 2003 can interoperate with the implementation of Kerberos authentication in other operating systems.

# Tools for Deploying Authentication

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The following tools are available to assist you in deploying authentication:

- **Active Directory Users and Computers.** A Microsoft Management Console (MMC) snap-in that allows you to create user and computer accounts in the Active Directory.

- **Group Policy.** An MMC snap-in that allows you to apply authentication Group Policy, including Kerberos, auditing, and NTLM authentication behavior.

- **Certificate Services.** An MMC snap-in used to establish the certification authorities (CAs) and issue the certificates used in public key authentication.

For more information about these tools, see the *Distributed Services Guide* of the *Windows Server 2003 Resource Kit* (or see the Distributed Services Guide on the Web at http://www.microsoft.com/reskit).

# Creating a Foundation for Authentication

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you deploy Windows Server 2003, you can create a foundation for secure authentication of users, computers, and services in your organization by creating accounts in Active Directory for all entities that require authenticated access to resources. Because a number of factors impact the authentication strategy that you deploy, you must evaluate the structure of your existing environment before you create the foundation for your authentication strategy.

For a worksheet to assist you in creating a foundation for authentication, see "Authentication Strategy Planning" (DSSAUT_1.doc) on the *Microsoft® Windows® Server 2003 Deployment Kit* companion CD (or see "Authentication Strategy Planning" on the Web at http://www.microsoft.com/reskit).

Figure 14.2 shows the process for creating a foundation for authentication.

**Figure 14.2 Creating a Foundation for Authentication**

# Evaluating Your Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you establish an authentication strategy for your organization, you must become familiar with your current environment, including the structure of your organization; the users, computers, and services in your organization that require authentication; and the applications and services that are in use. Specifically, identify the following:

- The number of domain controllers in your organization. Ensure that you have enough domain controllers in your environment to accommodate your users' authentication requests. If the number of domain controllers is insufficient, a large volume of client requests can result in failed authentication attempts. If you determine that you have an insufficient number of domain controllers, deploy more domain controllers to meet the logon needs of your users.

- The type of network connectivity between site locations in your organization. Domain controllers must be well connected to users to ensure reliable access for authentication. Clients that do not have access to local domain controllers might be unable to access resources if the network connection is unavailable. If the connectivity between domain controllers in remote sites is insufficient, deploy more domain controllers in those sites or improve the connectivity between the sites.

- The number of CAs that are available in your organization and their locations. As with domain controllers, a sufficient number of CAs must be available to handle client requests and they must be well connected in order to provide timely responses. For information about creating a CA infrastructure, see "Designing a Public Key Infrastructure" in this book.

- The number of users, groups, and computers in your organization and where computers are located. This impacts the number of domain controllers and CAs that are required to ensure consistent authentication.

- The number and locations of users who access the network by means of RADIUS and RAS servers.

  **Note**

  - Windows Server 2003 provides for remote user authentication by means of RADIUS and RAS servers. For more information about using RADIUS servers, see "Deploying IAS" in *Deploying Network Services* of this kit. For more information about using RAS servers, see "Deploying Dial-up and VPN Remote Access Servers" in *Deploying Network Services*.

- Whether your organization includes clients running versions of Windows earlier than the Microsoft® Windows® 2000 operating system or other non-native operating systems, or applications that require authentication protocols other than the Kerberos V5 authentication protocol or require special configuration to interoperate with the Kerberos authentication protocol. The operating systems and applications in use in your environment impact the authentication protocols that you can enable by means of authentication policy. For example, versions of Windows earlier than Windows 2000 require NTLM authentication or anonymous access. If clients in your environment are running these operating systems, you must configure the **LAN Manager authentication level** policy to enable those clients to access resources in your system.

  **Note**

  - When you enable LAN Manager authentication, you cannot take advantage of all of the security benefits that are available in Windows Server 2003. Therefore, if you do not need to support versions of Windows earlier than Windows 2000, it is best to use the Kerberos authentication protocol.

- The number and location of smart card users in your organization, if applicable, and any security-sensitive tasks or users, such as administrators, that might require smart cards in the future. The number of current and planned future smart card users in your organization impacts the number of CAs that you require.

# Creating User Accounts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

User accounts are required for authentication. Assign users the appropriate permissions to access resources by creating user accounts in Active Directory and adding the accounts to the appropriate groups. Adding accounts to security groups and applying access control settings to resources allows users to utilize their authenticated identity to access resources, and facilitates account management.

It is best to grant users and groups access to only those resources that are required for them to complete their job tasks. In this way, if any user account is compromised by a malicious user, he or she has limited access to resources, and therefore can cause only minimal damage.

For more information about user accounts and security groups, see "Designing a Resource Authorization Strategy" in this book.

**Note**

- Do not allow users to share accounts or passwords or to use weak passwords. Shared accounts and weak passwords compromise the security of your environment. For more information about creating password policies, see "Creating a Strong Password Policy" later in this chapter.

Creating user accounts involves creating a plan for user account management in your organization.

# Creating a User Account Management Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you deploy Windows Server 2003 and establish the appropriate user accounts in Active Directory, you need to create a plan for user account management. Creating a user account management plan involves determining which individuals in your organization have the right to create new user accounts, and establishing a plan for the disabling of and resetting of user accounts.

**Assign the User Account Creation Right**

Assigning the right to create new user accounts involves carefully balancing strong security and timely response to requests to create new accounts.

Because misuse of the user account creation right presents a security risk to your organization, assign this right to trusted administrators only. For many organizations, it is sufficient to limit the ability to create new user accounts to the members of the Domain Administrators group. In large organizations or in situations where administrators need to delegate tasks, you might need to assign the right to create new user accounts to another group, such as the IT staff or the Human Resources group.

Whoever you designate to create user accounts, a general guideline is to assign one individual the right to create new user accounts for every 100 employees. However, you might need to adjust this number based on the expected growth of your organization. For example, if your organization regularly adds new divisions, acquires companies, or expands into other markets, you need to plan for the creation of new user accounts by assigning the right to create new user accounts to the appropriate number of individuals to meet the requirements for your anticipated growth.

**Establish a Plan for the Disabling of User Accounts**

Because unused but active user accounts are a common target for security attacks, you must establish a clear, consistent policy for disabling user accounts.

You can choose one of the following solutions for disabling active unused user accounts in your organization:

- Include disabling user accounts as part of the employee departure procedure. Establish a policy by which user accounts are deleted from Active Directory when employees leave your organization.

- Create scripts that search for user accounts that have not been logged on to for a period of time or have not had their password changed, and delete the accounts that the script identifies. For example, you might decide to create a script that identifies accounts that have not been logged on to for six weeks, or that have not had their passwords changed for twice the password lifetime prescribed by domain Group Policy, and delete those accounts.

**Establish a Plan for Resetting User Accounts**

When a user forgets his or her password, the account must be reset before it can be used. An effective way to enable the resetting of user accounts in your organization is to grant help desk staff the right to reset passwords. Delegate the right to reset passwords to help desk staff so that members of the Domain Administrators group are not required to reset user account passwords.

# Creating a Computer Account Management Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows 2000 and Windows Server 2003 computers have accounts in Active Directory and are authenticated in a separate process that is transparent to the user.

You can use computer authentication to apply uniform security policies to groups of computers, such as computers contained in a domain, a site, or an organizational unit (OU) based on how the computers are grouped and which rights and policies are granted and applied to each group. For example, you can configure an OU for computers that are public kiosks on a retail floor and apply limited permissions to users. You can configure another OU for a computer stored in a locked office and allow users greater access to resources.

Evaluate the security needs for different types of computers in your organization. Determine which computers are more vulnerable to compromise and therefore require stronger security settings, and then apply policies to the domains, sites, and OUs as appropriate to your security needs. For more information about applying security policies, see "Deploying Security Policy" in *Designing a Managed Environment* in this kit.

**Managing Computer Accounts**

You also need to establish a plan for managing computer accounts, including:

- The creation of new accounts
- The deletion of old accounts
- Resetting of computer account passwords.

Because new computer accounts are created automatically whenever a computer is added to a domain, you need to decide who has the right to add computers to domains. You can delegate this responsibility to an individual or group in your organization by adding them to the **Add workstations to domain** Group Policy.

You can choose to manage new computer account creation in your organization in one of the following ways:

- **Allow authenticated users to create new computer accounts.** This approach might be desirable in organizations where users can be largely trusted. However, if you only want to trust a limited group of users, such as developers, for example, to create new computer accounts, you can control this by using the Security Configuration Manager to either assign or deny this right to users. By default, authenticated users are assigned the **Add workstations to domain** user right on the Group Policy object on domain controllers. This enables them to create up to 10 computer accounts in the domain by using the Network Identification Wizard. The wizard requests information about the computer name, the domain or workgroup that the computer is joining, and the domain users that are to be added to the local groups for local computer access, and uses this information and the credentials of the authenticated user to create a new account in Active Directory.

  **Note**

  - After a computer account is created, administrators must ensure that the account is a member of the appropriate groups, so that the appropriate Group Policies are applied.

- **IT staff joins each new computer to the domain individually during installation.** Although this approach can work for small organizations in which computer account creation occurs infrequently, it is impractical for large organizations with a high volume of new computer accounts.

- **IT staff uses scripts to create new accounts ahead of time, and assigns new computers to existing accounts during installation.** You can use an Active Directory Service Interfaces (ADSI) script to create computer accounts in advance of installing new computers. As new computers are brought online, their computer names must match the names that you have specified in the script. This approach works well for organizations in which many similar computers need to be added to a domain simultaneously, such as in a training lab or server farm. For more information about using scripts to create new computer accounts, see Windows Deployment and Resource Kits at

http://www.microsoft.com/reskit, or see the MSDN Scripting Clinic link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Note**

- It is more secure to create new computer accounts from the computer itself, rather than creating the accounts remotely or by using scripts. An attacker who gains access to some part of a domain can use existing scripts or remote account creation processes to create accounts to further compromise the system. Requiring that new accounts be created from the new computer protects against such attacks.

You can choose to delete computer accounts in your organization in one of the following ways:

- Include deleting users' computer accounts as part of the employee departure procedure. When employees leave your organization, establish a policy by which their computer accounts are deleted from Active Directory.

- Create scripts that search for computer accounts that havenot been logged on to for a period of time or have not had their password changed, and delete those computer accounts. For example, you might create a script that identifies accounts that have not been logged on to for six weeks or that have not had their passwords changed for twice the password lifetime as prescribed by domain Group Policy, and delete those accounts.

If a computer is unable to contact a domain controller to initiate a password change, the account might become unsynchronized with the domain and require a password reset. An effective way to enable the resetting of computer accounts in your organization is to assign help desk staff the right to reset passwords. Delegate the right to reset computer passwords to help desk staff so that members of the Domain Administrators group are not required to reset computer account passwords.

**Important**

- If you are migrating from Windows NT 4.0 domains, you must create a plan for the creation of new computer accounts. Computers running Windows NT 4.0 do not have computer accounts.

# Creating Service Accounts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Like users, services have accounts and authenticate to the network operating system. This ensures that only authorized services are able to complete tasks, and protects against attackers who create unauthorized services to infiltrate network systems.

Most service accounts are created automatically when a service is installed. Similarly, applications that act as services, such as print spoolers or messaging services, create accounts automatically to complete their tasks. Therefore, in general, you do not need to create or modify service accounts. However, if service accounts are deleted accidentally, you must recreate them manually.

Creating service accounts is similar to creating user accounts. The only additional configuration step that is needed is to set the service principal name (SPN) for the account. This needs to be done to ensure mutual authentication. For example, in the case of a web server, a SPN of http/*hostname* might need to be set for the service account. The SPN can be set for the account by using the Setspn utility. For more information about Setspn, in Help and Support Center for Windows Server 2003, click Tools, and then click Install Windows Support Tools.

There are also built-in service accounts that use the computer account credentials by default for network authentication. These include the LocalSystem account, which was already present in Windows 2000. However, LocalSystem is a privileged account and should be used only when required.

Windows Server 2003 includes the following new security contexts to provide a means by which you can further secure network service accounts:

- **LocalService.** This context is intended for services that run with limited access on local computers and do not require network authentication. In this way, a compromised service can do limited damage to the local computer and no damage to network computers.

- **NetworkService.** This context is intended for services that need to complete tasks on the network, but require only restricted local capabilities.

# Securing Service Accounts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Most services have specific functions, so it is best to grant them only those rights that are required for the services to perform those functions. In this way, if attackers compromise a service account, they have limited access and can do only a limited amount of damage. If a service account has rights that extend beyond its specific function, an attacker who compromises the account can do extensive damage.

To ensure maximum security, avoid running services on domain controllers. For example, do not make your domain controller a mail server, Web server, and file and print server. Adding multiple services on a critical link such as the domain controller is risky, because it increases the complexity of the system and therefore increases the potential for compromise. A problem with a print server that might otherwise only give an attacker the ability to create unauthorized print jobs can instead grant the attacker access to Active Directory, a critical data repository. The security benefits of using separate computers for services outweigh the initial investment in hardware equipment.

Also, you might need to reset service account passwords. Do not modify service accounts unless a problem occurs that interferes with the functioning of a service.

**To reset service account passwords**

1. In **Active Directory Users and Computers**, right-click the user's account.
2. Click **Reset Password**.
3. Enter and confirm the new password.

You must ensure that the service uses the newly selected password before the service can take advantage of the reset password. Ensure that the password that the service uses and the password that you reset the service account to have are the same.

# Applying Authentication Policies to Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can manage authentication in your organization by adding user, computer, and service accounts to groups and then applying authentication policies to those groups. For example, you can apply the following policies to groups, based on their function in the organization:

- **Log on locally**
- **Access this computer from the network**
- **Log on over network**
- **Reset accounts**
- **Create accounts**

If you want to make a computer less accessible to others, including both legitimate users and attackers, you can use policies in the following ways to restrict access for less trusted groups (such as Anonymous):

- Assign the **Deny access to this computer from the network** policy.
- Assign the **Deny logon locally** policy.
- Remove the **Remove computer from docking station** policy.

Other policies that you might assign or deny to users can also increase security or maximize flexibility, such as **Deny logon as batch job** or **Log on as service**. For more information about Group Policies that impact authentication, see "Deploying Security Policy" in *Designing a Managed Environment* of this kit.

# Example: Creating a Foundation for Authentication

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An organization that includes 2,100 users and 3,700 computers created an authentication strategy when they deployed Windows Server 2003 in their environment. Because computers in their environment are running versions of the Windows operating system earlier than Windows 2000, they need to support LAN Manager authentication. They decided to make members of the help desk staff and the Administrators group responsible for user account management, and delegated computer account management to the help desk staff.

The organization secured their service accounts by running only required services on domain controllers and restricting the number of individuals who are able to administer services. They assigned the **Log on locally**, **Access this computer from the network,** and **Log on over network** rights to Domain Admins and Domain Users, but not to Guest accounts, to protect the security of their system. They granted the **Reset accounts** and **Create account** policies to help desk staff to reduce the administrative burden on domain administrators.

Figure 14.3 shows the worksheet that the organization created to document their authentication strategy plan.

**Figure 14.3 Example of an Authentication Strategy Planning Worksheet**

| Authentication Strategy Planning | | | |
|---|---|---|---|
| Prepared By | | Date | |
| **Current Environment** | | | |
| | Number | | Number |
| Domain controllers | 5 | Certification authorities | 3 |
| Users | 2,100 | Computers | 3,700 |
| Smart card users | | | |
| Operating systems running: | | | |
| Windows 2000, Windows NT 4.0, Windows ME, Windows 98, Linux, Macintosh OS X | | | |
| **User Accounts** | | | |
| Users or groups to whom the following rights are assigned: | | | |
| Reset user passwords | Help desk, domain administrators | | |
| Reset account lockouts | Help desk, domain administrators | | |
| Create new user accounts | Help desk, domain administrators | | |
| Disabling user accounts plan: | | | |
| When a user leaves the organization, human resources is responsible for notifying the Help Desk team of the need to disable the user account. | | | |
| **Computer Accounts** | | | |
| Security policies that apply to computer groups: | | | |
| Log on locally; Access this computer from the network; Log on over network. | | | |
| Users or groups to whom the following rights are assigned: | | | |
| Create computer accounts | Help Desk | | |
| Delete computer accounts | Help Desk | | |
| Reset computer accounts | Help Desk | | |
| **Service Accounts** | | | |
| Services authorized to run in the organization | IIS, FTP, telnet, Windows Time Service, KDC, DHSP, DNS, WINS, proxy service | | |
| Services authorized to run on domain controllers | Due to security concerns, only those services that are installed when the operating system is installed are permitted to run on domain controllers. | | |
| Users authorized to reset service accounts | Members of the Domain Admins group. | | |

| Authentication Strategy Planning | | | |
|---|---|---|---|
| Prepared By | | Date | |

| Policies Assigned to Groups | |
|---|---|
| Groups to which the following policies are assigned: | |
| Log on locally | Domain Users, Domain Admins |
| Deny log on locally | Domain Users, Domain Admins |
| Access this computer from the network | Domain Users, Domain Admins |
| Deny access to this computer from the network | Guest |
| Log on over network | Domain Users, Domain Admins |
| Reset accounts | Help desk |
| Create accounts | Help desk |
| Remove computer from docking station | Domain Admins |

# Securing the Authentication Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is important to secure your authentication process to protect your system against various types of security threats, such as password-cracking tools, brute-force or dictionary attacks, abuse of system access rights, impersonation of authenticated users, and replay attacks. In addition, if you share resources on your network with other organizations, you must ensure that your authentication policies interoperate with the authentication policies that are in place on other systems.

For a worksheet to use in documenting authentication security policies, see "Authentication Security" (DSSAUT_2.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Authentication Security" on the Web at http://www.microsoft.com/reskit).

Figure 14.4 shows the process for securing authentication.

**Figure 14.4 Securing Authentication**

# Creating a Strong Password Policy

Updated: September 30, 2009

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2

Given enough encrypted data, time, and computing power, attackers can compromise almost any cryptographic system. You can prevent such attackers from succeeding by making the task of cracking the password as difficult as possible. Two key strategies to accomplish this are to require users to set complex passwords and to require users to change their passwords periodically, so that attackers do not have sufficient time to crack the complex encryption code.

**Complex Passwords**
You should set password policy to require complex passwords, which contain a combination of uppercase and lowercase letters, numbers, and symbols, and are typically a minimum of seven characters long or more for all accounts, including administrative accounts, such as local administrator, domain administrator, and enterprise administrator.

In this way, when users submit a new password, the password policy determines whether the password meets established requirements. You can set more complex password requirements; however, such password policies can increase costs to the organization if they obligate users to select passwords that are difficult to remember. Users might be forced to call the help desk if they forget their passwords, or they might write down their passwords, thus making them vulnerable to discovery. For this reason, when you establish password policies, you need to balance the need for strong security against the need to make the password policy easy for users to follow.

**Older Client Operating Systems**
Versions of the operating system earlier than Windows Server 2003 cannot handle passwords that contain more than 14 characters. For example:

- Attempts to log on to a Windows 2000–based computer running Terminal Services by using automatic logon settings configured in Client Connection Manager fail if your password is more than 14 characters long. Client Connection Manager has a 14-character limitation for passwords used for automatic logon. To work around this problem, you must manually enter a password to be used for the connection when prompted. You can prevent this by modifying the password used in Client Connection Manager and on your domain to be no more than 14 characters long.

- In the Microsoft Windows NT 3.51 operating system, Run.exe allows users to start utilities. When users start utilities, they can specify a user account and password to be used to start the application. When the password parameter is used, Run.exe stores the values in buffers limited to 14 characters. Passwords longer than 14 characters are truncated for storage and then passed to domain controllers in truncated form, causing authentication failures.

You can solve many of these problems by applying the latest service packs for operating systems. If your organization includes client computers running versions of the operating system earlier than Windows Server 2003 that do not support longer passwords, be sure to account for this when you set your password policies.

**Selecting Password Policy Options**
Windows Server 2003, Windows Server 2008, and Windows Server 2008 R2 provide security policies that ensure that all users select strong passwords. Creating a password policy involves setting the following options in the Default Domain Group Policy object. These policies are enforced on all user accounts in a domain.

**Enforce password history**
This policy setting determines the number of unique new passwords that have to be associated with a user account before an old password can be reused. This feature enables administrators to enhance security by preventing users from reusing their old password continually. The default value on domain controllers is 24, and the default value on stand-alone servers is 0. Most IT departments choose a value greater than 10.

**Maximum password age**
This policy setting determines the period of time (in days) that a password can be used before the system requires the user to change it. The best defense against impersonation is to require that users change their passwords regularly. This reduces the amount of time available for attackers to crack unknown passwords. The maximum password age can be set between 1 and 999 days. The default value of 42 days is generally appropriate; however, some IT departments shorten this to 30 days. To specify that passwords never expire, set this value to 0.

**Minimum password age**

This policy setting determines the number of days that must pass before a user can change his or her password. Defining a minimum password age prevents users from circumventing the password history policy by defining multiple passwords in rapid succession until they can use their old password again. The default value on domain controllers is 1, and the default value on stand-alone servers is 0. A value of a few days discourages rapid password recycling while still permitting users to change their own passwords if desired.

If you enable the **Enforce password history** policy setting, the minimum password age must be configured to a value greater than 0.

If **Maximum password age** is set between 1 and 999 days, **Minimum password age** must be less than **Maximum password age**. If **Maximum password age** is set to 0, **Minimum password age** can be any value between 0 and 998 days.

| **Note** |
| --- |
| Setting this parameter to a value higher than **Maximum password age** forces users to call the IT department to change their passwords, which increases costs to the organization. |

**Minimum password length**
The policy setting determines the minimum number of characters that a user's password must contain. You can set a value between 1 and 14 characters. To specify that no password is required, set the value to 0. The default value on domain controllers is 7, and the default value on stand-alone servers is 0.

**Passwords must meet complexity requirements**
This policy setting determines whether new passwords must meet complexity requirements. If this policy setting is enabled, passwords must meet the following minimum requirements:

- Passwords cannot contain the user's account name or parts of the user's full name that exceed two consecutive characters.
- Passwords must be at least six characters in length or the number of characters specified in the **Minimum password length** policy setting.
- Passwords must contain characters from at least three of the following four categories:
    - English uppercase alphabet characters (A–Z)
    - English lowercase alphabet characters (a–z)
    - Base 10 digits (0–9)
    - Non-alphanumeric characters (for example, !$#,%)

This policy setting is enabled by default on domain controllers and disabled by default on stand-alone servers.

**Store passwords using reversible encryption**
This policy setting determines whether the operating system stores passwords by using reversible encryption. It also provides support for applications that use protocols that require knowledge of user's password for authentication purposes.

| **Important** |
| --- |
| Storing passwords by using reversible encryption is the same as storing plaintext versions of the passwords. For this reason, this policy should not be enabled unless application requirements outweigh the need to protect password information. |

This policy setting must be enabled when using:

- Challenge Handshake Authentication Protocol (CHAP) authentication through remote access
- Internet Authentication Service (IAS)
- Digest authentication in Internet Information Services (IIS).

This policy setting is disabled by default.

# Establishing an Account Lockout Policy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You need to establish an account lockout policy at the same time that you establish a password security policy. Account lockout policies protect your environment against brute-force or dictionary attacks. Given enough tries, even complex passwords can be guessed. Account lockout policies reduce the number of guesses that an attacker can make.

It is best to establish an account lockout policy that is restrictive enough to prevent attacks, while still allowing for the occasional user error. An account lockout policy that is too strict might increase the number of support calls in your organization as users who type their passwords incorrectly are mistakenly locked out.

Creating an account lockout policy involves setting the following options in the Default Domain Group Policy object.

**Account lockout threshold**
The account lockout threshold limits the number of times that anyone can attempt to log on to a computer from a remote location. This prevents attackers from trying all possible passwords over the network. This setting is disabled by default in the Default Domain Group Policy object. You can turn it on by setting the value to a number within the accepted range of 1 through 999. Set the value high enough to ensure that occasional errors do not result in account lockout.

Note that this setting does not apply to attempts to log on at the console of a locked workstation or to attempts to unlock a screensaver. Locked workstations cannot be forced to run password-cracking programs.

**Account lockout duration**
The account lockout duration determines how long, in minutes, an account that has exceeded the account lockout threshold remains locked before it is automatically unlocked. Valid settings range from 0 through 99,999 minutes, or about 10 weeks. When the value is set to 0, an administrator must manually unlock the account. Because account lockout policies are designed to protect against brute-force attacks, setting even a low value for the account lockout duration reduces the number of possible attacks considerably. Note that setting a high value for the account lockout duration can increase help desk calls when legitimate users are mistakenly locked out, and aside from indicating that an attack was attempted, provides little additional protection.

By default, this policy is not defined, because it is only applicable when an account lockout threshold is specified.

**Reset account lockout counter after**
This setting determines the number of minutes that must elapse after a failed logon attempt before the counter is reset to 0 bad logon attempts. The range is 1 through 99,999 minutes. This value must be less than or equal to the account lockout duration.

**Enforce user logon restrictions**
When this option is enabled, the KDC validates every request for a session ticket by examining the user rights policy on the target computer. The user requesting the session ticket must be assigned the **Log on locally** policy (if the requested service is running on the same computer) or the **Access this computer from the network** policy (if the requested service is on a remote computer) to receive a session ticket. This option also serves as a means to ensure that the requesting account is still valid. Verification is optional because the extra step takes time and might slow network access to services, but if account rights have changed or user accounts have been disabled between the time when the initial ticket was issued and the time when a service ticket was requested, these changes do not take effect.

By default, the policy is enabled in the Default Domain Group Policy object. If the policy is disabled, this check is not performed. For greater security in an environment in which user accounts change frequently, enable this setting. For faster performance, particularly in a more stable user account environment, disable this setting.

# Assigning Logon Hours

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can assign logon hours as a means to ensure that employees are using computers only during specified hours. This setting applies both to *interactive logon*, in which a user unlocks a computer and has access to the local computer, and *network logon*, in which a user obtains credentials that allow him or her to access resources on the network.

Assigning logon hours is useful for organizations in which some users are less trustworthy than others or require supervision. For example, you might want to restrict logon hours when:

- Logon hours are a condition for security certification, such as in a government network.
- Your organization includes shift workers. In this case, allow shift workers to log on only during their scheduled hours.
- Your organization includes temporary employees.

The logon schedule is enforced by the Kerberos Group Policy setting **Enforce User Logon Restrictions**, which is enabled by default in Windows Server 2003. Whether users are forced to log off when their logon hours expire is determined by the **Automatically log off users** setting.

By default, all domain users can log on at any time. You can use the following procedure to limit the logon hours of an individual domain user.

**To restrict the logon hours of a domain user**

1. In **Active Directory Users and Computers**, right-click the user's account.
2. Click **Properties**, and click the **Account** tab.
3. Click **Logon Hours**. In the **Logon Hours** dialog box, indicate the hours and/or days of the week in which you are restricting the user from logging on.

When you have set the logon hours for an individual, you can copy that account to apply the same settings to a new user in the same department.

**To restrict the logon hours for multiple users in the same OU**

1. In **Active Directory Users and Computers**, select the user accounts, and then right-click any of the selected items.
2. Use the **Properties of Multiple Objects** dialog box to alter the properties for all of the selected users.

When you restrict logon hours, you might also want to force users to log off after a certain point. If you apply this policy, users cannot log on to a new computer, but they can stay logged on even during restricted logon hours. To force users to log off when logon hours expire for their account, apply the **Network security: Force logoff when logon hours expire** policy.

# Creating a Ticket Expiration Policy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is important to establish reasonable lifetimes for tickets in your organization. Ticket lifetimes must be short enough to prevent attackers from cracking the cryptography that protects the ticket's stored credentials. However, ticket lifetimes must also be long enough to be convenient for users and to ensure that requests for new tickets do not overload the network.

Creating a ticket expiration policy involves setting the following options in the Default Domain Group Policy object.

**Maximum lifetime for user ticket**
This setting indicates the amount of time for which a ticket is valid before it expires. Generally, it is best if the Maximum Lifetime for User Ticket setting reflects the average amount of time that users access their computers in one day. This is set to 10 hours in the Default Domain Group Policy object. At the end of the ticket lifetime, the user either obtains a new ticket or renews the existing ticket. This process is performed transparently by the computer, but each ticket request or renewal produces network traffic and domain controller loading.

A short maximum ticket lifetime provides greater security but also increases network traffic. A long maximum ticket lifetime decreases network traffic but does not provide the same level of security.

**Maximum lifetime for service ticket**
This setting usually matches the established user ticket lifetime. It might be shorter, however, if there is a need in your organization for secure authentication to services beyond what is required for user authentication. It might be longer if users require uninterrupted access to services for long periods of time. For example, you might need to extend the ticket lifetime if your users run jobs that have a duration that is longer than the duration of the user ticket lifetime. If you do not have any special requirements for service ticket lifetime, do not extend the lifetime of the ticket.

The maximum service ticket lifetime must be greater than 10 minutes and less than or equal to the Maximum Lifetime for User Ticket setting. By default, this value is set to 600 minutes (10 hours) in the Default Domain Group Policy object (GPO). Ongoing operations are not interrupted if the session ticket used to authenticate the connection expires before the operation is complete.

**Maximum lifetime for user ticket renewal**
This setting determines the period of time (in days) during which a user's ticket-granting ticket (TGT) can be renewed. By default, this is set to seven days in the Default Domain GPO. Shorter renewal times make it easier to require users to reauthenticate in the event that you suspect that there has been a security breach. An attacker with a renewable user ticket can continue to renew that ticket for as long as the policy allows. Shortening renewal times makes an attacker's task more difficult, but it also increases the authentication load on domain controllers.

# Establishing Network Authentication Standards

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 allows for interoperability with earlier versions of Windows and other operating systems. Interoperating with other operating systems, however, can negatively impact your network security. It is important, therefore, to establish standards for network authentication to minimize the effect that this interoperability has on your organization's security. You can do this by restricting LAN Manager authentication and by restricting anonymous access. You must also establish a plan for upgrading Windows NT 4.0 domain controllers to balance the Kerberos authentication load in Windows Server 2003 and Windows 2000 domains.

# Restricting LAN Manager Authentication

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Due to advances in cracking tools and hardware capabilities, LAN Manager authentication encryption is more vulnerable to attack than newer forms of encryption. For this reason, it is important to restrict the use of LAN Manager authentication whenever possible. Windows Server 2003 supports all versions of LAN Manager authentication, including LM, NTLM, and NTLM version 2 (NTLMv2), to allow for compatibility with clients that do not support newer authentication protocols.

If it is necessary in your organization to support LAN Manager authentication, you can increase security by enabling support of NTLMv2 whenever possible. Reducing or eliminating the use of LAN Manager authentication and NTLM version 1 (NTLMv1) removes password hash values from the network, and therefore increases network security. You can enable NTLMv2 support by doing the following:

- Upgrading to at least Service Pack 4 (SP4) on all Windows NT 4.0–based clients

- Installing the directory services client on all client computers that are running the Microsoft® Windows® 95 or Windows® 98 operating system You can install the directory services client from the Windows Server 2003 operating system CD.

- Tightening LAN Manager authentication policies. If all clients support NTLMv2, set Domain Group Policy for **LAN Manager Authentication Level** to **Send NTLMv2 response only\refuse LM & NTLM**. This policy is under Computer Configuration\Windows Settings\Security Settings\Local Policies\Security Options\. If some clients exist that do not support NTLMv2, set the **LAN Manager Authentication Level** to **Send NTLM response only**. This reduces the amount of ciphertext available to attackers.

**Note**

- Clients that do not typically support NTLMv2 include Macintosh and Windows Services for UNIX.

# Restricting Anonymous Access

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In Windows Server 2003, access that was available to Anonymous users in Windows NT 4.0 is available only to Everyone and Guest accounts. However, in some of the following situations you might still need to allow Anonymous access to portions of your network.

Some of the services running versions of Windows earlier than Windows 2000 use anonymous access to request user account information from domain controllers and to list network shares on file servers and workstations.

You also might need to allow Anonymous access when an administrator in the trusting domain of a one-way trust relationship across forests needs to list users and shares in the trusted domain of another forest.

In addition, the Windows NT Remote Access Service (RAS) uses anonymous logon to determine whether a user has permission to establish a RAS connection. Anonymous access to Active Directory is used to change passwords from earlier systems. This form of anonymous access is enabled by the Pre-Windows 2000 compatible access security group, which is a local group found only on Windows 2000 and Windows Server 2003 domain controllers. By default, this group has read access to user and group objects in Active Directory.

If you need to support networks containing a mix of Windows NT 4.0, Windows 2000, and Windows Server 2003 desktops and servers, you must take into account the new restrictions on anonymous access by doing the following:

- First determine which services and applications require anonymous access to network resources, and identify the servers to which anonymous access is needed.

- Then decide whether to add the Anonymous Logon identity to specific access control lists (ACLs), or to make security policy changes that relax the restrictions that Windows Server 2003 places on anonymous access.

You can regulate anonymous access by doing the following:

- Edit the ACLs of the resources, adding the Anonymous Logon identity to the list of authorized users. This approach is the most secure, but requires editing the ACLs of each resource, which might be difficult to manage or troubleshoot.

- Use the **Do not allow anonymous enumeration of SAM accounts and shares policy** Group Policy object, which can be found in Computer Configuration/Windows Settings/Security Settings/Local Policies/Security Options, to prevent attackers from using anonymous connections to obtain information about accounts and shares on a computer. Preventing Security Accounts Manager (SAM) account enumeration can help thwart attacks, but also prevents legitimate users in other domains from obtaining this information.

- Disable or do not configure this policy if your domain includes computers running versions of Windows earlier than Windows 2000 or if it has an outbound, one-way trust relationship with a domain in another forest. The browser service on computers running Windows NT 4.0 and earlier requires the ability to enumerate shares anonymously when it connects to backup browsers, master browsers, and domain master browsers to retrieve server lists and domain lists. Users on the trusting side of a one-way trust relationship need the ability to enumerate SAM accounts anonymously when they add domain accounts and groups on the trusted side of the relationship to security groups in the trusting domain.

  For more information about domain and forest trust relationships, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

- Use the **Let Everyone permissions apply to anonymous users** policy to extend anonymous access to match the Windows NT 4.0 model. If this policy is enabled, Anonymous users can access any resource that Everyone is allowed to access. Do not enable this policy unless there is a compelling business reason to compromise the security provided by requiring some form of authentication. If you do enable this policy, work to disable it by editing the ACLs of specific resources to allow anonymous access, as required in particular cases.

- If you need to permit clients running versions of Windows earlier than Windows 2000 to change their passwords, add the Everyone and Anonymous Logon groups to the Pre-Windows 2000 compatible access group, enabling anonymous access to the accounts. The membership of this group is determined by a user option during the installation of the first domain controller in the domain. You can change the group membership if necessary.

# Creating a Plan for Windows NT 4.0 Domain Controller Upgrade

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Workstations running the Microsoft® Windows® XP operating system that are joined to an existing Windows NT 4.0 domain use NTLM to authenticate to the Windows NT 4.0 domain controllers. When you add a Windows Server 2003– or Windows 2000–based domain controller to a domain, all clients running the Microsoft® Windows® XP, or Windows® 2000 Professional operating system and all servers running Windows Server 2003 or Windows 2000 automatically use Kerberos authentication when users log on interactively. Users at these computers therefore cannot log on by using the Windows NT backup domain controllers. This shifts the Windows Server 2003 and Windows 2000 user authentication load to the existing Windows Server 2003– or Windows 2000–based domain controllers. If the primary domain controller becomes overloaded or fails for any reason, users cannot log on to computers running Windows Server 2003 or Windows 2000.

For this reason, when you add Windows Server 2003– or Windows 2000–based domain controllers to a domain, you must continue to add Windows Server 2003– or Windows 2000–based domain controllers to keep pace with client demands. You can do this by installing new domain controllers or by upgrading existing Windows NT 4.0–based domain controllers.

Review your organization's plans for domain upgrade and consolidation and for the deployment of new Windows Server 2003–based workstations, and ensure that workstation upgrade does not proceed more rapidly than the domain controller upgrade. Add Windows Server 2003– or Windows 2000–based domain controllers to a domain only when you are certain that the domain controllers have the capacity to meet the authentication needs of all Windows Server 2003–based workstations in the domain.

For more information about upgrading Windows NT 4.0 domains to Windows Server 2003 Active Directory, see "Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory" in this book.

# Setting Clock Synchronization Tolerance to Prevent Replay Attacks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use the **Maximum tolerance for clock synchronization** Group Policy to protect your organization against replay attacks, in which attackers replay authentic network exchanges that they capture off the wire to cause the server to allow them access to the system. If your clock synchronization tolerance setting is low, the server rejects replayed messages for which the allowable time skew has passed.

The **Maximum tolerance for computer clock synchronization** Group Policy is set to 5 minutes by default. In most cases, this provides an acceptable level of security. You can increase protection against replay attacks by shortening the maximum tolerance for clock synchronization. Tighter synchronization requirements, however, might result in increased authentication traffic.

Shortening the maximum tolerance reduces replay attacks because the Kerberos V5 authentication protocol uses authenticators based on time to establish user identities. A shorter tolerance makes a replay attack more difficult.

The **Maximum tolerance for computer clock synchronization** Group Policy can be found in the Default Domain Policy object under Computer Configuration\Windows Settings\Security Settings\Account Policies\Kerberos Policy.

In general these settings should be changed only if there is a strong reason to believe you might be vulnerable to this type of attack.

For more information about time synchronization in Windows Server 2003, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

# Example: Securing Authentication

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An organization developed an authentication strategy to strengthen the default security that Windows Server 2003 provides. This is to protect data from attackers whose activity has been noted in audit logs and because management has made increasing the security of the system a top priority. To meet these security demands, administrators created password policies to ensure strong passwords, applied account lockout policies to prevent brute-force attacks, assigned logon hours to prevent users from working during unsupervised times, and established a ticket expiration policy to enforce logon hours for several groups, excluding batch jobs.

The organization chose to eliminate LAN Manager authentication by setting the **Restrict LanMan Authentication** policy to **Not supported** to prevent the use of authentication methods that are vulnerable to attack. They chose to eliminate anonymous logon by enabling **Restrict Anonymous Access** to limit the number of resources that attackers can access by impersonating anonymous users. In order to enable these policies, the organization chose to retire their Windows NT 4.0–based domain controllers, and replaced them with new Windows Server 2003–based computers.

Administrators in the organization accepted the default clock synchronization tolerance of five minutes. This setting protects the system against replay attacks while keeping authentication traffic to a minimum.

Figure 14.5 shows the worksheet that the organization created to document their authentication security plan.

**Figure 14.5 Example of an Authentication Security Worksheet**

## Authentication Security

| Maximum tolerance for computer clock synchronization | 5 minutes |

# Extending Your Authentication Framework

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If your environment includes more than one forest, or your organization needs to exchange information with other Kerberos clients and servers, you need to extend your authentication framework to accommodate those relationships and resources. You do this by establishing trust relationships and by creating Active Directory accounts as appropriate.

For a worksheet to assist you in documenting your plan for extending your authentication framework, see "Extended Authentication Framework" (DSSAUT_3.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Extended Authentication Framework" on the Web at http://www.microsoft.com/reskit).

Figure 14.6 shows the process for extending your authentication framework.

**Figure 14.6 Extending Your Authentication Framework**

# Establishing Interforest Authentication

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If your organization includes more than one forest, you need to enable the forests to allow authentication and resource sharing. You can do this by establishing trust relationships between some or all of the domains in the forests. The types of trust relationships that you establish will depend on the versions of the operating system that are running in each forest.

For more information about establishing trust relationships, see "Understanding Trusts" in Help and Support Center for Windows Server 2003.

**Authentication between Windows Server 2003 forests**
When all domains in two forests trust each other and need to authenticate users, establish a forest trust between the forests. When only some of the domains in two Windows Server 2003 forests trust each other, establish one-way or two-way external trusts between the domains that require interforest authentication.

**Authentication between Windows Server 2003 and Windows 2000 forests**
It is not possible to establish transitive forest trusts between Windows Server 2003 and Windows 2000 forests. To enable authentication with Windows 2000 forests, establish one-way or two-way external trusts between the domains that need to share resources.

**Authentication between Windows Server 2003 and Windows NT 4.0 forests**
It is not possible to establish transitive forest trusts between Windows Server 2003 and Windows NT 4.0 domains. Establish one-way or two-way external trusts between the domains that need to share resources.

In each of these cases you should consider whether the selective authentication option needs to be enabled. Selective authentication should only be enabled when the trusted domain is located in the extranet or in a different corporation, and therefore only requires access to a very limited set of resources.

The Kerberos V5 authentication protocol does not work across forests in Windows 2000 or Windows NT environments. In these situations, Windows Server 2003 relies on the NTLM protocol for authentication across forests. A direct trust relationship between two domains in separate forests enables NTLM authentication; however, NTLM enables client authentication only, and not mutual authentication. Therefore, if you must authenticate across forest boundaries, you need to ensure that all computers running versions of Windows earlier than Windows 2000 have been upgraded to use NTLMv2.

# Enabling Interoperability with Kerberos Clients and Servers Running Other Operating Systems

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Some organizations have clients running UNIX or other operating systems. To allow for the secure exchange of information with other clients, you can configure the clients to authenticate to Windows Server 2003 domain controllers in order to obtain the required credentials. Similarly, Windows clients can be configured to authenticate to other KDCs.

To enable interoperability with UNIX or other clients, you must:

- Establish a Realm trust, a particular type of external trust with a UNIX realm. This enables an authentication that is completed in one realm or domain to be trusted by another realm or domain.
- Create account mappings so that other clients have mapped accounts in Active Directory. This enables other clients to access resources that are secured in a Windows environment.

**Establishing Trusts with Kerberos Realms**

To enable authentication between Windows domains and UNIX realms or other clients, you must establish a one-way or two-way trust between the two so that tickets generated in one are recognized and accepted by resources in the other. For example, a one-way trust relationship in which a Kerberos realm trusts a Windows Server 2003 domain allows Windows Server 2003 users to log on to the Kerberos realm; in other words, the UNIX server accepts or trusts the authentication performed by the Windows Server 2003 KDC. Another trust can be created so that users logged on to the Kerberos realm can access resources in the Windows Server 2003 domain.

**Configuring Accounts for Kerberos Clients Running Other Operating Systems**

After you have established trusts between a UNIX or other realm and a Windows domain, you must coordinate accounts, enabling users to authenticate and access resources.

**User accounts**

You must configure clients to authenticate to the appropriate KDC. For example, you might configure a Linux desktop to authenticate to a Windows Server 2003–based KDC at logon. Most Kerberos clients allow for the specification of a KDC for authentication as part of the logon to the local computer. Windows Server 2003 provides the Kerberos KDC services as part of the domain controller, so the clients log on to the domain controller itself. The domain controller locates the KDC by means of service location records in the DNS. This frees the administrator from having to maintain explicit Kerberos configuration data for each client.

**Service accounts**

Windows Server 2003 supports the authentication of other Kerberos services in a Windows Server 2003 domain. If you require services to access resources across the domain or realm, you must create service accounts in Active Directory to represent those services. For example, you can make a UNIX-based telnet service accessible to Kerberos clients in a Windows domain by creating a service account in Active Directory for that service. In this case, the telnet service is part of the Windows domain, rather than the other Kerberos realm, as is the case with trust relationships established between Windows and other Kerberos realms.

**Account mappings**

When a Windows Server 2003 domain trusts a Kerberos realm, the principals in the Kerberos realm do not contain the group associations that are used for access control in the Windows Server 2003 environment. You can use account mapping in the Windows Server 2003 domain to provide authorization information for Kerberos principals from trusted realms. You can either map accounts one-to-one, by mapping each account in a realm to a corresponding account in the Windows Server 2003 domain, or you can use one-to-many mapping, by which multiple individual accounts in a realm are mapped to one account in the Windows Server 2003 domain. For more information about account mapping, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

To ensure seamless interoperability, you must keep the accounts in the Kerberos realm and the Windows Server 2003 domain synchronized. You can use ADSI and Lightweight Directory Access Protocol (LDAP) in Active Directory to synchronize accounts, or use metadirectory technology such as Zoomit Via.

# Deploying Smart Cards

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If your organization requires a more secure form of authentication, you can use certificates and smart cards for user logon. Smart cards provide additional security because they require both a password and a physical smart card for a user to log on. The smart card contains a public key certificate, and to unlock the certificate, the user must supply a password, or PIN. It is much more difficult for an attacker to obtain both a physical smart card and the PIN number that is used to unlock it in order to gain access to network resources.

In order to decide whether smart card authentication is appropriate for your organizations, evaluate the potential benefits against the following consideration:

- **Costs.** Deploying smart cards entails initial equipment costs for the purchase of smart cards and smart card readers, as well as administrative costs for preparing and distributing smart cards.

- **Infrastructure.** A public key infrastructure (PKI) is required for smart card authentication. For more information about establishing a PKI, see "Designing a Public Key Infrastructure" in this book.

- **Ongoing administration.** Unlike card keys, smart cards cannot be replaced easily if lost or forgotten. This introduces the potential for lost productivity if a user forgets or loses his or her card.

Because of the potential costs and administrative burden, many organizations choose to deploy smart cards only to certain groups of users, such as administrators or users who have access to extremely sensitive data.

For more information about deploying smart cards, see "Planning a Smart Card Deployment" in this book.

# Example: Extending the Authentication Framework

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An organization that is based on an Active Directory logical structure that includes four forests, forest A, forest B, forest C, and forest D, must extend its authentication framework in order to facilitate resource access for its clients in all locations. The organization needs to share resources with a Windows NT 4.0 domain, Domain E, and Kerberos clients running Unix in Unix realm F. Figure 14.7 shows the logical structure of the organization.

**Figure 14.7 Organization Logical Structure**

To enable the sharing of resources, administrators establish the following trust relationships:

- A forest trust between forests A and B
- External trusts from domains in forests A and B to domains in forests C, D, and E
- External trusts between domains in forests C, D, and E
- Realm trusts between all domains and realm F

The organization chooses to deploy smart cards to domain administrators, as these accounts are more sensitive to security attacks.

Figure 14.8 shows the worksheet that the organization created to document their extended authentication framework.

**Figure 14.8 Example of an Extended Authentication Framework Worksheet**

| Extended Authentication Framework | | | |
|---|---|---|---|
| Prepared By | | Date | |
| Domain | | | |

| Interforest Authentication | |
|---|---|
| List the Resources in other forests to which access must be enabled: | |
| Other Windows Server 2003 forests | Forest A, Forest B |
| Windows 2000 forests | Forest C, Forest D |
| Windows NT 4.0 domains | Domain E |
| Non-Windows structures such as UNIX realms | Unix Realm F |

# Enabling Supplemental Authentication Strategies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Some organizations require more complex authentication solutions to meet their user access needs. For example, if your organization includes Web-based clients that use applications such as Microsoft® Internet Explorer to access data stored on back-end servers, you must enable complex authentication strategies, such as delegation, constrained delegation, and protocol transfer, to allow those clients to access the requested services in a secure manner.

For a worksheet to assist you in documenting your plan for enabling supplemental authentication strategies, see "Supplemental Authentication Strategies" (DSSAUT_4.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Supplemental Authentication Strategies" on the Web at http://www.microsoft.com/reskit).

Figure 14.9 shows the process for enabling supplemental authentication strategies.

**Figure 14.9 Enabling Supplemental Authentication Strategies**

# Enabling Delegated Authentication

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Delegated authentication occurs when a network service accepts a request from a user and assumes that user's identity in order to initiate a new connection to a second network service.

To enable delegated authentication, you must establish front-end or first-tier servers, such as Web servers, that are responsible for handling client requests, and back-end or n-tier servers, such as large databases, that are responsible for storing information. You can delegate the right to enable delegated authentication to users in your organization in order to reduce the administrative load on your administrators. To delegate this right, assign the **Enable computer and user accounts to be trusted for delegation** user right to the selected individuals. Users who are assigned the right to enable delegated authentication can assign the **Trusted for delegation** right to computer and service accounts that are used to serve users information that is stored on back-end servers and must be accessed securely. The user account that is requesting the resource must not be marked as sensitive; marking an account as sensitive explicitly denies the right to delegation.

By establishing a service or computer as trusted for delegation, you enable that service or computer to complete delegated authentication, receive a ticket for the user who is making the request, and then access information for that user. Delegated authentication prevents an attacker who gains control of a front-end server, such as a Web server, from also gaining access to data stored on a back-end server. By requiring that all data be accessed by means of credentials that are delegated to the server for use on the client's behalf, you ensure that the server cannot be compromised and then used to gain access to sensitive information about other servers.

Delegated authentication is useful for multitier applications that are designed to use single sign-on capabilities across multiple computers. For example, domain controllers are automatically trusted for delegation. If this property is disabled on a domain controller, the Message Queuing service cannot run. Also, if you enable the Encrypting File System on a file server, the server must be trusted for delegation in order to store encrypted files on behalf of users. Delegated authentication is also useful on applications where Internet Information Services (IIS) supports a Web interface to a database running on another computer, such as Outlook Web Access in Exchange, or Web Enrollment Support pages for an enterprise certification authority, if the pages are installed on a separate Web server.

It is recommended that you deny the right to participate in delegated authentication to the computer accounts in Active Directory for computers that are not physically secure, and to domain administrator accounts. Domain administrator accounts have access to sensitive resources and, if compromised, poses a higher risk to your organization.

When computers that are trusted for delegation are compromised by an attacker, the attacker can use them to access data stored on other servers by using the delegated credentials of an authenticated user. Ensure that only secure computers are trusted for delegation, and do not allow the delegation of powerful user accounts, such as administrator accounts. Also, consider applying constrained delegation to computers that are trusted for delegation, to limit the ways in which delegated credentials can be used. In this way, an attacker who has access to the computer has access to only limited services.

For more information about enabling constrained delegation, see "Enabling Constrained Delegation" later in this chapter.

**To restrict delegated authentication**

1. In **Active Directory Users and Computers,** right-click the computer or user account and select **Properties**.

2. On the **Account** tab, under **Account Options**, select the **Account is sensitive and cannot be delegated** check box, and click **OK**.

3. You can also restrict delegated authentication to prevent the delegation of sensitive user accounts by marking the account as not enabled for delegation. Restrict delegated authentication for accounts that are less secure or that are particularly powerful.

# Enabling Constrained Delegation

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Constrained delegation allows administrators to specify particular services from which a computer that is trusted for delegation can request resources. By using constrained delegation, you can prevent attackers who compromise a server from accessing resources beyond the limited scope of that server's range.

Before you enable constrained delegation, isolate critical data that you must keep secure from data to which users require frequent access. For example, if your organization maintains an e-commerce Web site, you might choose to isolate customer credit cards numbers, internal accounting, or human resources information from order status information that customers access frequently.

**To enable constrained delegation**

1. In **Active Directory Users and Computers**,right-click the computer account and select **Properties**.
2. On the **Delegation** tab, click **Trust this computer for delegation to specified services only**.
3. Select **Use Kerberos only**,or select **Use any authentication protocol**.
4. Click **Add** and, in **Add Services**, click **Users and Computers**.
5. In **Add Services**, select the service or services that are trusted for delegation, and click **OK**.

You can further restrict the scope of delegation that is permitted, for example to disable delegation for highly sensitive accounts such as administrator accounts.

**To restrict delegation**

1. In **Active Directory Users and Computers,** right-click the user account and select **Properties**.
2. Select the **Sensitive** attribute check box for the user account, and click **OK**.

# Example: Supplementary Authentication Strategies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An organization chose to extend its authentication framework by enabling delegation and constrained delegation. To achieve this, they assigned the right to enable delegated authentication to specific user accounts, identified the computer accounts that are to be trusted for delegation, and established who is responsible for applying these policies. This allowed them to strengthen the security of their system by limiting the resources to which computers that are trusted for delegation have access. For example, they enabled the Web interface human resources database to access confidential data stored in databases in other servers, assigned the trusted for delegation right to workstations, and restricted delegation on the domain administrator user account.

Figure 14.10 shows the worksheet that the organization created to document their supplementary authentication strategies.

**Figure 14.10 Example of a Supplementary Authentication Strategies Worksheet**

| Supplementary Authentication Strategies | | | |
|---|---|---|---|
| Prepared By | | Date | |
| Delegated Authentication | | | |
| User accounts for which delegation is not permitted: | | | Individual responsible for marking the account as sensitive: |
| Domain Administrators | | | Enterprise Administrators |
| | | | |
| Computers in the organization that are trusted for delegation: | | | Individual responsible for enabling the computer for delegation: |
| Workstations | | | Domain Administrators |
| | | | |
| Constrained Delegation | | | |
| Services to which users in your organization require access: | | | Individual responsible for permitting delegation to the specified SPNs on the computer account: |
| HR database | SPN | HRdb | Domain Administrators |

# Educating Users About the Authentication Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Ensuring that users understand their role in the authentication process is an important step in establishing an authentication strategy. By giving users clear guidelines and explaining the justification behind the guidelines, you reduce the chances that users will fail to comply with the procedures that you put into place.

Figure 14.11 shows the process for educating users.

**Figure 14.11 Educating Users**

# Increasing Awareness of Social Engineering Attacks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Users must be cautioned against sharing their passwords with others. All legitimate users have their own accounts, and any administrator who needs to complete a task for a user can do so by using his or her own account, without knowledge of the user's password. Tasks such as the resetting of a user's password or the unlocking of a user's account do not require the use of a password.

One effective and simple way that an attacker can compromise the security of a system is to call users, claiming to be from the help desk, and request their passwords. Because users feel compelled to help solve problems, they are not motivated to question the authenticity of the caller. Caution users to beware of such calls and assure them that it is appropriate to be skeptical of requests for their passwords. Establish a procedure by which users who receive calls of this type request the caller's name and number and call them back. In this way, they can ensure that the call is legitimate before they reveal sensitive information.

# Communicating Password Creation Guidelines

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Educate your users about how to create strong passwords and how to keep them secret to help to protect your system from compromise as a result of simple carelessness.

Users must understand that their passwords must meet your organization's complexity guidelines. Incorporating uppercase and lowercase letters, numbers, and symbols into a password makes the password much more difficult to crack. Suggest to users that they insert numbers and characters into common phrases to protect against dictionary attacks. For example, the phrase "iamhappy" is easy to remember, but is hard to guess if some characters are changed so that the phrase appears as "1AmH@ppy!".

Caution users against writing their passwords down and leaving them in an accessible place. Be sure that users understand the danger of leaving their passwords in places where they can be discovered by an attacker. Although the need to remember complex passwords and reset them frequently might cause some inconvenience, the benefits of protecting your organization's resources far outweigh the costs.

# Additional Resources for Designing an Authentication Strategy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The following resources contain additional information and tools related to the chapter.

# Designing a Resource Authorization Strategy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Authenticated users need access to shared resources such as file shares and printers. An authorization strategy based on security groups enables you to effectively manage users' access to these resources. To create a resource authorization strategy, you need to decide what types of security groups to use and plan how to manage and maintain these groups.

**In This Chapter**

# Overview of Designing a Resource Authorization Strategy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

How you choose to give and manage appropriate access to individual users and groups of users is the key to your resource authorization strategy. Logging on does not automatically give users access to the resources they require. Users must be authorized to access specific resources, but only at the level of access they need. Moreover, many users have identical needs for access to a network resource. For example, all users in the accounting department might need access to a specific color printer, so you can easily manage access by putting every member of the accounting department into a security group that is authorized to access that printer.

Because security groups are so critical to efficiently controlling access, they form the main component of your authorization strategy. Consequently, you need to know what security group types are available and how they should be used. Before you design a resource authorization strategy, you also need to be familiar with trust relationships, domain and forest functional levels, and basic security principles. By applying this information appropriately for your organization, you can design a resource authorization strategy that is scalable, easy to maintain, and cost-effective.

# Process for Designing a Resource Authorization Strategy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Designing a resource authorization strategy involves selecting the best resource authorization method or methods for your environment. You must also consider and implement policies for security group management that determine who is allowed to create security groups, how security groups are named, how they can be nested, and how they are administered.

Figure 15.1 shows the process for designing a resource authorization strategy.

**Figure 15.1 Designing a Resource Authorization Strategy**

# Background Information for Designing a Resource Authorization Strategy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you design your resource authorization strategy, it is important that you understand security group types and scope, domain and forest functional levels, group nesting, and trust relationships between domains and forests.

**Security Groups**
Security groups are used to combine user accounts, computer accounts, and other groups of accounts into manageable units. Rights or permissions are then assigned to the security groups, rather than to individual accounts. Security groups are classified according to scope. In the Microsoft® Windows® Server 2003 operating system, these scopes include:

- Local
- Domain local
- Global
- Universal

It is important that you understand group scopes and how these groups can be used before you design your resource authorization strategy.

For more information about group scope and group usage, see the following topics in Help and Support Center for Windows Server 2003:

- Group types
- Group scope
- Understanding Local Users and Groups
- Where groups can be created
- Nesting groups
- Accessing resources across domains

For best results in identifying Help topics by title, in Help and Support Center, under the **Search** box, click **Set search options**. Under **Help Topics**, select the **Search in title only** checkbox.

**Domain and Forest Functional Levels**
The security group options that are available depend on the domain and forest functional levels at which your organization is operating. For example, if your domain is operating at the Microsoft® Windows® 2000 mixed functional level, then you can only add global groups to local groups. However, if your domain is operating at the Windows Server 2003 functional level, you can nest global groups within other global groups, giving you much greater flexibility in managing your security groups.

If your forest is operating at the Windows Server 2003 functional level, you can also enable trusts across forests. These two-way trusts enable you to authorize users to access resources across forests. You can also enable external trusts between single domains in different forests.

For more information about domain and forest functional levels, group nesting, domain trusts, and trusts across forests, see the following topics in Help and Support Center for Windows Server 2003:

- Domain and forest functionality

- Nesting groups
- Understanding Trusts

**Terms and Definitions**

It is important to be familiar with the following terms as you design your resource authorization strategy.

**Account Group** An account group is a security group whose members are user or computer accounts, all of which require the same permissions for a resource.

**Resource Group** A resource group is a security group that has been added to the access control list (ACL) of a resource and granted a specific set of access permissions.

**Principle of Least Access** The principle of least access states that users must have access to the software, data, and devices required to perform their daily duties, but must not have access to local or network resources that are not required for their job tasks. This minimizes potential security risks.

# Establishing a Resource Authorization Method

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can select one of three resource authorization methods to enable users to access shared resources in your organization. It is important to select the method that is the most appropriate for your environment and for the specific resource. Figure 15.2 shows the steps in this process.

**Figure 15.2 Establishing a Resource Authorization Method**

# Selecting a Resource Authorization Method

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Depending on the resource and the needs of your organization, you can choose to apply any or all of the following authorization methods to enable access to shared resources:

- User/ACL method
- Account Group/ACL (AG/ACL) method
- Account Group/Resource Group (AG/RG) method
- Role-based authorization

# User/ACL Method

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In the user/ACL method, the resource owner adds security principal accounts directly to the resource ACL. For example, Bob creates a file share and adds Alice as an authorized user, giving her read-only permission to the share. Individual resource owners often use this method.

Adding individual user accounts to individual resource ACLs might work for small organizations with few users and minimal resources. However, this approach does not scale well and is impractical for larger organizations.

Adding a large number of users to a large number of ACLs creates the following problems:

- Access to resources is inconsistent from one user to the next. For example, one engineer might have access to a laser printer, a plotter, a backup device, and many file shares. Another engineer in the same group might need access to the same resources, but have access to only a subset of those resources.

- The IT staff must handle a large volume of requests for updated or corrected access. In the previous example, Alice, the engineer who does not have sufficient access, might send individual requests to the IT group as she discovers that access to various resources is denied to her.

- There is no way to know which resources a specific user has access to without extensive tracking, and, therefore, permissions cannot be easily revoked when a user changes positions or leaves the organization.

- In very large organizations, unmanaged security descriptors waste disk space.

In most environments, it is better to use the AG/ACL or AG/RG methods rather than the limited user/ACL method. The general guideline is to assign permissions to groups, rather than to individual accounts. However, if a resource is sensitive for security reasons, it might be advisable to assign permissions to individual accounts.. For instance, suppose that you want to share a database of employee data and that you cannot control or easily determine which users belong to various account groups. In this case, rather than adding an account group to the database ACL or to the database's resource group, you might choose to add specific users directly to the database ACL. This requires more maintenance, but security concerns might outweigh maintenance requirements.

# AG/ACL Method

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In the Account Group/ACL (AG/ACL) method, security groups, rather than individual user accounts, are added to the resource ACL, and the group is given a set of access permissions. For example, Bob might grant the group Everyone access to his public file share. This method is more scalable and more easily maintained than the user/ACL method. Typically, domain users are added to various global groups when they join an organization. Members of these global groups usually have something in common. They might work in the same building or on the same team or they might have the same job function. Rather than adding individual accounts to a resource ACL, the resource owner simply gives the domain global group access permissions. When a user joins or leaves the organization and is thus added or deleted from domain security groups, she or he is granted or denied access to the resource without any modification of resource permissions.

The AG/ACL method is scalable in that security groups can be nested if your domain is configured for Windows 2000 native or Windows Server 2003 functional level. Groups from multiple domains, or from multiple forests (if forest trusts are enabled) can be grouped together into one encompassing security group, and this security group can be added to the resource ACL. This method can scale without modification to the resource ACL, assuming that all the users require the same permissions.

This method requires more administrative effort from the resource owner, however, if different groups require different access permissions. Some groups might require read-only access, while others might require read-write access or full access. In this case, each group must be added to the ACL separately, and access permissions must be granted to each group.

Even more administrative effort from the resource owner is required if your domains are configured for Windows 2000 mixed functional level. At this functional level, group nesting is limited. Global groups can join only local groups, and global groups cannot be nested within other global groups. In this situation, neither the user/ACL nor the AG/ACL methods are typically acceptable.

If your domains are all at either Windows 2000 native or Windows Server 2003 functional level and if group nesting is allowed by your group nesting policy, then you might use either the AG/ACL method or the AG/RG method. If you have many account groups that must be given different access permissions, then the AG/ACL method might be advisable, especially if account groups and the permissions they require change frequently. Using the AG/RG method requires that you create a different resource groups for each combination of special permissions.

# AG/RG Method

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In the Account Group/Resource Group (AG/RG) method, users with similar access requirements are grouped into account groups, and the account groups are added as members to a resource group that has been granted specific resource access permissions.

The AG/RG method is often most appropriate for large organizations with many shared resources because it is scalable and maintainable in all environments, at all domain functional levels. For example, suppose Bob maintains a print server that controls 50 printers that are used by 5,000 engineers. Bob might use the AG/RG method in several ways, but for this example he creates a local group on the printer server called Color Printer-Mail Room and gives this resource group permission to print to this print server. The group of 50 engineers working on the second floor needs access to this printer, and they are all members of an account group called Second Floor Engineers. All Bob needs to do is add the Second Floor Engineers account group to the Color Printer-Mail Room resource group. All 50 engineers now have access to the printer. Bob can use the AG/RG method for all 50 printers.

In this example, however, Bob could have used the AG/ACL method just as easily. The scalability of the AG/RG method is more apparent when Bob needs to add 25 different account groups to the printer. If he uses the AG/ACL method, he has to add 25 groups to the printer ACL and set permissions for each one. If he uses the AG/RG method, he only needs to add the account groups to the resource group.

The AG/RG method is also appropriate if a group of related resources are being shared to multiple account groups. For example, Bob might have a group of printers that are all shared to the same account groups. Suppose all of the printers on the sixth floor are used by five separate accounting teams. Rather than creating a separate local group for each printer, Bob creates one domain local group called Sixth Floor Printers. He adds this same resource group to the ACL for each printer and assigns permission to print. Now he can add the five global groups containing the five accounting team members to Sixth Floor Printers, and all five account groups gain access to all the printers on the sixth floor. If a new accounting team is formed and needs access to the printer, an account group containing the accountants' user accounts is added to the Sixth Floor Printers domain local group with no need to modify the ACLs of any printers.

Applying the AG/RG method facilitates the process of revoking users' access to one set of resources and granting them access to other resources. As users join, leave, or move within the organization, simply adding the user to or deleting the user from an account group allows or removes access to resources without the need to modify resource ACLs. For example, if engineers move to new offices on the third floor of their building, the resource owners can update printer access by removing the Engineering Users group from the Sixth Floor Printers group, and adding it to the Third Floor Printers group. In this way, all engineers receive immediate access to all of the printers near their new offices.

This method can be used in any environment. However, it is especially useful if your domains are at Windows 2000 mixed functional levels or if you need to share resources with Microsoft® Windows NT® 4.0 operating system domains. Without the ability to nest groups, it is easier to create a resource group with the appropriate permissions and to add account groups to the resource group rather than assigning individual permissions directly to each account group.

The AG/RG method is also preferable if your resources require a stable set of common permissions. For example, a file share typically requires full permissions for very few people, read-write permission for more people, and read-only permission for most people. In this situation, you might create three resource groups, one for each of the three common access levels. Account groups can be added to each resource group as needed to grant the correct access level.

The AG/RG method is also a good choice if you need to share groups of related resources that have the same access permissions, as described earlier in this section.

# Role-based Authorization

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Role-based authorization uses scripts called authorization rules to enable users with similar roles to be authorized to perform predefined sets of tasks in specific applications. This allows fine-grained control over the mapping between access control and the structure and tasks performed in your organization. In order to take advantage of role-based authorization, however, applications must be written to take advantage of this capability. In addition, the organization's Active Directory® directory service must be at the Windows Server 2003 domain functional level.

For more information about role-based authorization, see "Authorization Manager and role-based administration overview" in Help and Support Center for Windows Server 2003; also see "Role-based Access Control" in the Microsoft® Platform Software Development Kit (SDK).

# Selecting Local Groups or Domain Local Groups as Resource Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In both the AG/ACL and the AG/RG methods, you can select as resource groups either local groups on the computer that controls the resource or domain local groups in the computer's domain. This choice is typically relevant for administrators who manage network resources. If Bob shares a printer, he might create a local group to act as the resource group rather than ask a domain administrator to create a domain local group and grant him permission to manage it. Network resource managers, however, can choose either type of group as a resource group.

One advantage of using domain local groups as resource groups is that domain local groups can be managed anywhere in the domain. Creating local groups requires the resource manager to access the specific computer where the local group is to be created. Another advantage of using domain local groups as resource groups is that domain local groups are visible in Active Directory. Assuming that the domain local group is named in a meaningful way, it is relatively easy to locate the resource group and modify it to add or remove account groups.

However, there are also significant disadvantages to using domain local groups as resource groups. For example, suppose Bob is managing a file server with 500 shares, each of which has three resource groups to define the three common access levels. If Bob uses domain local groups for the resource groups, 1,500 groups will be displayed in Active Directory Users and Groups in the Microsoft Management Console (MMC). Furthermore, suppose that Bob has 50 file servers. Even with a meaningful group naming policy, it is not going to be easy to find the right resource group among 75,000 group names. In this case, Bob is much more likely to choose local groups as resource groups.

Another disadvantage of using domain local groups as resource groups is the relative difficulty of group retirement. As resources are changed, moved, or retired, the resource groups associated with the resource also must be changed, moved, or retired. A resource manager is more likely to keep up with the management of local groups than of domain local groups that are managed by another administrator. The closer the resource groups are to the actual resource, the more likely they are to be maintained or retired properly.

Security access token size also can be an issue if users are members of too many groups. A user's access token is built primarily from the security identifiers (SIDs) of the groups to which the user belongs. The default maximum token size for the Microsoft® Windows XP Professional operating system and Windows Server 2003 is 12,000 bytes. This token size enables users to belong to approximately 120 groups. If a user belongs to more than 120 groups, the buffer allocated for the user's token is exceeded. The result is that the user is unable to log on to the network or is otherwise denied access to network resources.

The maximum token size can be modified if necessary. With token-size modification, users can successfully belong to hundreds of groups. If you choose to use domain local groups as resource groups, token size issues are more likely to arise than if you use local groups on the computer where the resource is shared.

**Note**

- For more information about token size and default group membership limits, see article Q327825, "New Resolution for Problems That Occur When Users Belong to Many Groups" in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at www.microsoft.com/windows/reskits/webresources.

# Defining Policies for Security Group Management

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Policies for security group management are a significant part of your resource authorization strategy. For example, you need to establish a policy defining who can create security groups and when they should be created. You also need policies for security group naming, security group nesting, and security group retirement. Figure 15.3 shows the tasks for defining security group policies.

**Note**

- For the purposes of this chapter, "security group policies" refers to policies for security group management and is not related to Group Policy or Group Policy objects. For more information about Group Policy, see "Designing a Group Policy Infrastructure" in *Designing a Managed Environment* of this kit, and see "Group Policy" in Help and Support Center for Windows Server 2003.

**Figure 15.3 Defining Policies for Security Group Management**

# Defining a Security Group Creation Policy

Updated: December 7, 2007

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You need to define which members of your organization are allowed to create new security groups, and you need to identify the process that they use to create new security groups.

**Delegating Security Group Creation Rights**
Windows Server 2003 does not place any constraints on the ability to delegate permission to create security groups. You can edit the ACL of any security group and give any user in the forest permission to update the group's membership. This enables you to simplify the administration of groups in your organization.

By default, members of the Domain Admins, Enterprise Admins, and Account Operators groups have the Create Group Objects and Delete Group Objects permission. If it is appropriate for Account Operators in your organization to be responsible for managing the creation of security groups, there is no need to delegate this ability to others.

If there is a need for individuals other than members of the Administrators, Domain Admins, Enterprise Admins, or Account Operators groups to create security groups, you can delegate the ability to create and to delete new security groups within an organizational unit (OU) to individuals or groups in your organization. You might need to create a separate security group, such as Group Admins, and add the appropriate user accounts to this group. If the Group Admins have authority only within a single domain, this is a domain local group.

For more information about delegating the right to create security groups by using the Active Directory Delegation Wizard, see "Delegating administration" in Help and Support Center for Windows Server 2003.

**Defining a Security Group Request Process**
You need to define a process by which requests for the creation of security groups are submitted and approved. Requiring users to submit requests for the creation of new security groups and approving those requests before the groups are created limits the unnecessary proliferation of security groups in your organization.

A request for a new group should include the following information about the group:

- Purpose and scope
- Proposed membership
- Relationship to other groups
- Expected lifetime
- Group owner

Be sure that your IT staff keeps these requests on file or in a database as a source of information for various security maintenance tasks. This information is especially useful in identifying potentially obsolete groups. For more information about identifying obsolete security groups, see "Defining a Security Group Retirement Policy" later in this chapter.

# Defining a Security Group Naming Policy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Establishing a forest-wide or enterprise-wide naming convention for security groups helps to ensure that secure access control in your organization is not compromised. Without a universal naming convention, the potential for user error when adding or removing members and selecting the correct group increases substantially.

For example, when adding or removing members to groups, users select from a list of all groups in the forest, but cannot view information about the groups, such as membership or scope. Groups with similar or cryptic names might be selected accidentally. The consequences of granting access to the wrong group can be serious, causing members to have access to restricted resources or to be denied access to resources that are necessary for job tasks.

When establishing a security group naming convention for your organization, ensure that it does the following:

- Provides for the inclusion of information about the group's scope, purpose, and owner in its name and its description. This helps to differentiate each group from similar groups.
- Conforms to a hierarchy of standard labels to be used in a fixed order, beginning with the most general labels and ending with the most specific labels. This allows group names to be sorted alphabetically into an organized list.

In addition, consider the following when creating group names and descriptions:

- Both the name and description of a security group can include up to 256 characters.
- The first 20 characters of the name are usually visible in a list of security groups without resizing columns and scrolling. When viewing the **Properties** dialog box of the group, about 50 characters of the group name are viewable. You might want to abbreviate the organizational labels used in the group name to ensure that the distinguishing portion of the group name can be viewed in these environments.

You can apply any naming strategy that works for your organization, as long as group names provide enough information to distinguish them from other groups. A common approach is to create a security group naming standard that organizes groups according to the business structure of your organization. In this way, group names are composed of labels that represent your company's organization, such as division, department, team, and task.

Without descriptive labels, it is possible to create confusing group names. Three divisions, for example, might have similar group names for their sales groups. If someone searches for the sales group, it is difficult to know if "Sales," "Sales Group," or "AllSales" is the correct group. Adding more organizationally descriptive labels can take time and planning, but user group searches and rights assignments are more accurate as a result.

These labels are placed in order from most general to most specific, with the final label reflecting the purpose or content of the group, thus distinguishing the group name from similar names. For example, the following three group names represent different sales teams within the Avionics Division Sales Department of a corporation:

- Avionics Sales GovtContracts
- Avionics Sales RetailSales
- Avionics Sales TeleSales

Some organizations are based on domain membership. The following are examples of typical group names, where "Con" represents a domain in the fictional company "Contoso."

- Con-Sales-Clerical-Users
- Con-Sales-Mgmt-Users
- Con-Support-HelpDesk-Users

- Con-Support-HelpDesk-Resources
- Con-Support-Shipping-Users

Some organizations are based on geographical location. The following group names might represent printer resources in the Boston and Seattle remote offices:

- BOS-Printers-Floor3-Laser
- BOS-Printers-Floor3-Color
- SEA-Printers-Reception-Laser
- SEA-Printers-Lab-LargeFormat

An organized system for naming groups makes it easy to locate the correct security group, and helps protect against duplicate naming. Users can search for related groups by entering the first few letters of the group name in the **Select Users, Contacts, Computers or Groups** dialog box. For example, they can filter the list for "Avionics Sales" groups.

The list of group names in the **Select Users, Contacts, Computers or Groups** dialog box also displays each group's description string. This added field can be used to include other attributes of the group, such as the group scope, the name of the person who maintains the group, and a brief statement of the group's purpose. The following are examples of group descriptions:

- *Avionics Support HelpDesk Resources:* Domain local resource group for help desk resource ACLs, maintained by Bjones x2344.
- *Avionics HumanRes AllUsers:* Global account group of all human resources user accounts, maintained by Ssmith x9488.

**Important**

- Windows Server 2003 does not provide any software support for enforcing a naming standard. Establish your naming policy and communicate it to all employees in your organization who have been delegated the right to create security groups.

# Defining a Security Group Nesting Policy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Security group nesting occurs when one security group is made a member of another security group, and the nested group inherits all of the privileges and permissions that are granted to the parent.

**Note**

- A domain must be configured at the Windows 2000 native or Windows Server 2003 functional level in order for global groups to be nested within global groups or for domain local groups to be nested within domain local groups.

Unrestrained group nesting can result in access token size problems because the token contains the SIDs for each group of which the user is a member, either directly or indirectly. The default group membership limitation is 120 groups. For more information about issues related to group membership and access token size, see "Selecting Local Groups or Domain Local Groups as Resource Groups" earlier in this chapter. Additionally, if group nesting is not constrained by a nesting policy, it becomes difficult to know exactly which permissions might be inherited by members of a security group that is nested within another, or several other, security groups.

If your enterprise is organized according to the AG/RG model, you need to allow for some degree of nesting without allowing nested groups to proliferate. Design and follow an explicit nesting strategy so that nesting relationships among security groups are predefined and well understood. This helps to guard against including users in too many groups.

If you choose to apply a security group nesting policy in your organization, consider drafting specific guidelines for that policy and communicating them to all employees who have permission to add members to a group.

# Creating a Hierarchy of Nested Security Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Nested groups allow you to provide company-wide or department-wide access to resources with minimum maintenance. Placing every team account group into a single company-wide resource group is not an effective solution because it requires the creation and maintenance of a large number of membership links. To use nested groups, administrators create a series of account groups that represent the managerial divisions of the company.

The top account group might be called "All Employees," and would be attached to a resource group that gives access to resources and shared directories.

The next level might contain account groups that represent major divisions of the company. Each group at this level is a member of All Employees, and is attached to a resource group giving access to shares and other resources appropriate to the division it represents.

Within a division, the next level of account groups might represent departments. Shared resources for the department might include project schedules, meeting schedules, vacation schedules, or any network information appropriate to the whole department. The department account groups are all members of the division account group.

Within a department, the management structure can be organized into security groups to any required level of specificity. These might be team account groups, and might represent leaf nodes in the organization's hierarchical tree.

With this group hierarchy in place, you can give a new employee instant access to the resources of the team, the department, the division, and the company as a whole by placing him or her in a team account group. This system supports the principle of least access because the new employee cannot view the resources of adjacent teams, other departments, or other divisions.

Figure 15.4 shows an example of the nested security group hierarchy for the Avionics Division group of an organization; the vertical arrows represent group membership.

**Figure 15.4 Nested Account Group Hierarchy**

# Modifying a Nested Security Group Hierarchy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The hierarchical structure of nested security groups gives the broadest access to users in the leaf nodes of the tree, the team account groups. You can modify the structure to allow department managers full access to all team resources, for example, or to allow the company's CEO access to all company resources. Figure 15.5 shows how the nested security group hierarchy illustrated in Figure 15.4 might be modified to allow all managers full access to all team resources; the arrows represent group membership.

**Figure 15.5 Modified Nested Security Group Hierarchy**

To support this type of access, you create another hierarchical series of account groups, with the membership links going in the opposite direction. For example, you might create a group called Avionics Sales Managers, and add the appropriate users to the group, then add this group to the membership of all Sales team account groups. In this way, the Avionics Sales Managers are able to view the files of all Avionics Sales teams.

You can apply this model all the way up the organizational chart, giving the CEO complete access to every file in the forest. This approach, however, is problematic for two reasons. First, high-ranking executives are priority targets for attackers and do not need access to thousands of files scattered throughout the forest. An intruder who intercepts the password of the CEO can cause unlimited damage. Second, in a large organization this strategy can fill user access tokens with hundreds of group SIDs, leading to significant logon delays, denial of access to resources, or the inability to log on. For more information about issues related to group membership and access token size, see "Selecting Local Groups or Domain Local Groups as Resource Groups" earlier in this chapter.

# Defining a Security Group Retirement Policy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When security groups become obsolete due to personnel changes, project completion, or corporate reorganizations, they need to be identified and retired (deleted) to minimize security risks. This task usually falls to the organization's IT department. It is important to create a policy for the retirement of security groups.

In this policy, include procedures for:

- Gathering information about security groups, especially information related to the expected lifetime of the group or the group's renewal interval. For more information about sources for this information, see "Defining a Security Group Creation Policy" earlier in this chapter.
- Identifying potentially obsolete security groups.
- Deleting obsolete security groups from Active Directory.

**Important**

- Deleting a security group from Active Directory is non-reversible because access to resources is based on the group's unique SID. If the wrong group is deleted, or if a group is deleted because it is thought to be obsolete when it is not, the IT department must create a new group in place of the deleted group and reintegrate it into the domain.

**Identifying Obsolete Security Groups**

Although account groups for very small teams might not change frequently, large account groups experience almost constant turnover in membership. If an account group's membership has not changed at all for some time, the group might be obsolete. The Active Directory Users and Computers snap-in allows you to search for potentially obsolete groups by entering a Lightweight Directory Access Protocol (LDAP) query for a list of security groups whose definitions, including membership, have not changed since a specified date. A query in the format (&(objectCategory=group)(whenChanged<=YYYYMMDDHHMMSS.0Z)) returns groups that have not been modified past the specified date. For example, to query for groups that have not been modified since midnight on December 31, 2002 in Pacific Standard Time, the query is (&(objectCategory=group)(whenChanged<=20021231240000.0-8)). The last portion of the query (0-8) signifies the Pacific Standard time zone, which is eight hours less than Greenwich Mean Time.

**Note**

- For more information about building LDAP queries and about generalized time, see the Windows Platform SDK link on the Web Resources page at www.microsoft.com/windows/reskits/webresources.

After you have identified groups whose membership has not changed for a period of time, you can verify the status of each group by querying the group owner, the group members, or the appropriate departmental administrators. Be sure to keep a record of your investigation for future reference.

Resource groups typically become obsolete when the resource is no longer needed, perhaps because projects requiring the resource have ended or because the hardware resource is moved or retired. Because resource groups are often configured as local groups on the computer that controls the resource, identifying obsolete resource groups is often a task for the computer owner or the resource manager. Finding obsolete local groups configured as resource groups is more challenging than finding domain-based account groups. Computers controlling resources are typically not domain controllers, so Active Directory is not available, and LDAP queries for unmodified local groups are not possible.

One approach is not to track local resource groups because local groups do not populate Active Directory. If your reason for identifying obsolete groups is to reduce the number of Active Directory objects, monitoring domain-based account and resource groups might be all that you require.

Another approach is to document and create a database of shared network resources. Typically, this database would include information about corporate resources rather than file shares or similar resources shared from a user's desktop, for instance. If the share type, location, owner, creation date, and any other relevant information are recorded, then periodic reviews can be

conducted to verify that resources and their associated resource groups are needed or obsolete.

**Deleting Obsolete Security Groups**
When you have identified an obsolete group, you can disable it for a trial period before deleting it from your domain. You can disable a security group by changing it into a distribution group for a set period of time, such as two months. Changing a security group into a distribution group does not alter its SID, scope, or membership; however, it effectively disables all access provided by the group because SIDs of distribution groups are not included in a user's access token. If you do not receive any notification that a user's access permissions have changed after the established wait period has expired, you can safely delete the group.

You must have the appropriate permissions to delete a security group. By default, Account Operators, Domain Admins, and Enterprise Admins have the ability to delete security groups. This permission can be granted to other individuals or administrative groups by editing the ACLs of OUs and containers.

### Caution

- Group deletion is immediate and permanent. Limit the number of persons to whom you delegate the ability to delete groups.

# Delegating Security Group Maintenance

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In large organizations, it is not possible for IT staff to be responsible for performing routine membership maintenance on large numbers of account groups, or to administer the ACLs and resource groups for resources in all departments. After a security group has been created and named, you can delegate the management of the group to other members or your organization. This can relieve the burden on your IT department.

Figure 15.6 shows the tasks for delegating security group maintenance.

**Figure 15.6 Delegating Security Group Maintenance**

# Identifying Individuals to Maintain Security Groups

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

By delegating security group maintenance to the appropriate individuals, you can ensure that requests for changes in membership are evaluated by individuals who can judge the appropriateness of the request, have the authority to make the change, and are motivated to keep group membership and access permissions correct and up-to-date.

Ideally, an employee who is familiar with the personnel, such as a department administrative assistant, is responsible for managing the membership of an account group. Because security groups in Windows Server 2003 can also be used as Microsoft® Exchange 2000 mailing lists, it is both convenient and cost-effective to have an individual maintain the account group for both purposes. This requires delegating read and write permissions for the group to the selected individual.

It is recommended that resource owners set ACLs because they are best able to supervise access to the resource. For example, the file server operator who maintains a department's shared directories is the logical candidate to be responsible for adding resource groups to the ACLs of the shares. Similarly, the person who is responsible for departmental printers is the best choice to manage the membership of the applicable printer resource groups.

# Delegating Account Group Maintenance

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To delegate permission to maintain account group memberships, you can apply the *account group/resource group/admin group model*, by which you extend the AG/RG model to accommodate a third kind of security group, the departmental admin group.

*Admin groups* are usually domain local groups that consist of members of the local business unit, such as managers or trusted clerical workers. A *departmental* admin group has permission to manage the membership of the department's security groups, and sometimes manages other department resources as well. The departmental admin group is added to the ACL of a business unit's OU, or to the ACLs of the individual user and resource groups. Although the departmental admin group has permission to manage group membership, it cannot create and delete groups.

Each department has its own departmental admin group with specific permission to change membership of the department's account groups. Because membership in the departmental admin group gives a user the ability to add any forest user to departmental account groups, the departmental administrators must be highly trusted employees.

Consequently, you also must carefully determine who controls the membership of the admin group itself. Allowing departmental administrators to self-administer their admin groups is a security risk, because such delegated authority can be misused. Relatively little effort is required to maintain the departmental admin groups, so it is more secure to have the central IT department administer them. In this way, the IT department can delegate account group maintenance to specific individuals in each department, and these assignments cannot be changed without IT participation.

# Delegating Resource Group Maintenance

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In the AG/RG model, related resources are collected into resource groups, although the resources themselves are not members of the resource groups. Instead, the ACLs of the individual resources are edited to grant the resource group appropriate access, and then account groups are added as members of the resource group, which gives the members of the account group access to the resources.

If you have adopted this model for your organization, you need to decide who sets the ACLs on the resources, and who controls the membership of the resource groups. In some cases, the departmental administrators (who maintain departmental account groups) have control over both the resources and resource groups in their departments.

In large organizations, however, the departmental admin group can become overwhelmed with requests for resource access or with other resource management duties. One solution to this problem is to enable resource owners to control access to their resources. The resource owner has full knowledge of the resource and is motivated both to make the resource available to legitimate users and to protect it from unauthorized access. Resource owners have control over access to their resources by default in Windows Server 2003.

For resource owners to have full control over access to their resources, they also must control the membership of the resource group. In this way, they control which account groups can become members of their resource groups.

In some cases, you must delegate resource group maintenance to resource owners. To do so, you must establish that the resource owner is responsible for editing the ACLs of the resource in order to grant appropriate access to specific resource groups. By default, the owner of a file or directory, a Server Operator, a Domain Admin, or an Enterprise Admin has permission to edit the ACLs of a resource. You must also grant resource owners control over the membership of the resource groups (but not the right to create or delete the resource groups) that must access their resource.

For more information about editing ACLs, see "Access Control" in Help and Support Center for Windows Server 2003.

# Additional Resources for Resource Authorization Strategy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information related to this chapter.

# Designing a Public Key Infrastructure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

| **Note** |
| --- |
| To download a copy of this document, see http://go.microsoft.com/fwlink/?LinkId=50360. |

Windows® Server 2003 enables a variety of secure applications and business scenarios based on the use of digital certificates. Before you can use digital certificates, however, you need to design a public key infrastructure (PKI), which involves planning configuration options for one or more certification authorities, preparing certificates to meet the needs of your organization, and creating a PKI management plan.

**In This Chapter**

Overview of the PKI Design Process

Defining Certificate Requirements

Designing Your CA Infrastructure

Extending Your CA Infrastructure

Defining Certificate Configuration Options

Creating a Certificate Management Plan

Deploying the PKI

Additional Resources for Designing a Public Key Infrastructure

**Related Information**

- For more information about Windows Server 2003 public key features, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection.
- For more information about using certificates in conjunction with Encrypting File System, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection.
- For more information about deploying smart cards, see "Planning a Smart Card Deployment" in this book.

# Overview of the PKI Design Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Organizations use a variety of technology solutions to enable essential business processes, such as online ordering, exchanges of contracts, and remote access. A public key infrastructure based on Microsoft Windows Server 2003 Certificate Services provides a means by which organizations can secure these critical internal and external processes.

Deploying a PKI allows you to perform tasks such as:

- Digitally signing files such as documents and applications.
- Securing e-mail from unintended viewers.
- Enabling secure connections between computers, even if they are connected over the public Internet or through a wireless network.
- Enhancing user authentication through the use of smart cards.

If your organization does not currently have a public key infrastructure, begin the process of designing a new public key infrastructure by identifying the certificate requirements for your organization. If your organization already uses a public key infrastructure based on Microsoft® Windows NT® version 4.0, Microsoft® Windows® 2000, or third-party certificate services, you can improve your PKI capabilities by taking advantage of new and enhanced features in Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; and Windows® Server 2003, Datacenter Edition. When you have completed the PKI design process, you can deploy a public key infrastructure that provides solutions for all of your internal security requirements, as well as security requirements for business exchanges with external customers or business partners.

**Note**

- For a list of the job aids that are available to assist you with the PKI design process, see "Additional Resources for Designing a Public Key Infrastructure" later in this chapter.

# Process for Designing a PKI

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Designing a PKI for your organization involves defining your certificate requirements, creating a design for your infrastructure, creating a certificate management plan, and deploying your PKI solution. Figure 16.1 shows the steps that are involved in designing a public key infrastructure.

**Figure 16.1 Designing a PKI**

**Note**

- The steps involved in designing a PKI are interdependent. For example, defining certificate server configurations, locations, and roles has a significant impact on how you address key certificate management issues. Your evolving certificate management standards in turn have significant implications for the certificate server roles, locations, and configurations that you develop.

# Basic PKI Concepts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Public key infrastructure is the term used to describe the laws, policies, procedures, standards, and software that regulate or control the operation of certificates and public and private keys. More specifically, a PKI is a system of digital certificates, certification authorities, and other registration authorities that verify and authenticate the validity of each party involved in an electronic transaction.

A PKI consists of the following basic components:

**Digital certificates** Electronic credentials, consisting of public keys, which are used to sign and encrypt data. Digital certificates provide the foundation of a PKI.

**One or more certification authorities (CAs)** Trusted entities or services that issue digital certificates. When multiple CAs are used, they are typically arranged in a carefully prescribed order and perform specialized tasks, such as issuing certificates to subordinate CAs or issuing certificates to users.

**Certificate policy and practice statements** The two documents that outline how the CA and its certificates are to be used, the degree of trust that can be placed in these certificates, legal liabilities if the trust is broken, and so on.

**Certificate repositories** A directory service or other location where certificates are stored and published. In a Windows Server 2003 domain environment, the Active Directory® directory service is the most likely publication point for certificates issued by Windows Server 2003–based CAs.

**Certificate revocation lists (CRL)** Lists of certificates that have been revoked before reaching the scheduled expiration date.

**Note**

- With Certificate Services in Windows Server 2003, Microsoft introduces a new type of certificate revocation list called a delta CRL, which allows you to publish information about recently revoked certificates more frequently without using the bandwidth required for publishing full CRLs.

**Certificate trust lists** These are signed lists, which are located on the client, of trusted CA certificates. Certificate trust means that a certificate is part of a certificate trust list (CTL) or that the CTL contains a trusted certificate from another CA that is part of the certificate's certificate chain. Windows Server 2003 domain administrators can use Group Policy objects (GPOs) to publish and maintain CTLs.

**Key archival and recovery** A feature that makes it possible to archive and recover the private key portion of a public-private key pair, in the event that a user loses his or her private keys, or an administrator needs to assume the role of a user for data access or data recovery. Private key recovery does not recover any data or messages; it merely enables the recovery process.

**Public key standards** Standards developed to describe the syntax for digital signing and encrypting of messages and to ensure that a user has an appropriate private key. To maximize interoperability with third-party applications that use public key technology, the Windows Server 2003 PKI is based on the standards recommended by the Public-Key Infrastructure (X.509) (PKIX) working group of the Internet Engineering Task Force (IETF). Other standards that the IETF has recommended also have a significant impact on public key infrastructure interoperability, including standards for Transport Layer Security (TLS), Secure/Multipurpose Internet Mail Extensions (S/MIME), and Internet Protocol security (IPSec).

# Windows Server 2003 PKI

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use PKI-based applications on workstations and servers running Microsoft® Windows® XP Professional, Windows Server 2003, Windows® 2000, or Windows NT 4.0, as well as on workstations running Microsoft® Windows® 95 and Microsoft® Windows® 98. The ability to create and manage a PKI is available in Microsoft® Windows NT® 4.0 Server, Microsoft® Windows® 2000 Server, and Windows Server 2003. However, Windows Server 2003 provides more extensive support for a PKI.

In addition, a growing number of applications and system services that require the secure transfer of information also rely on the Windows Server 2003 PKI. Applications that are enabled for certificate-based security include Microsoft® Outlook®, Internet Explorer®, Internet Information Services, Microsoft® Exchange Server, Microsoft® Commerce Server 2000 and Commerce Server 2002, Outlook Express, and Microsoft® SQL Server™. A number of third-party applications also take advantage of the Windows Server 2003 PKI.

**How a Public Key Infrastructure Works**

A Windows Server 2003 PKI makes it possible for an organization to do the following:

- **Publish certificates.** The PKI administrator makes certificate templates available to clients (users, services, applications, and computers) and enables additional CAs to issue certificates.

- **Enroll clients.** To participate in a PKI, users, services, or computers must request and receive certificates from an issuing CA or a Registration Authority (RA). Typically, enrollment is initiated when a requester provides unique information and a newly generated public key. The CA administrator or enrollment agent uses the information provided to authenticate the identity of the requester before issuing a certificate.

- **Use certificates.** Clients use their certificates, which are validated or invalidated in a timely manner as long as CAs and certificate revocation lists are available to verify or deny their authenticity. If they are validated, a PKI provides an easy way for users to use keys in conjunction with applications that perform public key cryptographic operations, making it possible to provide security for e-mail, e-commerce, and networks.

- **Renew or revoke certificates.** A well-designed PKI makes it easy for you to renew or revoke existing certificates, and to manage the trust level associated with certificates used by different clients or for different applications.

The status of a public key certificate is determined by means of the chain building process. Chain building is the process of building a trust chain, or certification path, from the end certificate to a root CA that is trusted by the security principal. Figure 16.2 shows a certification path in a two-level CA hierarchy.

**Figure 16.2 Certification Path in a Two-Level CA Hierarchy**

In this example, the issuing CA issued the User certificate, and the root CA issued the certificate of the issuing CA. This is considered a trusted chain, because it terminates with a root CA certificate that has been designed and implemented to meet the highest degree of trust.

The chain building process validates the certification path by checking each certificate in the certification path from the end certificate to the certificate of the root CA. If the CryptoAPI discovers a problem with one of the certificates in the path, or if it cannot find a certificate, the certification path is either considered invalid or is given less weight than a fully validated certificate.

For more information about how PKIs function, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

# Defining Certificate Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use a Windows Server 2003 public key infrastructure to provide a wide range of strong, scalable, cryptography-based solutions for network and information security. The value of the information that you want to protect, as well as the costs involved with implementing a strong security system, impact the level of security that you choose for your organization.

Figure 16.3 shows the steps that are involved in determining your certificate requirements.

**Figure 16.3 Defining Certificate Requirements**

# Determining Secure Application Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you begin to design your public key infrastructure and configure certificate services, you need to define the security needs of your organization. For example, does your organization require electronic purchasing, secure e-mail, secure connections for roaming users, or digital signing of files? If so, you need to configure CAs to issue and manage certificates for each of these business solutions.

A Windows Server 2003 PKI can support the following security applications:

- Digital signatures
- Secure e-mail
- Software code signing
- Internet authentication
- IP security
- Smart card logon
- Encrypting file system user and recovery certificates
- 802.1x authentication

**Digital Signatures**

A digital signature is a means for originators of a message, file, or other digitally encoded information to bind their identities to the data. This can be extremely useful for important documents such as legal opinions and contracts. The process of digitally signing information involves transforming the information, together with some secret information held by the sender, into a tag called a *signature*. Digital signatures are used in public key environments to help secure electronic commerce transactions by providing verification that the individual sending the message is who he or she claims to be, and by confirming that the message received is identical to the message sent.

You can use digital signatures even when data is distributed in plaintext, such as with e-mail. In this case, while the sensitivity of the message itself does not warrant encryption, it can be important as a means to ensure that the data is in its original form and has not been sent by an impostor.

One way that your organization can capitalize on the use of digital signatures is by using CAPICOM. CAPICOM is an ActiveX control that provides a COM interface to Microsoft CryptoAPI. It exposes a select set of CryptoAPI functions to enable application developers to incorporate digital signing and encryption functionality into their applications. Because CAPICOM uses COM, application developers can access this functionality in a number of programming environments, such as Microsoft® Visual Basic®, Microsoft® Visual Basic® Scripting Edition, Active Server Pages, Microsoft® JScript®, C++, and others. CAPICOM is packaged as an ActiveX control, allowing Web developers to use it in Web-based applications as well.

You can use CAPICOM for:

- Digitally signing data with a smart card or software key.
- Verifying digitally signed data.
- Displaying certificate information.
- Inspecting certificate properties such as subject name or expiration date.
- Adding and removing certificates from the certificate stores.

- Encrypting and decrypting data with a password.
- Encrypting and decrypting data by means of public keys and certificates.

**Secure E-mail**

Standard Internet mail is sent as plaintext over open networks with no security. In the increasingly interconnected network environments of today, intruders can monitor mail servers and network traffic to obtain proprietary or sensitive information. You also risk exposure of proprietary and confidential business information when you send mail over the Internet from within your organization.

Another form of intrusion is impersonation. On IP networks, anyone can impersonate mail senders by using readily available tools to counterfeit the originating IP address and mail headers. When you use standard Internet mail, you can never be sure who really sent a message or whether the contents of the message are valid. Moreover, malicious attackers can use mail to cause harm to the recipient computers and networks (for example, by sending attachments that contain viruses).

For these reasons, many organizations have placed a high priority on implementing secure mail services that provide confidential communication, data integrity, and non-repudiation. A Windows Server 2003 public key infrastructure allows you to enhance e-mail security by using certificates to prove the identity of the sender, the point of origin of the mail, and the authenticity of the message. It also makes it possible to encrypt mail. To provide message authentication, data integrity, and non-repudiation, secure mail clients can sign messages with the private key of the sender before sending the messages. The recipients then use the public key of the sender to verify the message by checking the digital signature.

S/MIME clients that run on any platform or operating system can exchange secure mail because all cryptographic functions are performed on the clients, not on the servers.

**Software Code Signing**

A growing number of applications, ActiveX® controls, and Java applets are being downloaded and installed on computers with little or no user notification.

In response to this problem, Microsoft introduced Authenticode™ digital signature technology in 1996, and in 1997 added significant enhancements to this technology. Authenticode technology allows software publishers to digitally sign any form of active content, including multiple-file archives. These signatures can be used to verify both the publishers of the content and the content integrity at time of download. Many software vendors already sign their applications and you can use these signatures to manage the software applications used on your network.

Authenticode relies on a certification authority structure in which a small number of commercial CAs issue software-publishing certificates. If you want to expand the use of software-publishing certificates in your own organization, the Windows 2000 and Windows Server 2003 PKI allows you to issue your own Authenticode certificates to internal developers or contractors and allows any employee to verify the origin and integrity of downloaded applications.

**Internet Authentication**

The Internet has become a key element in the growth of electronic commerce. However, for many users, security considerations impact how much and what kind of information they are willing to share across the Internet. The major concerns are:

- **Confidentiality.** Data that is transferred between clients and servers needs to be encrypted to prevent its exposure over public Internet links.
- **Server authentication.** Clients need a way to verify the identity of the servers they are communicating with.
- **Client authentication.** Servers need a way to verify the identity of clients.

Client authentication of the server takes place when the client verifies the cryptographic signatures on the certificate of the server, and any intermediate CA certificates, to a root CA certificate located in the trusted root store on the client. Server authentication of the client is accomplished when the server verifies the cryptographic signatures on the certificate of the client, and any intermediate CA certificates, to a root CA installed in the trusted root store on the server. When the identity of the client is verified, the server can establish a security context to determine what resources the client is allowed or not allowed to use on the server.

**IP Security**

Windows 2000 and Windows Server 2003 incorporate Internet Protocol security (IPSec) to protect data moving across the

network. IPSec is a suite of protocols that allows encrypted and digitally signed communication between two computers or between a computer and a router over an insecure network. The encryption is applied at the IP network layer, which means that it is transparent to most applications that use specific protocols for network communication. IPSec provides end-to-end security, meaning that the IP packets are encrypted or signed by the sending entity, are unreadable en route, and can be decrypted only by the recipient entity. Due to a special algorithm for generating the same shared encryption key at both ends of the connection, the key does not need to be passed over the network.

You do not need to use public key technology to use IPSec; instead you can use the Kerberos version 5 authentication protocol or shared secret keys that are communicated securely by means of an out-of-band mechanism at the network end points for encryption. However, if you use public key technology in conjunction with IPSec, you can create a scalable distributed trust architecture in which IPSec devices can mutually authenticate each other and agree upon encryption keys without relying on prearranged shared secrets, either out-of-band or in-band. This, in turn, yields a higher level of security than IPSec without a PKI.

For more information about deploying IPSec solutions, see "Deploying IPSec" in *Deploying Network Services* of this kit.

**Smart Card Logon**

Smart card logon is integrated with the Kerberos version 5 authentication protocol implemented in Windows Server 2003. When smart card logon is enabled, the system recognizes a smart-card insertion event as an alternative to the standard Ctrl + Alt + Del secure attention sequence to initiate a logon. The user is then prompted for the smart card PIN code, which controls access to operations performed by using the private key stored on the smart card. In this system, the smart card also contains a copy of the certificate of the user (issued by an enterprise CA). This allows the user to roam within the domain.

Smart cards enhance the security of your organization by allowing you to store extremely strong credentials in an easy-to-use form. Requiring a physical smart card for authentication virtually eliminates the potential for spoofing the identities of your users across a network. In addition, you can also use smart card applications in conjunction with virtual private networks and certificate mapping, and in e-commerce. For many organizations, the potential to use smart cards for logon is one of the most compelling reasons for implementing a public key infrastructure.

For more information about deploying smart cards, see "Planning a Smart Card Deployment" in this book.

**Encrypting File System Use and Recovery**

The Windows Server 2003 Encrypting File System (EFS) allows users and services to encrypt their data to prevent others who authenticate to the system from viewing the information. However, EFS also provides for data recovery if another means is needed to access this data — for example, if the user who encrypted the data leaves the organization, or if the original encryption key is lost. To support this requirement, EFS allows recovery agents to configure public keys that are used to enable file recovery. The recovery key only makes available the randomly generated file encryption key, not a private key of the user. This ensures that no other private information is accidentally revealed to the recovery agent.

### Note

- You do not need to have a public key infrastructure to use Windows Server 2003 Encrypting File System. However, the use of public keys improves the manageability of EFS. In a Windows domain environment, it is recommended that EFS be used in conjunction with a PKI.

For more information about EFS, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

**Wireless (802.1x) Authentication**

A growing number of organizations and facilities such as airports and hotels are implementing wireless network access. This creates the challenge of ensuring that:

- Only authenticated users can access the wireless network.
- Data transmitted across the wireless network cannot be intercepted.

Public key infrastructures, in conjunction with the IEEE 802.1x standard for port-based network access control, support both of these goals by providing centralized user identification, authentication, dynamic key management, and accounting to provide authenticated network access to 802.11 wireless networks and to wired Ethernet networks.

For more information about deploying a wireless network, see "Deploying a Wireless LAN" in this book.

# Determining Certificate Requirements for Users, Computers, and Services

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you have identified the security technologies that you need to implement to meet the business needs of your organization, you need to identify the categories of users, computers, and services that will use these technologies and for which you need to provide certificate services. For example, certificate use might be based on job function, location, organizational structure, or a combination of these three, or all computers or users in the organization might use certain certificate applications.

For each of the groups that you have identified, you need to determine:

- **The types of certificates to be issued.** This is based on the security application requirements of your organization and the design of your PKI infrastructure.
- **The number of users, computers, and applications that need certificates.** This number can include as few as one or as many users, computers, or applications as are in an entire organization.
- **The physical location of the users, computers, and applications that need certificates.** Different certificate solutions might be required for users in remote offices or for users who travel frequently than are required for users in the headquarters office of an organization. Also, requirements can differ based on geography. For example, you might want to restrict users in one country/region from using their certificates to access data in an organizational business unit in another country/region.
- **The level of security that is required to support the users, computers, and applications that need certificates.** Users who work with sensitive information typically require higher levels of security than other members of the organization.
- **The number of certificates required for each user, computer, and application.** In some cases, one certificate can meet all requirements. Other times, you need multiple certificates to enable specific applications and meet specific security requirements.
- **The enrollment requirements for each certificate that you plan to issue.** For example, do users have to present one or more pieces of physical identification, such as a driver's license, or can they simply request a certificate electronically?

**Note**

- For a worksheet to assist you in identifying user certificate requirements, see "Summary of User Certificate Requirements" (DSSPKI_1.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Summary of User Certificate Requirements" on the Web at http://www.microsoft.com/reskit).

# Documenting Certificate Policies and Practices

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Designing a public key infrastructure involves configuring certificates and certification authorities, developing support procedures, and establishing a system of checks and balances for administrative authority. Only by effectively addressing both the technical and administrative issues related to your public key infrastructure can you ensure that your certificate services provide the level of security that your organization requires

It is helpful to record the decisions that you make as you design your PKI by creating certificate policy statements and certificate practice statements. These documents assist you in planning and in communicating with individuals and businesses outside your organization. For many organizations and certificate uses, certificate policy statements and certificate practice statements are considered legal documents or legal disclaimers.

In general, the IT department is responsible for setting and maintaining PKI policies and practices. However, because of the legal, financial, and tactical uses of PKIs, representatives from outside the IT department, such as human resources, finance, legal, and marketing, might also be involved in establishing certificate policies.

A *certificate policy* is a set of rules that indicates the applicability of a certificate to a particular group of clients or applications that have common security requirements. Certificate policy statements generally include the following types of information:

- How users are authenticated to the CA.
- Legal issues, such as liability, that might arise if the CA is either compromised or used for something other than its intended purpose.
- The intended purpose of the certificate.
- Private key management requirements, such as storage on smart cards or other hardware devices.
- Whether the private key can be exported or archived
- Requirements for users of the certificates, including what users must do in the event that their private keys are lost or compromised.
- Requirements for certificate enrollment and renewal.
- Minimum length for the public key and private key pairs.

**Important**

- You can implement many of the decisions that you document in your certificate policy statements by creating a CAPolicy.inf file and copying it to the system directory of the CA before the CA is installed or renewed. For more information about CAPolicy.inf file contents and configuration, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

A *certificate practice statement* is a statement of the practices that IT uses to manage the certificates that it issues. It describes how the certificate policy of the organization is interpreted in the context of the system architecture of the organization and its operating procedures. The IT department is responsible for preparing and maintaining the certificate practice statement.

A certificate practice statement usually includes the following types of information:

- Positive identification of the CA (including CA name, server name, and DNS address).
- The certificate policies that are implemented by the CA and the certificate types that are issued.

- The policies, procedures, and processes for issuing, renewing, and recovering certificates.
- Cryptographic algorithms, cryptographic service providers (CSPs), and key length used for the CA certificate.
- Physical, network, and procedural security for the CA.
- The certificate lifetime of each certificate issued by the CA.
- Policies for revoking certificates, including conditions for certificate revocation, such as employee termination and misuse of user rights.
- Policies for CRLs, including where to locate CRL distribution points and how often CRLs are published.
- A policy for renewing the certificate of the CA before its expiration.

It is best to create a certificate practice statement for each CA in your public key infrastructure. The certificate practice statement associated with a CA can incorporate multiple certificate policies. Also, to consolidate information, the certificate practice statement for a subordinate CA can reference common or general information in the certificate practice statement of a parent CA.

For an outline to assist you in creating a certificate practice statement, see "Certificate Practice Statement Outline" (DSSPKI_2.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Certificate Practice Statement Outline" on the Web at http://www.microsoft.com/reskit).

**Important**

- In some situations, such as when digital signatures are used on binding contracts, the certificate practice statement can also be considered a legal statement about the level of security that is provided and the safeguards that are being used to establish and maintain the security level.

# Example: Defining Certificate Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An organization decides to implement a public key infrastructure because a number of business units within the organization are using certificate services independently. The business units use similar infrastructures that include many of the same components — such as CAs and certificate templates — and have similar goals. Therefore, the organization develops a PKI with a central corporate root that also allows individual business units to implement certificate services for their specific needs.

The organization chooses to use certificate services for the following:

- E-mail
- Internet authentication
- Encrypting File System
- Software code signing
- Smart card logon

In addition, they identify the following requirements:

- All users throughout the organization are required to use certificates in order to secure e-mail traffic.
- Individual business units need to use Internet authentication to facilitate the sharing of data on their local networks with their joint venture partners.
- All users are able to use Encrypting File System.
- Developers and network administrators must use software code signing for the custom applications and scripts of the organization.
- Administrators are required to log on using a smart card before they can perform certain tasks, such as administering domain controllers.

The organization then divides these requirements into the following security classifications:

- Medium security, which includes the e-mail and EFS certificates.
- Internal high security, which includes the software code signing and smart card logon certificates, and serves the needs of network administrators and developers.
- External high security, which includes the Internet authentication certificates and meets the need of the organization to share information with joint venture partners.

Figure 16.4 shows an example of the User Certificate Requirements worksheet that the organization created to summarize these classifications.

**Figure 16.4 Example of a User Certificate Requirements Worksheet**

| Summary of User Certificate Requirements | | | |
|---|---|---|---|
| Prepared By | | Date | |

Instructions: Col.1 List the names of groups of users, computers, services, business units, or network roles requiring certificates. Col. 2 Enter the number of clients in the group that will be issued certificates. Col. 3 Indicate whether the users are internal employees or external customers, and where they are located. If appropriate, include the owner name. Col. 4 List one or more certificate-enabled applications that will be used by the users in the group in that location. Indicate the name of either the parent domain or the account OU. Col 5 Enter a value such as high, medium, or low.

| Group | Number | Location | Applications | Security Level |
|---|---|---|---|---|
| Users | 45,000 | Internal | E-mail, EFS | Medium |
| Administrators and Developers | 250 | Internal | Smart card logon, code signing | High |
| Computers | 45,000 | Internal | Wireless Authentication | High |
| Partners | 35 | External | Internet Authentication | High |
| | | | | |

For a worksheet to assist you in documenting your certificate requirements, see "User Certificate Requirements" (DSSPKI_1.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "User Certificate Requirements" on the Web at http://www.microsoft.com/reskit).

After they have planned the trust relationships for the internal CA infrastructure and extended external CA infrastructure, the organization can design its certificates and certificate management processes. Administrators must examine the security and user requirements to develop a secure certificate services solution. For more information about designing certificates and configuring CAs, see "Creating a Certificate Management Plan" later in this chapter.

# Designing Your CA Infrastructure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To support the certificate-based applications of your organization, you must establish a framework of linked CAs that are responsible for issuing, validating, renewing, and revoking certificates as needed. The goal in establishing a CA infrastructure is to provide reliable service to users, manageability for administrators, and flexibility to meet both current and future needs, while maintaining an optimum level of security for the organization.

Figure 16.5 shows the steps involved in designing your CA infrastructure.

**Figure 16.5 Designing Your CA Infrastructure**

# Planning Core CA Options

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you can establish a CA infrastructure that meets the security needs and certificate requirements for your organization, you need to make decisions about a number of core CA options that are available. Planning the CA infrastructure for your organization involves making decisions about the following:

- Location of the root certification authorities.
- Internal versus third-party CAs.
- Requirements for CA capacity, performance, and scalability.
- Your Active Directory structure.
- Your PKI management model.
- CA types and roles.
- Use of hardware cryptographic service providers.
- Number of CAs required.

# Designing Root CAs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A CA infrastructure consists of a hierarchy of CAs that trust one another and authenticate certificates belonging to one another. Within this infrastructure, a final authority, called a root CA, must be in place. The root CA certifies other certification authorities to publish and manage certificates within the organization. Before you establish a CA hierarchy, you must determine the following:

- Who designates the root certification authority in the organization. For example, determine whether this is the responsibility of central IT, divisional IT departments, or a third-party organization.
- Where the root certification authority is to be located.
- Who manages the root certification authority.
- Whether the role of the root CA is only to certify other certification authorities, or also to serve certificate requests from users.

After you have made these determinations, you can define the roles for any additional certification authorities, including who manages them and what trust relationships they have with other CAs. For more information about CA roles, see "Defining CA Roles in the Trust Hierarchy" later in this chapter.

# Selecting Internal CAs vs. Third-Party CAs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Depending on the functionality that you require, the capabilities of your IT infrastructure and IT administrators, and the costs that your organization can support, you might choose to base your certification authority infrastructure on internal CAs, third-party CAs, or a combination of internal and third-party CAs.

**Internal CAs**
If your organization conducts most of its business with partner organizations and wants to maintain control of how certificates are issued, internal CAs are the best choice. Internal CAs:

- Allow an organization to maintain direct control over its security policies.
- Allow an organization to align its certificate policy with its overall security policy.
- Can be integrated with the Active Directory infrastructure of the organization.
- Can be expanded to include additional functionality and users at relatively little extra cost.

The disadvantages associated with using internal CAs include:

- The organization must manage its own certificates.
- The deployment schedule for internal CAs might be longer than that for CAs available from third-party service providers.
- The organization must accept liability for problems with the PKI.

**External CAs**
If your organization conducts most of its business with external customers and clients and wants to outsource certificate issuing and management processes, you might choose to use third-party CAs. Third-party CAs:

- Allow customers a greater degree of confidence when conducting secure transactions with the organization.
- Allow the organization to take advantage of the expertise of a professional service provider.
- Allow the organization to use certificate-based security technology while developing an internally managed PKI.
- Allow the organization to take advantage of the provider's understanding of the technical, legal, and business issues associated with certificate use.

The disadvantages associated with use of third-party CAs include:

- They typically involve a high per-certificate cost.
- They might require the development of two different management standards, one for internally issued certificates and one for commercially issued certificates.
- They allow less flexibility in configuring and managing certificates.
- The organization must have access to the third-party CAs in order to access the CRLs.
- Autoenrollment is not possible.
- Third-party CAs allow only limited integration with the internal directories, applications, and infrastructure of the

organization.

You might need to use both internal and third-party CAs. For information about using a combination of internal and third-party CAs in your organization, see "Extending Your CA Infrastructure" later in this chapter.

# Evaluating CA Capacity, Performance, and Scalability

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Organizations must agree upon a definition of acceptable CA performance. To determine the appropriate number of CAs and the best configuration for your CA infrastructure, you need to evaluate and address the factors in your organization that impact CA capacity, performance, and scalability. These include:

- The number of certificates that you need to issue and renew.
- The key lengths of the issuing CA certificates.
- The type of hardware that is used for your CAs.
- The number and configuration of the client computers that you need to support.
- The quality of your network connections.

A stand-alone Windows Server 2003 CA supports more than 35 million certificates per physical CA without any degradation of performance.

An individual departmental certification authority running on a server with a dual processor and 512 megabytes (MB) of RAM can issue more than 2 million standard-key-length certificates per day. Even with an unusually large CA key, a single stand-alone CA with the appropriate hardware is capable of issuing more than 750,000 user certificates per day.

Using a greater number of small CAs with strategically located CRL distribution points reduces the risk that your organization might be forced to revoke and reissue all its certificates if a large CA is compromised. However, using a greater number of CAs might increase your administrative overhead.

For many organizations, the primary limitations to CA performance are the amount of physical storage available and the quality of the clients' network connectivity to the CA. If too many clients attempt to access your CA over slow network connections, autoenrollment requests can be delayed.

Another significant factor is the number of roles that a CA server performs on the network. If a CA server is operating in more than one capacity in the network — for example, if it also functions as a domain controller — it can negatively impact the capacity and performance of the CA. It can also complicate the delegation of administration for the CA server. For this reason, unless your organization is extremely small, use your CAs only to issue certificates.

Some hardware components impact PKI capacity and performance more than others. When you are selecting the server hardware for your CAs, consider the following:

- **Number of CPUs.** Large CA key sizes require more CPU resources. The greater the number of CPUs, the better the performance of the CA. CPU power is the most critical resource for a Windows Server 2003 certification authority.

  **Note**

  - Because of the architecture of their databases, Windows Server 2003 certification authorities are CPU-intensive and use a substantial amount of the disk subsystem. However, other hardware resources can also impact the performance of a CA when the system is put under stress.

- **Disk performance.** In general, a high-performance disk subsystem allows for a faster rate of certificate enrollment. However, key length impacts disk performance. With a shorter CA key length, the CPU has fewer calculations to perform and, therefore, it can complete a large number of operations. With longer CA keys, the CPU needs more time to issue a certificate and this results in a smaller number of disk input/output (IO) operations per time interval.

- **Number of disks.** You can improve performance slightly by using separate physical disks for the database and log files. You can improve performance significantly by placing the database and log files on RAID or striped disk sets. In general, the drive that contains the certification authority database is used more than the drive hosting the log file.

**Note**

- Using separate logical disks does not provide any performance advantages.

- **Amount of memory.** The amount of memory that you use does not have a significant impact on CA performance, but must meet general system requirements

- **Hard disk capacity.** Certificate key length does not affect the size of an individual database record. Therefore, the size of the CA database increases linearly as more records are added. In addition, the higher the capacity of the hard disk, the greater the number of certificates that a CA can issue.

**Tip**

- Plan for your hard disk requirements to grow over time. In general, every certificate that you issue requires 17 kilobytes (KB) in the database and 15 KB in the log file.

The type of hardware that your clients use can also impact performance. When you are selecting or evaluating the capabilities of the hardware for your CA clients, consider the following:

- **Key length.** The greater the key length of a requested certificate, the greater the impact on the CPU of the server hosting the CA.

- **Network bandwidth.** Assuming that the CA is not serving in more than one capacity, a 100-megabit network connection is sufficient to prevent performance bottlenecks.

As you plan your CA infrastructure, you also need to ensure that your design is flexible enough to accommodate changes to your organization. For example, you need to be able to accommodate:

- Changes in the functionality that you require from your public key infrastructure.

- Growth or decline in demand for certificates.

- The addition or removal of locations that CAs need to serve.

- The effect of revocation. Revoking large numbers of certificates can take several minutes and increase the size of the database.

Using multiple CAs is an excellent way to ensure that your infrastructure can support enterprise scalability. The use of multiple CAs, even for organizations with minimal certificate requirements, provides the following advantages:

- **Greater reliability.** If you need to take an individual CA offline for maintenance or backup, another CA can service its requests.

- **Scalability.** Increases in demand, either from new users or from new applications, can be accommodated more easily.

- **Distributed administration.** Many organizations distribute security administration across a number of IT administrators to prevent one individual or team from controlling the entire security technology infrastructure of the organization.

- **Improved availability.** Users in remote offices can access a CA that is local to them rather than accessing a CA across slow Wide Area Network (WAN) links.

**Note**

- You can reorganize your CA infrastructure by adding or removing a CA and its associated users from a CA hierarchy. However, you cannot move a subset of users on a single CA to a new CA without forcing the users to re-enroll with the

new CA.

# Integrating the Active Directory Infrastructure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Your CA infrastructure is independent of the domain structure of your Windows environment. For example, one CA can service requests from multiple domains, or multiple CAs can serve a single domain. CA hierarchies with stand-alone CAs can even span multiple Active Directory forests.

If possible, take your PKI requirements into account when you design your Active Directory infrastructure. Active Directory and PKI technology impact each other in the following ways:

- **Enterprise CAs are bound to the forest.** As a result, enterprise CAs can only issue certificates to computers and users in the forest. In addition, you cannot change the name of the CA or the computer after it is deployed. Moreover, the computer cannot be removed from the domain or forest. Because much of the security of an organization is established at the forest level, the security of an enterprise CA is connected to the forest in which it is located. For this reason, each forest requires its own enterprise CAs.

  **Note**

  - If certificates from stand-alone CAs are published to Active Directory, these stand-alone CAs cannot be renamed or removed from the forest without their certificates becoming invalid. However, you can rename stand-alone CAs that belong to workgroups without impacting the status of their certificates.

- **Certificate storage affects the size of your directory.** If you store certificates in user objects, the size of the directory increases and replication time might increase. Because the userCertificate attribute contains data about all the user certificates, the addition of a certificate to that multivalued attribute causes Active Directory to replicate attribute data for all certificates.

- **Complications such as failure to recognize the user or the certificate can occur.** This happens if you do not apply a consistent naming structure for both your distinguished names (also known as DNs) and your user principal names (UPNs).

- **Enterprise CAs rely on the existence of an Active Directory schema.** If your schema is based on Windows 2000 Active Directory, you might need to extend it to support Windows Server 2003 Certificate Services functionality, such as version 2 certificate templates. For more information about version 2 templates, see "Selecting Certificate Templates" later in this chapter.

For certificates with a long life, the availability of the CA services themselves is much less important than the availability of the directory that holds the certificates and the certificate revocation lists. If you integrate your CAs with Active Directory, your certificates and CRLs are automatically published to the directory and replicated throughout the forest as part of the global catalog.

**Note**

- If you use Active Directory to publish and replicate information about CRLs throughout your organization, be sure to review Active Directory replication schedules and policies in order to ensure that this data is distributed in a timely manner.

Windows Server 2003 Certificate Services functions whether Active Directory in your organization is based on Windows 2000 or Windows Server 2003. It also functions if your organization is operating in mixed mode.

#### Configuring Public Key Group Policy

If you have an Active Directory environment, Group Policy allows you to link certificate services to groups of users or computers based on their domains or organizational unit membership. You must configure public key Group Policy in order to perform the following tasks:

- **Add trusted root certificates for groups of computers.** You can define the following:

- Which root CAs users can trust when verifying certificates.
- Whether users are allowed to trust additional CAs of their own choosing.
- The purposes for which certificates issued by each CA can be used.

Enterprise root CAs within your domain forest are automatically added to these policies.

- **Distribute certificate trust lists for computers and users.** For more information about certificate trust lists, see "Evaluating Factors That Affect Extended Trusts" later in this chapter.
- **Enable autoenrollment.** For more information about autoenrollment, see "Selecting a Certificate Enrollment and Renewal Method" later in this chapter.
- **Designate EFS recovery agent accounts.** You can define an EFS recovery policy within the scope of the policy object. If a recovery policy is defined, it is populated with the certificates of the recovery agents.

In many organizations, users and computers are already organized into domains and organizational units that are based on the organization structure, location, and job function. If your organization has not already created an Active Directory domain structure, the best way for you to take advantage of Public Key Group Policy is to define the groups of users and computers that will use your Certificate Services and communicate this information to the Active Directory and Group Policy administrators, so that they can address your public key requirements in their planning.

For more information about how to plan for the use of Group Policy, see "Designing a Resource Authorization Strategy" in this book.

# Defining PKI Management and Delegation

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is important to define a PKI management model early in the process of designing your CA infrastructure. This PKI management model must complement your existing security management delegation plan and help you to meet Common Criteria requirements for role separation. To ensure that a single individual cannot compromise PKI services, it is best to distribute management roles across different individuals in your organization. This involves deciding which individuals are to perform each of the following tasks:

- Creating or modifying existing CAs
- Managing certificate templates
- Issuing cross certificates
- Issuing or revoking user certificates
- Configuring and viewing audit logs

You can use discretionary access control lists (DACLs) to manage CA permissions and delegate CA management tasks.

Windows Server 2003 includes the following CA management roles:

- **Service Manager.** Configures and manages Certificate Services for local users, assigns certificate managers, and renews CA certificates.
- **Certificate Manager.** Issues and revokes certificates.
- **Auditor.** Audits the actions of local administrators, service managers, and certificate managers.

The extent to which you separate roles depends on the level of security that you require for a particular service. Assign the fewest possible rights to users in order to achieve the greatest level of security. For example, you can adopt the following rules:

- No user can assume the roles of both CA Administrator and Certificate Manager.
- No user can assume the roles of both User Manager and Certificate Manager.

If you need stricter guidelines, you can include the following:

- No user can assume the roles of both Auditor and Certificate Manager.

To facilitate this delegation process, you need to understand how various PKI administrative roles align with Windows Server 2003 administrative roles. Table 16.1 lists the Windows Server 2003 administrative roles that correspond to each PKI administrative role.

**Table 16.1 PKI Administrative Roles and Their Corresponding Windows Server 2003 Administrative Roles**

| PKI Administrative Role | Description | Windows Server 2003 Administrative Role |
|---|---|---|
| PKI Administrator | Configures, maintains, and renews the CA. | User |
| Backup Operator | Performs system backup and recovery. | Backup Operator on the server on which the CA is running |

| | | |
|---|---|---|
| Audit Manager | Configures, views, and maintains audit logs. | Local Administrator on the server on which the CA is running |
| Key Recovery Manager | Requests retrieval of a private key stored by the service. | User |
| Certificate Manager | Approves certificate enrollment and revocation requests. | User |
| User Manager | Manages users and their associated information. | Account Operators (or person delegated to create user accounts in Active Directory) |
| Enrollee | Requests certificates form the CA | Authenticated Users |

Table 16.2 lists the actions that each PKI administrative role can perform.

**Table 16.2 Actions Performed By PKI Administrative Roles**

| **Action** | **Enrollee** | **CA Admin** | **Certificate Manager** | **Audit Manager** | **Backup Operator** | **Local Server Admin** |
|---|---|---|---|---|---|---|
| Install a CA | | | | | | • |
| Configure a CA | | • | | | | • |
| Policy and exit module configuration | | • | | | | |
| Stop/start service | | • | | | | • |
| Change configuration | | • | | | | |
| Assign user roles | | • | | | | |
| Establish user accounts | | • | | | | • |
| Maintain user accounts | | • | | | | • |
| Configure profiles | | • | | | | • |
| Renew CA keys | | | | | | • |
| Define key recovery agent(s) | | • | | | | |
| Define officer roles | | • | | | | |
| Enable role separation | | • | | | | |
| Issue/Approve certificates | | | • | | | |
| Deny certificates | | | • | | | |
| Revoke certificates | | | • | | | |
| Unrevoke certificates | | | • | | | |

| | | | | | | |
|---|---|---|---|---|---|---|
| Renew certificates | | | ● | | | |
| Enable, publish, or configure CRL schedule | | ● | | | | |
| Configure audit parameters | | | | ● | | ● |
| Audit logs | | | | ● | | ● |
| Back up system | | | | | ● | ● |
| Restore system | | | | | ● | ● |
| Read CA properties, CRL | ● | | | | | |
| Request certificate | ● | | | | | |
| Read CA database | | ● | ● | ● | ● | |
| Read CA configuration information | | ● | ● | ● | ● | |
| Read issued, Revoked, pending certificates | | ● | ● | ● | ● | |

**Note**

- As you delegate roles and responsibilities, be sure to keep track of the permissions that you configure on certificate directories. Distributing access to a PKI to a number of individuals creates greater security risks.

# Defining CA Types and Roles

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To plan your CA infrastructure, you need to understand the different types of CAs available with Windows Server 2003 and the roles that they can play. Windows Server 2003 Certificate Services supports the following two types of CAs:

- Enterprise
- Stand-alone

Enterprise and stand-alone CAs can be configured as either Root CAs or Subordinate CAs. Subordinate CAs can further be configured as either Intermediate CAs (also referred to as a policy CA) or Issuing CAs.

Before you create your CA infrastructure, you need to determine the type or types of CAs that you plan to use, and define the specialized roles that you plan to have each CA assume.

**Enterprise vs. Stand-Alone CAs**

*Enterprise CAs* are integrated with Active Directory. They publish certificates and CRLs to Active Directory. Enterprise CAs use information stored in Active Directory, including user accounts and security groups, to approve or deny certificate requests. Enterprise CAs use certificate templates. When a certificate is issued, the enterprise CA uses information in the certificate template to generate a certificate with the appropriate attributes for that certificate type.

If you want to enable automated certificate approval and automatic user certificate enrollment, use enterprise CAs to issue certificates. These features are only available when the CA infrastructure is integrated with Active Directory. Additionally, only enterprise CAs can issue certificates that enable smart card logon, because this process requires that smart card certificates be mapped automatically to the user accounts in Active Directory.

*Stand-alone CAs* do not require Active Directory and do not use certificate templates. If you use stand-alone CAs, all information about the requested certificate type must be included in the certificate request. By default, all certificate requests submitted to stand-alone CAs are held in a pending queue until a CA administrator approves them. You can configure stand-alone CAs to issue certificates automatically upon request, but this is less secure and is usually not recommended, because the requests are not authenticated.

From a performance perspective, using stand-alone CAs with automatic issuance enables you to issue certificates at a faster rate than you can by using enterprise CAs. However, unless you are using autoissuance, using stand-alone CAs to issue large volumes of certificates usually comes at a high administrative cost because an administrator must manually review and then approve or deny each certificate request. For this reason, stand-alone CAs are best used with public key security applications on extranets and the Internet, when users do not have Windows 2000 or Windows Server 2003 accounts, and when the volume of certificates to be issued and managed is relatively low.

You must use stand-alone CAs to issue certificates when you are using a third-party directory service or when Active Directory is not available.

**Note**

- You can use both enterprise and stand-alone certification authorities in your organization.

Table 16.3 lists the options that each type of CA supports.

**Table 16.3 Options for Enterprise vs. Stand-Alone CAs**

| Option | Enterprise CA | Stand-alone CA |
|---|---|---|
| Publish certificates in Active Directory and use Active Directory to validate certificate requests. | • | |
| Take the CA offline. | | • |
| Configure the CA to issue certificates automatically. | • | |

| | | |
|---|---|---|
| Allow administrators to approve certificate requests manually. | | • |
| Use certificate templates. | • | |
| Authenticate requests to Active Directory. | • | |

**Root CAs**

A *root CA* is the CA that is at the top of a certification hierarchy and must be trusted unconditionally by clients in your organization. All certificate chains terminate at a root CA. Whether you use enterprise or stand-alone CAs, you need to designate a root CA.

Because there is no higher certifying authority in the certification hierarchy, the subject of the certificate issued by a root CA is also the issuer of the certificate. Likewise, because the certificate chain terminates when it reaches a self-signed CA, all self-signed CAs are root CAs. Windows Server 2003 only allows you to designate a self-signed CA as a root CA. The decision to designate a CA as a trusted root CA can be made at either the enterprise level or locally, by the individual IT administrator.

A root CA serves as the foundation upon which you base your certification authority trust model. It guarantees that the subject public key belongs to the subject identity information that is contained in the certificates it issues. Different CAs might also verify this relationship by using different standards; therefore it is important to understand the policies and procedures of the root certification authority before choosing to trust that authority to verify public keys.

The root CA is the most important CA in your hierarchy. If your root CA is compromised, every other CA and certificate in your hierarchy might have been compromised. You can maximize the security of the root CA by keeping it disconnected from the network and using subordinate CAs to issue certificates to other subordinate CAs or to end users.

For more information about using a third-party CA as the root CA, see "Extending Your CA Infrastructure" later in this chapter. For more information about disconnecting CAs from the network, see "Using Offline CAs" later in this chapter.

**Subordinate CAs**

CAs that are not root CAs are considered subordinate. The first subordinate CA in a hierarchy obtains its CA certificate from the root CA. This first subordinate CA can, in turn, use this key to issue certificates that verify the integrity of another subordinate CA. These higher subordinate CAs are referred to as intermediate CAs. An intermediate CA is subordinate to a root CA, but also serves as a higher certifying authority to one or more subordinate CAs.

An intermediate CA is often referred to as a policy CA because it is typically used to separate classes of certificates that can be distinguished by policy. For example, policy separation includes the level of assurance that a CA provides or the geographical location of the CA to distinguish different end-entity populations. A policy CA can be online or offline.

### Note

- Most organizations use one root CA and two policy CAs — one to support internal users, the second to support external users.

The next level in the CA hierarchy usually contains the issuing CA. The issuing CA issues certificates to users and computers and is almost always online. In many CA hierarchies, the lowest level of subordinate CAs is replaced by RAs, which can act as an intermediary for a CA by authenticating the identity of a user who is applying for a certificate, initiating revocation requests, and assisting in key recovery. Unlike a CA, however, an RA does not issue certificates or CRLs; it merely processes transactions on behalf of the CA.

# Using Offline CAs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Securing your CA hierarchy is a critical task. If an intruder can gain access to a CA, either physically or by means of the network, he or she might retrieve the private key of the CA and then impersonate the CA to gain access to valuable network resources. The compromise of even one CA key invalidates the security protection that it and any CAs below it in the hierarchy provide. For this reason, it is important to avoid connecting root CAs to the network.

To ensure the reliability of your CA infrastructure, specify that any non-issuing root and intermediate CAs must be offline. This minimizes the risk of the CA private keys becoming compromised. You can take a CA offline in any of the following ways:

- By installing a CA on a stand-alone Windows 2000 or Windows Server 2003 and configuring it as a stand-alone CA.
- By physically removing the computer from the network.
- By shutting down the CA service.
- By shutting down the computer.

**Caution**

- Shutting down a CA computer prevents auditing from taking place. Therefore, if a CA computer is compromised, a hardware failure does not generate an audit notification.

Make sure that you keep CAs in a secure area with limited access.

Installing an offline CA on a server that is a member of a domain can cause problems with a secure channel when you bring the CA back online after a long offline period. This is because the computer account password changes every 30 days. You can get around this by making offline CA computers members of a workgroup. Installing an offline CA as an enterprise CA can cause Active Directory to have problems updating when you disconnect the server from the network. Therefore, do not use an enterprise CA as a root CA.

Because they can operate offline, it is a good idea to use stand-alone CAs for root and intermediate CAs.

When a CA is supposed to be an offline CA, you can still publish its certificate and CRL in Active Directory. You must be sure to bring an offline CA online at regular intervals, based on your CRL publication schedule, to generate a new CRL for the CA. You must also bring the CA online to process certificate requests for subordinate CA certificates.

**Important**

- In general, the CRL and Authority Information Access (AIA) paths of an offline CA have to be modified before the first certificate is issued because the CRL and AIA paths, by default, point to the local http server and the local file system. Because the CA is offline and not accessible to other members of a network, the functionality of the CA must be separated from CRL and AIA distribution.

Because offline CAs process a small number of certificate requests at infrequent intervals, the administrative costs of maintaining offline CAs is low.

The client-side certificate validation process is not affected when a CA is offline because the client verifies the validity of the certificate by checking the certificate chain and the CRL. You cannot store both sources on the offline CA because clients need access to the CRL and AIA paths that are part of the certificate.

**Important**

- Taking a root CA offline does not reduce its importance, so be sure to use reliable hardware for offline root CAs. A hardware failure on an offline CA prevents you from publishing CRLs or issuing certificates to new subordinate CAs.

# Using Hardware CSPs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Hardware CSPs can support a wide range of cryptographic operations and technologies. Keys stored in tamper-resistant hardware crypto-devices are more secure than keys stored on local computer hard disks. Therefore, keys stored in hardware cryptographic devices can have key lifetimes that are longer than keys stored by software CSPs on hard disks.

**Note**

- Another advantage to using hardware CSPs is that the key material is kept outside the memory of the computer and within the hardware device. This makes it impossible to access the key of the CA by means of a memory dump.

If you determine that a hardware CSP is too costly, consider using smart cards for key storage. When you store cryptographic keys on a smart card, no one in your organization can issue or revoke certificates without the appropriate smart card together with the correct personal identification number (PIN).

If you choose to use hardware cryptographic service providers for CA private key storage, you must ensure that the hardware device is physically secured, or at least back up the operator cards or tokens. You might, for example, keep it in a highly secured area in the computer room of your company, or lock it in a safe.

# Determining Number of CAs Required

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you have identified your application and user requirements, you can begin to estimate the number of CAs that you need to deploy. If your organization has limited certificate requirements, a small user base, and limited expansion goals, a single CA might be sufficient. By using a single CA, you can still meet a variety of needs by customizing and deploying certificate templates and using role separation. However, if availability or distributed functionality of Certificate Services is a priority, you must deploy multiple CAs. You also need multiple CAs if you want separate CAs to issue certificates for different purposes.

To determine the number of CAs required, answer the following questions:

- Do you require more than one CA? If you are only supporting a single application and location, and if 100 percent availability of the CA is not critical, you might be able to use a single CA. Otherwise, you probably require at least one root and multiple subordinate CAs.

- If you need more than one CA, how many root CAs do you require? Generally, it is recommended that you have only one root CA as a single point of trust. This is because significant cost and effort is required to protect a root CA from compromise. With multiple root CAs, root maintenance becomes much more difficult.

  However, organizations with a decentralized security administration model, such as corporations with multiple, largely independent business units and no strong central administrative body, might require more than one root CA. For more information about using more than one root CA, see "Extending Your CA Infrastructure" later in this chapter.

- How many intermediate or policy CAs do you need?

- How many issuing CAs or RAs do you need?

  The number of intermediate and issuing CAs that you deploy depends on the following factors:

  - **Usage.** Certificates can be issued for a number of purposes (for example, secure e-mail, network authentication, and so on). Each of these uses might involve different issuing policies. Using separate CAs provides a basis for administering each policy separately.

  - **Organizational or geographic divisions.** You must have different policies for issuing certificates, depending on the role of an entity or its physical location in the organization. You can create separate subordinate CAs to administer these policies.

  - **Distribution of the certificate load.** You can deploy multiple issuing CAs to distribute the certificate load to meet site, network, and server requirements. For example, if network links between sites are slow or discontinuous, you might need to place issuing CAs at each site to meet Certificate Services performance and usability requirements.

  - **The need for flexible configuration.** You can tailor the CA environment (key strength, physical protection, protection against network attacks, and so on) to provide a balance between security and usability. For example, you can renew keys and certificates more frequently for the intermediate and issuing CAs that are at high risk for compromise, without requiring a change to established root trust relationships. Also, when you use more than one subordinate CA, you can turn off a subsection of the CA hierarchy without affecting established root trust relationships or the rest of the hierarchy.

  - **The need for redundant services.** If one enterprise CA fails, redundancy makes it possible for another issuing CA to provide users with uninterrupted service.

Strive to have only as many CAs and RAs as you need to function efficiently. Deploying more CAs than you need creates an unnecessary management burden, and introduces additional areas of security vulnerability.

**Note**

- You cannot install more than one CA on a server.

# Selecting a Trust Model

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Windows Server 2003 PKI is based on a hierarchical CA model that is composed of well-defined trust and CA naming standards. This type of CA trust model provides scalability, easy administration, and consistency with a growing number of third-party CA products.

In a hierarchical CA model, multiple CAs are organized into clearly defined parent-child relationships. Child CAs are certified by parent CA-issued certificates, which bind the public key of a CA to its identity.

With a hierarchical CA model, you minimize the number of root CAs that you need in order to verify certificates. At the same time, hierarchical CAs allow you great flexibility in the number of certificate-issuing subordinate CAs that you can use.

The basic types of CA trust hierarchies include:

- **Rooted trust model.** In a rooted trust model, a CA is either a root or a subordinate, and you can use offline root CAs for the highest level of security.
- **Network (or cross-certification) trust model.** In a network trust model, every CA is both a root and a subordinate.
- **Hybrid trust model.** Hybrid trust models combine elements of both the rooted and network trust models.

Your PKI trust hierarchy must be based on one of these three trust models.

Whether you choose to apply a rooted, network, or hybrid trust model to your CA infrastructure, you need to base your trust structure on the business requirements of your organization and on the way your organization delegates responsibility for IT administration. In this way, your trust model might be based on one or a combination of the following:

- Quality of identification
- Organizational structure
- User location

# Rooted Trust Model

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In a rooted trust model, the root CA is the trust anchor and has a self-signed certificate. The root CA issues a certificate to all direct subordinate CAs, if needed, which, in turn issue certificates to their subordinate CAs. A subordinate CA is trusted cryptographically, based on the signature of its parent.

Figure 16.6 illustrates the rooted trust model.

**Figure 16.6 Rooted Trust Model**

Numerous products and services offered by major software vendors, including Microsoft, support rooted trust hierarchies. You can add a new CA to a rooted trust hierarchy by enrolling it to a CA anywhere in the trust hierarchy. If you create a new trust hierarchy, it only needs to trust the root CA of the new PKI in order to trust all the subordinate CAs in the new hierarchy.

A rooted trust model enables you to compartmentalize risks, management, and certificate processing. Rooted trust hierarchies are more scalable and easier to administer than other hierarchies because each CA serves a single role within the hierarchy and is not operationally dependent on other CAs.

Any CA in a rooted trust hierarchy is either a root or a subordinate but never both. Each CA is responsible for processing requests and issuing certificates signed by its own key; each CA is responsible for revoking certificates and publishing CRLs to accessible locations; and each CA can be managed separately by different personnel in different parts of an organization.

Because CAs in a rooted trust hierarchy can be online or offline, rooted trust hierarchies allow great flexibility in the ways in which you can deploy and manage a PKI. You can protect the private key of a CA by taking the CA offline. Because offline CAs are typically the root and/or policy CAs that only issue certificates to other CAs, taking the CA offline does not impact other parts of the hierarchy.

Because most protocols deliver a chain of certificates that terminates in a trusted root CA, rooted trust hierarchies provide a straightforward means by which CAs can determine whether a certificate can be trusted.

**Note**

- If the certificate of a root CA expires, all certificates that are issued by the root CA or by its subordinate CAs also expire. For more information about managing certificate lifetimes, see "Selecting Certificate Security Options" later in this chapter.

# Network Trust Model

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If your organization has multiple, distributed IT departments, you might not be able to establish a single, trusted root. In this situation, you can implement a network trust model, in which all CAs are self-signed and trust relationships between CAs are based on cross-certificates. Cross-certificates are special certificates that are used to establish complete or qualified one-way trusts between otherwise unrelated CAs. For more information about the use of cross-certificates and how to manage cross-certified relationships, see "Selecting an Extended CA Infrastructure Configuration" later in this chapter.

A network trust model can be viewed as a hierarchy because a cross-certificate is essentially the same as a subordinate CA certificate in a rooted trust model. The cross-certifying CA is the issuer and the cross-certified CA is the subject.

Because a cross-certificate is a logical subordination of one CA to another CA, a network trust model is in effect a hierarchy, with the added property that a root CA is also a subordinate CA in the cross-certifying PKI.

Unlike the rooted trust model, in which a global directory such as Active Directory is not required, a global directory is essential in a network trust hierarchy. Without a global directory, cross-certificates need to be preinstalled on all clients of the PKI; otherwise there is no way to discover them.

Figure 16.7 shows an example of a network trust model.

**Figure 16.7 Network Trust Model**

The trusts in Figure 16.7 are bidirectional, which means that CA1 issued a cross-certificate of trust to CA2 and CA2 issued a cross-certificate of trust to CA1. It is also possible to rescind trust for a CA by revoking its cross-certificate.

Cross-certification does not need to be bidirectional, and a cross-certifying CA does not need the cooperation of the CA being certified. For example, CA1 can cross certify CA2, without CA2 cross certifying CA1. In such a case, clients of CA1 trust CA2 and CA3, while clients of CA2 and CA3 do not trust CA1. To do this, CA1 creates a cross-certificate without the knowledge of CA2, because all that CA1 needs is the public key certificate of CA2. This is known as *unilateral cross-certification*, where one CA cross-certifies another CA but not the reverse.

Bidirectional cross-certificates are usually preferred, although with this model you need to manage a greater number of cross-relationships as the number of cross-certificates increases.

Full trust between cross-certified CAs also means that the client trusts all certificates issued by the other CA, regardless of the purpose of the certificate. In a native Windows Server 2003 environment, however, you can filter by certificate types. You can also limit trust between CAs by means of qualified subordination, which can be implemented in the form of name constraints, policy constraints, policy mapping, and path constraints. For more information about these methods, see "Extending Your CA Infrastructure" later in this chapter.

Cross-certification enables you to create bridges between separate PKIs without either PKI being directly subordinate to the other. Because cross-certification is an indirect subordination of one PKI to another, the trust point does not change relative to either PKI. In fact, bidirectional cross-certification models the way in which companies form relationships; that is, each side participates in establishing the relationship. A network trust model, however, is much more difficult to maintain and troubleshoot than a rooted trust model.

**Note**

- Use a network trust model only in conjunction with name constraints. For more information about name constraints, see "Using Name Constraints" later in this chapter.

# Hybrid Trust Model

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Some organizations might find a pure rooted trust model too restrictive, because no single CA can serve as the root for all other CAs. At the same time, a pure network model can become prohibitively complex if too many different CAs are involved. If you use a hybrid approach, however, you can cross-certify only certain CAs and thus use the benefits of both the rooted and network trust models.

# Trust Hierarchy Based on Quality of Identification

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A trust hierarchy based on quality of identification enables an organization to configure CAs to issue certificates to specific groups of users. This type of trust hierarchy is ideal for organizations in which different identification and authentication requirements are applied to different groups of users, computers, and activities.

For example, an organization requires employees to appear in person to provide identification such as a driver's license or passport to a security officer, who checks an employee database to ensure that the individual is authorized, before they can receive appropriate credentials. However, because computers cannot assert an identity, managers in the organization are responsible for ensuring that computer names are correct and that computers are authorized to have a certificate. Because the organization requires CAs for employee certificates and computer certificates and each requires a different form of identification, the organization chooses to create a trust hierarchy based on quality of identification.

In a trust hierarchy based on quality of identification, the CAs subordinate to the root CA are organized according to the quality of identification required for the certificate to be issued. The subordinate CAs use certificates signed by the root CA in order to issue certificates to users, computers, services, or another CA.

A typical CA hierarchy based on quality of identification includes two or three issuing CAs for each of the following:

- Employee certificates
- Computer certificates
- Contractor certificates, if applicable. These certificates might require the same identification that employee certificates require, but contain an issuer statement stating that the individual is not a full-time employee.

# Trust Hierarchy Based on Organizational Structure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Although a two- or three- tier trust hierarchy based on the quality of identification is sufficient for most organizations, some organizations might need to deploy a three-tier CA trust hierarchy based on the administrative structure of the organization.

In a trust hierarchy based on organizational structure, issuing CAs are configured to support different organizational divisions, such as permanent employees and contractors. The issuing policy, for example, might be based on the organization of user accounts, so that stronger security measures are applied to independent contractors, temporary employees, or external business partners.

Figure 16.8 shows a rooted trust hierarchy based on organizational structure.

**Figure 16.8 Rooted Trust Hierarchy Based on Organizational Structure**

Design your trust hierarchy according to organizational structure if your certificate requirements vary according to organizational units; for example, all employees receive certain certificates, all partners receive a different set of certificates, and so on. Do not use this type of design if you can define too many different groups of requirements; in this case, a trust hierarchy based on certificate usage is more appropriate.

# Trust Hierarchy Based on Location

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Some organizations might find it necessary to implement a three-tier trust hierarchy based on location. This configuration allows regional administrators to manage the certificate requirements for users in a defined area such as a continent, country/region, or locale. Figure 16.9 shows a CA trust hierarchy based on location.

**Figure 16.9 Trust Hierarchy Based on Location**

Depending on the nature of your business, you might need to issue certificates based on location to comply with legal requirements — for example, if you perform work for a government agency — or other local regulations.

# Defining CA Roles in the Trust Hierarchy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you have designed the trust hierarchy for your organization, you must define the roles for your root, policy, and issuing CAs.

The root CA, for example, might be used to sign, certify, and/or revoke subordinate CAs. Intermediate or policy CAs might serve internal or external customers, or, in larger organizations, might serve more specialized functions or locations. Issuing CAs and RAs might be defined according to the clients that they serve or the certificates that they issue.

You might choose to select some or all of the following roles for your intermediate and issuing CAs:

- **Intermediate CA.** Certifies subordinate CAs to issue certificates.
- **Rudimentary CA.** Issues certificates for the most basic operations, such as user authentication without an identity check.

  **Note**

  - Stand-alone CAs are primarily used in intermediate and rudimentary roles.

- **Basic security CA.** Issues certificates, based on an Active Directory identity check, to users and computers that do not have special security requirements.
- **Medium security CA.** Issues certificates to users and computers that meet special security requirements and whose identities are validated in Active Directory.
- **High security CA**. Issues certificates to users or computers that meet especially high security requirements, and whose identities must be verified by means of the examination of physical credentials.

  **Note**

  - Enterprise CAs are primarily used for basic, medium, and high security roles.

Keep the following considerations in mind as you define CA roles:

- Use a three-tier hierarchy with policy CAs only if necessary.
- Third-party CAs can form all or part of a Windows Server 2003 CA trust hierarchy.
- Some third-party products might require other CA trust models that might not be interoperable with rooted CA hierarchies. Windows Server 2003 and most commercial CAs support rooted CA hierarchies.

# Establishing a CA Naming Convention

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you configure CAs in your organization, you must establish a CA naming convention. Names for CAs cannot be more than 64 characters in length. You can create a name using any Unicode character, but you might want to use the ANSI character set if interoperability is a concern. The CA name does not have to be identical to the name of the computer.

The name that you specify when you configure a server to be a CA becomes, in Active Directory, the common name of the CA, and is reflected in every certificate that the CA issues. For this reason, it is important that you do not use the fully qualified domain name (FQDN) for the common name of the CA. This way, malicious users who obtain a copy of a certificate cannot identify and use the fully qualified domain name of the CA to create a potential security vulnerability.

**Note**

- You cannot change the name of a server after Certificate Services has been installed without invalidating all the certificates issued by the CA. To change the server name after Certificate Services has been installed, you must uninstall the CA, change the name of the server, reinstall the CA, and reissue all the certificates issued by the CA. You do not have to reinstall a CA if you rename a domain; however, you will have to reconfigure the CA to support the name change.

# Selecting a CA Database Location

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you install a CA in your organization, you must specify a location for the database and log files of the CA. You must also indicate whether you want to store the configuration information for the CA. Storing the CA configuration information is helpful for backing up and, if necessary, restoring your CA.

You can choose to copy the naming information and the certificate for the CA to the file system (the configuration directory is automatically shared by means of a share named certconfig).

**Note**

- You can change the location of the database and log files manually at a later time. However, you cannot perform this task by using the user interface.

Windows Server 2003 uses the JET database engine for the CA database. As with any JET database, it is a good idea to place the database and its log files on different physical disk drives, in order to improve fault tolerance and performance. By default, all these files are located in the certlog subdirectory of the system directory.

**Tip**

- Use a separate RAID for both the database and log files for the highest level of fault tolerance between backup intervals.

The CA database consists of the files listed in Table 16.4.

**Table 16.4 CA Database Files**

| Database file | Purpose |
|---|---|
| <CA name>.edb | The CA store |
| edb.log | The transaction log file for the CA store |
| res1.log | Reservation log file to store transactions if disk space is exhausted |
| res2.log | Reservation log file to store transactions if disk space is exhausted |
| edb.chk | Database checkpoint file |

**Note**

- You can determine the location of the database files for a CA by typing **`certutil -databaselocations`** at a command prompt or by looking in the Certificate Services snap-in user interface.

# Example: Designing a CA Infrastructure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After an organization defines its certificate requirements, it creates a linked hierarchy of certification authorities to enable it to distribute certificates as needed, and to validate or reject certificates as appropriate.

In creating this CA infrastructure, the organization takes the following elements into account:

- **The security administration model of the organization.** For example, security administration is managed centrally from the headquarters of the organization, but individual business units create and support their own security requirements as needed for individual projects and business relationships. Some units operate autonomously, but report back to corporate IT.

- **The Active Directory infrastructure of the organization.** Because the organization has a single-forest logical structure, the CA infrastructure design is simple. The existing single-forest structure allows them to set up CAs, based on geography and bandwidth, to serve clients in multiple domains. For example, one or more common CAs support clients in offices on opposite coasts.

- **Potential use of a third-party CA.** The organization is concerned about IT costs and also prefers to manage its own security infrastructure. It addresses both concerns by creating and administering its own CA infrastructure. When joint venture business partners deploy PKIs, it is possible to integrate the two CA infrastructures without having to rely on a third-party CA.

  For more information about using third-party CAs to extend the CA infrastructure, see "Extending Your CA Infrastructure" later in this chapter.

Although the organization deploys Active Directory, it places a stand-alone root CA in a workgroup, rather than in the domain, for increased security. Also, it keeps this root CA offline and in a secure location that can only be accessed by an administrator who is authenticated by means of a smart card.

Directly below the root CA, the organization adds three policy CAs. One CA signs all certificates that have been issued to meet the high security standards of the organization, including software code signing, smart card logon, and Internet authentication certificates. The second CA signs all certificates that have been issued to meet the medium security standards of the organization, such as e-mail and EFS certificates. The third signs certificates for the CAs that issue certificates to external partners. These are also offline.

Figure 16.10 shows the CA infrastructure for the organization.

**Figure 16.10 Example of a CA Infrastructure of an Organization**

Table 16.5 summarizes the configuration of these CAs.

**Table 16.5 CA Configuration**

| CA | Name | State | Role | Domain |
|---|---|---|---|---|
| Root CA | RtCA01 | Offline | Stand-alone | None |
| Internal medium security policy | PolCA01 | Offline | Stand-alone | None |
| Internal high security policy | PolCA02 | Offline | Stand-alone | None |
| External high security policy | PolCA03 | Offline | Stand-alone | None |
| Internal medium security issuing 1 | IsCA01 | Online | Member server | Corp |
| Internal medium security issuing 2 | CA06 | Online | Member server | Corp |
| Internal medium security issuing 3 | CA07 | Online | Member server | Corp |
| Internal high security issuing 2 | CA08 | Online | Member server | Corp |
| Internal high security issuing 3 | CA09 | Online | Member server | Corp |
| External high security issuing 1 | CA01 | Online | Member server | Corp |

# Extending Your CA Infrastructure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use a rooted CA hierarchy to enable many PKI applications. However, you might find that your PKI needs are too complex to be met by a simple rooted hierarchy. For example, you might need to extend your CA infrastructure to accommodate joint ventures, mergers, geographic, or other business requirements.

Figure 16.11 shows the steps involved in extending your CA infrastructure.

**Figure 16.11 Extending Your CA Infrastructure**

# Evaluating Factors That Affect Extended Trusts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Extending and refining your trust hierarchy is a critical step in the process of creating a secure PKI, and it involves complex decisions. It is important to define appropriate and inappropriate uses for certificates in your organization before you extend your CA infrastructure. Without proper planning, you might grant business partners and users more trust than you intend.

If you want to link your established Windows Server 2003 trust hierarchy with an external PKI, a number of factors can impact interoperability. Before you extend your CA infrastructure, evaluate the following features and standards in both PKIs:

- Standards support
- Algorithm support
- CRL distribution points
- Authority information access (AIA)
- Authority key identifier (AKI)
- Certificate extensions
- Key length
- Extended key usage (EKU)
- Directory integration

Determine whether any other PKIs with which you need to establish trust support these features and standards, and how you can accommodate differences. Addressing these issues when you design your PKI can help you to ensure the extensibility and interoperability of your PKI environment.

**Standards Support**
A number of technical standards provide a basis for interoperability between Windows Server 2003 and other PKI applications. To promote third-party interoperability with the Windows Server 2003 API, Microsoft supports the following standards:

- *PKIX*. Defines interoperable PKI standards for the Internet.
- *X.509*. Describes the standard format of a certificate.
- *PKCS*. Provides a standard for public key message exchanges.
- *TLS*. Provides a secure and authenticated channel between hosts on the Internet above the transport layer.
- *S/MIME*. Serves as a standard for secure e-mail across the Internet.
- *Kerberos authentication protocol*. Provides a symmetric key framework for authentication in large networks.
- *PC/SC*. Serves as a standard for integrating smart cards and smart card readers.

Most PKI vendors have adopted many or all of these PKI standards. Different vendors, however, can implement the standards in different ways. While it might be possible to link external PKI implementations to yours, this might involve making some changes to your existing design. For this reason, it is strongly recommended that you evaluate the external PKI to determine whether it meets all your critical requirements.

**Algorithm Support**
It is important for a PKI to interoperate with many different hardware vendors and to provide a hardware abstraction layer so that applications do not have to know where keys are stored.

Windows Server 2003 uses CryptoAPI to abstract hardware-based key management from applications, and it uses the PC/SC standard instead of PKCS#11 to communicate with smart cards and readers. Many third-party CAs have their own cryptographic APIs and use PKCS#11 to interface to hardware tokens such as smart cards. Because Windows 2000 and Windows Server 2003 require hardware devices to support Plug and Play and power management features, and PC/SC includes support for these ease-of-use features, Windows Server 2003 does not support PKCS#11.

### Note

- The Windows Server 2003 PKI can use third-party CSPs, and can enroll users for certificates that have keys that were generated by third-party CSPs.

**CRL Distribution Points**
The CRL distribution point (CDP) extension in a certificate identifies how revocation information for the certificate can be obtained. If a CRL distribution point is not always available, certificate chain building can be delayed, causing inconvenience for the user. If a CRL is not available at the distribution point that has been specified in the certificate, CRL retrieval might even fail and the certificate will be considered invalid.

### Note

- Publish CDP URLs for all CAs so that users who need to know whether or not issued certificates have been revoked can find that information.

You need to compare any third-party CRL support with the Windows Server 2003 CRL support. For example, the third-party PKIs might not support the Windows Server 2003 CRL process, which includes the use of delta CRLs. Conversely, the Windows Server 2003 PKI might not support the methods of the third-party PKI for processing CRL information. Your extended PKI deployment plan needs to account for these differences.

In general, follow these guidelines when you configure the CDP extension:

- If available, use Active Directory to support internal corporate clients.
- Use an externally referenced and trusted Lightweight Directory Access Protocol (LDAP) directory to support business partners and customers.
- Consider using HTTP distribution points, especially for certificates that will be used externally.

**Authority Information Access**
The Authority Information Access (AIA) extension is a pointer to the most currently published CA certificate of a CA. The AIA extension helps clients find CA certificates dynamically during chain building. The Windows Server 2003 PKI uses this extension to assist in building trust chains to validate certificates.

It is recommended that you publish AIA URLs for all PKIs for which users might need to retrieve up-to-date CA certificates. Whether a CA is online or offline, and whether it is a root, intermediate, or issuing CA, using the AIA extension minimizes the likelihood that PKI clients will encounter unverified certificate chains or revocation data. Such encounters can result in unsuccessful VPN connections, failed smart card logons, or unverified e-mail signatures.

Some third-party PKIs do not provide the AIA extension. In this case, parent certificates need to be distributed to domain clients so that the certificates are available before the chain building process begins. Cross-certificates must also be available locally on domain clients, because there is no information in a certificate specifying where it can be found.

**Authority Key Identifier**
The Authority Key Identifier (AKI) extension provides a means to identify the public key of the CA that validates the signature on a CRL. This identification is based on either the subject key identifier (SKI) or the issuer name and serial number from the certificate issued by the CRL issuer. The AKI extension is useful in cases when a CRL issuer has more than one signing key.

An organization that expects its PKI certificates to be used by other Windows Server 2003 PKIs must populate the Authority Key Identifier extension with a unique key identifier and an issuer name and serial number. The Windows Server 2003 PKI attempts to construct certificate chains by using the issuer name and serial number in the AKI first, and then the subject key

identifier.

### Note

- By default, Windows Server 2003 does not automatically add issuer names and serial numbers to the AKI extension. This data must be added manually by means of Certutil.exe, although in most cases it is not necessary to do so.

**Certificate Extensions**
Not all certificate extensions are universally recognized. If a CA does not recognize a certificate extension in a request and it has been marked critical, it rejects the certificate. Unless you intend to limit the use of the certificate to a specific application that understands the critical extension, avoid putting critical extensions in certificates because it limits interoperability.

**Key Length**
When different PKIs support different minimum and maximum key lengths, an interoperability problem results. Be sure that your internal PKI and the external PKI support the necessary encryption keys.

**Extended Key Usage**
The Extended Key Usage (EKU) extension indicates the purposes for which the public key contained in the certificate can be used. The Windows Server 2003 PKI uses the EKU extension to indicate certificates that support special functions, such as IPSec and EFS file encryption backup. The EKU extensions of other organizations might be used for different purposes.

**Directory Integration**
Windows Server 2003 PKI certificates can be published to any directory or repository, although the default CA exit module only supports Active Directory. However, by default, a Windows Server 2003 PKI relies on Active Directory and the LDAP for authentication, including smart card logons and certificate autoenrollment, as well as for certificate management.

With Microsoft Certificate Services, certificates issued by a third-party CA can be associated with a Windows Server 2003 user account stored in Active Directory. This is possible because applications such as Internet Explorer and Internet Information Services (IIS) can be used to authenticate a user to an account stored in Active Directory, based on the UPN name information in a certificate. The account to which the certificate maps provides information about user access rights on the server. This is an extremely powerful feature for Web-based applications and third-party CAs because it combines strong authentication by means of public key technology with the native authorization model of Windows Server 2003. For example, to enable extranet and remote access scenarios without requiring the application and certificate to manage access rights, administrators can use certificates from partner companies and map them to accounts in Active Directory by means of one-to-one or many-to-one mappings.

For more information about using one-to-one and many-to-one mapping, see "Map certificates to user accounts" later in this chapter.

# Selecting an Extended CA Infrastructure Configuration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use one of three configurations to create an extended CA trust infrastructure:

- **Third-party root CA.** Use a third-party CA as a root CA for a new extended CA hierarchy shared between two organizations.
- **New root CA.** Establish your own new root CA to combine separate CA hierarchies for two organizations.
- **Cross-certification and qualified subordination .** Keep the existing CA hierarchies separate, but use cross-certification and qualified subordination to implement as much or as little trust as needed between the two organizations.

There are advantages and disadvantages to each approach. If you need to extend your CA infrastructure to include third-party PKIs, you need to evaluate the requirements of your organization to determine the method that is most appropriate for you.

# Using Third-Party Root CA Configuration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Building a new public key hierarchy from an existing third-party root CA is an appropriate solution if you want to cross-certify with multiple business partners simultaneously. The third-party root CA is used to build a new public key hierarchy designed specifically to serve the needs of multiple organizations. Figure 16.12 shows an example of an extended CA infrastructure built from an existing root CA. In this example, organization A and organization B maintain their existing PKIs and share a new PKI that serves the specific needs of their business relationship.

**Figure 16.12 Extended CA Infrastructure Built from an Existing Third-Party Root CA**

The advantage to this approach is that you can off-load responsibility for maintaining the new infrastructure to an organization that specializes in this type of service. The intermediate and issuing CAs that you create on your side of the shared infrastructure can be administered separately from your existing internal PKI. In this way, the functions of the external PKI cannot compromise the internal PKI, and the organizations that share the extended infrastructure do not have to share transitive trust between their existing PKIs.

The disadvantage to this approach is that it involves the creation of a new, separate infrastructure with its own administrative requirements. Although much of this administration is off-loaded to a third party, this approach involves considerable additional cost. The costs can multiply each time you add a new business relationship that requires a separate shared PKI infrastructure.

You need to plan for an extended PKI based on an existing root CA in the same way that you plan for your existing internal PKI, in that you must decide where to locate intermediate and issuing CAs, how to manage them, how to protect them, and so on. In this case, you must work with your business partner and the root CA provider to make these decisions.

Third-party CAs can form all or part of a CA trust hierarchy. To ensure that third-party CAs provide interoperability with your existing infrastructure, test all proposed interoperability scenarios in your lab.

**Note**

- Some PKIs require CA trust models that are not interoperable with rooted CA hierarchies. Windows 2000 and most commercial CAs support rooted CA hierarchies.

**Adding Trusted Root Certificates to Group Policy**

If a stand-alone CA is not a domain member buts runs as a member of a workgroup, the root CA certificate must be added manually to the domain Group Policy. In contrast, when you install a stand-alone root CA on a computer that is a domain member, the certificate of the CA is added to the Trusted Root Certification Authorities Group Policy for the domain.

You can also add certificates for other root CAs to Trusted Root Certification Authorities Group Policy manually. These root CAs then become trusted root CAs for the computers within the scope of the Group Policy. For example, if you want to use a third-party CA as a root CA in a certification hierarchy, you must add the certificate for the third-party CA to the Trusted Root Certification Authorities Group Policy.

# Using a New Root CA Configuration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You or your partner organization can create a new root CA to establish an extended CA infrastructure that supports your business requirements. The structure of this extended CA infrastructure is similar to that of an extended infrastructure based on a third-party rood CA. With a new root CA configuration, however, you and your partner organization must create a security management infrastructure, and must take responsibility for administering and maintaining the extended PKI. If one organization assumes this responsibility, the other organization must trust that its partner will protect the security interests of both parties.

This option can be more cost-effective than using a third-party root CA. In addition, you can use Windows Update to distribute new root certificates, improving reliability and decreasing costs.

The planning considerations for a new root CA–based extended infrastructure are similar to those that apply to your existing internal PKI. You and your partner organization are responsible for creating administrative policies for the root CA and enforcing the integrity of the new root.

# Using a Cross-Certification Configuration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

With the cross-certification method for extending the CA infrastructure, neither party creates a separate PKI; instead, cross-certificates, accompanied by qualified subordination, enable communication between existing public key infrastructures of two organizations to the degree of trust that their business relationship dictates.

Cross-certification creates a shared trust between two CAs that do not share a common root CA. These CAs exchange cross-certificates that allow their organizations to communicate. In this way, the organizations do not have to create and manage additional root CAs. Cross-certification might be the best option if a common root CA for both PKIs does not exist.

Figure 16.13 shows an example of an extended CA infrastructure based on cross-certification between the root CA of organization 1 and a subordinate CA in organization 2.

**Figure 16.13 Extended CA Infrastructure Based on Cross-Certification**

The advantages to using cross-certification to extend the PKI include low cost and a high degree of flexibility, as you can cross-certify at any level in the hierarchy. For example, if a division of organization 2 wants to share information with all of organization 1, the division can cross-certify with the root CA of organization 1. This, however, creates a security risk, as it exposes resources in parts of the organization that are not part of the business relationship. On the other hand, if a division of organization 1 and a division of organization 2 want to share information, the two divisions can cross-certify CAs that are lower in the CA hierarchy. This option is more secure, as the other divisions of the organizations are not unnecessarily exposed.

Cross-certification requires greater administrative overhead than other methods for extending the CA infrastructure, and entails the risk that outsiders might unintentionally be given access to internal resources. If an organization becomes involved in many cross-certification relationships with different levels of trust and different applications, the management overhead can be significant.

# Limiting Unplanned Trusts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you extend your CA trust infrastructure beyond the boundaries of the PKI of your organization, you can inadvertently create unplanned trust relationships.

Unplanned trusts that can occur include:

- Allowing certificates to be used for unintended applications
- Allowing external certificates to be used for longer than intended
- Enabling trust with the extended business partners of a business partners

For example, if company A trusts company B by means of an unconstrained cross-certificate, and company B trusts company C, then company A unintentionally trusts company C. Equally serious problems can occur when company A and company B cross-certify, and company A does not realize that company B does not have the same level of control over the manner in which its certificates are issued and used.

To limit the creation of unplanned trust relationships and the potential security risks that they pose, you can use CA constraints to define limits on your cross-certificate relationships. Constraints in Windows Server 2003 can be based on:

- Use and path length (basic constraints)
- Names
- Issuance policy
- Application policy
- Policy mapping

Implement these constraints when you configure your CA and end user certificates. For more information about defining constraints, see "Using Qualified Subordination to Restrict Certificates" later in this chapter.

**Using Certificate Trust Lists to Limit Unplanned Trusts**

You can use certificate trust lists (CTLs) to limit unplanned trusts. CTLs are the primary means of limiting unplanned trust relationships in Windows 2000 environments.

A CTL is a predefined list of certificates that is signed by a trusted entity. The CTL includes either hashes of certificates or a list of the actual certificate names. In most cases, the CTL is a list of hashed certificate contexts. The CTL allows you to limit the purposes for which certificates issued by an external CA can be used, and the validity period of those certificates.

Windows Server 2003 certificate trust lists allow you to do the following:

- **Create trust certificates from specific CAs without requiring broader trust for the root CA.** For example, you can use certificate trust lists on an extranet to trust certificates issued by certain commercial CAs. If you map certificates that are issued to an account stored in Active Directory, you can grant appropriate permission to users who need access to restricted extranet resources. This is possible because they have certificates issued by the trusted commercial CAs.
- **Restrict the permitted use of certificates issued by trusted CAs.** For example, you can use a certificate trust list on an extranet to restrict the permitted use of certificates to applications such as secure mail.
- **Control the period of time in which third-party certificates and CAs are valid.** For example, the CA of a business partner can have a lifetime of five years and issue certificates with lifetimes of one year. However, you can create a certificate trust list with a lifetime of six months to limit the time that certificates issued by the CA of the business partner are trusted on your extranet.

You might use a CTL to allow users to trust certificates that are issued by a commercial CA and restrict the permitted uses for those certificates. You might also use CTLs to control trust on an extranet for certificates that are issued by CAs that are managed by your business partners.

**Note**

- After a CTL is defined, it must be applied to client computers by means of Group Policy.

# Example: Selecting an Extended CA Infrastructure Configuration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Organizations frequently enter into joint ventures, which can involve the sharing of confidential information, such as engineering data that stored is on an internal network. To facilitate this type of data sharing, an organization can initiate a cross-certified relationship that allows some, but not all, employees of another organization to access data on its network.

One way to enable this cross-certified relationship is to create a subordinate CA to a high security Issuing CA. This subordinate CA is then used to facilitate the joint venture relationship. Although it is possible to cross-certify directly with a corporate high security CA, the advantage of using a separate CA specifically for the joint venture is that it allows you to restrict the capabilities of the people who work for the other partners in the joint venture. They cannot, for example, use their certificates for unintended purposes or to access portions of the network that are not relevant to the joint venture.

Figure 16.14 illustrates the position of the new CA in the CA infrastructure of one organization.

**Figure 16.14 Extended CA Infrastructure**

Creating the CA alone does not enable the new joint venture operations. To enable this sharing, before the CAs are created, administrators must configure the cross-certificates that qualify the trust relationship between the two organizations. These cross-certificates define where, in the first organization, holders of the certificates belonging to the second organization can and cannot go, and which applications they can and cannot use. For information about how to implement these namespace and application limits, see "Using Constraints and Policy Mapping" later in this chapter.

# Defining Certificate Configuration Options

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After your CA infrastructure is in place, you can begin to define the certificate configuration options that you need to meet the requirements of your users, as well as the security needs of your organization. Figure 16.15 shows the steps involved in defining certificate configuration options.

**Figure 16.15 Defining Certificate Configuration Options**

# Selecting Certificate Templates

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The certificate services that you deploy and the security requirements that are specific to your organization impact the types of certificates that you issue. You can issue multiple types of certificates to meet a variety of security requirements.

The certificate templates available with an enterprise CA in Windows Server 2000 and Windows Server 2003 provide the default contents of all certificates that can be requested from a Windows enterprise CA. These certificate templates are stored in Active Directory and cannot be used with stand-alone CAs.

Certificate templates can serve a single purpose or multiple purposes. Single-purpose templates generate certificates that can be used for a single application. For example, the Smart Card Logon certificate template is designed for smart card logon only. Multipurpose templates generate certificates that can be used for a number of applications, such as Secure Sockets Layer (SSL), S/MIME, and EFS. For example, a user certificate can be used for both user authentication and EFS encryption.

Both Windows 2000 and Windows Server 2003 support single-purpose and multipurpose templates. However, Windows 2000 and Windows Server 2003 Standard Edition only support version 1 templates, which have read-only attributes that cannot be customized or extended. Windows Server 2003, Enterprise Edition supports version 2 templates, which allow you to create new certificate templates, clone an existing template, and replace templates that are already in use.

**Important**

- If you are already using version 1 templates, you can upgrade them to version 2 templates. However, the domain admins in your top level domain must have full access control permissions on the version 1 templates in order to complete this upgrade. Domain administrators do not need to have full access control over the templates after the upgrade has been completed.

Both version 1 and version 2 certificate templates include the following information:

- Intended user of the certificate.
- CA that issued the certificate.
- Serial number that uniquely identifies each certificate.
- Public key value for the user identified in the subject field.
- Validity period of the certificate.
- Extensions, if any, which apply to the certificate, includingadditional information that can define certificate purposes, restrictions, and management.
- Digital signature of the CA, which verifies the relationship of the certificate to the issuing CA.

  **Note**

  - You can also create your own certificate templates.

Before the certificates are issued, you need to determine the following critical information:

- Certificate key length
- Certificate validity period
- Optional certificate extensions

**Note**

- Certificate templates, in conjunction with the CA policy module, allow you to define certificate policy for CA certificates.

In addition, version 2 templates allow you to configure the following:

- Customized enrollment policies
- Policies related to validity periods
- Policies related to application usage
- Policies related to key usage
- Policies related to key archiving
- Certificate authorization
- Domain authentication
- Certificate administrators
- Signed enrollment agents
- Key creation
- Key and CSP types
- Certificate contents

**Important**

- You must upgrade the schema in an Active Directory forest to Windows Server 2003 in order to support version 2 templates. You do not need to upgrade all domain controllers to Windows Server 2003 to perform a schema upgrade.

Certificate templates can only be used when the server that is running Certificate Services is an enterprise CA. Enterprise CAs can issue a variety of certificate types based on the templates. You can configure each enterprise CA to issue only specific types of certificates. Table 16.6 lists the different types of version 1 certificate templates that are available, and the purposes for each.

**Table 16.6 Version 1 Certificate Templates**

| Certificate template name | Certificate purposes | Issued to |
|---|---|---|
| Administrator | Code signing, Microsoft trust list signing, EFS, secure e-mail, client authentication | Users |
| Authenticated Session | Client authentication | Users |
| Basic EFS | Encrypting File System | Users |
| CEP Encryption | Act as a registration authority | Users |
| Code Signing | Code signing | Users |

| | | |
|---|---|---|
| Domain Controller | Client authentication, server authentication | Computers |
| EFS Recovery Agent | File recovery | Users |
| Enrollment Agent (Computer) | Certificate request agent | Computers |
| Exchange Enrollment Agent (Offline Request) | Certificate request agent | Users |
| Exchange User Signature | Secure e-mail, client authentication | Users |
| Exchange User | Secure e-mail, client authentication | Users |
| IPSEC | IP Security | Computers |
| IPSEC (offline request) | IP Security | Computers |
| Root Certification Authority | Identify the root CA | Computers |
| Router | Client authentication | Computers/routers |
| Smartcard Logon | Client authentication | Users |
| Smartcard User | Client authentication, secure e-mail | Users |
| Subordinate CA | All | Computers |
| Trust List Signing | Microsoft trust list signing | Users |
| User | Authentication, secure e-mail, and EFS | Users |
| User Signature | Secure e-mail, client authentication | Users |
| WebServer | Server authentication | Computers |

Table 16.7 lists the version 2 certificate templates that are available in Windows Server 2003 Advanced Server and the purposes for each.

**Table 16.7 Version 2 Certificate Templates**

| Certificate template name | Certificate purposes | Issued to |
|---|---|---|
| CA Exchange | CA encryption | Computer |
| Cross certification authority | Qualified subordination | Computer |
| Directory E-mail Replication | Directory replication | Users |
| Domain Controller Authentication | Client authentication, server authentication | Users |
| Key Recovery Agent | Key recovery | Users |

**Note**

- When you select and modify templates, create function-based names for the templates, such as domainA_e-mail or

legal_signing. Function-based names help users to select the appropriate certificate for the task that they need to perform.

**Delegating Administration of Certificate Templates**

Although the majority of CA-related tasks are performed by administering the CA itself, certain tasks, including the administration of certificate templates, are controlled through Active Directory.

**To delegate the administration of certificate templates:**

- Right-click the **Certificate Templates** node in the **Certification Authority** snap-in and select **Manage**.
- Double click a certificate template.
- Under the **Security** tab, check the **Allow** boxes for the **Read** and **Write** permissions.

For more information about certificate templates, see *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

# Selecting Certificate Security Options

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The security requirements for your certificates are based on the following four critical factors:

- **Risk of attack.** The security of your network, the value of the network resources protected by the CA trust chain, and the cost of initiating an attack all impact the security requirements for your certificates.

- **The degree to which you trust your certificate users.** In general, the less you trust your users, the shorter the certificate lifetimes and CRL lifetimes, and the tighter the control over renewals. For example, you might trust temporary users less than you trust normal business users, and therefore you might set shorter lifetimes on the certificates of temporary users and require stricter controls for their renewal.

- **The amount of administrative effort that you are willing to devote to certificate renewal and CA renewal.** For example, to reduce the administrative effort required to renew CAs, you can specify long, safe lifetimes for your certification trust hierarchies.

- **The business value of the certificate.** For example, you place tighter restrictions on certificates used to validate critical data such as purchase contracts than you place on certificates for routine e-mail.

The standard settings for certificates issued by Microsoft Certificate Services meet most security needs. However, you might want to specify stronger security settings for certificates that are used by certain user groups. For example, you can specify longer private key lengths and shorter certificate lifetimes for certificates used to provide security for valuable information.

To ensure that your certificates meet the security requirements of your organization, you need to configure the following:

- The cryptographic algorithms and private key lengths for CAs and issued certificates.

- The amount of time for which the certificates and their keys are valid.

- Certificate renewal and permitted renewal frequency.

# Selecting Cryptographic Algorithms and Key Lengths

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows 2000 and Windows Server 2003 support several well-known cryptographic algorithms that are also supported by other PKI products. When you install a Windows Server 2003 CA, you can select CA key lengths from 384 bits to 16,384 bits, depending on the CSP that you select. In a typical deployment, user certificates have 1,024-bit keys and root CAs have 4,096-bit keys.

Key length is determined in part by the cryptographic algorithm that you select. Table 16.8 lists the algorithms that Windows Server 2003 supports and their minimum and maximum key lengths.

**Table 16.8 Windows Server 2003 Algorithms and Key Lengths**

| Algorithm | Minimum Key Length | Maximum Key Length |
|---|---|---|
| RSA | 384-bit | 16,384-bit |
| DSA | 512-bit | 1,024-bit |

In most cases, the default key length provides an acceptable balance between security and CA performance. However, to provide the maximum possible protection without degrading CA performance, select the largest keys that are practical for CAs. Keys that are at least 1,024 bits long are the best choice for CA certificates.

Keep in mind that generating large keys can place a high load on computer processors and might also increase the amount of time needed for signing operations to excessive levels.

**Note**

- Key length has a minimal impact on the size of a certificate. However, it can be a significant consideration for smart card deployments because of the space constraints of the card.

In general, public and private key lengths do not impact interoperability as long as both environments support a common range of key lengths. If one PKI supports large public keys and another does not, however, the two cannot exchange symmetric keys or sign and verify data.

**Note**

- While key exchange and digital signature operations performed between PKIs do not require the same public and private key lengths, symmetric key algorithms do. In addition, if different key lengths are used, both key lengths must be supported in both environments.

When PKIs do not support the same key lengths, some applications cannot decrypt data that other applications have encrypted. In addition, the PKIs might not be able to establish secure communications channels between applications if the applications cannot agree on symmetric key lengths, as required by protocols such as SSL and TLS.

If a PKI uses public/private keys based on an algorithm such as RSA, all PKI operations can be accomplished with only one key pair. However, single key pairs might not meet the security requirements of your organization or its choice of algorithm. For this reason, Windows Server 2003 supports both single key pairs and dual key pairs. A good PKI is flexible enough to allow as many or as few key pairs as are required by applications.

If one PKI operates according to the number of keys that applications use, it can impact interoperability with other PKIs. For example, an e-mail application could sign a message with a signature-only key and include the associated certificate in a message sent to a recipient without also sending an encryption certificate as part of the message. The recipient might then be unable to discover the encryption certificate of the sender to reply with an encrypted message back to the sender.

# Establishing Certificate and Key Lifetimes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A number of factors impact certificate lifetimes, such as the type of certificate, the security requirements of your organization, the standard practices in your industry, and government regulations. In general, longer keys support longer certificate lifetimes and key lifetimes.

When establishing certificate and key lifetimes, you must consider how vulnerable your keys are to compromise and what the potential consequences of compromise are. The following factors impact the lifetimes that you choose for certificates and keys:

- **The length of private keys for certificates.** Because longer keys are more difficult to break, they justify longer safe key lifetimes.
- **The security of the CAs and their private keys.** In general, the more secure the CA and its private key, the longer the safe certificate lifetime. CAs that are operated offline and stored in locked vaults or data centers are the most secure.
- **The strength of the technology used for cryptographic operations.** In general, stronger cryptographic technology supports longer key lifetimes. You can extend key lifetimes if you enhance private key storage by using smart cards and other hardware cryptographic service providers. Some cryptographic technologies provide stronger security, as well as support for stronger cryptographic algorithms. For example, you might use smart cards for user logon or FIPS 140-1 Crypto Cards for secure mail and secure Web browsers.
- **The vulnerability of the CA certification chain to attack.** In general, the more vulnerable your CA hierarchy is to attack, the longer the CA private keys and the shorter the key lifetimes required.
- **The users of your certificates.** Organizations typically trust their own employees more than they trust employees of other organizations. If you issue certificates to external users, you might want to shorten the lifetimes of those certificates.
- **The number of certificates that have been signed by a dedicated CA.** The more public the CA public key that is used to sign an issued certificate, the more vulnerable it becomes to attempts to break its key.

An expiration date is defined for each certificate at the time that it is issued. An enterprise CA issues certificates with lifetimes that are based on the certificate template for the requested certificate type.

Most certificate templates specify a lifetime of one year. However, the following version 1 certificate templates specify a lifetime of two years:

- CEP Encryption (offline request)
- Enrollment Agent
- Enrollment Agent (computer)
- Enrollment Agent (offline request)
- IPSec
- IPSec (offline request)
- Router (offline request)
- Web Server

The following certificate templates specify a lifetime of five years:

- Domain Controller
- Subordinate certification authority

The lifetimes of certificates issued by stand-alone CAs are determined by system registry settings for the CA.

The certificates for enterprise root CAs and enterprise stand-alone root CAs have a default lifetime of two years. However, you can specify a different lifetime for the CA during installation. The parent CA that approves the certificate request and issues the certificate determines the lifetime of a subordinate CA certificate.

# Creating a Certificate Renewal Strategy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

CAs continue to issue and renew certificates until they reach the end of their established lifetimes. Certificates expire when the issuing CA reaches the end of its established lifetime, unless:

- They are renewed with a new key pair to extend their lifetime.
- They are revoked before the expiration date is reached.
- They are considered to have expired because an issuing CA is unavailable to verify their validity.

Certificate lifetimes impact the security of your PKI for the following reasons:

- Over a period of time, encryption keys become more vulnerable to attack. In general, the longer the period of time that a key pair is in use, the greater the risk that the key can be compromised. To mitigate this risk, you must establish maximum allowable key lifetimes and renew certificates with new key pairs before these limits are exceeded.
- When a CA certificate expires, all subordinate CAs that depend upon this CA for validation also expire.
- When a CA certificate is renewed, all certificates that have been issued by the CA can be renewed for a period based on the nesting guidelines described in the following section.

To reduce the risk of a private key becoming compromised, the private key and public key sets for certificates can be renewed each time the certificates are renewed, instead of when the keys reach their maximum lifetimes. You can renew CAs by assigning them a new key pair or by using the existing key pair. If you create a new key pair and the original certificate has not yet expired, it must have a new Subject Key Identifier (SKI) and a separate CRL. Renewing certificates with new key sets is not possible for some hardware-based CSPs, either because key storage limits prohibit this or because key generation takes a long time.

**Note**

- For more information about configuring certificate renewal, see "Selecting a Certificate Enrollment and Renewal Method" later in this chapter. For more information about the impact of certificate renewal on the use of certificate revocation lists, see "Establishing Certificate Revocation Policies" later in this chapter.

Certificate lifetimes affect the number of certificate renewal requests that are transmitted across your network. For users in remote offices who are connecting to the network across slow links, you might want to lengthen certificate lifetimes to reduce the number and frequency of these requests.

To create a certificate renewal strategy, determine the following:

- Which certificates, if any, are you allowed to renew?
- How often can a certificate be renewed before its key is retired?

In general, certificates with stronger keys that are used less frequently and that are less available to potential attackers can justify longer lifetimes and at least one renewal. Certificates with average key lengths and shorter lifetimes can be renewed more frequently — but not beyond the validity date for the certificate that authorizes the CA that issued the certificate. This is called nested validity or nested expiration.

**Nesting Certificate Lifetimes**

In addition to defining certificate lifetimes for your Windows Server 2003 CAs, you need to confirm that certificate lifetimes and renewals do not extend beyond the lifetimes of the CAs that are above them in the hierarchy.

By default, the certificate for the root CA has a longer lifetime than certificates for the other CAs in the hierarchy. This is

because a Windows Server 2003 CA cannot issue certificates with a lifetime that extends beyond the validity period of its own certificate. If the lifetime specified for a requested certificate type exceeds the expiration date of the certificate of the CA, the CA truncates the lifetime of the issued certificate to match the expiration date for its own certificate.

For example:

- If the end date of a Windows Server 2003 root CA certificate is January 2, 2012, no Windows Server 2003 child CA in the chain below the root can issue a certificate with a date that is past January 2, 2012.

- If a Windows Server 2003 intermediate CA has a certificate end date of January 2, 2008, no Windows Server 2003 child CA can issue certificates with an end date that is past January 2, 2008.

- If a Windows Server 2003 issuing CA has a certificate end date of January 2, 2004, no certificate that the CA issues can have an end date that is past January 2, 2004.

- If the end date of a Windows Server 2003 CA certificate is January 2, 2004, and it receives a request to issue a one-year certificate on August 1, 2002, the CA issues the one-year certificate with an end date of July 31, 2003. However, if the CA receives a request to issue a one-year certificate on August 1, 2003, the CA issues the certificate with an end date of January 2, 2004.

- A Windows Server 2003 CA with a certificate lifetime of five years with an end date of January 2, 2007, can issue one-year certificates until January 2, 2006, or two-year certificates until January 2, 2005. After January 2, 2005, the CA does not issue two-year certificates. It truncates the validity end date to January 2, 2007. Likewise, after January 2, 2006, the CA truncates the validity end date of both one-year and two-year certificates to January 2, 2007.

The more nesting you have in your certification hierarchy, the shorter the certificate lifetimes become. Configure your certificate life cycles in such a way as to avoid short certificate lifetimes and certificate renewal cycles. If you specify long lifetimes for CAs and later discover that the CAs are not secure, you can renew CAs in the certification hierarchy with shorter lifetimes to reduce the potential security risks.

**Note**

- For a worksheet to assist you in preparing your certificate life cycle plan, see "Windows Server 2003 Certificate Life Cycle Plan" (DSSPKI_3.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Windows Server 2003 Certificate Life Cycle Plan" on the Web at http://www.microsoft.com/reskit).

# Using Qualified Subordination to Restrict Certificates

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Many of the certificates that you issue can be used without any further customization. However, you might want to limit the scope of your certificates, whether they are intended to validate a subordinate CA, to cross-certify an external CA, or to enable an end user application. You can limit the scope of a certificate by:

- Defining the namespaces for which a subordinate CA will issue certificates.
- Specifying the acceptable uses of certificates issued by a qualified subordinate CA.
- Creating trust between separate certification hierarchies.

Qualified subordination restricts the certificates issued by the qualified subordinate CA, or by CAs that chain through the qualified subordinate CA, that are acceptable to your organization. You accomplish this by defining the following in the Policy.inf file:

**Note**

- The Policy.inf file is different from the CAPolicy.inf file. The Policy.inf file impacts qualified subordination, whereas the CAPolicy.inf file impacts the CA certificate.

    - **Basic constraints.** Define the certification path length required and allowed for policy identifiers and policy mapping.
    - **Name constraints.** Define the range of namespaces that are permitted or excluded by the qualified subordinate CA and its subordinates.
    - **Issuance policies.** Define the extent to which your organization trusts the identity presented in a certificate. These policies are identified in a certificate by object identifiers.
    - **Application policies.** Define the applications that can be used in conjunction with certain certificates.

In addition, if you are attempting to connect two different PKIs, whether within your organization or with a third-party, you need to use policy mapping to achieve equivalency between the policy constraints that you have defined and the policy constraints defined in the other PKI. The use of constraint extensions and policy mapping allows you to control certificate usage more effectively, and to administer your certificates more effectively.

Qualified subordination allows you to ensure that specific constraints are applied when a CA issues or an application uses a certificate. These constraints ensure that all certificates issued by the CA apply the policy restrictions that you have defined.

By definition, your root CA applies all policies. You can use intermediate CAs to issue certificates that enable different levels of security, such as High Security, Medium Security, and so on. The security policies that you define are identified by means of object identifiers. When certain object identifiers are applied to a CA certificate, all certificates below that CA in the hierarchy must also have a subset of those object identifiers. If you create a certificate chain with no valid policy, any certificates that are issued are considered invalid. However, if you create a certificate chain with no policy object identifiers at all, then the certificates that you issue are considered to match the "any policy" object identifier. Figure 16.16 shows how policy is applied to CAs.

**Figure 16.16 How Policy Is Applied to CAs**

The policies and constraints of each qualified subordinate CA are a subset of the policies and constraints of the parent CA.

# Using Basic Constraints

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Basic constraints allow an application to determine whether a certificate is a CA certificate, which can then be used by the certificate chain engine to build certification paths, or an end-certificate, which cannot.

You can also use basic constraints to limit the maximum number of CA certificates that can be included in a CA path. For example, setting a path length of zero in the basic constraints section of the CAPolicy.inf file allows only certificates issued by that specific CA to be included in the CA path. A path length of two allows only a total of three CA certificates in a certification path. In the latter case, any certification paths that include more than three CAs are discarded.

Use basic constraints if you do not want to trust additional CAs that are created lower in the CA hierarchy of your organization. You can also use basic constraints in cross-certified relationships if you trust your business partner and the certificates from all their existing CAs, but you do not want to trust certificates from any additional CAs that they authorize.

# Using Name Constraints

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Name constraints allow you to designate which namespaces are either permitted or excluded for certificates issued by a qualified subordinate CA. When the qualified subordinate CA receives a request, it compares the names present in the subject and the subject alternate name fields to the configured name constraints, to determine whether the namespace is permitted or excluded. As you design your PKI, you need to decide which individual clients and business units are able to enroll for and use certain certificates. For many organizations, the selected users, computers, and services are members of specific Active Directory domains and subdomains.

You can base name constraints on any of the following types of name formats:

- **X.500 Directory name.** Distinguished names identify users and resources on the network in Active Directory. This allows you to constrain a qualified subordinate CA to permit or exclude users in Active Directory by using the distinguished names of the users. Active Directory also uses distinguished names to create and reference groups of objects in the directory, such as users and computers. The distinguished names of these object groups can also be used as name constraints, allowing you to constrain a qualified subordinate CA to permit and exclude certificate issuance for entire groups in the directory.

- **DNS domain name.** You can apply the DNS namespaces that your network uses for name resolution as name constraints for a qualified subordinate CA. When the qualified subordinate CA receives a certificate request, it compares the DNS name associated with the computer requesting the certificate to its DNS name constraints and decides whether or not to issue a certificate. You can specify a DNS name constraint as a **DNS host name**, such as host1.example.microsoft.com, or as a **DNS namespace**, wherein all DNS host names are permitted or excluded, such as .example.microsoft.com.

- **E-mail and user principal name.** You can specify e-mail and UPN name constraints for an individual subject, such as person@example.contoso.com, or you can specify constraints for all subjects whose e-mail names or UPNs end in a specific name, such as @example.contoso.com. Typically, you need to specify e-mail or UPN name constraints for all subjects whose e-mail addresses and UPNs end in a specific name.

- **Universal Resource Identifier (URI).** URIs are used to identify resources on the Internet by means of identifiers such as URL, FTP, HTTP, telnet, mailto, news, and gopher. When validating the URI names in a certificate request, the qualified subordinate CA ignores the protocol element in the URI, such as http:// or ftp://, and uses the domain or host names only.

- **IP address.** IP address name constraints follow the formatting conventions specified in RFCs 791 (IPv4) and 1883 (IPv6). The IP addresses contained in the certificate requests made to a qualified subordinate CA are compared to the IP addresses in the name constraints of the qualified subordinate CA.

You can configure name constraints to result in the following outcomes:

- **Permitted.** The certificate request contains all names that are listed as permitted in the CA name constraints extension of the issuer.

- **Not permitted.** The certificate request contains a name that is not listed as permitted in the name constraints extension of the issuer.

- **Excluded.** The certificate request contains a name that is listed as excluded in the name constraints extension of the issuer.

A CA certificate can contain name constraints that are applied to all certificate requests made to the CA. Each request is compared to the list of permitted and excluded names to determine whether the name in the certificate is considered permitted, not permitted, excluded, or not defined. When you include name constraints in a CA certificate, the following rules are applied to the subject name and alternate subject name fields:

- **Excluded namespaces take precedence over permitted namespaces.** A qualified subordinate CA will not issue a certificate to a user within an excluded namespace even if the user is also within a permitted namespace. For example, a user might be within the permitted Active Directory namespace *.contoso.com* but also within the excluded DNS namespace *.uvw.contoso.com*. The excluded DNS namespace overrides the permitted Active Directory namespace and the certificate request of the user fails.

- **If the name constraints extension exists in a CA certificate, all name constraints must be present in the appropriate format.** Any name formats that are not included are considered to be wild cards that match all possibilities. For example, if the DNS name constraint is absent, the entry is treated as DNS="".

- **All name constraints are considered, even if they are not specified.** No precedence is applied to the listed name constraints. For this reason, name constraints that are not present are treated as wildcards. For example if you only restrict the DNS name space, the Name Constraints extension sets the remaining name constraints to allow all name spaces.

- **Name constraints are applied to the Subject Name extension and any existing Subject Alternate Name extensions.** For example, if a user can be identified by a DNS domain name and an alternate e-mail name, name constraints apply to both.

- **Name constraints apply to all names contained in a certificate request.** Each name in the subject or subject alternate name extensions must match at least one of the name constraints listed for that name type. A certificate request that includes a subject name or subject alternate name that does not match a listed name type is rejected.

- **Name constraints are not case sensitive.** For example, *.contoso.com* is treated the same as *CONTOSO.COM or ConToso.Com*.

**Important**

- Name constraint validation is performed on the CA, not on the client. However, you must have Windows XP and Windows Server 2003 clients in order to use name constraints.

# Using Issuance Policies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use issuance policies to define the extent to which your organization trusts the identity presented in a certificate. For example, you can set an issuance policy stipulating that you only trust certificates that were issued during a face-to-face meeting with a network administrator, such as when a smart card certificate is issued.

An object identifier must describe every issuance policy that you define. The inclusion of an issuance policy object identifier in an issued certificate indicates that the certificate was issued in a manner that meets the issuance requirements associated with the issuance policy object identifier.

**Note**

- Issuance policy is only available on Windows Server 2003 CAs. Windows 2000 does not provide issuance policy.

You can use a specific certificate template to define one or more issuance policy object identifiers that need to be included in any certificates issued. Windows Server 2003 includes four predefined issuance policies:

- **All Issuance (2.5.29.32.0).** The all issuance policy indicates that the issuance policy contains all other issuance policies. Typically, this object identifier is only assigned to CA certificates.

- **Low Assurance (1.3.6.1.4.1.311.21.8.x.y.z.1.400).** The low assurance object identifier is used to represent certificates that are issued with no additional security requirements.

  **Note**

  - The *x.y.z* portion of the object identifier is a randomly generated numeric sequence that is unique for each Windows Server 2003 forest.

- **Medium Assurance (1.3.6.1.4.1.311.21.8. *x.y.z* .1.401).** The medium assurance object identifier is used to represent certificates that have additional security requirements for issuance. For example, a smart card certificate that is issued in a face to face meeting with a smart card issuer might be considered a medium assurance certificate and contain the medium assurance object identifier.

- **High Assurance (1.3.6.1.4.1.311.21.8. *x.y.z* .1.402).** The high assurance object identifier is used to represent certificates that are issued with the highest security. For example, the issuance of a key recovery agent certificate might require additional background checks and a digital signature from a designated approver because a person holding this certificate can recover private key material from a Windows Server 2003, Enterprise Edition CA.

In addition, you can create your own object identifiers to represent custom issuance policies. For example, two organizations involved in a purchaser/seller relationship can define custom object identifiers to represent digital signature certificates for specific purchase amounts. In such a case, an object identifier can be defined for purchase between $100,000 and $500,000 and another object identifier can be defined for purchases greater than $500,000. Applications can then use these object identifiers to recognize whether a person had the appropriate signing authority for a specific volume purchase.

**Applying Policy Mapping**

In many cases, the administrators of two PKIs define their own policies and object identifiers. In some cases these policies are identical, but in most cases there are small differences between them. For example, one organization might stipulate that one physical form of identification is sufficient to grant a certificate request, while a second organization requires three forms of physical identification to grant a similar request. In these cases, you need to negotiate with the administrators of the other PKI to define terms of equivalence before the cross-certified relationship can be established. This is called policy mapping.

Policy mapping enables interoperability between two organizations that apply similar issuance and application policies, but have deployed different object identifiers. If the policy object identifier (for example, 1.2.3.4) of one company represents a specific function, and the policy object identifier of another company (for example, 11.22.33.44) represents the same function, they can be mapped, so that 11.22.33.44 and 1.2.3.4 are interchangeable.

The qualified subordinate CA that contains this mapping is called the *issuer CA* and the subordinate CA whose policies have been mapped is called the *subject CA*. In mapping some or all of the policies of the subject CA to the policies of the issuer, the issuer CA effectively subordinates the subject CA. The result of this mapping is that users and computers in the issuer CA trust hierarchy can use their own certification paths to validate certificates from users and computers in the subject CA trust hierarchy. The separate trust hierarchy can be within the same intranet or in separate PKI environments over an extranet.

**To apply policy mapping**

1. Identify the trust hierarchy with which you want to establish a trust relationship.

2. Establish equivalence in the assurance levels used by the two trust hierarchies involved in the trust relationship.

3. Obtain the issuance and application policy object identifiers used in both trust hierarchies involved in the trust relationship.

4. Map the issuance and application policy object identifiers in the separate trust hierarchies, and define their policy constraints in the CA certificate request for the qualified subordinate CA that you are installing in your trust hierarchy.

5. Install the qualified subordinate CA with the policies, policy mappings, and policy constraints in your trust hierarchy.

**Constraining Policy Mapping**

You can refine policy mapping by setting parameters for how the issuance policy defined in qualified subordination affects other CAs below the qualified subordinate CA. These parameters can help to limit unplanned trust relationships. The following two settings define this relationship:

- **Require explicit policy.** Specifies the number of certificates that can exist in the hierarchy below a certificate before an explicit policy must exist. For example, if the explicit policy is configured with a setting of three, the defined issuance policy must exist for three layers of the hierarchy. The CA on which the qualified subordination is defined is the first level.

- **Inhibit policy mapping.** Specifies the number of additional certificates that can appear in the path before policy mapping is no longer permitted. For example, an inhibit policy mapping value of three restricts the policy mapping to only three levels of CAs below the qualified subordinate CA.

# Using Application Policies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Certificates provide important information that is not specific to an application. However, you might need to define which applications can be used in conjunction with certain certificates. Application policy allows you to ensure that certificates are only used with the applications that you specify.

An application can also be written to accept only certificates that contain specific application policies. When the application receives signed information from a user, the application reviews the certificate associated with the private key used to sign the information, and ensures that the application policy extension contains the object identifiers required by the application.

Application policies are similar to the Extend Key Usage (EKU) extension in a certificate, as both use one or more object identifiers to prescribe how the public key in a certificate must be used. Windows Server 2003 supports Extend Key Usage to support PKIs that use this extension, but application policies are used in place of EKU.

Application policy is Microsoft specific and is treated much like Extended Key Usage. If a certificate has an extension containing an application policy and also has an EKU extension, the EKU extension is ignored. If, however, a certificate has only an EKU extension, the EKU extension is treated like an application policy extension. If a certificate has an application policy extension and an EKU property, the effective policy for the certificate is the common policy between the EKU property object identifiers and the application policy object identifiers.

**Note**

- If you are issuing certificates that include both application policy and EKU extensions, ensure that the two extensions contain identical object identifiers.

# Using Constraints and Policy Mapping

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The method or methods that you use to limit unplanned trust depend in large part on the security challenges that you must address in your organization.

For example, use name constraints to limit unplanned domain-based trusts. If your organization has more than one domain — such as contoso.com and subdomain.contoso.com — you might only want cross-certificates to map to CAs in the contoso.com domain and not to CAs in the subdomain.contoso.com domain. On the other hand, if you have five different domains and want your cross-certificates to apply to three of them, path constraints provide a more flexible solution.

Use path constraints if transitive trusts create problems for your organization — for example, if you have an environment in which users can freely install subordinate CAs and you do not have strong security guidelines governing CA creation and management.

Policy constraints are the most useful of the constraint options, both internally and externally. Name and path constraints might not provide you with sufficient protection in certain cross-certified relationships if the security standards of your business partners are not as strong as yours. For example, organization A might have a policy that all user certificates must be approved manually by an administrator, while organization B approves certificate requests automatically as long as the user has an e-mail account. The security administrators for organization A must ensure that the certificates that users in organization B use to access resources meet the higher security standards that are necessary in organization A. They can accomplish this by using policy constraints.

Use policy mapping if the organization that you are cross-certifying with has policies that are similar to those of your organization. Policy mapping is less useful when the policies of your organization are stricter than the policies of the other organization, or vice versa. If this is the case, use policy constraints to restrict your trust relationship instead of using policy mapping.

# Example: Configuring Certificates

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After an organization has defined its certificate requirements, internal PKI configuration, and external infrastructure, it needs to determine the certificate lifetimes, encryption key lengths, renewal policies, and other restrictions, if any, that apply to the use of each type of certificate. Figure 16.17 shows the certificate design decisions of one organization.

**Figure 16.17 Example of a Windows Server 2003 Certificate Lifecycle Plan Worksheet**

Windows Server 2003 Certificate Lifecycle Plan

| Prepared By | | Date | |
|---|---|---|---|

Instructions: Col 1. Start with the standalone root CA certificate. Then, in subsequent rows, list the certificates for the policy CA certificates it authorizes. Next, list the issuing CA certificates authorized by the policy CAs. Finally, list the end user certificates issued by the issuing CAs. Col. 4. Describe how often the certificate can be renewed and how often a new key should be used.

Notes: (1) The greater the security requirement, the larger the key should be. (2) The root CA has to have the longest life of all CA certificates. (3) Set the certificate and key renewal frequency to avoid invalidating subordinate CA certificates.

| Name and Purpose of Certificate | Key Length (bits) | Certificate Life | Private Key Renewal Strategy |
|---|---|---|---|
| Stand-alone root CA | 4,096 | 20 years | Renew at least every 10 years to ensure that policy CA certificates can be issued with lifetimes of 10 years. Renew by using a new key at least every 20 years. |
| Stand-alone policy CAs | 2,048 | 10 years | Renew at least every 5 years to ensure that child issuing CAs can be issued for a full 5 years. Renew by using a new key at least every 10 years. |
| Enterprise issuing CA s for medium security certificates | 2,048 | 5 years | Renew at least every 3 years to ensure that certificates can be issued for a full 2 years. Renew by using a new key at least every 5 years. |
| Enterprise issuing CA s for high security certificates | 2,048 | 5 years | Renew at least every four years to ensure that certificates can be issued for a full year. Renew by using a new key at least every 5 years. |
| Enterprise issuing CA for external certificates | 2,048 | 5 years | Renew at least every 4 years to ensure that certificates can be issued for a full year. Renew by using a new key at least every 5 years. |
| Secure mail and secure browser certificates | 1,024 | 1 year | Renew by using a new key at least every 2 years. |
| Smart card certificates | 1,024 | 1 year | Renew by using a new key at least every 2 years. |
| Administrator certificates | 1,024 | 1 year | Renew by using a new key at least every 2 years. |

| Name and Purpose of Certificate | Key Length (bits) | Certificate Life | Private Key Renewal Strategy |
|---|---|---|---|
| Secure Web server certificates | 1,024 | 2 years | Renew by using a new key at least every 2 years. |
| Business partner user certificates for an extranet | 1,024 | 6 months | Renew by using a new key at least every year. |

For a worksheet to assist you in documenting your certificate lifecycle plan, see "Windows Server 2003 Certificate Lifecycle Plan" (DSSPKI_3.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Windows Server 2003 Certificate Lifecycle Plan" on the Web at http://www.microsoft.com/reskit).

All certificates are issued by Windows Server 2003 CAs. The certificates for the people working for the business partners (for the extranet) can be issued by the Windows Server 2003 CA or by the CA of the business partner. CTLs allow the extranet domain to trust the certificates of the business partners. Where appropriate, stand-alone CAs provide flexible lifetimes for CAs. The renewal of certificates with new keys limits the amount of time that keys are in use and reduces the risk of key compromise.

This organization does not have unusual security requirements that require the use of one cryptographic algorithm over another. Therefore, they chose to accept the default cryptographic algorithms that have been established for each type of certificate and CA.

The certificates issued to the business partners of this organization are constrained by namespace, by path length, and to specific applications. In addition, the corporation uses policy mapping to specify the authentication procedures required of business partner users who are issued certificates to access the resources of the first organization.

# Creating a Certificate Management Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you have configured certificates for your organization, you need to create a plan for managing certificates throughout their lifetimes.

Figure 16.18 shows the process for creating a certificate management plan.

**Figure 16.18 Creating a Certificate Management Plan**

# Selecting a Certificate Enrollment and Renewal Method

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To enable enrollment, you need to specify the enrollment and renewal processes for your certificates. Enrollment involves either configuring permissions to establish which security principals have Enroll permissions for specific templates (in the case of enterprise CAs) or appointing a certificate administrator who reviews each certificate request and issues or denies the request based on the information provided.

Microsoft Certificate Services supports the ability to process certificate requests manually, if administrative approval is required, or automatically, if no approval is necessary. The following enrollment and renewal methods are available:

- **Certificate autoenrollment and renewal.** Allows you to automatically issue certificates that enable PKI applications, such as smart card logon, EFS, SSL, and S/MIME, to users and computers within an Active Directory environment. Certificate autoenrollment is based on a combination of Group Policy settings and certificate templates, which allows you to enroll computers when they start up and to enroll users when they log on to their domain.

  **Note**

  - To use autoenrollment, you need a Windows Server 2003 domain controller, a Windows XP Professional client, and a Windows Server 2003 Advanced Server enterprise CA.

- **Certificate Request Wizard and Certificate Renewal Wizard.** Available from the Certificates console, you can use the Certificate Request Wizard to request a certificate from an active enterprise CA on behalf of a user, computer, or service.

  **Note**

  - This option can only be used for Windows 2000, Windows Server 2003, and Windows XP users, computers, and services.

- **Web Enrollment Support pages.** Contain Active Server Pages and ActiveX controls that provide a Web-based user interface to a CA. By default, the Web Enrollment Support pages are automatically installed on the computer on which the CA is installed, but you can also install the Web Enrollment Support pages on another Windows Server 2003 computer. You can also customize Web Enrollment Support pages. For example, you can limit user options or provide additional links to online user instructions and user support information.

  **Note**

  - You can use Web Enrollment Support pages on stand-alone CAs to issue most of the same types of certificates that enterprise CAs can issue, with the exception of certificates for smart card logon and for autoenrollment, which must be issued and renewed by an enterprise CA. The Web Enrollment Support pages that are installed on stand-alone CAs do not use certificate templates, so all information about the certificate, including information about the requester (and, if asking for a specific application, a correct object identifier), must be specified in the certificate request.

- **Smart card enrollment station.** Advanced version of the Web Enrollment Support pages that allows trusted administrators or security personnel to enroll for smart card certificates on the behalf of other users. For more information about using the smart card enrollment station, see "Planning a Smart Card Deployment" in this book.

To select the certificate enrollment and renewal processes that are appropriate for your organization, you need to consider the following:

- **The users, computers, and services for which you intend to provide services.** Determine whether they are internal or external to the organization. Identify the operating systems they are running and determine whether or not they are connected to Active Directory.

- **The operating system that your clients are using.** Clients running Windows Server 2003 and Windows XP can use the Certificate Request Wizard, autoenrollment, or the smart card enrollment station. Windows 2000 supports the Certificate Request Wizard but does not support smart card autoenrollment. Autoenrollment and the smart card enrollment station also require Active Directory. Most other clients can use their Web browsers to access Web-based enrollment and renewal services.

- **The policies that you establish in order to manage certificate distribution.** This includes both the procedural policies that you establish for your PKI, and the Group Policy settings that you use to implement those policies.

- **The type of CA that is issuing the certificates.** For example, you must have a Windows 2000 or Windows Server 2003 enterprise CA to use the smart card enrollment station. Only Windows Server 2003 CAs support smart card autoenrollment.

Selecting certificate enrollment and renewal processes involves making decisions about the following:

- Automatic versus manual requests

- Automatic versus manual approval

- An enrollment and renewal user interface

- CA certificate renewal

# Selecting Automatic vs. Manual Requests

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Whether you choose to generate certificate requests automatically or manually depends on the types of certificates that you intend to use and the number and type of clients that you enroll. For example, if you want all users or computers to use a certain type of certificate, it is not practical for you to require that each certificate be requested individually. Although rolling out a new certificate to all users or computers at one time can generate a large amount of network activity, you can control that activity by deploying the certificate requests for each organizational unit one at a time.

On the other hand, you might want to have users or an administrator request certain high-security certificates, such as those used for digital signing or administrative tasks, only when needed. This can improve administrative control over these certificates — particularly if certificate use is not limited by a user or computer OU, or security group membership.

You can improve control over your certificates by using one of the following options to limit user certificate requests:

- **Restrict access to specific templates.** Configure the discretionary access control list (DACL) for each template so that only the required security principals have Enroll and Read permissions for particular templates.

- **Automate the deployment of computer certificates.** Configure Group Policy to automatically assign the necessary computer certificates by adding the certificate template to the Automatic Certificate Request Settings option in Group Policy.

  **Tip**

  - Autoenrollment is most useful for issuing and renewing computer and IPSec certificates.

# Selecting Automatic vs. Manual Approval

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Users can request a certificate from a Windows Server 2003 CA either manually or automatically. This request is held until an administrator approves it, if manual approval is required, or until the verification process is completed. When the certificate request has been approved, the autoenrollment process installs the certificate automatically, or automatically renews the certificate on behalf of the user, based on the specifications in the certificate template.

Most of the time, you choose the same method for certificate approval that you choose for certificate requests — but not always. For example, if you have the appropriate Group Policy and DACL restrictions on your certificate templates, you might decide to approve automatically a certificate request that was generated manually. Conversely, in some cases, it is appropriate to manually approve certificate requests that are automatically generated.

**Note**

- You can use strong authentication to enhance the security associated with autoenrollment. With strong authentication, the certificate template uses a specify policy object identifier to require an additional signature on the certificate request. For example, you can set a policy that requires the use of a smart card to provide a stronger authentication method for autoenrollment requests, or you can require approval for automatic certificate requests, so that administrators must approve pending requests.

However, in general:

- For routine and high volume certificates, such as e-mail certificates, automatic approval is the best option for certificate approval as long as the certificate requester has already been authenticated with a valid set of domain credentials.

- When a high degree of administrative oversight is required, such as for software code signing certificates, consider processing certificate requests manually. By using the Certificate Request Wizard, you can evaluate every certificate request individually — or you can delegate this responsibility to another administrator.

# Selecting an Enrollment and Renewal User Interface

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The user interface that you select for certificate request and approval processing depends on whether you choose automatic or manual certificate request and approval methods. If you decide to use autoenrollment for both certificate requests and certificate approval, you must use a minimal user interface.

However, if all or part of the enrollment process is manual, you must decide between using the Web Enrollment Support pages or the Certificate Request Wizard. The Web Enrollment Support pages are the easier interface for users to use. Users can perform the following tasks from the Web Enrollment Support pages:

- Request and obtain a basic user certificate.
- Request and obtain other types of certificates by using advanced options.
- Request a certificate by using a certificate request file.
- Renew certificates by using a certificate renewal request file.
- Save a certificate request to a file.
- Save the issued certificate to a file.
- Check on pending certificate requests.
- Retrieve a CA certificate.
- Retrieve the latest certificate revocation list from a CA.
- Request smart card certificates on behalf of other users (for use by trusted administrators).

However, administrators might prefer to use the Certificate Request and Renewal Wizard. You can start the wizard from the Certificates snap-in. Because the wizard is linked to the Certificates snap-in, you can also create custom snap-ins that you can distribute to certification authority administrators to whom you have delegated specific roles.

Unless an organization uses firewalls between one part of the organization and another, you can use the Certificates snap-in or the Web interface interchangeably. If a firewall exists between the CA and the requesting client, you must request certificates by means of the Web Enrollment Support pages or ensure that port 135 and a dynamic port above 1024 is open for MMC DCOM communication.

Whether you choose to use the Web Enrollment Support Pages or the Certificate Request and Renewal Wizard, you might need to prepare documentation that describes how users can request a user certificate, what users can expect after they request the certificate (for example, automatic enrollment or a delay pending administrator approval), and how they can use the certificates after they receive them.

# Using CA Certificate Renewal

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When a CA has issued and supports a large number of certificates, the quality of service and user satisfaction can decline. However, enrollment and renewal are relatively infrequent activities that can be anticipated and therefore planned for well in advance. Many organizations fail to plan for certificate renewal because this activity does not occur until some point well into the future.

When the certificate of a CA expires, the CA can no longer provide certificate services. To provide uninterrupted certificate services, use the Certificates console to renew the CA certificate before its expiration date. The interval that is required for CA renewal depends on the certificate lifetime of the CA.

After you renew a CA, the CA continues to issue certificates by using the new CA certificate, and the cycle starts over. Unexpired certificates that were issued by the pre-renewal CA continue to be trusted until they expire or are revoked.

You can use the standard enrollment and renewal methods that are available in Windows Server 2003 to renew your CAs and certificates. You can renew certificates with the same private key and public key set or with new private and public keys. However, if you have special needs, you can develop custom certificate enrollment and renewal applications for CAs.

**Caution**

- Do not renew certificates with the same private and public key sets if the renewal period exceeds the maximum safe key lifetime. The safe key lifetime is based on your choice of key lengths. Longer keys allow for longer safe key lifetimes.

The Windows Server 2003 Certificate Services Entry module supports industry-standard certificate requests by using remote procedure call (RPC) requests or HTTP requests. You can develop custom applications that make certificate requests to Certificate Services CAs.

# Map certificates to user accounts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you have decided how you are going to distribute your certificates, you must decide how to get the certificates to the intended clients, whether they are computers, internal users, or external users. You need to use certificate mapping for many types of certificates, such as those used for smart card logons.

If you have Active Directory, you can map certificates to clients based on their domain or organizational unit membership.

You must decide how you define subject and issuer name information in certificates because this directly impacts applications that use PKIs. For example, if a certificate does not contain the e-mail address name as part of the Subject or Subject Alternative name, some older e-mail applications cannot accept the certificate for digitally signing or encrypting e-mail messages.

Certificate mapping allows you to provide a more secure method for user authentication. With certificate mapping, you link a specific certificate to the account of a user. A server application can then use public key technology to authenticate the user by means of this certificate.

When certificate mapping is enabled, users are authenticated in Active Directory on the authority of the mapped certificates, and are granted rights and permissions based on the authentication.

You can map certificates to user accounts in the following ways:

- One-to-one mapping. This creates an association between an individual certificate and a corresponding user account in Windows 2000 or Windows Server 2003.

- Many-to-one mapping. This creates an association for all certificates from a specific CA to a Windows 2000 or Windows Server 2003 user account.

You can also use certificate mapping to authenticate external users who do not have an account in Active Directory.

**Using One-to-One Mapping**
One-to-one mapping requires more administrative effort than many-to-one mapping. Use one-to-one mapping when you have a relatively small number of clients. If you decide to use one-to-one mapping for a large number of clients, develop custom Web enrollment pages by using Active Server Pages (ASP) technology to automate the mapping process.

**Using Many-to-One Mapping**
Many-to-one mapping is useful for authenticating large numbers of users who require access to a given resource on your network, such as an internal Web site. The CA that issues certificates to these users must be chained to a trusted root for your site, domain, organizational unit (OU), or forest. You can then set rules that map all certificates issued by that CA to a single user account in Windows Server 2003.

Mapping rules check the information that is contained in the certificates of users, such as user organization and the issuing CA, to determine whether the information matches certain criteria. When the information in a user certificate matches the criteria, the user is mapped to a specified user account. The permissions set on the user account apply to all users who hold certificates issued from the trusted CA.

You can use separate many-to-one certificate mappings for different groups that require access to resources on your network. You can configure user accounts that grant different sets of rights and permissions on the basis of client ownership of valid certificates that match the mapping rules. For example, you can map your employees to a user account that grants read access to the entire Web site. Then, you can map consultants and employees of business partners to other user accounts that allow access only to non-confidential information and selected proprietary information.

**Selecting IIS vs. Active Directory Mapping**
You can use either Internet Information Services (IIS) or Active Directory to create your mapping. When IIS does the mapping, the certificate is compared to a list of rules that IIS maintains in its database until it finds a rule that matches the account indicated. You can configure IIS mapping for each Web server. This type of mapping is useful if you need only a limited number of mappings or a different mapping on each Web server.

In Active Directory mapping, when the IIS server receives a certificate from the user, it passes it on to Active Directory, which maps it to a Windows 2000 or Windows Server 2003 user account. The IIS server then logs on the account.

You can create an Active Directory mapping in one of two ways. You can rely on UPN mapping, or, if UPN mapping is not possible, you can manually map a certificate to the account of a user.

Use Active Directory mapping when the account mappings are identical on all IIS servers. Active Directory mapping is easier to maintain than IIS mapping because you only have to create the mapping in one location.

For more information about creating a mapping, see "Mapping certificates to user accounts" in Help and Support Center for Windows Server 2003.

# Establishing Certificate Revocation Policies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

All certificates have specified lifetimes. However, in some situations, you might need to invalidate a certificate before it has reached the end of its lifetime. Creating policies for certificate revocation involves the following tasks:

- Defining the conditions that warrant the revocation of a certificate.
- Selecting a certificate revocation list publication location.
- Selecting the type or types of CRLs that you intend to use.
- Establishing schedules for the publication of CRLs.
- Establishing a cached CRL validity period.

# Defining Conditions for Certificate Revocation

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Not all PKIs need to be supported by the publication of CRLs. For example, if your certificates provide only a low- or medium-level of security and are unlikely to be misused, or if they have short lifetimes, there might not be a need to create and distribute lists of revoked certificates. If, on the other hand, your certificates have a high perceived value and a lifetime that is long enough to cause potential misuse, you need to create and distribute certificate revocation lists on a regular basis.

Before you create certificate revocation schedules, define all the circumstances that justify the revocation of certificates in your organization. For example, you might choose to revoke certificates for any of the following reasons:

- An unauthorized user has gained access to the private key of the certificate.
- An unauthorized user has gained access to the CA. In this case, all the certificates that the CA has published must be revoked and reissued.
- Certificate criteria have changed; for example, an employee has moved to a different department.
- The certificate has been superseded. For example, you might decide to use a different encryption protocol or a longer key.
- The CA that issued the certificate is no longer operating.
- The status of the certificate is on hold. When a certificate has been revoked, it cannot be renewed. However, if the status of a certificate is questionable, you can revoke it and then rescind the revocation if necessary, or re-revoke it for another reason.

  **Note**

  - Use Certificate Hold sparingly because issues can develop involving the period that the certificate was on hold. For example, if a certificate was on hold for three hours but the hold is then removed, attempts to use the certificate during the hold period can yield unexpected results.
- Users misuse their security permissions or the private keys of users are compromised (a smart card is lost, for example).
- A computer is replaced or permanently removed from service, or the private key of the computer is compromised.

**Note**

- A root certificate cannot be revoked by means of a CRL because a root CA is self-signed. A CRL includes only certificates that are issued by a dedicated CA. The alternative is to revoke all the certificates issued by the root CA. The CA certificate becomes obsolete if there are no more valid certificates.

# Selecting a CRL Publication Location

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Selecting a location for CRL publication involves answering the following questions:

- Are the certificate revocation lists needed internally, externally, or both?

  CRLs have to be published where they can be accessed to validate or invalidate certificates. If the PKI is within the firewall of the organization and certificates are published to Active Directory, then LDAP can be used to publish CRLs. If the certificates are used outside the organization or if there is no directory service, http can be used to publish CRLs to a Web server because HTTP traffic can travel more reliably through a firewall than LDAP traffic.

- Do you require multiple CRL publication locations for fault tolerance or to support greater numbers of geographically diverse clients?

  If the answer is yes, choose the domain controllers and Web servers that provide you with greater coverage and improved response times. This way, if one CRL publication point becomes unavailable, the information is available from other publication points.

Figure 16.19 shows this decision process.

**Figure 16.19 Selecting a CRL Publication Location**

# Selecting a CRL Distribution Point

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Because CRLs are valid only for a limited time, PKI clients need to retrieve a new CRL periodically. Windows Server 2003 PKI applications look in the CRL distribution point extension for a URL that points to a network location from which the CRL object can be retrieved. Because CRLs for enterprise CAs are stored in Active Directory, they can be accessed by means of LDAP. In comparison, because CRLs for stand-alone CAs are stored in a directory on the server, they can be accessed by means of HTTP, FTP, and so on as long as the CA is online. Therefore, you should set the CRL distribution point after the CA has been installed.

The system account writes the CRL to its distribution point, whether the CRL is published manually or is published according to an established schedule. Therefore you must ensure that the system accounts for CAs have permission to write to the CRL distribution point.

Because the CRL path is also included in every certificate, you must define the CRL location and its access path before deploying certificates. If an application performs revocation checking and a valid CRL is not available on the local computer, it rejects the certificate.

You can modify the CRL distribution point by using the Certification Authority MMC snap-in. In this way, you can change the location where the CRL is published to meet the needs of users in your organization. You must move the CRL distribution point from the CA configuration folder to a Web server to change the location of the CRL, and you must move each new CRL to the new distribution point, or else the chain will break when the previous CRL expires.

**Note**

- On root CAs, you must also modify the CRL distribution point in the CAPolicy.inf file so that the root CA certificate references the correct CDP and AIA paths, if specified.

If you are using certificates on the Internet, you must have at least one HTTPs-accessible location for all certificates that are not limited to internal use.

# Selecting a CRL Type

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 includes two types of CRLs: base CRLs and delta CRLs. Base CRLs include a complete list of revoked certificates, and therefore they can grow quickly in organizations that issue a large number of certificates. Because updating base CRLs consumes a large amount of network bandwidth, you must weigh the benefits of publishing expired certificates against the costs in terms of time and network resources. Base CRLs must be published frequently to ensure that they remain current.

Delta CRLs enable you to simplify CRL management. A delta CRL contains information only about the certificates that have been revoked after the last base or delta CRL was published; therefore the data in a delta CRL is accurate throughout its lifetime. Because delta CRLs are smaller than base CRLs, they require less bandwidth to replicate across the network, and they can be published more frequently, thereby enhancing the security of your PKI. By combining base and delta CRLs, you can maximize the effectiveness of the CRLs in your organization and reduce the management effort required.

Whether to use delta CRLs in conjunction with your base CRLs depends on the following factors:

- **Compatibility.** Only Windows XP clients can recognize delta CRLs.
- **Volume.** If you revoke a large number of certificates, your delta CRLs can approach base CRLs in size. Therefore, it is not useful to use delta CRLs when large numbers of certificates are revoked between base CRL publication dates.
- **Online status.** It is best if delta CRLs are not used with offline CAs.

Figure 16.20 shows the process for selecting a CRL type.

**Figure 16.20 Selecting a CRL Type**

# Establishing a CRL Publication Schedule

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

CAs publish CRLs listing the serial numbers of certificates that have been revoked according to an established publication schedule. The frequency of publication is based on the number of changes that take place in a given period of time, and how critical the need to maintain up-to-date revocation information is to your organization.

As you create your CRL policies, you need to specify publication schedules for CRLs. By default, enterprise CAs publish CRLs weekly to Active Directory, and stand-alone and enterprise CAs publish CRLs weekly to a directory on the CA server. For example, you can specify that certain CRLs are distributed to Web pages as well as to Active Directory, and that certain CRLs are published daily instead of weekly.

If you use delta CRLs, a typical publication schedule might look like this:

- Publish base CRLs every week.
- Publish delta CRLs every day.

The CRL schedule for the certificates of your issuing CA must account for potential network and server downtime. In addition, it must account for latency in Active Directory replication. For these reasons, make the CRL publication schedule longer than the maximum replication latency.

Make sure that your publication schedule is shorter than the validity period of the CRL. With a validity period of one week, your CRL will be up-to-date for most purposes. If you require an additional buffer to protect against interruptions in communications, you can publish the CRL every two days.

Your strategy for renewing CAs also impacts your CRL publication strategy. If you choose to reuse the existing key pair when you renew a certificate for a CA, the existing CRL covers certificates issued under both the old and new CA certificates. If you choose to renew certificates by using a new key pair for the CA, you need to issue one CRL for the certificates issued with the old key pair, and another CRL for certificates issued with the new key pair. Although both old and new certificates were issued by the same CA, the validity of the older certificates will be validated against one CRL, and the validity of the newer certificates will be validated against the other CRL.

**Note**

- CRLs are published for all CA keys. You cannot selectively publish a CRL for only one CA key pair.

# Setting the Cached CRL Validity Period

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To reduce the amount of network bandwidth needed to retrieve CRLs, the CRL that is specified in the CRL attribute of the certificate is cached on the client system using the certificate. You can control the schedule by which the client retrieves updated CRLs by setting the CRL lifetime.

CRL publication and client use of the most recent CRL are independent. The client does not retrieve a new CRL from its distribution point unless the lifetime of a matching cached CRL has expired. Therefore, when you set the CRL validity period, be sure to balance the intended and actual CRL lifetime.

The only way to force a client to retrieve the latest CRL from the CRL distribution point before the CRL cache on the client has expired is by clearing the CRL cache — a task that is difficult to perform in many networks.

# Planning for Data Recovery and Key Recovery

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If public key pairs and certificates are lost due to system failure, it can be time consuming and expensive to replace them and the data that they protect. For this reason, as part of your certificate management plan, you need to evaluate the potential consequences of loss of public keys and the data that they secure, and create a strategy for data and key recovery.

Data recovery is a process by which data is encrypted in such a way that more than one person can retrieve the data in plaintext form. Data recovery does not always imply that private key recovery has occurred; however, key recovery is one method for data recovery.

Use data recovery if you need to be able to recover data in your organization, but do not need to have access to individual private keys of users.

The advantages of data recovery include:

- It does not require a certification authority or PKI infrastructure.
- Data recovery policies can be managed centrally by means of Active Directory.
- Users do not have to manage certificates or private keys for data recovery.
- Decryption can be limited to the user alone.

The disadvantages of data recovery include:

- An administrative process must recover user data. Users cannot recover their own data.
- You cannot define the scope of what data can be recovered by a data recovery agent and what data cannot be recovered by a data recovery agent.
- Data recovery occurs manually on a file-by-file basis.
- Only data is recovered, and not the user keys. Therefore, after data recovery is completed, the user must re-enroll for new certificates.
- It is assumed that, when a key is lost, the certificate is compromised. Therefore, administrators must revoke old certificates.
- Stand-alone workstations or workstations in non-Active Directory environments cannot be centrally managed.

Key recovery allows a trusted agent to gain access to user private keys. For this reason, it is best to use key recovery only if your organization permits a person other than the original requester to have access to the private key of another user.

Use key recovery if organization policy permits the retrieval of user private keys and certificates. Key archiving and recovery implies that a person such as an administrator can gain access to the private keys of another user. Even when policies and procedures are in place to protect against unauthorized key recovery, issues with non-repudiation might still exist. If your organization does not permit a person other than the original requester to have access to the private keys of another user, do not implement key archival and recovery.

The advantages of key recovery include:

- Users do not have to re-enroll for certificates, change security settings, and so on.
- Existing certificates do not have to be revoked.
- Users do not have to recover any data or e-mail due to lost private keys.

- All data encrypted by means of a public key in a certificate can be recovered after a private key has been recovered.
- Windows Server 2003 does not accept signing keys for archival and recovery.

The disadvantages of key recovery include:

- User key recovery is a manual process that must be performed by administrators and users.
- Key recovery allows administrative access to the private keys of users.
- Non-repudiation assurance might not be available with key archival and recovery.
- Key recovery does not work with hardware security tokens such as smart cards.

**Note**

- Only a Windows Server 2003 Enterprise Edition CA can implement Windows Server 2003 key recovery.

Windows Server 2003 includes a new certificate template to support the key recovery agent role. A Windows Server 2003 CA can use only key recovery agent certificates that have been properly formatted and that have not expired. To enable key recovery, you need to complete the following tasks:

- Configure the key recovery agent template.
- Configure the CA to allow key archiving.
- Enroll and archive users.

Do not use either data recovery or key recovery if your organization wants to protect data from all parties except for the original user.

# Configuring the Key Recovery Agent Certificate

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you configure a key recovery agent certificate, you must decide which users or groups can have Read and Enroll permissions on the key recovery agent certificate template. By default, only an Enterprise Administrator or a Domain Administrator can request a key recovery agent certificate. If you choose to change these defaults, you need to configure the new Read and Enroll permissions on the template itself.

You must configure an enterprise CA to issue key recovery agent certificates.

When you have configured permissions on the key recovery agent template and authorized an enterprise CA to issue key recovery agent certificates, a user with the appropriate permissions can request a key recovery agent certificate.

You must also select an encryption key length for the key recovery agent certificate. An encryption key of 2,048 bits satisfies most security needs. Keys that are 8,192 bits or larger can take the client CSP several hours to generate and can slow down public key operations on the CA when keys are archived.

You must mark the keys as exportable to enable the key recovery agent to export the private keys from the local store of the workstation to a floppy disk or other medium for safe storage. It is also best to protect the key recovery agent certificate private key with a strong password requirement. You can use a smart card as a key recovery agent.

The default key recovery agent certificate template requires manual approval of requests for key recovery agent certificates. It is best if a certificate manager manually approves all key recovery agent certificate requests. The certificate manager might choose to use fewer key recovery agents than the number of available key recovery agent certificates. In this way, no individual key recovery agent can decrypt all the private keys in the CA database. The CA chooses the key recovery agent certificate randomly as a means to ensure that the key recovery agent selection is not predictable.

Several cautions apply to key archiving. First, the default templates in Windows Server 2003 do not allow for key archiving. You must create new version 2 templates, which are available only in Windows Server 2003, Enterprise Edition, to support user enrollment with archiving.

Second, although you can configure the cryptographic service providers that are used for the private keys that are to be archived, you can only archive keys that are generated by means of a Rivest-Shamir-Adleman (RSA)-based CSP. The Digital Signature Standard (DSS) and Diffie-Hellman CSPs are not supported for key archiving.

# Establishing Key Recovery Agent Policies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Allowing someone other than the original user to recover keys presents a security risk. Although you trust your administrators, there are limits to how much any individual can be trusted with the ability to recover other the key pairs of other users. For example, your key recovery agent might leave the organization, taking a copy of the key. Therefore it is recommended that you monitor key recovery plans carefully.

Consider limiting the time that any one individual serves as the key recovery agent, or consider dividing the responsibility between several individuals and requiring that a smart card be used to perform key recovery tasks.

In addition, employ the following key recovery strategies:

- If you know that a key has been compromised, revoke it immediately.
- Do not recover keys or certificates that are used to secure high-value transactions or are associated with high-value certificates.
- Do not archive or recover private keys that are used for signing. This creates uncertainty in situations in which non-repudiation is the primary concern.

If possible, recover encryption keys only after the original certificates have been revoked. Issue a new key at the time of recovery. Revocation ensures that the user can still decrypt data with the old key but cannot encrypt new data.

# Educating Users About Planning for Data Recovery and Key Recovery

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Although the process of certificate enrollment and use is nearly transparent to end users, it is important to educate users about certificates and their use. Specifically, be sure to provide end users with the following information:

- How to use the certificate enrollment user interface and certificate-enabled applications.
- The capabilities of certificates.
- The limitations of certificates.
- Inappropriate or ineffective uses for certificates.
- How to evaluate certificates received from others.
- The importance of retaining expired certificates.
- What to do in the event of an error message or if certificates fail to function as expected.

# Example: Creating a Certificate Management Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A PKI cannot be effective and secure unless an organization implements a management plan that includes strategies for enrolling and renewing certificates, mapping certificates to user accounts, revoking certificates and distributing CRLs, and using key recovery.

Many organizations base their certificate enrollment and renewal methods on the level of security associated with each type of certificate and the volume of certificate requests that they anticipate. For example, an organization makes the following decisions regarding certificate enrollment and renewal:

- Autoenrollment is the preferred enrollment method for e-mail and EFS certificate requests, which represent the majority of their certificate activity. Only clients who have already been authenticated by the network can request these certificates. The risks associated with the use of these certificates are relatively low.

- Manual approval is required for all certificates that are needed to perform network administration and software development.

- Manual approval is required for certificates that are issued to joint venture partners.

The basic user certificates of the organization (for e-mail and EFS) are distributed according to the domain membership of a user.

The distribution of high-security certificates is enforced with a one-to-one mapping. This is intended to further enforce the usage restrictions that have been placed on these certificates. Also, to improve the ability of the organization to define which file shares and other resources are available to their joint venture partners, a many-to-one mapping to a single account in Active Directory restricts their joint venture certificates.

Similarly, organizations are concerned about the timeliness of CRLs associated with their high-security certificates. Therefore, they decide to distribute CRLs for these CAs once a day, with delta CRLs published every two hours, or as needed. Because network bandwidth and replication can impact the distribution of CRLs and delta CRLs to their remote offices, they choose a less stringent publication schedule for their medium security CAs — new CRLs are published once a week, and delta CRLs are published at the close of every business day. Publishing at the end of the business day ensures that the updated information is replicated overnight and is available on the next business day.

# Deploying the PKI

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After your public key design has been validated and refined by lab testing and pilot programs, you can deploy the PKI in your production environment. A disciplined approach to deploying a PKI is absolutely essential in order to establish the security of the applications that you are enabling. Figure 16.21 shows the PKI deployment process.

**Figure 16.21 Deploying the PKI**

**Important**

- Advanced planning is critical to the success of your PKI. Therefore, it is strongly recommended that you complete your PKI design before you deploy your PKI.

# Schedule Production Rollout

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For large enterprise deployments, schedule the public key production rollout in stages. You can roll out different portions of the infrastructure at different times as necessary to support your security goals and business needs.

For example, you might begin by deploying EFS and IPSec because you do not have to establish a large CA hierarchy to take advantage of the security benefits of these features. You might place the next highest priority on secure mail and smart card authentication. You can schedule the rollout of the secure mail infrastructure before rolling out the smart card infrastructure, or you can choose to schedule the deployment of secure mail to one group or site and simultaneously roll out the smart card infrastructure to another group or site.

**Important**

- In many organizations, responsibility for the PKI deployment is transferred from a high-level design team to a more tactically focused implementation team at this time. If this is the case in your organization, be sure to provide the implementation team with all the documentation, including worksheets that you have created up to this point.

# Install Certification Authorities

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Most organizations require a CA hierarchy to provide the required certificate services to meet their security and business needs. If you plan to use a CA hierarchy, you must install the root CA first and then install each subordinate CA in the hierarchy. For example, to create a three-level CA hierarchy and trust chain, install CAs on server computers in the following order:

1. Root CA
2. Intermediate CAs
3. Issuing CAs

For more information about installing CAs, see "Installing and configuring a certification authority" in Help and Support Center for Windows Server 2003.

# Install Offline Root CAs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In addition to the configuration options that you selected for your offline root CA, configure the following options when installing your offline root CA:

- Select **Certificate Services Web Enrollment Support**. Hosting the Web Enrollment service for an Offline Root CA on a separate system forces you to run both systems during the enrollment or renewal of subordinate CAs, which requires you to enable network connectivity between the two systems at that time.

- In the **Public and Private Key Pair** dialog box, leave the default **CSP** selection (Microsoft Strong Cryptographic Provider) and default **Hash** selection (SHA-1). Increase the **Key length** to meet your needs — for most root CAs, use the largest interoperable key length (4,096 bits).

  **Note**

  - For the purposes of Microsoft CAs, the Strong and Enhanced CSPs are considered equivalent. Both provide support for large key lengths (1024-bit keys or greater). Also, it is recommended that you use a hardware cryptographic service provider (CSP) or Hardware Security Module (HSM) to enhance the security of the signing keys of the certification authority.

- If you are installing a stand-alone CA as the root CA, the CA identification data must be entered manually. If you plan to publish the root CA certificate and CRL in your Active Directory environment, you have to enter the namespace of your Active Directory forest as the distinguished name suffix. In the **CA Identifying Information** dialog box, enter a customized distinguished name if you plan to publish your offline CA to a directory other than Active Directory. Use a customized distinguished name if you plan to use the offline CA as a trust anchor outside the enterprise.

  **Note**

  - The **Common name for this CA** fieldmust be filled in, but the customized field **distinguished name suffix** is optional. Your common name and distinguished name for the CA must reflect the organization and purpose of the CA to make the CAs easy for administrators and users to identify. The name of the CA must be unique within the organization, and possibly outside the organization as well. This information is filled in automatically if your CA is joined to an Active Directory–based domain.

- When you are asked to enter the Data Storage Locations, format the paths as local paths (such as C:\WINDOWS\System32\CertLog).

  **Note**

  - Although it is generally good practice to place the Certificate Database and Certificate Database log directories on a separate volume from the system partition, you do not need to do this for a root CA. The only data that is generated and must be stored concerns the certificates that correspond to a few subordinate CAs.

# Install Intermediate and Subordinate CAs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When installing Windows Server 2003 intermediate and issuing CAs, you can request the CA certificate from an online CA, or you can save the certificate request to a request file and make the certificate request offline. If you make an offline CA certificate request, the CA is not valid immediately upon installation. You must use the Certification Authority MMC snap-in to import the certificate of the CA and complete the installation process after the parent CA signs the CA certificate. You can also use the Certification Authority MMC snap-in to import subordinate CA certificates that are issued by third-party parent CAs.

# Publish the Offline CA Certificate

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Use secure procedures to publish the certificate and certificate revocation list (CRL) of the offline root CA. You only need to publish the certificate of the root CA one time. However, the CRL for the root CA must be published at regular intervals that correspond to the CRL publication interval value configured in the **Revoked Certificates Properties** of the root CA.

If the root CA is maintained in a secure location, such as a data center or vault, it is best if more than one administrator or trusted person publishes the offline CRL within that location, as prescribed in the certificate policy and certificate practice statements for your organization. After the CRL is published, you must transfer it manually from the data center or vault to a location where it can be distributed to your CRL distribution points.

Publish the offline CRL at least several days before the previously issued CRL is set to expire. This allows you to correct any hardware problems or publication failures in advance, ensuring that no interruption in service happens when your offline CRLs are published and replicated to all CDP locations.

After the offline root CA is installed, configure the various constraint and policy options for certificates that the offline CA issues. These extensions are necessary to ensure that the applications and clients that use the certificates in the hierarchy can perform revocation and chain building as needed.

# Apply CA Policy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you intend to implement your certificate practice statement, you need to create and format a issuer policy statement file, and place this file in the %windir% path of the root or subordinate CA before the CA is installed. This file, named CAPolicy.inf, serves two purposes:

- It provides basic information about the root CA, such as distribution points for the self-signed certificate, and the object identifier (also known as OID) information.
- It includes information for certificate renewal, such as the certificate lifetime of the self-signed certificate.

CAPolicy.inf is processed for root CA and subordinate CA installations and renewals. The CDP and AIA extensions in CAPolicy.inf are used for root CA installations and renewals only. Subordinate CA certificates inherit the CDP and AIA extensions of the issuing parent CA.

The CPS statement extension is applied when root CA certificates and subordinate CA certificates are requested. The CAPolicy.inf mechanism can only be used to include a CPS statement extension in a CA certificate and not an end-client certificate.

**Important**

- When CAPolicy.inf is used to install a CA, it must also be used for renewal; otherwise, the settings that have been defined might not be retained when the CA keys are renewed.

For more information about creating and using CAPolicy.inf files, see "Installing and configuring a certification authority" in Help and Support Center for Windows Server 2003.

# Configure CDP and AIA Extensions

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After a root or subordinate CA is installed, you must configure the Authority Information Access (AIA) and CRL distribution point (CDP) extensions before the CA issues any certificates. The AIA extension specifies where to find up-to-date certificates for the CA. The CDP extension specifies where to find up-to-date CRLs that are signed by the CA. These extensions apply to all certificates that are issued by that CA.

Configuring these extensions ensures that this information is included in each certificate that the CA issues so that it is available to all clients. This ensures that PKI clients experience the least possible number of failures due to unverified certificate chains or certificate revocations that can result in unsuccessful VPN connections, failed smart card logons, or unverified e-mail signatures.

Follow these guidelines when configuring CDP extension URLs:

- Avoid publishing delta CRLs on offline root CAs. Because you do not revoke many certificates on an offline root CA, a delta CRL is probably not needed.

- Adjust the default LDAP:/// and HTTP:// URL locations on the **Extensions** tabof the certification authority **Properties** page according to your needs. Do not remove the local CDP location, however. The CA requires the local CDP location in order to publish the CRL to itself. The CA uses the local CRL to validate all certificates before they are issued to users. The local path does not show in the CDP extension of issued certificates.

- Enable the publication of delta CRLs, regardless of whether delta CRLs are going to be published, to allow for the potential use of delta CRLs in the future. Enable delta CRL publication by selecting the **Publish Delta CRLs to this location** check box.

- Publish both the LDAP and HTTP URLs for CDP locations to enable clients to retrieve CRL data with HTTP and LDAP. If required, publish a CRL on an HTTP Internet or extranet location so that users and applications outside the organization can perform certificate validation.

- Consider using Active Directory–based publication. An LDAP certificate revocation list URL distributed by means of Active Directory is replicated in a fault-tolerant, distributed, highly available manner. However, replication of CRL data among Active Directory domain controllers introduces some latency.

- For certificates that are to be validated by clients that use Active Directory, place the LDAP CDP location first in the list to optimize client revocation checking. Windows clients always retrieve the list of URLs in sequential order until a valid CRL is retrieved.

- Provide an additional HTTP CDP location or an alternative LDAP path to CRLs for clients that cannot use Active Directory or LDAP.

Follow these guidelines when publishing HTTP-based CRLs:

- If you are providing an HTTP CDP location, use round robin DNS or Web server virtual names to provide redundancy in the HTTP URL.

- Use HTTP CDP locations to provide accessible CRL locations for non-Windows brand operating system clients.

- Place HTTP CDP URLs second in the list of the URLs in the CDP extension if the CRL is distributed with Active Directory as well.

# Configure Certificate Templates

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

By default, Windows Server 2003 enterprise CAs are enabled upon installation to issue a variety of types of certificates. You can use the Certification Authority MMC snap-in to make the following modifications to this default configuration:

- Specify the certificate types that are to be issued by each CA.
- Delete any default certificate templates that you do not want the CA to issue from the certificate templates container.
- Add additional certificate templates that the CA can issue.

You can configure CAs to support one or multiple security functions by:

- Configuring root or intermediate CAs to issue subordinate certification authority certificates only.
- Configuring an issuing CA that supports secure Web communication services to issue authenticated session, computer, and Web server certificates only.
- Configuring an issuing CA that supports general business users to issue user certificates only, or configuring a CA that supports administrators to issue administrator certificates only.
- Configuring an issuing CA that supports smart card enrollment to issue smart card logon and smart card user certificates only.

The access control lists (ACLs) for each certificate template control the permissions needed to request certificate types. An enterprise CA grants certificate requests only for users, computers, or services that have the Enroll permission selected in the ACLs for that certificate template. The ACLs for certificate templates are preconfigured to enable various default user accounts and security groups to enroll for certificate types.

You can use the Certificate Templates MMC snap-in to modify the ACLs for each certificate template. For example, by default, only members of the Domain Administrators security group can request and obtain enrollment agent certificates. However, to specify that only certain members of your security department can request and obtain enrollment agent certificates, you can change the ACLs for the enrollment agent certificate template. You can remove domain admins from the ACL and add the appropriate user accounts or security groups.

For Windows Server 2003 stand-alone CAs, information about the certificate type must be included in the certificate request because stand-alone CAs do not use certificate templates. You can use stand-alone CAs with custom policy modules and custom certificate request applications to control the types of certificates that are issued.

# Configure Public Key Group Policy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use the Group Policy MMC snap-in to configure the following optional categories of public key Group Policy for sites, domains, and organizational units:

- **EFS Recovery Agents.** By default, the local Administrator user account for the first domain controller installed in the domain is the EFS recovery account for that domain. You can specify alternate encrypted data recovery agents for EFS by importing into the policy the EFS recovery agent certificate for the appropriate alternate agent. You must first issue EFS recovery agent certificates to the user accounts on the local computers that you want to use as alternate recovery agents.

- **Automatic Certificate Enrollment.** You can specify automatic enrollment and renewal for computer certificates. When automatic enrollment is configured, the specified certificate types are issued to all computers within the scope of the public key Group Policy. Computer certificates issued by means of automatic enrollment are renewed from the issuing CA. Automatic enrollment does not function unless at least one enterprise CA is on line to process certificate requests.

In addition, you can use Group Policy to configure a number of CA trust options. Group Policy trust is configured and enforced within a single domain only. This allows different users in different domains to trust different root CAs.

When possible, manage trust of third-party root certification authorities by using Group Policy, and limit their scope by using qualified subordination. Third-party root CAs can be constrained by namespace and purpose to prevent unwanted trust and namespace violations within the organization.

Group Policy trust configuration is found in the computer policy for \Windows Settings\Security Settings\Public Key Policies\Trusted Root Certification Authorities. Users inherit policy from the computer policy. You can enable all computers and users to trust a root CA by adding the root CA certificate to Group Policy.

You can configure the following alternate trust options by selecting the **Trusted Root Certification Authorities** node in the Domain Security Policy MMC snap-in:

- **Enable or disable the ability for users to trust root CAs on a per-user basis.** Use this option to disable users from trusting a root CA outside the Enterprise root trust, Group Policy, the default computer store root CA list, and the list of root CA certificates provided by Windows Update.

- **Allow both Enterprise CA trust and third-party CA trust or only Enterprise root trust.** You can disable trust of third-party root CAs in the domain outside the enterprise root CA trust, including root certificates downloaded from the Windows Update. This disables user installation of root CA certificates.

**Note**

- Disabling third-party CAs can impact user access to applications such as SSL-secured Web sites.

# Configure CRL Publication

Updated: May 1, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you have updated the CDP extensions on the CA, you need to publish a new CRL so that all clients can access the new CRL data. For more information about configuring CRL publication, see "Manage Certificate Revocation" in Help and Support Center for Windows Server 2003.

**Modifying the Default Certificate Publication Period**
Certificates that are revoked prior to expiration remain in a published base CRL for one full base CRL period (defined by the CA) after they expire. Certificates that expire are no longer included in published CRLs after one additional base CRL expires.

Although applications do not check CRLs for certificates that have expired, you might in some cases want to maintain a public list of signing certificates that have been revoked. You can enable a registry setting on a CA to ensure that revoked certificates that have expired are not removed from the CRL.

**To modify the default CRL publication period for revoked and expired certificates on a CA**

- At the command prompt, type:

```
certutil -setreg ca\CRLFlags +CRLF_PUBLISH_EXPIRED_CERT_CRLS
```

| **Warning** |
| --- |
| Consider that large CRLs can cause performance issues for certificate clients and domain controllers. For more information on what could cause large CRLs, see TechNet Wiki article Large CRLs: What is added to a Certificate Revocation List (CRL)? |

**Ensuring Application Reliability**
Many applications rely on CRL availability and fail if the CRL is inaccessible or out-of-date. Follow these guidelines when publishing CRLs to ensure the reliability of your applications:

- Configure the CRL to be valid for a long enough period of time to allow for the recovery of the CA if there is a hardware or software failure.
- Set a reasonable CRL overlap period to protect against CRL publication or replication failures.
- Keep the private key of the CA and a copy of the CRL in a secure offline location so that you can sign and publish a valid CRL manually by using Certutil.exe when a catastrophic failure occurs.
- Use Active Directory to publish CRLs whenever possible. This maximizes availability and network performance. However, always consider the amount of time needed to replicate Active Directory data between domain controllers.
- Do not publish CRLs to Active Directory when the CRL publication period is shorter than the replication convergence time for the Active Directory forest.
- To prevent the use of a logon certificate, disable the account in Active Directory.

**Controlling CRL Size**
You can partition a base CRL to control its size. In this way, you can control the amount of data that is replicated to Active Directory and the size of the data object that clients download when they perform revocation checks on certificates. You partition base CRLs by renewing the CA key. This creates a partitioned CRL for all certificates that are issued after the key is renewed.

The CRL increases by about 29 bytes for every certificate that is revoked, depending on the reasons that you specify for the revocation. You might want to use a new key to renew the CA every time it reaches 100-125 kilobytes (KB) in size, to minimize download times. This strategy is based on the assumption that approximately 10 percent of the certificates that you issue are revoked before their natural expiration date. If your actual or planned revocation rate is higher or lower than this, adjust your

key renewal strategy as needed.

**Removing Expired CRLs**
By default, a CA maintains an expired CRL in the database and keeps it in the directory at the last known CDP publication point.

When the key for a CA expires, the CA continues to publish CRLs that are signed by the expired CA certificate. It is recommended that you maintain this CRL in the CA database to allow for long-term validation and auditing. You can, however, remove the CRL to clean out the database.

**To remove a CRL after a CA key expires**

- At the command prompt, type:

```
certutil -setreg ca\CRLFlags + CRLF_DELETE_EXPIRED_CRLS
```

# Delegate CA Administration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you begin to issue certificates, you need to delegate CA administrator roles. For information about defining CA administrator roles, see "Defining PKI Management and Delegation" earlier in this chapter.

You can assign CA Administrator and Certificate Manager permissions by using the Certification Authority MMC snap-in. Other roles, users, and groups are specified in the consoles used to perform particular tasks, such as Certificate Templates and Certificates. To change the roles of a user, you must change the security permissions, group membership, or rights of the user.

# Configure Certificate Enrollment and Renewal

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Microsoft Certificate Services supports a variety of enrollment and renewal methods, such as the Certificate Request Wizard or the Microsoft Certificate Services Web pages. However, if you deploy third-party certificate services or custom certificate enrollment and renewal applications, you must perform any configuration required for those services and applications.

# Issue Certificates

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can issue certificates to users, computers, and services after the required certificate services are installed and configured. Keep the following considerations in mind when you start to issue certificates:

- Certificates are issued for computers within the scope of the Automatic Certificate Request settings of the Group Policy. Domain Administrators can also manually request certificates for local computers by using the Certificate Request Wizard or the Microsoft Certificate Services Web pages. Consider scheduling manual enrollment in stages to help distribute the administrative workload for computer enrollment.

- Smart card administrators can start issuing smart card certificates by using the Smart Card Enrollment Station available on the Microsoft Certificate Services Web pages. Consider scheduling smart card enrollment in stages to help distribute the administrative workload for smart card enrollment.

During the transition to smart cards, both smart card authentication and interactive logon with domain credentials should be enabled. Because this weakens network security, configure user account policy to require smart cards for interactive logon as soon as smart card users are trained and are using their cards.

Monitor the performance of certificate services closely as you start issuing certificates to ensure that CAs handle the certificate load. To correct excessive load conditions, consider adding more issuing CAs or scheduling certificate enrollment in smaller stages. Certificate renewal might also produce excessive load conditions. Adding more CAs and scheduling certificate enrollment in smaller stages can also help distribute peak renewal loads.

# Additional Resources for Designing a Public Key Infrastructure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information and tools related to this chapter.

**Related Information**

- The *Distributed Services Guide* of the *Windows Server 2003 Resource Kit* (or see the Distributed Services Guide on the Web at http://www.microsoft.com/reskit) for more information about public key features in Windows Server 2003 and using certificates in conjunction with Encrypting File System.

# Planning a Smart Card Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Smart card support in Microsoft® Windows® Server 2003 enables you to enhance the security of many critical functions, including client authentication, interactive logon, and document signing, in your organization. If you are using or planning to use public key certificates, deploy smart cards to increase security for your network and critical applications.

**In This Chapter**

Overview of Smart Card Deployment

Creating a Plan for Smart Card Use

Selecting Smart Card Hardware

Creating a Smart Card Deployment Plan

Planning for Ongoing Smart Card Support

Additional Resources for Smart Card Deployment

**Related Information**

- For more information about creating a public key infrastructure, see "Designing a Public Key Infrastructure" in this book.
- For more information about Windows Server 2003 Certificate Services and public key infrastructure features, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

# Overview of Smart Card Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Most organizations use passwords to manage access to computer networks and resources. However, some users set weak passwords, write passwords down in insecure locations, or forget their passwords and require help desk assistance for password reset. For this reason, passwords alone might not provide the level of security and manageability that your organization requires.

Smart card support in Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; and Windows® Server 2003, Datacenter Edition operating systems provides users with stronger credentials than even the most complex passwords. If you use, manage, and deploy smart cards properly, you can enhance the security of your organization and reduce your support costs.

Smart cards offer the following benefits:

- **Protection.** Smart cards provide tamper-resistant storage for private keys and other data. If a smart card is lost or stolen, it is difficult for anyone except the intended user to use the credentials that it stores.

- **Isolation.** Cryptographic operations are performed on the smart card itself rather than on the client or on a network server. This isolates security-sensitive data and processes from other parts of the system.

- **Portability.** Credentials and other private information stored on smart cards can easily be transported between computers at work, home, or other remote locations.

The number and variety of smart card–enabled applications is growing to meet the needs of organizations that want to rely on smart cards to enable secure authentication and to facilitate services.

Before you can deploy smart cards in your organization, you must have a public key infrastructure (PKI) in place. Next, you need to identify applications to enable for use with smart cards, and plan how to implement and support a smart card infrastructure before you can take advantage of the security benefits of smart cards.

**Note**

- For a list of the job aids that are available to assist you in deploying smart cards, see "Additional Resources for Smart Card Deployment" later in this chapter.

# Process for Planning a Smart Card Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Planning a smart card deployment involves making decisions about technical standards, hardware purchases, smart card management, and the logistics of smart card distribution.

Figure 16.1 shows the process for planning a smart card deployment.

**Figure 16.1 Planning a Smart Card Deployment**

# Smart Card Fundamentals

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 supports a variety of secure smart card applications and business scenarios. Before you begin to plan your smart card deployment, it is important to understand the basic components of smart card technology.

**Components of a Smart Card Infrastructure**

A number of hardware and software components are required in order to support a smart card infrastructure.

**Certificates** Digital data that securely bind a public key to the entity that holds the corresponding private key.

**Certification authorities** Trusted entities or services that issue digital certificates.

**Active Directory** The Windows Server 2003 directory service that serves as a repository for account information, primarily user credentials, security group memberships, and certificate templates. In addition, you can also use the Active Directory® directory service to store certificates, certificate revocation lists, and delta certificate revocation lists, and to publish root certification authorities (CAs) and cross-certificates.

**Smart cards** Hardware tokens containing integrated processors and memory chips that can be used to store certificates and private keys and to perform public key cryptography operations, such as authentication, digital signing, and key exchange.

**Smart card readers** Devices that connect a smart card to a computer. Smart card readers can also be used to write certificates to the smart card.

**Smart card software** The software provided by the smart card vendor to manage smart cards. In some cases, organizations might choose to create their own software tools if customized functionality is required.

# Creating a Plan for Smart Card Use

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before deploying smart cards in your organization, you must determine which processes, users, and groups of users require smart cards.

Figure 16.2 shows the process for creating a plan for smart card use in your organization.

**Figure 16.2 Creating a Plan for Smart Card Use**

# Identifying the Processes That Require Smart Cards

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A smart card deployment can help your organization meet numerous sensitive business requirements. You can use smart cards for any or all of the following processes:

- Interactive user logons, including remote access connections to the network
- Administrator logons
- Third-party authentication across the Internet
- Signing and encrypting e-mail

Evaluate additional equipment and administrative costs, procedures, and changes to user work patterns that each smart card–enabled process requires. Ensure that the benefits of deploying smart cards for each process outweigh the costs from hardware, administration, and potential user difficulties.

For a worksheet to assist you in documenting the processes in your organization that require smart cards, see "User and Group Smart Card Requirements" (DSSSMC_1.doc) on the Microsoft® *Windows® Server 2003 Deployment Kit* companion CD (or see "User and Group Smart Card Requirements" on the Web at http://www.microsoft.com/reskit).

# Interactive User Logons

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Use smart cards for an interactive user logons if you want to enforce the use of secure encrypted logon credentials. If you require users to log on by using smart cards, you do not have to worry about the quality and security of user passwords.

Requiring smart cards for interactive user logons requires additional network administration for smart card distribution and support. This is problematic for organizations that are spread across different geographic locations and that do not have network or physical security personnel in each location to administer and support smart cards.

You can also use smart cards for remote access logons, and for Terminal Services and shared client logons.

**Remote Access Logons**
Local interactive logons require that users have both physical access to a computer that is a logical member of the organization and a network password. Remote users, however, can log on from any computer outside of the organization. If a malicious user obtains the password of a remote user, he or she can use it to access network resources from any computer. For this reason, conventional password-based remote access logons are more vulnerable to attack than local interactive logons.

You can secure the remote access process by requiring users to use smart cards when they connect to the corporate network by means of remote access logon. This solution prevents attackers from using the remote access dial-up or Internet connections to compromise the network, even if they have physical access to laptops or home computers.

One problem with requiring the use of smart cards for remote access logons is the fact that remote users often own computer hardware and software that does not conform to minimum corporate standards and, therefore, might not support smart card use. This complicates the process of administering and supporting smart cards for remote access logons. Also, users might experience longer logon times when they use smart cards, especially over slow dial-up connections.

**Terminal Services and Shared Clients**
If your organization is deploying Terminal Services, consider using smart cards for kiosk computers that are shared by multiple users. This can improve security in environments in which multiple users share a single computer terminal, relocate frequently, and do not use the conventional logoff procedure every time they move away from the terminal. This is often the case in hospitals, factories, or other businesses.

**Note**

- Smart card logons require Microsoft® Windows® XP or Windows Server 2003 Terminal Services clients, even on computers running Microsoft® Windows® 2000.

Providing smart card support for kiosks or Terminal Services clients that are in critical locations in your organization and are shared by several users is less costly than providing smart card support for interactive user logons, because you do not need to purchase and deploy a large number of smart card readers.

For more information about deploying Windows Server 2003 Terminal Services, see "Hosting Applications with Terminal Server" in *Planning Server Deployments* in this kit.

# Administrator Logons

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

There is greater potential for harm to the network when administrator credentials, as opposed to user credentials, are misused. As a result, preventing unauthorized users from using administrative credentials to access their network is an important security priority for most organizations. Another vulnerability is introduced when you allow people to perform network administration tasks by using generic administrator accounts that are shared by multiple users; this limits the ability of the organization to track which user performs a specific action. Allowing administrators to log on by using administrative credentials when they are not performing administrative tasks also creates a significant security risk because attackers who compromise an administrator account can do a greater amount of damage to the system.

By requiring individuals to use smart cards to perform administrative tasks, you can significantly reduce the possibility that unauthorized users can gain administrative access to your network. You can use smart cards for administrator logons in the following two ways:

- By using smart cards for individual administrative operations.
- By using smart cards for an administrative shell.

In most cases, the best solution is to use a combination of these two strategies. For example, you can require that all administrators use smart cards to access data center servers. If the administrator is using a Windows 2000 or Windows XP client, he or she can use a smart card and administrative credentials to open a Terminal Services client session in order to log on to the data center servers.

**Important**

- It is not possible to utilize multiple credentials stored on a single smart card. Therefore, administrators who have more than one domain account require a smart card for each account.

**Using Smart Cards for Individual Administrative Operations**

When you use smart cards for individual administrative operations, administrators log on by using their standard user credentials, and then use administrative credentials when they need to perform specific administrative operations. For example, you might require an administrator to log on by using a smart card in order to install Active Directory on a member server. Administrative credentials apply only to the specific operation, which helps to protect the security of the system.

An administrator can also use smart cards to perform individual administrative operations on target computers running versions of the Windows operating system earlier than Windows XP or Windows Server 2003, as long as they use a smart card to log on to a computer running Windows XP or Windows Server 2003.

Not all administrative tools work with smart cards. Therefore, before you implement this solution, test it to ensure that you can perform the required administrative tasks and use the necessary administrative tools. If some of your required tools and tasks are incompatible with using smart cards, you must communicate to your administrators which tasks require smart cards and which must be completed by using administrative credentials.

**Using Smart Cards for an Administrative Shell**

When you use smart cards for an administrative shell, administrators log on by using user credentials. Then, when the administrator needs to perform administrative operations, he or she logs on by using a smart card and administrative credentials to open a Terminal Services client session. The administrator then performs the required administrative operations within the administrative shell.

This approach simplifies the process of performing multiple sequential administrative operations during a single session. However, the server that has Terminal Server enabled must be running Windows Server 2003. Although the Windows XP Terminal Services client can run on Windows 2000, the server-side support is only provided by Windows Server 2003.

# Authenticating Third Parties

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Use smart cards for third-party authentication if you want to verify that queries, orders, or other communications originate from the appropriate individual or organization and that they conform to preestablished standards, such as purchase order limits. For example, banks that allow users to check their transaction histories or pay bills online, and distributors that accept purchase orders over the Internet can benefit from using smart cards for third-party authentication.

Deploying smart cards to third parties, however, requires careful administration. For example, you must ensure that attackers cannot obtain smart cards and guess the PIN to gain unauthorized access to the system. Also, if the customer services that are based on smart card authentication are an important part of your business, you need to ensure that the services are always available. If you do not administer your third-party smart card authentication process effectively, it can have a negative impact on your Internet business transactions.

# Signing and Encrypting E-mail

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use smart cards to enable digital signing and the encryption of electronic communications such as e-mails or contracts.

If you choose to deploy smart cards for digital signing, you need to determine the types of e-mail messages that require smart card–validated digital signatures. Use smart cards for the digital signing of e-mail messages where it is important to verify the identity of the sender and that the message has not been tampered with while in transit. Digitally signing routine e-mails creates unnecessary network traffic and can slow down ordinary communication between users. Note that when you use smart cards for the digital signing of sensitive documents, such as legal contracts or purchase orders, you must configure the certificate policies and extensions that control smart card certificate use.

Depending on the types of documents that you want users to sign digitally, you also need to make additional decisions about smart card–enabled digital signatures, such as whether assistants are allowed to sign documents on behalf of their superiors, whether send and read receipts are required, and how the receipts are to be stored.

For more information about certificates and certificate use, see "Designing a Public Key Infrastructure" in this book.

**Note**

- You must ensure that users know how to verify digital signatures. Unlike a hand-written signature, a digital signature is not embedded in a message or document, and might be overlooked.

# Defining Smart Card Service Level Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you deploy smart cards, establish service level agreements to help your IT organization align smart card performance with the objectives of the organization in areas such as reliability, response times, and support procedures.

For example, you need to define smart card service level standards for:

- **The types of identification required to obtain a smart card.** You might choose to require a specific type of personal identification, such as a driver's license or other photo ID, in order for a user to obtain a smart card.

- **Unique service guarantees for special classes of employees, such as executives or roaming employees.** Define whether certain classes of employees are permitted to operate under support agreements that differ from those of other users.

- **Acceptable time needed for users to log on.** It is best to ensure that the different steps and time needed for smart card logon time are comparable to the steps and time needed for conventional password logons.

- **Acceptable logon times for remote access users.** Remote access logon times are more vulnerable to slowdowns than local network connections, especially if users have slow dial-up access connections. You might need to upgrade your remote access configuration in order ensure acceptable logon times for remote users.

- **Remote access exceptions.** The computer configurations of some users might not be compatible with smart cards, and remote users might lose or forget their smart cards. Identify the circumstances, if any, in which remote users are allowed to use remote access without using a smart card.

- **Number of unsuccessful PIN entries allowed.** Do not allow an unlimited number of attempts to enter a PIN. Allowing three or four attempts is generally adequate.

- **PIN reset requirements.** Decide whether users are allowed to reset their own PINs, or whether they need to provide personal identification to security or help desk personnel to have their PINs reset. If you decide that users need to provide positive identification, decide whether the user must present the identification in person, such as a photo ID, or demonstrate knowledge of a predefined secret, such as a mother's maiden name.

- **Service guarantees to users who cannot use their smart cards because of loss, damage, or blocking.** This includes:

  - Establishing when and how users can regain access to the network.

  - Determining whether to restrict these users' access to the network to certain areas, or to allow them access to any areas of the network that were previously accessible to them.

  Defining these limits helps you to establish user expectations and support procedures.

Document your service level standards. You will need to apply these standards in your smart card operations plan, test them in your lab and pilot deployments, communicate them to help desk personnel and to your users, and include them in your support and maintenance plan.

For a worksheet to assist you in documenting your service level agreement, see "Smart Card Service Level Agreement" (DSSSMC_2 .doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Smart Card Service Level Agreement" on the Web at http://www.microsoft.com/reskit).

**Important**

- Incorporate your smart card service level agreements in the Certificate Practice and Policy Statements for your public key infrastructure. For more information about creating Certificate Practice and Policy Statements, see "Designing a Public

Key Infrastructure" in this book.

# Selecting Smart Card Hardware

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Single smart cards and smart card readers are relatively inexpensive. However, when you deploy smart cards and smart card readers to hundreds or even thousands of users, equipment cost becomes an important consideration. You must evaluate smart card hardware in order to select the devices that best meet the needs of your organization at the best price.

Figure 16.3 shows the process for selecting smart card hardware.

**Figure 16.3 Selecting Smart Card Hardware**

# Creating a Smart Card Specification

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A wide variety of smart cards and smart card readers are available to choose from. Windows Server 2003 is designed to work with any cryptographic smart card that has an associated CryptoAPI cryptographic service provider. The physical characteristics of smart cards and readers are governed by published standards. Cards from any manufacturer that adheres to the ISO 7816 standard will likely be compatible with the reader you select. Be sure, however, to test smart cards and smart card readers to verify compatibility before deploying them in your production environment.

For more information about testing smart cards and smart card readers, see "Evaluating Smart Cards and Readers" later in this chapter.

**Note**

- For more information about ISO 7816, see the Smart Card Alliance link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

Because smart cards both store *and* process data, it is important to create a specification for your smart cards. Creating a smart card specification involves making decisions about the following:

- Smart card hardware type
- Amount of memory required
- Intended useful smart card lifetime
- Intended smart card roles
- Smart card reader hardware
- Smart card management software

Table 16.1 lists some of the critical specifications that you need to define when you create your smart card specification.

**Table 16.1 Smart Card Hardware Specifications**

| Specification | Description |
|---|---|
| Memory | How much data you need to store on the smart card. |
| Life expectancy | The useful lifetime of the smart card. |
| Reuse | Whether or not the smart card can be configured for use by a second user, if the original user leaves the organization. |
| Type of card | The type of card that is most appropriate for your organization. You might choose one or more of the following:<br>• Credit card or token style<br>• Single purpose or dual purpose |
| Card dimensions | The size, length, and thickness of the card, depending on the type of card that you specify. |

| | |
|---|---|
| Number of cards | How many cards you need.<br>• If you have more users than computers, you need fewer readers than smart cards.<br>• If you use your smart cards on multiple systems, you need more readers than smart cards.<br>• If you specify more than one type of card, indicate the number of each type. |
| Type of smart card reader | The type of reader that is most appropriate for your organization. Options include:<br>• USB<br>• PCMCIA<br>• Serial |
| Number of smart card readers | How many readers you need.<br>• If you have more users than computers, you need fewer readers than smart cards.<br>• If you use your smart cards on multiple systems, you need more readers than smart cards.<br>• If administrators use one smart card for user logons and a second smart card for logging on with their administrative credentials, this will also impact the number of smart card readers that you require. |
| Performance requirements | The type of performance that you can expect. This includes:<br>• Minimum acceptable logon times for direct network logons.<br>• Minimum acceptable logon times for remote access logons.<br>• Ability to handle alternate credentials.<br>• Ability to restrict logons by using alternate credentials. |
| Smart card management tools | The types and quality of the tools provided by the hardware vendor to manage smart cards. |

For a worksheet to assist you in preparing a product specification, see "Smart Card Hardware Specification" (DSSSMC_3 .doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Smart Card Hardware Specification" on the Web at http://www.microsoft.com/reskit).

In the beginning of your deployment, you can meet user needs by using a single type of smart card with a single configuration option. However, as you expand your smart card infrastructure, you might need to deploy a variety of smart card types and configuration options.

**Smart Card Type**
Two types of smart cards are available for use with Windows Server 2003 and Windows XP: conventional credit card–shaped contact cards and smaller token-style cards that plug directly into the USB port of a computer.

**Note**

- Another type of smart card, called a contactless smart card, is not supported by Windows XP or Windows Server 2003.

**Credit card–shaped contact cards**
Credit card–shaped smart cards are available in three-volt and five-volt versions. They are the most common smart card solution, in part because they resemble the corporate card keys or badges that many organizations use.

### Note

- You can specify that your smart cards be screen-printed with your corporate logo and a picture of the user. If you plan to add graphics to smart cards, ask your vendor about the methods available for bulk printing and customizing cards.

If your organization uses card keys or badges, you can apply smart card chips to the existing card key or badge as a sticker or "skin." However, your card keys or badges need to fit into your smart card readers with a minimal amount of friction; therefore, be sure to include the physical thickness of the smart card in your specifications. This is an important factor to consider when you select a vendor to manufacture the stickers, as the material thickness for smart card chips can vary.

**Token-style smart cards**
Token-style smart cards are typically the size of a house key or automobile key. They plug directly into a USB port, providing a more compact solution than separate cards and readers. Token-style smart cards are ideal for laptop users who want to carry a minimum number of peripherals, or for workers who use a number of different computers. However, you cannot use token-style smart cards if your computers do not have USB connections, or if the USB connections are full or difficult to access.

**Memory**
Your smart card requires enough memory to store the certificate of the user, the smart card operating system, and additional applications. Smart cards run embedded operating systems, and in many cases, a form of file system in which data can be stored. To enable Windows smart card logon, you must be able to program the card to store a user's key pair, retrieve and store an associated public key certificate, and perform public and private key operations on behalf of the user.

To calculate the amount of memory that you need, determine the space requirements for:

- User certificates. A certificate typically requires about 1.5 kilobytes (KB). A smart card logon certificate with a 1,024-bit key typically requires 2.5 KB of space.
- The smart card operating system. The Windows for Smart Cards operating system requires about 15 KB.
- Applications required by the smart card vendor. A small application requires between 2 KB and 5 KB.
- Your custom applications.
- Future applications.

Figure 16.4 shows the additional space requirements of a typical 32 KB smart card. The smart card operating system requires about 15 KB, leaving 17 KB for the file system, which includes space for the card management software, the certificate, and any other custom applications.

**Figure 16.4 Memory Use on a 32 KB Smart Card**

It is possible to configure smart card file systems into public and private spaces. For example, you can define segregated areas for protected information, such as certificates, e-purses, and entire operating systems, and mark this data as Read Only to ensure the security of the smart card and restrict the amount of data that can be modified. In addition, some vendors provide cards with sub-states, such as Add Only, which is useful for organizations that want to restrict the ability of a user to revise an existing credential, and Update Only, which is useful for organizations that want to restrict ability of a user to add new

credentials to a card.

The data capacity available on smart cards is increasing as smart card technology improves. However, storage space on smart cards is expensive. Card vendors often restrict the amount of storage available to individual applications so that multiple applications or services can be stored on the card. Therefore, in your vendor specification, define all of your anticipated present and future card usage requirements and the memory requirements for each certificate and application that you require. If you plan to use your smart cards for multiple purposes, such as physical access to facilities and user logon, or to store additional data, you must increase your memory requirements. Also, when planning storage space on the chip, allocate space for applications that you are planning for future implementation.

**Note**

- Windows Server 2003 and Windows XP do not support the use of multiple certificates on a smart card.

#### Life Expectancy

You must define the length of time for which you will use a smart card before you replace or upgrade it. Contact your vendor for information about smart card life expectancy based on normal wear and tear.

In addition, you must take into account your current and future space requirements, including the anticipated need for additional applications and certificates with larger keys. Anticipate adding new applications, and potentially issuing new smart cards, over an 18-24 month card lifecycle. In the future, vendors are likely to introduce smart cards with more memory and other enhancements for a lower cost.

Also, determine whether you want your smart cards to be reusable in the event that users leave the organization. Reusing smart cards reduces the costs associated with issuing new ones. However, the cost associated with removing existing data and writing new data and applications is often equal to or more than the cost of preparing and issuing new smart cards.

#### Smart Card Roles

You can use smart cards for one of three roles. Determine how many smart cards you need to issue for each of the following roles:

- **Enrollment card.** Issue enrollment cards to individuals who enroll smart cards on behalf of other users. Enrollment cards have a special enrollment agent certificate. Issue the smallest possible number of enrollment cards that will enable you to enroll all required smart card users. This protects the security of your system.

- **User cards.** These are the standard cards that you issue to each user. Two types of user cards are available:

    - **Permanent.** Permanent user cards are cards that employees carry with them. They contain the cardholders' credentials, certificates, data, and applications. They might also have a photograph or a decal applied to the card. In a Windows Server 2003 environment, the permanent card points to a permanent certificate server.

    - **Temporary.** Temporary cards are a limited-use cards that are issued to guests, temporary employees, and users who have forgotten their permanent cards. They point to a temporary certificate server and can have a limited lifetime.

For a worksheet to assist you in documenting the roles for the smart cards that you issue, see "Smart Card Hardware Specification" (DSSSMC_3 .doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Smart Card Hardware Specification" on the Web at http://www.microsoft.com/reskit).

**Important**

- To ensure system security, issue master and enrollment cards to the smallest possible number of trusted employees. For more information about issuing enrollment agent cards, see "Establishing Enrollment Agents" later in this chapter.

#### Smart Card Readers

A variety of types of smart card readers are available. The majority of smart card readers connect to the computer through an RS-232 serial port, a Type II Personal Computer Memory Card International Association (PCMCIA) slot, or a universal serial bus (USB) port.

Although USB-compatible smart readers are the simplest type of reader to connect, the USB ports on some computers might already be used. For this reason, it is best to order a mix of card reader connector types based on the types of connections that

are available on your systems.

For a list of Windows-compatible smart card readers, see the Windows Catalog link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Smart Card Management Tools**

You can perform most smart card–related tasks by using the Windows Server 2003 Certificate Services and software tools provided by the smart card vendor. However, it is important to assess the smart card tools that are available to determine whether they are sufficient to meet your needs. You might need to create additional tools for some smart card tasks.

For example, you might require tools to assist you in moving from a limited pilot phase to a full production deployment. Also, developers in your organization might need to create a direct interface between the smart card certificate and your building access systems. You might also choose to write a script that automatically enters critical data into a database when a smart card is created. This includes data such as smart card serial numbers, the names or e-mail names of the users who are assigned smart cards, the types of certificates that are issued to the users, when the certificates are issued, and when they expire.

For more information about creating scripts for Windows Server 2003, see the at http://www.microsoft.com/reskit, or see the TechNet Script Center link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Evaluating Smart Cards and Readers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You need to evaluate your prospective smart cards and readers throughout your smart card deployment process. Initially, obtain and evaluate a variety of smart cards and smart card readers to determine which vendors provide the best balance of specifications, performance, and price. As you deploy your smart card infrastructure, continue to evaluate your hardware to make sure that it performs as expected.

The smart cards and smart card readers that you deploy and the smart card production processes that you develop are likely be used many times every day. Therefore, you must ensure that your hardware is reliable. The service level agreements that you created when you defined your smart card requirements provide objective standards for measuring and documenting satisfactory performance.

To minimize user dissatisfaction and maximize manageability, be sure to test the following:

- **Installation and removal of the smart card software.** Make sure the smart cards work after you install the software. If the installation is faulty, use the Windows Event Viewer to access error messages that might explain the cause of the failure.

- **Fit of smart cards in readers.** Smart card dimensions, such as thickness, are governed by international standards. However, some organizations have found that, if the card-to-reader interface is too tight or abrasive, the cards deteriorate more rapidly.

- **Reader reliability.** To test reliability, create an environment that includes systems that have slower CPUs and less memory than computers in your organization. Test how well your smart card readers operate in this environment, as well as in other configurations. You can, for example, run a number of memory-intensive applications or use the smart cards and readers over slow connections to evaluate how each combination of smart cards and readers functions in these conditions. Your smart card service level agreements provide objective criteria for acceptable and unacceptable performance.

- **Card production.** Slow card production processes can impede your deployment. If your organization is unable to produce cards efficiently, use a third-party vendor to produce smart cards.

- **Ability to deploy multiple types of cards and readers.** If you are unable to efficiently deploy the types of cards, readers, and servers that you require, your service might be inconsistent and inefficient.

For a worksheet to assist you in documenting the results of your smart card reader evaluation, see "Smart Card Reader Evaluation" (DSSSMC_4 .doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Smart Card Reader Evaluation" on the Web at http://www.microsoft.com/reskit).

Figure 16.5 shows an example of a completed Smart Card Reader Evaluation worksheet.

**Figure 16.5 Example of a Smart Card Reader Evaluation Worksheet**

| Smart Card Reader Evaluation | | | |
|---|---|---|---|
| Prepared by | | Date | |

| Criteria | Manufacturer 1 | Manufacturer 2 | Manufacturer 3 |
|---|---|---|---|
| Cost | $15 | $22 | $18 |
| Usability | Good | Fair | Poor |
| Card Fit | Good | Good | Fair |
| Software Included in Windows Server 2003 | | | |
| PCMCIA Version | Yes | Yes | Yes |
| USB Version | Yes | Yes | Yes |
| Serial Version | No | Yes | Yes |
| Relationship | Good | No data | No data |
| Future Tests | Need to test more portable computers and typical home office systems | Need to test more portable computers and typical home office systems | Need to test more portable computers and typical home office systems |

# Creating a Smart Card Deployment Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Deploying a smart card infrastructure is a time-consuming process because it involves deploying physical components (smart cards and smart card readers) and issuing digital certificates individually to every user who requires a smart card. Careful planning can significantly reduce the amount of time this process takes and enable you to enhance the security of your organization. Figure 16.6 shows the steps involved in creating a smart card deployment plan.

**Figure 16.6 Creating a Smart Card Deployment Plan**

# Establishing Certification Authorities

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is important to ensure that your public key infrastructure can support the issuance and verification of smart card certificates for the users and applications that you have identified. To ensure that your PKI can support a smart card infrastructure, you must do the following

- Configure your certification authorities (CAs) as enterprise CAs. Windows Server 2003 smart card certificates require enterprise CAs.

  **Important**

  - CAs that issue smart card certificates need to be trusted in the CA hierarchy and must be continuously online while the user is enrolled.

- Make sure that your issuing CAs are installed on servers that have enough storage and central processing power to support the smart card users in your organization.

For more information about planning your CA infrastructure, see "Designing a Public Key Infrastructure" in this book.

# Planning Smart Card Certificate Templates

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use any of the following types of Windows Server 2003 certificate templates to enable smart card use in the Windows Server 2003 PKI:

- **Enrollment Agent**. Allows an authorized user to serve as a certificate request agent on behalf of other users.
- **Smart Card User**. Enables a user to log on and sign e-mail.
- **SmartCardLogon**. Enables a user to log on by using a smart card.

You can also create your own certificate templates to serve multiple purposes. For example, the smart card logon certificate template is designed for smart card logon only. If you intend to use your smart card infrastructure to support multiple applications, you can choose multipurpose templates instead. Multipurpose templates generate certificates that you can use for multiple applications, such as smart card logon and e-mail signing.

**Note**

- Windows 2000 only supports version 1 templates, which cannot be customized or extended. Use Windows Server 2003, Enterprise Edition, which supports version 2 templates, if you need to create new certificate templates, copy an existing template, or replace templates that are already in use.

As part of your planning for smart card certificate templates, you need to establish values for public keys, certificate lifetimes, and certificate renewal policies. These values are interrelated. For example, if you select a larger key value, you can implement a longer certificate lifetime. Or, you can use a small public key value if a certificate has a relatively short lifetime. Note, however, that the amount of memory that is available on the smart cards that you select also limits the size of the public keys that you can use.

**Important**

- Many organizations pre-enroll users for smart card certificates several weeks before they distribute smart cards to users. The certificate lifetime is determined by the date that you issue the certificate, not the date that you distribute the card to the user. Therefore, factor any distribution delays into your certificate lifetime and renewal strategy.

A Windows Server 2003 CA allows you to select a certificate public key length from 384 bits for minimal security to 16,384 bits for maximum security. For typical logon applications, a 1,024-bit key is adequate.

You can establish certificate lifetimes that are as long or as short as you need, and you can configure certificates to be nonrenewable, renewable a finite number of times, or renewable indefinitely.

To define public key values and certificate lifetimes and renewal policies, take into account:

- **The physical capacity of your smart cards**. Most of the smart cards that are available today have adequate space for all but the largest certificates.
- **How you define acceptable logon times**. Public key–based authentication often takes longer than authentication without certificates.

  **Note**

  - The smart card and smart card reader that you choose might also impact logon performance. Test different combinations until the terms specified in your service level agreements are satisfied.
- **The nature of the business relationship**. Smart card certificates issued to permanent employees usually warrant a longer lifetime and renewal cycle than certificates issued to short-term workers or to nonemployees.

- **The level of security that you want to enforce**. Highly sensitive operations warrant larger public key values and, typically, shorter certificate lifetimes.

For more information about planning public key and certificate renewal values, see "Designing a Public Key Infrastructure" in this book. For more information about how to configure certificate templates, see "Certificate Templates" in Help and Support Center for Windows Server 2003.

# Establishing Issuance Processes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You must establish a plan for the issuance of the smart cards and for the writing of smart card certificates to the cards. This involves making decisions about the following:

- Smart card distribution requirements
- Certificate enrollment options
- Physical distribution of smart cards
- A user preparation plan

# Defining Smart Card Distribution Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Define the procedures for preparing and distributing smart cards and smart card certificates and replacing lost, stolen, or damaged smart cards, as well as contingencies such as when employees change jobs, names, or occupational status.

If you have an existing employee badge process, one solution for smart card distribution is to combine smart card preparation and distribution with badge preparation and distribution. Obtaining a badge typically requires a visit to a security office where the employees must prove their identity and then have their pictures taken. With smart cards, employees can have company-issued certificates attached to the badges that they use for building entry. In this case, the security office requests and installs the certificates on employees' badges, which also serve as their smart cards.

Requiring a person to appear in person and with physical credentials such as a driver's license is the most secure way to distribute smart cards, but this is not always possible. If your organization includes remote offices or traveling users, you need to establish a distribution strategy that accommodates the users' circumstances while minimizing the security risk. For example, you can have a receptionist or administrative assistant give the user a blank smart card and then have the user download the smart card certificate by using self-enrollment. The administrative assistant has physical access to the cards, but not to the PINs or the certificates necessary to activate the card.

You can also use registered mail or another delivery service that requires a signature upon receipt to distribute smart cards to individuals who do not have access to a security office. Otherwise, you can choose a designated individual to physically distribute smart cards. This is the least secure method of smart card distribution.

You must also plan for the physical distribution of replacement cards, especially for mobile or remote office users.

For more information about replacement card planning, see "Planning for Ongoing Smart Card Support" later in this chapter.

# Selecting Certificate Enrollment Options

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

By default, only domain administrators can modify smart card certificate templates. Domain administrators can modify the access permissions on the certificate template to enable either of the following enrollment options:

- Enrollment agents, which allows one or more agents to initialize smart cards on behalf of users.
- Self-enrollment, which allows end users to initialize their own smart cards.

You need to select between the enrollment agent or self-enrollment options, based on the security requirements of your organization and your plan for smart card management and distribution. Using an enrollment agent provides the greatest level of security, but requires the highest level of IT support and is the most expensive. Self-enrollment provides the greatest amount of flexibility, and accommodates remote users, but is not as secure.

**Establishing Enrollment Agents**
If you decide to control smart card issuance from a central location, you need to authorize one or more individuals within the organization to be enrollment agents.

The enrollment agent needs to be issued an Enrollment Agent certificate, which makes it possible for the agent to enroll for certificates on behalf of users.

The advantages of using an enrollment agent include:

- A highly trusted individual processes all certificate and smart card requests.
- Domain administrators can delegate a potentially time-consuming task.
- It simplifies the smart card setup process for users.

The disadvantages include:

- It is difficult to ensure that enrollment agents are trustworthy. One way to enhance this trust is to require approval from several enrollment agents.
- Users in remote locations might not be able to obtain new or replacement smart cards when and where they need them.

Enrollment agents are typically members of the security, IT security, or help desk teams because these individuals have already been trusted with safeguarding valuable resources. In some organizations, such as banks that have many branches, help desk and security workers might not be conveniently located to perform this task. In this case you might need to designate a branch manager or other trusted employee to act as an enrollment agent.

The number of enrollment agents you need depends on:

- The number and proximity of locations in your organization, especially if enrollment agents will be authenticating users in person.
- The number of smart cards that need to be prepared by the enrollment agent.
- The number of other duties that enrollment agents need to perform.

Select the individuals to whom you issue Enrollment Agent certificates carefully. These individuals can enroll for smart card certificates on behalf of any domain user, including an administrator. If these individuals are not trustworthy, they can compromise the security of your organization. To ensure the security of your organization, allow only a limited number of your most trusted employees to serve as enrollment agents.

If you decide to use enrollment agents, prevent unauthorized users from becoming enrollment agents by placing strict controls on the CA used to issue Enrollment Agent certificates. Establish a subordinate CA that is only used to issue Enrollment Agent certificates. After you issue the initial Enrollment Agent certificates, you can either disable certificate issuance or take the CA offline until you require additional enrollment certificates.

**Note**

- For information about delegating enrollment agent authority to individuals who are not domain administrators, see "Prepare a smart card certificate enrollment station" in Help and Support Center for Windows Server 2003.

**Pre-Enrolling User Smart Cards**

If you decide to pre-enroll users for smart card certificates, make sure that the enrollment agent has the blank smart cards as well as the following information:

- The CA selected to issue the smart card certificates to the user, if there are multiple CAs in the organization. If there is only one CA in the organization with smart card certificate templates enabled, that CA is automatically selected.
- The cryptographic service provider that matches the brand of smart card that is to be issued to the user.
- The name of the user to be enrolled. This user must have Enroll permissions for the Smart Card certificate template. A domain administrator can set this either for the individual or for a group of users, such as Authenticated Users or Purchasing.
- The default PIN for the smart card, which is set by the card manufacturer.

  **Note**

  - You can create a script to force the user to change the PIN upon first use of the smart card.

Also, ensure that your enrollment agents review the certificates to verify that the information is correct before they distribute them to users.

**Using Self-Enrollment**

Although using enrollment agents requires more administrative time than allowing users to enroll themselves, the security benefits usually outweigh the overhead costs. However, using enrollment agents might not always be possible or necessary. For example, if it is unlikely that smart cards will be misused, or if the consequences of misuse are minimal, then you might use self-enrollment. In situations in which physical distribution is not possible, self-enrollment is the best alternative.

If you decide to use certificate self-enrollment, users can request a certificate from a Windows Server 2003 CA either manually or automatically. This request can be held pending administrator approval, if you decide that manual approval is required, or until the verification process is completed. Whichever option you choose, the certificate self-enrollment process installs the certificate automatically, or automatically renews the certificate on behalf of the user as soon as the certificate request is approved, based on the specifications in the certificate template.

# Educating Users About Establishing Issuance Processes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

User education is an important component of a smart card management plan. Ensure that users understand the purpose of the smart card deployment. Educate them about proper smart card handling and protection so that they can help the organization to meet its security goals. Emphasize that a smart card is a valuable resource that needs to be protected.

For example, be sure that users understand:

- The hardware and software that they need in order to use smart cards.
- How to install and use their smart cards and readers.
- How they can obtain their smart cards and smart card readers.
- What they need to do in order to configure their systems to use their smart cards.

  **Note**

  - Setup instructions are particularly important for traveling users, or for users who use remote access connections on their home computers.

- What to do if a smart card is lost or stolen.
- Who to call or contact for help and support.

In addition, provide the following guidelines to users:

- **Protect the external smart card chip**. If the chip becomes damaged (scratched, dented, and so forth) the reader might not be able to read the data on the chip.
- **Do not bend the card**. This can break critical internal components. It is risky, for example, to put a smart card in a back pocket, because the individual might sit on it and break its internal components.
- **Do not expose the smart card to temperature extremes**. Leaving a smart card on the dashboard of a car on a hot day can melt or warp the card and harm the chip. Cold temperatures can make the smart card brittle and easier to break.
- **Keep the smart card away from magnetic sources**. This includes credit cards and scanners at retail stores.

It is useful to have a printed version of this user training information available for distribution along with the smart card itself. If your organization also maintains an intranet, publish this information as an easy-to-locate Web page so that users can refer back to your instructions at a later date.

# Preparing a Smart Card Deployment Schedule

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Deploying smart cards to a large organization is a major undertaking, often involving thousands of employees. It is essential that you plan the deployment schedule so that your deployment is orderly, controlled, efficient, and secure. For example, you might stagger your deployment so that a defined number of users migrate each week. You can organize this by building or by organizational unit structure.

For a worksheet to assist you in documenting your smart card deployment schedule, see "Smart Card Deployment Schedule" (DSSSMC_5.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Smart Card Deployment Schedule" on the Web at http://www.microsoft.com/reskit).

Figure 16.7 shows an example of a completed Smart Card Deployment Schedule worksheet for an organization that deployed smart cards according to building.

**Figure 16.7 Example of a Smart Card Deployment Schedule Worksheet**

| Smart Card Deployment Schedule | | | | | |
|---|---|---|---|---|---|
| Prepared by | | | Date | | |
| Location | Deployment Dates | Number of Cards | Cards Prepared (Y/N) | Cards Distributed (Y/N) | Users Enrolled (Y/N) |
| Building 1 | 1/14 to 1/17 | 350 | Yes | Yes | Yes |
| Building 2 | 1/21 to 1/23 | 350 | Yes | No | No |
| Toronto | 1/28 to 1/30 | 425 | No | No | No |
| Edmonton | 2/4 to 2/6 | 300 | No | No | No |
| | | | | | |

In this example, smart card–enabled badges replace the existing building access badges. The plan is to have one member of the distribution team verify the credentials and status in the corporate database, while a second person deactivates the old physical access badge and activates the new smart card. The users receive the smart card, and a document that includes basic instructions, links for more information, an initial PIN, and a reminder that they need to change their PINs within eight hours.

For more information about preparing users for the smart card deployment, see "Educating Users About Establishing Issuance Processes" earlier in this chapter.

# Planning for Ongoing Smart Card Support

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is important to have all of the smart card management processes and policies in place before you distribute the smart cards to your users. Therefore, you need to create a plan for the ongoing use of and support for smart cards in your organization. When creating a smart card management plan, balance the level of security that you require against the need for ease of use and supportability. Figure 16.8 shows the steps for planning for ongoing smart card support.

**Figure 16.8 Planning for Ongoing Smart Card Support**

# Selecting Group Policy Settings to Manage Smart Card Use

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Several Group Policy settings are specific to smart card management. You can use these Group Policy settings to manage smart cards in your organization.

**Note**

- Other security policy settings, such as lockout policy or restricted logon times, can also impact smart card users if they use their cards for account logon.

**Smart card required for interactive logon**

When you set this policy on a user account, the user cannot log on to the account by using a password. They can only log on by using a smart card.

The advantage of using this policy setting is that it enforces strict security. However, if users are unable to log on by using conventional passwords, you must provide an alternate solution in the event that smart cards become unusable.

**Note**

- This policy setting applies to interactive and network logons only. It does not apply to remote access logons, which are managed by policy settings that are configured on the remote access server.

The **Smart card required for interactive logon** policy is not recommended for users who need to:

- Join a computer to a domain.
- Perform administrative tasks such as installing Active Directory on a member server.
- Configure a network connection for remote access.

If you choose not to use this security policy setting, users can revert to their standard network passwords if their smart cards are damaged or unavailable. However, this weakens security. In addition, users who use their passwords infrequently might forget them, and either write them down, or call the help desk for a password reset, increasing help desk costs to the organization.

**On smart card removal**

Users who walk away from computers that are running an active logon session create a security risk. To enforce the security of your system, it is best if users either log off or lock their computers when they leave. The **On smart card removal** policy allows you to force users to log off or lock their computers when they remove their smart cards.

**Note**

- If you select the forced logoff option, users need to make sure they have saved changes to documents and other files before they remove their smart cards. Otherwise, they lose any changes they have made.

Whether or not you set the **On smart card removal** policy depends on how your users interact with their computers. For example, this policy is a good choice if using computers in an open floor or kiosk environment. This policy might not be necessary when users have dedicated computers or exclusive use of multiple computers. You can use a password-protected screensaver or other means to lock the computers of these users.

**Note**

- The On smart card removal policy is a local computer policy that is administered on a per computer basis. Set the On smart card removal policy on a per user account basis, along with other domain security policy settings.

**Do not allow smart card device redirection**

Use the **Do not allow smart card device redirection** policy if you do not want to use smart cards in conjunction with Terminal Services sessions. Restrict this use of smart cards if you are concerned about the network resources required for Terminal Services sessions in your environment.

**Account lockout threshold**

Use the **Account lockout threshold** policy to disable accounts after a set number of failed logon attempts. An account that is locked out cannot be used until an administrator resets it, or until the account lockout duration expires. You can specify a value of between 1 and 999 failed logon attempts, or you can specify that the account is never locked out by setting the value to 0.

To thwart unauthorized attempts to use a smart card and PIN, establish account lockout thresholds to a low value, such as four or five attempts.

For more information about creating a strategy for unlocking smart cards, see "Defining Administrative and Support Processes" later in this chapter.

# Defining Administrative and Support Processes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Many smart card–related problems cannot be addressed by means of Group Policy. In some cases, such as with account lockout policy, Group Policy settings can create support issues for smart card users. You must create a support plan to address potential contingencies related to smart card use. Use the following steps to create your plan:

- Identify the person in your support organization who is authorized to perform security-related smart card administrative tasks, such as resetting PINs, distributing temporary smart cards, or enabling temporary passwords.
- Define and document your plan for escalating and resolving smart card logon problems.
- Define and document any special policies and procedures that you want to establish for specific types of employees, such as senior executives, support personnel, or traveling users.
- Define and document the processes for handling name changes.
- Define and document processes for handling changes in employee status, such as when employees change from contract to full-time employment, or from full-time to part-time employment.
- Define and document the level of smart card support that users can expect to receive outside of regular business hours.

**Creating a Plan for Forgotten Smart Cards**

Before you deploy smart cards, you must establish a contingency plan in the event that users forget their smart cards. You can choose to do one of the following:

- Allow users to maintain passwords that they use for interactive logons when their smart cards are not available. This is the simplest, but least secure option.
- Issue temporary smart cards with certificates that have short lifetimes, such as one day. This solution is useful if your organization has someone on site who is authorized to distribute alternate smart card credentials. However, if an authorized agent is unavailable when the user needs assistance, the user cannot access the network.
- Enable help desk or security personnel to issue users limited-time passwords that are valid for the day. This solution is helpful when no one at the location is authorized to distribute temporary or replacement smart cards, or when you need to provide assistance to traveling users. If you use this option, you must identify how the identity of the user can be validated. Make sure your plan requires the help desk or security administrator to reset the limited-time password after the allotted time has expired.

**Tip**

- When you issue temporary smart cards or passwords to users, you can place those users in a security group that is only able to access a subset of the network resources of your organization. In this way, they can perform their job tasks without compromising the security of your resources.

**Managing PINs**

Using smart cards in combination with PINs simplifies the credential management process for your network. However, you need to create a plan for use in the event that a PIN is forgotten or the account lockout policy causes contingencies related to PIN management. Specifically, you need to define:

- **How locked smart cards can be unlocked**. Decide whether you want the help desk to unlock smart cards or enable users to unlock their own smart cards.
- **How to enable the help desk to unlock locked smart cards**. If you determine that the help desk is responsible for

unlocking smart cards, you need to use some form of secret information to verify that the user is who he or she claims to be.For example, you could have every user complete a set of predefined questions and answers, which are then stored in a secure database. Help desk personnel cannot view the answers to questions. Instead they type in user-provided answers to the questions. The database reports back to the help desk staff member whether the answers match the predefined answers in the database.

**Tip**

- Allow users only one attempt to answer the questions correctly, so that an impersonator does not have multiple opportunities to guess the correct responses to the questions.

- **How to enable users to unlock their own smart cards**. You can enable users to unlock their own smart cards by using a secure Web page linked to a database. The user answers a list of personal questions, the correct answers to which are stored in the secure database. When users need to reset their PINs, they must answer the questions correctly. If they do so, they are allowed to reset their PINs.

  This solution does not require help desk support. However, it exposes the PIN reset user interface to a larger audience, which is a potential security risk. In addition, it requires the user to have Internet access, which might not be possible if the user's smart card is locked.

# Additional Resources for Smart Card Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

## Defining Administrative and Support Processes

These resources contain additional information and job aids related to this chapter.

**Related Information**

- The *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).
- "Connecting Remote Sites" in *Deploying Network Services* in the *Windows Server 2003 Deployment Kit*.
- "Hosting Applications with Terminal Server" in *Planning Server Deployments* in this kit.
- The Microsoft Platform SDK link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Related Help Topics**

For best results in identifying Help topics by title, in Help and Support Center, under the **Search** box, click **Set search options**. Under **Help Topics**, select the **Search in title only** checkbox.

- "Certificate Templates" in Help and Support Center for Windows Server 2003 for information about how to configure certificate templates.
- "Prepare a smart card certificate enrollment station" in Help and Support Center for Windows Server 2003 for information about delegating enrollment agent authority to individuals who are not domain administrators.

**Related Job Aids**

# Planning, Testing, and Piloting Deployment Projects

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Welcome to *Planning, Testing, and Piloting Deployment Projects* of the *Microsoft Windows Server 2003 Deployment Kit*.

This book provides guidelines for planning, testing, and piloting the deployment of Windows Server 2003 and Windows XP Professional operating systems in medium and large organizations. IT professionals can use this book to create a comprehensive project plan, which serves as a framework for designing and deploying complex technologies and operating system features.

A key component of this book is a roadmap that summarizes each of the chapters in the *Windows Server 2003 Deployment Kit*. The roadmap can be used to match business solutions with the design guidelines discussed in the kit. In addition, because testing and piloting are critical tasks in any deployment project, this book contains guidelines for designing and setting up a test lab, testing applications and resolving application compatibility issues, and designing and implementing a pilot project.

This book contains the following chapters:

Planning for Deployment

Designing a Test Environment

Planning and Testing for Application Deployment

Designing a Pilot Project

# Planning for Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To deploy the Microsoft® Windows® Server 2003 operating system, you need a detailed plan that describes how to move from the current state of your IT infrastructure to the new state. To develop a deployment plan, you need to choose a planning framework, establish clear goals and objectives, assess your current environment, create functional designs, and test your deployment in a pilot. The plan you develop and the documents associated with it provide the foundation for your deployment.

**In This Chapter**

Overview of the Deployment Planning Process

Choosing a Deployment Planning Framework

Defining Project Scope and Objectives

Assessing the Current Environment

Creating and Testing Functional Designs

Testing and Conducting the Pilot

Rolling Out the Deployment

Additional Resources for Planning for Deployment

**Related Information**

- For more information about setting up a test lab, see "Designing a Test Environment" in this book.
- For more information about testing to ensure that your applications are compatible with Windows Server 2003, see "Planning and Testing for Application Deployment" in this book.
- For more information about conducting a pilot project, see "Designing a Pilot Project" in this book.

# Overview of the Deployment Planning Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Microsoft Windows Server 2003 can provide your organization a reliable, secure, and scalable platform for applications and network services. Windows Server 2003 takes the best of the Microsoft® Windows® 2000 Server operating system technology and makes it easier to deploy, manage, and use. The form your organization's deployment will take is influenced by your organization's size, capabilities, and goals.

Begin the deployment process by forming a deployment team and uniting them behind a single vision. Define the roles on your deployment team, and choose the personnel to perform those roles. Choose a deployment planning methodology, or framework, to organize your team and the tasks required to deploy Windows Server 2003. After assessing your business needs and the way that Windows Server 2003 can help you meet those needs, your team can identify the objectives and scope of the deployment. Next, conduct an inventory of your organization's hardware, software, and network infrastructure to assess the changes you will need to make to deploy the new operating system. Then, using the information contained in this kit, develop functional designs for each component of the deployment. Complete the planning process by developing plans for testing, piloting, and deploying Windows Server 2003.

Many organizations that plan to deploy Windows Server 2003 also plan to deploy Microsoft® Windows® XP Professional operating system on client computers. Throughout this kit, when a task requires Windows XP Professional, information about deploying that operating system is included with the task.

# Choosing a Deployment Planning Framework

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Deploying a large-scale IT project, such as Windows Server 2003, can be a daunting prospect. In fact, many IT deployment projects are not completed on time and within budget, and often the deployment does not include all of the features initially specified.

The failure of an IT deployment to meet its goals generally can be attributed to one or more of the following problems:

- **Disparity between goal and function.** Often, IT projects are viewed by an organization exclusively in terms of the functions and features they provide, not in terms of the business goals that those functions and features can help the organization achieve.

- **Lack of a common language between business and technical groups.** An IT group must understand the organization's business problems and needs in order to assess how a proposed solution can solve those problems and meet those needs. Establishing good communication between business and IT groups ensures that the deployment meets the organization's needs.

- **Inflexible processes.** In large, complex projects, changes are inevitable. Rigid rules and practices prevent a team from responding when circumstances change.

- **Complexity in the technical environment.** Increased reliance on servers and Web-distributed applications demands greater collaboration and cooperation within the IT department to assure interoperability and reliable operations. Within highly structured organizations, creative problem-solving is both challenging and vital.

- **Resource constraints.** Staffing a deployment team can be difficult because the demand for highly qualified IT personnel is always high. Often, budgets for new project development are constrained.

To avoid or mitigate these pitfalls, your organization can employ an IT deployment planning methodology. If your organization already uses a deployment methodology, you can use it to deploy Windows Server 2003. If you have not used a deployment planning methodology, you might want to consider using the Microsoft Solutions Framework (MSF), upon which the deployment of Windows Server 2003 has been based, as described in this kit.

MSF is an IT deployment planning methodology that was developed by Microsoft Consulting Services in conjunction with Microsoft business groups, Microsoft partners, and other industry sources. MSF provides the principles, models, and disciplines for managing the people, processes, and technology elements of an IT deployment, such as the deployment of Windows Server 2003.

Two business models form the foundation of MSF:

- The MSF team model, which ensures that all project goals are met by linking each team role, or area of expertise, with a major project responsibility

- The MSF process model, which organizes the process of creating and deploying an IT project by dividing it into distinct phases marked by milestones

# MSF Team Model Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Identifying the individuals with the right mix of technical and project management skills for deploying Windows Server 2003 is one of the first decisions that you will make. Even before staffing can begin, however, you need to identify the team roles, or areas of expertise, required for an IT project.

The MSF team model is based on six interdependent, multidisciplinary roles: product management, program management, development, testing, user experience, and release management.

**Product management** Product management is responsible for identifying the organization's business needs and the needs of the end users, and for making sure those needs are met.

**Program management** The program management team's goal is to deliver Windows Server 2003 within project constraints. The team is responsible for managing the project schedule and budget, and for reporting project status, managing risk factors, and managing the functional design of the deployment.

**Development** The development team builds the Windows Server 2003 implementation according to specification. The team's responsibilities include specifying the features of the Windows Server 2003 physical design, estimating the time and effort required to develop each feature, and preparing the product for deployment.

**Testing** The testing team ensures that Windows Server 2003 is released into the production environment only after all quality issues have been identified and resolved. The team's responsibilities include developing the testing strategy, designing and building the test lab, developing the test plan, and conducting tests.

**User experience** The user experience team ensures that Windows Server 2003 meets the users' needs. The team gathers, analyzes, and prioritizes user requirements and develops user training.

**Release management** The release management team is responsible for deploying Windows Server 2003. By designing and managing a pilot deployment of Windows Server 2003, the release management team ensures that Windows Server 2003 is sufficiently stable for deployment into the production environment.

The MSF team roles are flexible; they can be adapted to your organization's own processes and management philosophy. In a small organization or a limited deployment, one individual might play multiple roles. In larger organizations, a team might be required to perform all of the tasks assigned to each role.

For more information about the MSF team model, see the "MSF Team Model" white paper in the MSF Resource Library, which is available from the Microsoft Solutions Framework link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# MSF Process Model Overview

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The MSF process model divides the process of creating and deploying a solution, such as Windows Server 2003, into five distinct, timed phases, as illustrated in Figure 1.1.

**Figure 1.1 Microsoft Solutions Framework Phases**

Each of the five phases focuses on one major cluster of activities required to successfully deploy a solution, and each phase culminates in the completion of a major milestone:

- During the envisioning phase, the team identifies the high-level requirements and business goals of the project. Using this information, the team then develops the Vision/Scope document, which states the project goals and scope. This phase ends when the Vision/Scope document is approved.

- During the planning phase, the team identifies the Windows Server 2003 features that it will implement and decides how to implement them. In addition, the team develops a schedule. This phase ends when the master project plan is approved.

- During the developing phase, the appropriate teams develop and test the Windows Server 2003 code, infrastructure, and documentation. This phase ends when all of the components are complete.

- During the stabilizing phase, the appropriate teams test, stabilize, and prepare your organization's Windows Server 2003 implementation for release into your production environment. This phase ends when your organization's management approves Windows Server 2003 for release.

- During the deploying phase, the release team deploys Windows Server 2003 into your production environment.

For more information about the MSF process model, see the "MSF Process Model" white paper in the MSF Resource Library, which is available from the Microsoft Solutions Framework link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Defining Project Scope and Objectives

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Defining your deployment objectives helps you to determine which Windows Server 2003 features you need to implement and how those features relate to your existing environment. Defining the project's scope helps you to identify exactly what the team can and cannot deliver within the project constraints.

To identify your organization's objectives in deploying Windows Server 2003, consider the following questions:

- Why is your organization deploying Windows Server 2003?
- What business benefits will your organization derive from deploying Windows Server 2003?
- What IT benefits will your organization derive from deploying Windows Server 2003?
- How does your organization's current IT environment prevent you from meeting your organization's business needs?
- Who will be affected by the move from your current operating system to Windows Server 2003?
- What must the deployment accomplish to be deemed successful?
- To define the scope of the deployment, ask yourself what can reasonably be accomplished by this project and what cannot, given the time frame, your budget, and other resources.

For a list of Windows Server 2003 features, see the Windows Server 2003 Features link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Assessing the Current Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before your team can begin planning the deployment of Windows Server 2003, you need to assess your organization's current IT environment. Doing so helps you understand your organization's structure, so that you can create a deployment plan that addresses real business needs.

Document the hardware and software used in your organization by conducting an inventory. Then, document your network and your IT environment by drawing diagrams and work process flowcharts that represent infrastructure relationships and processes, such as the relationship between your network and Microsoft® Active Directory® directory services architecture. After you have collected all relevant data about your environment, include these diagrams and flowcharts in your deployment plan.

# Conducting Hardware and Software Inventories

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you deploy Windows Server 2003, you might need to upgrade the hardware and software used in your organization. Therefore, it is essential that you conduct comprehensive hardware and software inventories of all computers on your network before you begin planning your deployment.

You can use Microsoft® Systems Management Server (SMS) to conduct an inventory of the hardware and software on your network. For more information about SMS, see the Microsoft Systems Management Server link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

To obtain a hardware and software inventory from Microsoft® Windows® and Microsoft® Windows NT® operating system networks that use Windows Management Instrumentation (WMI), you can use scripts and a variety of third-party applications. For more information about scripting, see the at http://www.microsoft.com/reskit, or see the MSDN Scripting Clinic link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Conducting a Hardware Inventory

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For each computer in your organization, document the following:

- Location of the computer
- Number of processors it has and the speed of each processor
- Amount of RAM
- Available disk space
- Type of monitor
- BIOS settings
- Configurations for peripheral devices, such as printers, scanners, and input devices
- Driver version numbers and other software and firmware information

In addition, document every device that is connected to your network, including network adapters. Also note departmental and geographic differences in the types of hardware used within your organization.

# Conducting a Software Inventory

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Conduct a complete inventory of the applications that are used in your organization, including all custom (in-house) applications. Documenting the software installed on each computer will help you to identify the applications that will need to be reinstalled or upgraded after you have installed Windows Server 2003 or Windows XP Professional.

For each client and server computer in your organization, document the following:

- Applications that are installed
- Operating system that is installed
- Service packs that have been applied to the operating system
- Service packs that have been applied to applications
- Version numbers (or date and time-stamp data) of dynamic-link libraries (DLLs) associated with each application

Note whether each application is a standard desktop application, a line-of-business application, or a server-based application or service, as described in Table 1.1.

**Table 1.1 Application and Service Types**

| Application and Service Type | Description |
|---|---|
| Standard desktop | An application, such as Microsoft® Word or e-mail client software, that is required by a wide variety of users throughout the organization. |
| Line of business | An application that is more specialized and that is used only by specific departments, groups of users (such as developers), or geographic locations. Line-of-business applications can be developed internally or by third-party vendors. In your inventory, note where these applications are used within the organization. |
| Server–based application or service | These might include Microsoft® Internet Information Services (IIS), Microsoft® Exchange Server, database software, security services, or other services hosted on servers within your organization. |

Also note how important each application is to your organization by assigning it to one of the categories listed in Table 1.2.

**Table 1.2 Application and Service Categories**

| Category | Description |
|---|---|
| **Mission-critical** | An application or service that is essential to business operations. |
| **Tactical** | An application or service that is valuable to the business, but does not provide optimal benefit. |
| **Legacy** | An application or service that is still used by some groups or departments, but is nearing the end of its usefulness. Your plan should call for removing legacy applications before they become obsolete. |

| | |
|---|---|
| **Obsolete** | An application or service that provides no benefit to the business. Plan to remove obsolete applications as soon as possible because they can present interoperability problems that are not worth solving. |

For more information about conducting a software inventory, see "Planning and Testing for Application Deployment" in this book.

# Determining Hardware Requirements for Windows Server 2003

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you have a complete list of the hardware and supporting software used in your organization, compare the data you collected with the hardware requirements in Table 1.3 and Table 1.4 to determine whether your hardware is compatible with Windows Server 2003 and — where applicable — with Windows XP Professional. All of the client and server computers on which you plan to install these operating systems must be capable of supporting the installation.

**Important**

- When determining the minimum hardware requirements for your deployment project, account for all of the applications and services that computers in your organization use. Some applications might require faster processors or more RAM than Windows Server 2003 requires. When evaluating the published hardware requirements for your applications, account for the complete desktop and server configuration.

**Table 1.3 Windows Server 2003 Hardware Requirements**

| Windows Server 2003 Edition | Number of Processors | Processor Speed | RAM | Available Disk Space (for Setup) | Monitor |
|---|---|---|---|---|---|
| Web | 1–2 | 133 megahertz (MHz) minimum; 550 MHz recommended | 128 megabytes (MB) minimum; 256 MB recommended; 2 GB maximum | 1.5 gigabytes (GB) | Video Graphics Adapter (VGA) or higher; Super VGA (SVGA) (800 × 600) or higher recommended |
| Standard | 1–4 | 133 MHz minimum; 550 MHz recommended | 128 MB minimum; 256 MB recommended; 4 GB maximum | 1.5 GB | VGA or higher; SVGA (800 × 600) or higher recommended |
| Enterprise | 1–8 | 133 MHz minimum; 550 MHz recommended | 128 MB minimum; 256 MB recommended; 32 GB maximum | 1.5 GB | VGA or higher; SVGA (800 × 600) or higher recommended |
| Datacenter | 8–32 | 400 MHz minimum | 512 MB minimum; 64 GB maximum | 1.5 GB | VGA or higher; SVGA (800 × 600) or higher recommended |

**Note**

- Upgrade your organization's devices, remote access, and applications before deploying Windows Server 2003. For information about upgrading, see "Designing Unattended Installations" in *Automating and Customizing Installations* of this kit.

Table 1.4 lists the minimum and recommended hardware requirements for installing Windows XP Professional.

**Table 1.4 Windows XP Professional Hardware Requirements**

| Minimum Requirements | Recommended Requirements |
|---|---|
| Intel Pentium (or compatible) 233 MHz or higher processor | Intel Pentium II (or compatible) 300 MHz or higher processor |
| 64 MB of RAM | 128 MB (4 GB maximum) of RAM |

| | |
|---|---|
| 2 GB hard disk with 650 MB of free disk space (additional disk space required if installing over a network) | 2 GB of free disk space |
| VGA or higher video adapter | SVGA video adapter and Plug and Play monitor |
| Keyboard, mouse, or other pointing device | Keyboard, mouse, or other pointing device |
| CD-ROM or DVD-ROM drive (required for CD installations) | CD-ROM or DVD-ROM drive (12X or faster) |
| Network adapter (required for network installation) | Network adapter (required for network installation) |

# Assessing Your Network Infrastructure

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Assess your network infrastructure by identifying existing network protocols, network bandwidth, and network hardware, such as routers, switches, and firewalls. Be sure to assess topology, network size, type of network, and traffic patterns, in addition to the logical organization of your network, name-resolution and address-resolution methods, naming conventions, and network services in use. You must also include the location of network sites and the available bandwidth between sites: This information can help you choose an installation method.

After you have identified the primary features of your network, you can start documenting your network infrastructure. You can use Windows Server 2003 diagnostic applications, such as Network Monitor, to gather information about your network. Or, you can use troubleshooting and configuration software offered by OEMs or software vendors. Then, create physical and logical network diagrams using a product such as Microsoft® Visio® drawing and diagramming software.

The physical and logical network diagrams should include the following information:

- Physical communication links, including cables and the paths of analog and digital lines.
- Server names, IP addresses, and domain membership.
- Location of printers, hubs, switches, routers, bridges, proxy servers, and other network devices.
- Wide area network (WAN) communication links, their speed, and available bandwidth between sites. If you have slow or heavily used connections, it is important to note them.
- Physical network infrastructure.
- Addressing infrastructure.
- Naming infrastructure.
- Authentication infrastructure.
- Security infrastructure.
- Intranet infrastructure.
- Management infrastructure.

The logical network diagram should also include the following information:

- Domain architecture
- Server roles
- Trust relationships and any policy restrictions that might affect your deployment

In addition, you need to indicate where your Windows environment is connected to other networking environments, such as UNIX or Novell NetWare. Identify the tools that you use to maintain this connectivity, and determine whether they are supported under Windows Server 2003.

Finally, be sure to address network security measures in your assessment of the network. Include information about how you manage client authentication, user and group access to resources, and Internet security. Also include your firewall and proxy configurations.

For detailed information about planning your network infrastructure, see the related chapters in *Deploying Network Services* of

this kit.

# Assessing Your IT Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Document the following key components of your IT environment.

**Business organization and geographical requirements** Conduct a site analysis of each physical location in your organization. Document the number of physical locations, the geographic distribution of locations, and the speed and reliability of network connections between locations. For each location, record the number of client and server computers, the function of the client and server computers, and the availability of support staff.

**Information architecture** Diagram your key business processes to illustrate how the information needed to make critical decisions will be available when needed. For example, are sales and marketing personnel able to confirm precise delivery dates for customer orders?

**Administrative model** By examining your existing administrative model, you identify the administrative tasks that IT personnel perform in all areas of your organization. This helps determine whether you need to change any aspect of the administrative operations design to accommodate the Windows Server 2003 features that you want to deploy. This also will highlight opportunities for improving administrative efficiency and security in your organization.

**IT standards** Over time, the network and application standards in many organizations become fragmented or obsolete. This is common in organizations that have merged with or acquired other companies. Disparate systems, built over time, designed by different people, and often geographically separated, are a potential risk to a successful deployment. Audit your existing systems to identify problem areas.

**Active Directory design** If your organization is planning to upgrade Active Directory directory service, be sure to document your directory infrastructure. For information about upgrading Active Directory to meet your organization's growth and business needs see "Designing the Active Directory Logical Structure" in *Designing and Deploying Directory and Security Services* of this kit.

**Security architecture** Security issues, such as who has access to your network and to your databases and how your organization is protected from the Internet, are vital considerations in all aspects of your Windows Server 2003 deployment plan. For information about how to secure your Windows Server 2003 environment, see "Designing the Active Directory Logical Structure" and the security chapters in Part 2 of *Designing and Deploying Directory and Security Services* of this kit.

# Creating and Testing Functional Designs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The next step in the deployment planning process is creating the actual design, or functional specification, for the Windows Server 2003 features that you intend to implement in your organization. The process of creating the functional specification and testing your implementation of Windows Server 2003 begins in the MSF planning phase and continues through the developing and stabilizing phases.

In the functional specification, describe the operating system features that you will implement, and how they will be configured and deployed. Many features of Windows Server 2003 are interrelated, particularly for implementations that include Active Directory. For this reason, create a dependencies matrix by using the information provided in the tables in this section, and include it in your functional specification.

Also describe the different types of computer users in your organization, the key tasks they perform, how these tasks are currently performed, and how performance can be improved in the new network environment. If yours is a large organization with multiple sites, or an international organization, include geographical concerns in your functional specification.

Creating a functional specification is an iterative process. As you develop your functional specification, test your proposed implementation in your test lab. Testing your functional specification helps you determine the best way to use Windows Server 2003 features to meet your project objectives. For information about creating a test lab to test your deployment of Windows Server 2003, see "Designing a Test Environment" in this book.

The following tables describe the contents of each chapter in this kit. Use these tables to find the information that you need to create your functional specification and plan your deployment.

Each table contains the following information:

- Chapter title, along with a brief description of the topics addressed in the chapter.
- Prerequisites for reading the chapter. Prerequisites may include one or all of the following:
    - **Tasks**. Occasionally you must perform certain tasks before you design or implement the feature or technology described in the chapter. For example, most Windows Server 2003 deployments will include Active Directory and DNS. Organizations that also will deploy Remote Installation Services (RIS) will need to take RIS into account when creating their Active Directory and DNS designs.
    - **Reading**. Your network designers should consult other chapters in the kit before creating their functional specifications.
    - **Technical background**. Your network designers should understand certain technological concepts and issues before deploying the technology described in the chapter.

Table 1.5 and Table 1.6 describe the chapters in *Deploying Network Services*, which is divided into two parts.

**Table 1.5 "Part 1: Core Network Infrastructure"**

| Chapter | Prerequisites |
|---|---|

| | |
|---|---|
| Designing a TCP/IP Network<br><br>Describes how to design a TCP/IP infrastructure for a new environment or for an existing environment. Explains the fundamental design decisions that you need to make about your networking infrastructure, addressing such issues as routing, addressing, multicasting, security, and introducing IP version 6 (IPv6) in your IP version 4 (IPv4) network. | **Technical Background**<br><br>General knowledge of TCP/IP.<br><br>**Tasks**<br><br>Might require changes to your Internet Protocol security (IPSec) design.<br><br>**Reading**<br><br>"Deploying DHCP"<br><br>"Deploying Domain Name System (DNS)"<br><br>"Deploying WINS"<br><br>"Deploying IPSec"<br><br>"Designing the Active Directory Logical Structure" in *Designing and Deploying Directory and Security Services* |
| Deploying DHCP<br><br>Describes DHCP server design considerations, and explains how to integrate DHCP with other services, define and activate scopes for your DHCP clients, and implement your DHCP solution. | **Technical Background**<br><br>Familiarity with your organization's DNS and WINS design. |
| Deploying Domain Name System (DNS)<br><br>Describes planning and designing your DNS infrastructure (DNS namespace, DNS server placement, DNS zones, and DNS client configuration). Also explains how to plan the level of integration with Active Directory that you require and how to identify security, scalability, and performance requirements, which is a concern for those who are integrating DNS with Active Directory. | **Technical Background**<br><br>Familiarity with your organization's DHCP and WINS design.<br><br>**Tasks**<br><br>Might require changes to your organization's cross-forest trusts in your Active Directory installation.<br><br>**Reading**<br><br>"Designing the Active Directory Logical Structure" in *Designing and Deploying Directory and Security Services* |
| Deploying WINS<br><br>Describes how to develop a server strategy, design a replication strategy, secure your WINS solution, integrate WINS with other services, and implement your WINS solution. | **Technical Background**<br><br>Familiarity with your organization's DNS and DHCP design.<br><br>**Reading**<br><br>"Deploying DHCP"<br><br>"Deploying Domain Name System (DNS)" |

| | |
|---|---|
| Deploying ISA Server<br><br>Describes how to identify the most appropriate deployment mode (cache, firewall, or integrated) for your organization and how to integrate Microsoft Internet Security and Acceleration (ISA) Server with other components in your network. Other topics include security considerations and implementing your deployment design. | **Tasks**<br><br>You must deploy your network infrastructure first.<br><br>Might require simultaneously designing your remote access server deployment.<br><br>**Reading**<br><br>"Deploying Dial-up and VPN Remote Access Servers"<br><br>"Connecting Remote Sites" |
| Deploying IPSec<br><br>Describes the design decisions that you must make and the planning tasks you must perform to use Internet Protocol security (IPSec) for end-to-end secure networks. Topics include determining where and how you must secure computers on your network, and deciding which policy provides the security measures you require. | **Technical Background**<br><br>Familiarity with your organization's public key infrastructure (PKI) design and IP design.<br><br>**Tasks**<br><br>Usually requires deployment of Group Policy.<br><br>Might also require deployment of Active Directory.<br><br>**Reading**<br><br>"Designing a TCP/IP Network" |

**Table 1.6 "Part 2: Network Access Infrastructure"**

| Chapter | Prerequisites |
|---|---|
| Deploying Internet Authentication Service (IAS)<br><br>Describes how to decide what role Internet Authentication Service (IAS) should play in your network infrastructure, how to configure connection request and remote access policies that allow users to access the network, and how to secure and optimize the deployment of Windows Server 2003. | **Reading**<br><br>"Deploying Dial-up and VPN Remote Access Servers"<br><br>"Designing a Public Key Infrastructure" in *Designing and Deploying Directory and Security Services*<br><br>"Deploying a Wireless LAN" |
| Deploying Dial-up and VPN Remote Access Servers<br><br>Describes dial-up and virtual private network (VPN) remote access and helps you to decide which solution will best serve your organization. Also describes the network infrastructure needed to support your remote access server design. | **Reading**<br><br>"Designing a Public Key Infrastructure" in *Designing and Deploying Directory and Security Services*<br><br>"Deploying Internet Authentication Service (IAS)"<br><br>"Deploying ISA Server" |

| | |
|---|---|
| Deploying Remote Access Clients Using Connection Manager<br><br>Provides information about remote access clients and describes how to provide phone book support, how to implement Connection Manager, and how to customize Connection Manager for your organization using the Connection Manager Administration Kit (CMAK). | **Technical Background**<br><br>Familiarity with your organization's security practices, such as smart card usage.<br><br>**Tasks**<br><br>You must first deploy an authentication service, such as IAS, to enable authentication, authorization, and auditing.<br><br>**Reading**<br><br>"Deploying Dial-up and VPN Remote Access Servers"<br><br>"Deploying Internet Authentication Service (IAS)" |
| Connecting Remote Sites<br><br>Describes how to choose the remote site connection type and its configuration options, which security features to use, and how to integrate the remote site connection into your existing network infrastructure. Also describes how to deploy your remote site connection after all the design decisions have been made. | **Reading**<br><br>"Deploying Dial-up and VPN Remote Access Servers"<br><br>"Deploying a Public Key Infrastructure" and "Designing the Site Topology" in *Designing and Deploying Directory and Security Services* |
| Deploying a Wireless LAN<br><br>Describes how to design and deploy a secure, manageable wireless local area network (WLAN) in an enterprise environment. | **Tasks**<br><br>You must deploy your network infrastructure first. In addition, to provide authorization and authentication for wireless users, automatic IP address assignment, and name resolution, your networking infrastructure should include the following components and services:<br><br>• Active Directory<br><br>• Remote Authentication Dial-In User Service (RADIUS) servers and proxies<br><br>• A certificate infrastructure (also known as a public key infrastructure, or PKI)<br><br>• DHCP services<br><br>• DNS services |

Table 1.7 and Table 1.8 describe the chapters in Designing and Deploying Directory and Security Services, which is divided into two parts.

**Table 1.7 "Part 1: Designing and Deploying Directory Services"**

| Chapter | Prerequisites |
|---|---|
| Planning an Active Directory Deployment Project<br><br>Provides the planning information necessary to help you determine your Active Directory deployment strategy, which will vary depending on your existing network configuration. Also provides a roadmap of the rest of "Part 1: Designing and Deploying Directory Services" to help you identify your next steps in the Active Directory deployment process. | **Technical Background**<br><br>Familiarity with all applications in your organization that use Active Directory, such as Microsoft Exchange Server. |

| | |
|---|---|
| Designing the Active Directory Logical Structure<br><br>Provides detailed information on designing an Active Directory logical structure for organizations that have no Active Directory structure and for those that want to change their current Active Directory deployment. | None |
| Designing the Site Topology<br><br>Provides information on designing a site topology for your environment, including information on how to sufficiently route query and replication traffic in ways that minimize both cost and administrative effort. Also explains how to determine which locations require domain controllers and where you need to create sites, site links, and site link bridges. | **Reading**<br><br>"Designing the Active Directory Logical Structure" |
| Planning Domain Controller Capacity<br><br>Provides guidelines for planning domain controller hardware needs and placement in a Windows Server 2003 environment, with an emphasis on monitoring needs. | **Technical Background**<br><br>General knowledge of your organization's logical structure and site topology.<br><br>**Reading**<br><br>"Designing the Active Directory Logical Structure"<br><br>"Designing the Site Topology" |
| Enabling Advanced Windows Server 2003 Active Directory Features<br><br>Provides information about Active Directory functional levels and the features that are enabled at each functional level. Also describes the process for raising functional levels in a Windows Server 2003 environment. | **Reading** (especially for new deployments):<br><br>"Designing the Active Directory Logical Structure"<br><br>"Designing the Site Topology"<br><br>"Planning Domain Controller Capacity" |
| Deploying the Windows Server 2003 Forest Root Domain<br><br>Describes the process for deploying a forest root domain in an environment that has no Active Directory structure. Steps include reviewing the Active Directory designs created in preceding chapters and configuring DNS for the root domain. | **Reading**<br><br>"Designing the Active Directory Logical Structure"<br><br>"Designing the Site Topology"<br><br>"Planning Domain Controller Capacity"<br><br>"Enabling Advanced Windows Server 2003 Active Directory Features" |
| Deploying Windows Server 2003 Regional Domains<br><br>Describes the process for deploying Windows Server 2003 regional domains. Also includes steps for reviewing your regional domain design and for delegating the DNS domain for the new regional domain. | **Reading**<br><br>"Designing the Active Directory Logical Structure"<br><br>"Designing the Site Topology"<br><br>"Planning Domain Controller Capacity"<br><br>"Enabling Advanced Windows Server 2003 Active Directory Features"<br><br>"Deploying the Windows Server 2003 Forest Root Domain" |

| | |
|---|---|
| Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory<br><br>Provides detailed steps for upgrading from Windows NT 4.0 to an existing forest or to a single domain forest. Also describes tasks that need to be performed prior to and after upgrading. | **Reading**<br><br>"Deploying the Windows Server 2003 Forest Root Domain"<br><br>"Deploying Windows Server 2003 Regional Domains"<br><br>If you plan to upgrade some Windows NT 4.0 domains and restructure others, you also should read "Restructuring Windows NT 4.0 Domains to an Active Directory Forest" |
| Upgrading from Windows 2000 Domains to Windows Server 2003 Domains<br><br>Provides detailed steps for upgrading from Windows 2000. Also describes tasks that need to be performed prior to and after upgrading. | **Reading**<br><br>"Enabling Advanced Windows Server 2003 Active Directory Features"<br><br>If you plan to change your current Active Directory structure, also read "Designing the Active Directory Logical Structure" and "Designing the Site Topology" |
| Restructuring Windows NT 4.0 Domains to an Active Directory Forest<br><br>Describes how to complete the necessary planning and preparation tasks, and how to migrate Windows NT 4.0 Server accounts and resources to an Active Directory domain or domains using the Active Directory Migration Tool (ADMT v2). | **Reading**<br><br>"Deploying the Windows Server 2003 Forest Root Domain"<br><br>"Deploying Windows Server 2003 Regional Domains"<br><br>If you plan to upgrade some domains and restructure others, also read "Upgrading Windows NT 4.0 Domains to Windows Server 2003 Active Directory." |
| Restructuring Active Directory Domains Between Forests<br><br>Describes how to complete the necessary planning and preparation tasks, and how to migrate accounts and resources between Active Directory domains in two different forests using ADMT v2. | **Reading** (if you plan to change your existing Active Directory structure):<br><br>"Designing the Active Directory Logical Structure"<br><br>"Designing the Site Topology"<br><br>"Enabling Advanced Windows Server 2003 Active Directory Features"<br><br>"Designing and Deploying File Servers" in *Planning Server Deployments* (for potential issues related to File Replication service [FRS]) |

| | |
|---|---|
| Restructuring Active Directory Domains Within a Forest<br><br>Describes how to complete the necessary planning and preparation tasks, and how to migrate accounts and resources between Active Directory domains located in the same forest by using ADMT v2. | **Reading** (if you plan to change your existing Active Directory structure):<br><br>"Designing the Active Directory Logical Structure"<br><br>"Designing the Site Topology"<br><br>"Enabling Advanced Windows Server 2003 Active Directory Features"<br><br>"Designing and Deploying File Servers" in *Planning Server Deployments* (for potential issues related to FRS) |

**Table 1.8 "Part 2: Deploying Distributed Security Services"**

| Chapter | Prerequisites |
|---|---|
| Planning a Secure Environment<br><br>Provides an overview of the security-related solutions discussed throughout this kit. Introduces the components of a secure Windows Server 2003 environment, explains how to securely address user needs, and describes how to establish a secure common infrastructure. | None |
| Designing an Authentication Strategy<br><br>Describes how to create an authentication strategy that includes account management, authentication protocol selection, and configuration options. The strategy you devise enhances the security of the authentication process. | **Technical Background**<br><br>Familiarity with your organization's implementation of Microsoft® Outlook® messaging and collaboration client and Microsoft Exchange Server.<br><br>**Reading**<br><br>"Planning a Smart Card Deployment" (if you plan to use smart cards in your organization)<br><br>"Designing the Active Directory Logical Structure" |
| Designing a Resource Authorization Strategy<br><br>Provides background information on security groups and domain and forest functional levels. Also describes how to develop a strategy for using security groups to effectively manage access to resources, and how to delegate security group maintenance. | **Task**<br><br>You must deploy Active Directory first.<br><br>**Reading**<br><br>"Designing the Active Directory Logical Structure"<br><br>"Restructuring Windows NT 4.0 Domains to an Active Directory Forest"<br><br>"Deploying Windows Server 2003 Regional Domains" |
| Designing a Public Key Infrastructure<br><br>Describes how to create an infrastructure of certification authorities, for the purpose of issuing and managing certificates for a variety of purposes. Steps include defining your certificate requirements, creating a design for your infrastructure, creating a certificate management plan, and deploying your PKI solution. | **Task**<br><br>You must deploy Active Directory first, if your organization uses Active Directory. You do not need Active Directory to deploy a PKI; however, the capabilities of the Windows Server 2003 PKI are greatly enhanced by Active Directory. |

| | |
|---|---|
| Planning a Smart Card Deployment<br><br>Describes how to develop specifications and management protocols that make it possible to secure various user activities through the use of smart cards. | **Reading**<br><br>"Designing a Public Key Infrastructure"<br><br>"Deploying Remote Access Clients Using Connection Manager" in *Deploying Network Services*<br><br>"Designing an Authentication Strategy" |

Table 1.9 describes the contents of *Planning Server Deployments*.

**Table 1.9 Planning Server Deployments**

| Chapter | Prerequisites |
|---|---|
| Planning for Storage<br><br>Provides an overview of Windows Server 2003 storage solutions and discusses how to determine application and organizational storage requirements, and how to plan for storage scalability, storage area network (SAN) deployment, fault tolerance, and disaster recovery. | None |
| Designing and Deploying File Servers<br><br>Provides an overview of new file server features in Windows Server 2003 and discusses how to identify file service goals, design Distributed File System (DFS) namespaces, plan file server availability by using server clusters or File Replication service (FRS), design a standard file server configuration, and secure and deploy file servers. | **Task**<br><br>You must deploy Active Directory first.<br><br>**Reading**<br><br>"Designing and Deploying Server Clusters"<br><br>"Designing a Resource Authorization Strategy" in *Designing and Deploying Directory and Security Services* |
| Designing and Deploying Print Servers<br><br>Describes the processes for inventorying your current print environment, identifying and resolving client print driver compatibility issues, creating a standard print server hardware design, designing your new print environment, increasing your print server availability, and deploying Windows Server 2003 print servers. | **Task**<br><br>You must deploy Active Directory first.<br><br>**Reading**<br><br>"Designing and Deploying Server Clusters"<br><br>"Designing a Resource Authorization Strategy" in *Designing and Deploying Directory and Security Services* |
| Hosting Applications with Terminal Server<br><br>Describes how to create an application hosting plan, how to plan network and hardware resources for Terminal Server, and how to design user and domain configurations for Terminal Server. | **Task**<br><br>You must design your Windows Server 2003 domain infrastructure first. |

| | |
|---|---|
| Planning for Remote Server Management<br><br>Helps you determine which servers to manage and whether to manage them remotely or locally. Explains how to identify the appropriate tools to use for management. Describes the required supporting hardware components and configurations. Also discusses network and security considerations and remediation, and whether and how to deploy Windows Server 2003 remotely. | **Technical Background**<br><br>Knowledge of your organization's server configurations, such as server location and role.<br><br>Knowledge of the availability requirements for the servers you plan to manage remotely and who the administrators are. |
| Planning for High Availability and Scalability<br><br>Introduces IT practices and hardware solutions that can increase the availability of your Windows Server 2003 servers. Also introduces the two clustering technologies available in Windows Server 2003: server clusters and Network Load Balancing (NLB). | None |
| Designing and Deploying Server Clusters<br><br>Describes how to plan and deploy server clusters. Includes discussions of application analysis and deployment strategies, failover strategies, network configuration, data storage considerations, and security considerations. Also explains how to start planning geographically dispersed clusters. | **Reading**<br><br>"Planning for High Availability and Scalability"<br><br>"Designing and Deploying File Servers"<br><br>"Designing and Deploying Print Servers" |
| Designing Network Load Balancing<br><br>Describes how to create designs that include NLB clusters. Topics include how to determine the number of clusters required, how to determine the number of cluster hosts required, the use of virtual clusters, securing the administration of the cluster, scaling applications and services by using NLB, and improving the availability of services by using NLB. | **Reading**<br><br>"Planning for High Availability and Scalability" |
| Deploying Network Load Balancing<br><br>Describes how to deploy the design created in the previous chapter without affecting existing services. Includes information about how to install a new NLB cluster, upgrade an existing NLB cluster, or migrate an existing NLB cluster. | **Reading**<br><br>"Planning for High Availability and Scalability"<br><br>"Designing Network Load Balancing" |

Table 1.10 describes the content of *Designing a Managed Environment*.

**Table 1.10 Designing a Managed Environment**

| Chapter | Prerequisites |
|---|---|
| Planning a Managed Environment<br><br>Describes how to define the scope of your project, assess your current environment, determine your requirements for change and configuration management technologies, and design managed solutions. | None |

| | |
|---|---|
| Designing a Group Policy Infrastructure<br><br>Describes how to design your organizational unit (OU) structure, define the scope of the application of Group Policy, test your design, and deploy it. | **Reading**<br><br>"Planning a Managed Environment"<br><br>"Designing the Active Directory Logical Structure" in *Designing and Deploying Directory and Security Services* |
| Staging Group Policy Deployments<br><br>Describes the process for staging Group Policy, which includes creating a staging environment that mimics the production environment, testing new Group Policy settings, and deploying those settings in the production environment. | **Reading**<br><br>"Designing a Group Policy Infrastructure" |
| Deploying Security Policy<br><br>Provides specific instructions for using Group Policy to secure your managed environment. Includes information about how to assess potential security risks, how to analyze the consequences of security breaches and how to develop countermeasures for them, and how to plan a security strategy with Group Policy. | **Reading**<br><br>"Designing a Group Policy Infrastructure"<br><br>"Staging Group Policy Deployments"<br><br>All of the chapters in "Part 2: Deploying Distributed Security Services" in *Designing and Deploying Directory and Security Services* (see<br><br>Table 1.8) |
| Deploying Software Update Services<br><br>Describes using Software Update Services (SUS) to manage security updates for your clients and servers. Topics include how to design the SUS server configuration, how to deploy the SUS server component, and how to deploy the Automated Updates feature. | None |
| Migrating User State<br><br>Describes how to migrate user state, including identifying the best methods for collecting, storing, and restoring user state data and deciding which user data and settings should be migrated. Other topics include preparing a migration plan that addresses storage and security requirements; potential registry, drive, and domain changes; and training users. | None |
| Implementing User State Management<br><br>Describes how to use IntelliMirror® management technologies to ensure that a user's data, applications, and settings remain constant throughout the user's environment. This process includes defining your objectives for managing user data and settings, determining which IntelliMirror technologies meet the needs of your users and your organization, and testing your designs in a controlled environment. | **Reading**<br><br>"Planning a Managed Environment"<br><br>"Designing a Group Policy Infrastructure"<br><br>"Staging Group Policy Deployments" |

| | |
|---|---|
| Deploying a Managed Software Environment<br><br>Describes the process of deploying a managed software environment. Topics include how to prepare and deploy applications, how to migrate applications to a managed environment, and how to update, upgrade, and remove applications. | **Reading**<br><br>"Planning a Managed Environment"<br><br>"Designing a Group Policy Infrastructure"<br><br>"Staging Group Policy Deployments" |
| Deploying a Simple Managed Environment<br><br>Provides an end-to-end deployment scenario based on the information presented in this book. The scenario covers deploying your network infrastructure, preparing your logical infrastructure, creating shared folders, publishing software, configuring user data and settings, using RIS to deploy Windows XP Professional, testing your deployment, and backing up a domain controller. | **Reading**<br><br>All of the chapters in this book |

Table 1.11 describes the contents of *Deploying Internet Information Services (IIS) 6.0*.

**Table 1.11 Deploying Internet Information Services (IIS) 6.0**

| Chapter | Prerequisites |
|---|---|
| Overview of Deploying IIS 6.0<br><br>Describes the high-level processes for deploying IIS Web servers in your organization. | None |
| Deploying ASP.NET Applications in IIS 6.0<br><br>Describes how to deploy ASP.NET applications and individual application files to a Web server. | **Task**<br><br>You must first deploy Windows Server 2003 with the default options, and enable IIS 6.0 with the default settings. |
| Securing Web Sites and Applications<br><br>Describes how to configure IIS 6.0 to provide optimal security for Web sites and applications hosted on the Web server. Topics include reducing the attack surface of the Web server, preventing unauthorized access, and configuring user authentication. | **Task**<br><br>You must first deploy Windows Server 2003 with the default options, and enable IIS 6.0 with the default settings.<br><br>**Reading**<br><br>The other chapters in this kit that address security concerns |
| Ensuring Application Availability<br><br>Information in this chapter describes how to achieve high application availability by setting availability goals, how to configure IIS to achieve those goals, and how to test your applications to ensure that they perform to meet the availability goals you have set. | **Task**<br><br>You must first deploy Windows Server 2003 with the default options, and enable IIS 6.0 with the default settings.<br><br>**Reading**<br><br>"Securing Web Sites and Applications" |
| Upgrading an IIS Server to IIS 6.0<br><br>Describes how to upgrade existing Web servers running IIS 4.0 on Windows NT 4.0 and IIS 5.0 on Windows 2000 to IIS 6.0 on Windows Server 2003. Topics include how to prepare for the upgrade, how to perform the upgrade, and how to further customize the configuration of IIS 6.0 after performing the upgrade. | None |

| | |
|---|---|
| Migrating IIS Web Sites to IIS 6.0<br><br>Describes how to migrate Web sites and applications from existing Web servers running Internet Information Services (IIS) 4.0 or IIS 5.0 to a freshly installed Web server running IIS 6.0 and Windows Server 2003 manually or by using the IIS Migration Tool. Explains how to prepare for and perform the migration and how to further customize the configuration of IIS 6.0 after migration is complete. | **Reading**<br><br>The documentation for the IIS Migration Tool, which is installed with the tool. To find the documentation, on the **Start** menu, point to **All Programs**, point to **IIS Resources**, and then click **IIS 6.0 Tools Documentation**. |
| Migrating Apache Web Sites to IIS 6.0<br><br>Describes how to migrate Web sites from existing Web servers running Apache on Linux to a freshly installed Web server running IIS 6.0 and Windows Server 2003 by using the Apache to IIS 6.0 Migration Tool. | **Reading**<br><br>The documentation for the Apache to IIS 6.0 Migration Tool, which is installed with the tool. To find the documentation, on the **Start** menu, point to **All Programs**, point to **IIS Resources**, and then click **IIS 6.0 Tools Documentation**. |

Table 1.12 describes the contents of Automating and Customizing Installations.

**Table 1.12 Automating and Customizing Installations**

| Chapter | Prerequisites |
|---|---|
| Choosing an Automated Installation Method<br><br>Provides guidelines for choosing which automated installation solution is best for a particular large-scale operating system rollout. Three automated installation solutions are evaluated: unattended installation, image-based installation with the System Preparation (Sysprep) tool, and Remote Installation Services (RIS) installation. | **Task**<br><br>You must first design your network, Active Directory, and servers (such as file servers, terminal servers, or print servers). |
| Designing Image-based Installations with Sysprep<br><br>Describes how to plan and design disk-imaging deployment solutions, including how to use Sysprep to perform large-scale operating system rollouts. Also explains how to assess your current environment, define disk image requirements, and design the overall deployment process. | **Task**<br><br>You must first design your network, Active Directory, and servers (such as file servers, terminal servers, or print servers). |
| Designing Unattended Installations<br><br>Describes how to plan and design unattended installation solutions for large-scale operating system rollouts. Explains how to perform unattended clean installations from CD or from a distribution folder, and how to perform unattended upgrade installations. Also describes how to assess your current environment, decide whether to upgrade or to perform clean installations, and design the overall deployment process. | **Task**<br><br>You must first design your network, Active Directory, and servers (such as file servers, terminal servers, or print servers). |
| Designing RIS Installations<br><br>Describes how to plan and design RIS deployment solutions for large-scale operating system rollouts. RIS solutions that are image-based (Riprep solutions) and solutions that are distribution-folder-based (Risetup solutions) are both discussed. | **Task**<br><br>You must first design your network, Active Directory, and servers (such as file servers, terminal servers, or print servers).<br><br>**Reading**<br><br>"Deploying DHCP" in *Deploying Network Services* |

| | |
|---|---|
| Migrating User State<br><br>Describes how to migrate user state, including identifying the best methods for collecting, storing, and restoring user state data and deciding which user data and settings to migrate. Other topics include preparing a migration plan that addresses storage and security requirements; identifying potential registry, drive, and domain changes; and educating users. | None |

# Testing and Conducting the Pilot

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In the early phases of the project, you test the components of your Windows Server 2003 implementation to validate your design, as described in the functional specification. Later, you will test the interoperability of components to ensure that all of the elements of the implementation work together, and you will ensure that all the applications used in your organization are compatible with Windows Server 2003.

After verifying your Windows Server 2003 implementation in your test lab, conduct at least one pilot deployment before deploying the operating system into your production environment. In a pilot, you deploy a limited number of computers in a controlled environment, evaluate the results, and fix problems. Deploy successive pilots until you determine that Windows Server 2003 is ready for full deployment.

In addition to testing your implementation of Windows Server 2003, conducting a pilot provides an opportunity to test your deployment plan and the deployment processes. It helps you to determine how much time is required to install Windows Server 2003, and the personnel and tools needed to do so. It also provides an opportunity to train support staff and to gauge user reaction to the new operating system, so that you can anticipate support needs.

After your pilot is stable, meet with management to assess the functionality of the new Windows Server 2003 infrastructure and to receive approval to continue with deployment.

For more information about testing your Windows Server 2003 deployment plan, see "Designing a Test Environment" in this book. For more information about conducting a pilot, see "Designing a Pilot Project" in this book. For more information about testing the compatibility of your applications with Windows XP Professional and Windows Server 2003, see "Planning and Testing for Application Deployment" in this book.

# Rolling Out the Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After testing your implementation in the lab and conducting a pilot program to refine your plan and further test your implementation, you are ready to deploy Windows Server 2003 throughout your enterprise. For some organizations, the initial pilot project is the first phase of the rollout. Others remove their pilot project installations and start their production rollout with clean installations. During the production rollout, testing and support activities remain important while iterative cycles of deployment, testing, validation, and support become the primary focus.

After Windows Server 2003 has been rolled out, responsibility for maintaining the new operating system infrastructure is formally turned over to the operations and support groups. At this point, you might want to develop a project closeout report, which includes final versions of all major project deliverables, sign-off by the team and management, and a summary of the next steps that need to be taken.

You might also decide to conduct a project review. Use the project review to objectively assess the strengths and weaknesses of your entire project and to analyze how you could improve future infrastructure deployments.

# Additional Resources for Planning for Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

# Designing a Test Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you deploy Microsoft® Windows® Server 2003 or Microsoft® Windows® XP Professional operating systems, even in a pilot, you need to test your proposed design in an environment that simulates and protects your production environment. It is critical to the success of your deployment to develop an environment specifically for testing. In this test environment, you can test hardware, operating systems, or applications designed to run together before introducing them into your production environment.

**In This Chapter**

Overview of Designing a Test Environment

Creating a Test Plan

Planning the Test Lab

Designing the Test Lab

Developing the Test Lab

Designing Test Cases

Conducting Tests

Using the Test Lab After Deployment

Additional Resources for Designing a Test Environment

**Related Information**

- For more information about planning application testing, see "Planning and Testing for Application Deployment" in this book.
- For more information about planning a pilot in your production environment, see "Designing a Pilot Project" in this book.

# Overview of Designing a Test Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A key factor in the success of your Windows Server 2003 or Windows XP Professional deployment project is thorough testing in a test environment that simulates your production environment as closely as possible. A *test environment* consists of a test lab or labs and includes test plans that detail what you will test and test cases that describe how you will test each component.

The test lab can be comprised of a single lab or of several labs, each of which supports testing without presenting risk to your production environment. In the test lab, members of the testing team can verify their deployment design assumptions, discover deployment problems, and improve their understanding of the Windows Server 2003 and Windows XP Professional technology. Such activities reduce the risk of errors occurring during deployment and minimize downtime in your production environment.

You might already have a lab that you use for testing, or maybe you hope to build a new test lab for your Windows Server 2003 deployment project. Regardless of your current situation, you need to think through and clearly define your goals for the test lab and its long-term purpose.

# Test Environment Design and Testing Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Many organizations divide their testing teams into two subteams: the design team and the deployment team. The testing design team is responsible for the first three phases of the testing process: creating a test plan, planning the test lab, and designing the test lab. The design team collects information that is vital to the deployment process, identifies immediate and long-term testing needs, proposes a test lab design, or recommends improvements to the existing test lab.

The testing deployment team completes the process by implementing the design team's decisions and performing tests. The deployment team's responsibilities include developing the test lab, designing test cases, conducting tests, and using the lab after deployment.

Figure 2.1 illustrates the process of designing a test environment.

**Figure 2.1 Designing a Test Environment and Conducting Tests**

# Using the Test Lab Throughout the Project Life Cycle

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A well-designed test lab provides a controlled environment for the full range of testing required throughout the project life cycle — from experimenting with the technology through fine-tuning the rollout process. Figure 2.2 lists some of the tasks that can be performed in the test lab and indicates the Microsoft Solution Framework (MSF) phases during which each of these activities might occur. The time frames are estimations and might vary from deployment to deployment.

**Figure 2.2 Role of the Test Lab in the Project Life Cycle**

# Setting Up a Preliminary Test Lab

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You need a preliminary test lab early in the project's planning phase for learning about the product, proving concepts, testing various scenarios against your business model, and validating solutions. During this phase, your project team can use the preliminary test lab to establish your basic namespace design and high-level deployment plan, which you can then use as a baseline for further testing and development. By using the preliminary test lab as a baseline configuration and then adding functionality in stages, you can avoid the problems that occur when component designs are developed independently of each other.

If you do not already have a lab, it is important to start building one as soon as possible. If you plan to build a permanent test lab, you might need to obtain management approval and funding that is independent of your deployment project. If so, start the approval process as early as possible.

You can build a preliminary test lab with just two or three servers and client computers. If your organization has a lab, you can set up and configure your computers there. If you do not have a lab, an office that will accommodate this minimal configuration will do.

After you have selected a site for the preliminary lab, start assessing hardware requirements, reconfiguring existing test lab equipment, and purchasing or recycling hardware for the lab as needed. Then, as you refine the lab design, start putting together the pieces for your formal test lab. As you make decisions regarding hardware, software, and personnel requirements for testing, be sure to document them in your test plan. For more information about the test plan, see "Creating a Test Plan" later in this chapter.

# Creating a Test Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Early in the deployment planning phase, the testing team creates a test plan. The *test plan* defines the objectives and scope of the testing effort, and identifies the methodology that your team will use to conduct tests. It also identifies the hardware, software, and tools required for testing and the features and functions that will be tested. A well-rounded test plan notes any risk factors that jeopardize testing and includes a testing schedule.

If your testing team is divided into technology subteams, each subteam should develop a test plan for that team's specific technology area. For example, the networking team would write a test plan for testing networking features. All members of each subteam should review and approve its team's test plan before it is integrated into the general test plan.

Figure 2.3 illustrates the tasks you must perform to create the test plan.

**Figure 2.3 Creating a Test Plan**

You will use the test plan to design your test lab and to develop test cases. For information about test cases, see "Designing Test Cases" later in this chapter.

# Defining Testing Scope and Objectives

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In the scope and objectives section of the test plan, the testing team describes specifically what you want your testing to accomplish. For example, the objective of one team was to migrate the Microsoft® Windows NT® Server 4.0 operating system environment to a Windows Server 2003 environment, component by component, keeping the access control lists (ACLs) and Exchange permissions intact. Another team's objective was to provide a means to measure network traffic and observe server performance during specific directory service tasks.

Also, you need to define the scope of your testing by identifying what you will test and what you will not. For example, you might limit your testing of client computer hardware to the minimum supported configurations or to the standard configurations.

# Defining Testing Methodology

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Describe the general methodology that your team will use for testing. For example, your approach to testing schema changes might be to configure an isolated domain in the test lab where schema changes can be applied without affecting other lab tests. This section of the test plan might address the following:

- The domain architecture used for testing
- The tools and techniques used to conduct the tests or to measure results
- Automated techniques you plan to use during testing

For information about methodologies for testing application compatibility, see "Planning and Testing for Application Deployment" in this book.

# Identifying Required Resources

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Identify the resources required for the test lab:

**Hardware** List the hardware that you need to conduct tests. For example, identify the standard configurations you plan to support for client computers. Include components such as video cards, modems, and external drives.

**Software** List the software that you need to test the compatibility of your applications with Windows Server 2003. For example, include Microsoft® Systems Management Server (SMS) or other server-based products that you need for testing. For more information about software required for application compatibility testing, see "Planning and Testing for Application Deployment" in this book.

**Databases** Include databases that you need to prepare for testing applications. Also include a description of the resources that you need to populate the databases, such as personnel and business data.

**Personnel** Identify the number of testers you need and the skill level required. Include consultants and other support personnel, as necessary.

**Training** Specify the Windows XP Professional or Windows Server 2003 training that your testers need to complete prior to testing their assigned applications or technologies.

**Tools** Include all tools or scripts that you need to automate testing and to track test results. For example, if you do not have a second test lab that you can use for testing wide area network (WAN) links, include link simulators. For more information about developing a test result tracking system, see "Developing an Incident-Tracking System" later in this chapter.

# Identifying the Features and Functions to Test

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

List all the features or aspects of features that need to be tested. This part of the test plan describes what to test, not how to test.

The following is an example of a feature test description:

- Test 1 — Trust retention

  Description: All trusts to and from a domain should be retained when the domain controllers are upgraded to Windows Server 2003. Use the Domain Tree Manager to view the trusts. If the trusts do not appear, then the test failed.

Note that the description does not include instructions on how to perform the test.

Include tests that verify or address:

- The functionality of each feature and service that you will implement.
- Interoperability with existing components and systems in the production environment, both during the phase-in period, when there is a mix of old functionality and new Windows Server 2003 functionality, and after the Windows Server 2003 environment has been rolled out.
- Hardware and driver compatibility for every type of client computer that will be running Windows XP Professional.
- Application compatibility for every application that will run on Windows XP Professional.
- Application compatibility for every server application that will run on Windows Server 2003.
- Optimization of configurations, such as those for standardized desktops on client computers.

For more information about planning for application compatibility testing, see "Planning and Testing for Application Deployment" in this book.

In addition, list:

- *Baselines* (a range of measurements derived from performance monitoring that represents acceptable performance under typical conditions) for performance monitoring.
- Baselines and stress tests for capacity planning.
- Procedures for deployment and post-deployment administration, such as procedures for upgrading a client computer and for backing out of a faulty rollout process.
- Required tools and utilities.

During the developing phase, the testing team will develop test cases that describe how to perform each test listed in the test plan. For more information about test cases, see "Designing Test Cases" later in this chapter.

# Identifying Risk Factors

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Describe the risk factors that could prevent the successful completion of all required tests. For example, you might find that the test lab is behind schedule, or that required hardware or software is unavailable, or that testers are working on other projects or need additional training. After you have identified the risk factors, decide what you will do to avoid or mitigate each risk.

# Establishing a Testing Schedule

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Draft a preliminary schedule that includes each test listed in the test plan. The schedule can help you coordinate test lab use among subteams. Assign a team member, ideally the test lab manager, if your team has one, to maintain and update the lab schedule. Having an up-to-date schedule is critical when unscheduled lab requests are submitted.

# Planning the Test Lab

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A *test lab* is a network that is designed for testing and that is isolated from the corporate network. In the test lab, you can verify that components and features work together in an integrated environment that simulates your target production environment. The simulated environment should reflect both the phase-in period, when you have a mix of functionality, and the end of the project, when you have completely implemented Windows Server 2003 and Windows XP Professional.

Begin the lab planning process by evaluating test lab models, and then select the appropriate site for your lab.

Figure 2.4 illustrates the activities you undertake when planning the test lab.

**Figure 2.4 Planning the Test Lab**

**Note**

- If you already have a permanent test lab that you plan to use for testing your Windows Server 2003 design, you can to go directly to "Designing the Test Lab" later in this chapter.

# Evaluating Test Lab Models

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As your team considers its test lab needs, you will need to make several basic decisions. Can you upgrade an existing lab or will you need to develop a new one? Will an ad hoc lab do, or can your organization afford to build a permanent lab? Will your organization be better served by a centralized lab or by several labs that are distributed across your organization's various sites?

Your team might determine that one type of lab fits your goals best, but circumstances might dictate establishing another type of lab. For example, you might see advantages to having a permanent test lab that you can use for testing software patches and upgrades, but realize that your organization does not have the budget to build and maintain a permanent lab. Although you need to weigh the possible outcomes of using the opposing model, you might come up with creative ways to support your ideal solution.

Ask yourself:

- How will the decision affect test quality?
- How will the decision affect team training and design support?
- Will the test lab also benefit other existing projects?
- Can other projects combine efforts and budgets to share a test lab?
- Can you build the test lab in stages, starting with the most essential components and then adding to it as the budget allows?
- Will hardware vendors agree to a special arrangement?

  For example, can the vendors provide equipment on loan before it is purchased, or will they give you the equipment in return for using your organization's name for marketing purposes?

# Upgrading an Existing Test Lab vs. Building a New Test Lab

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If your organization already has a test lab, your team should decide if the lab can be upgraded to meet your current and future testing needs. You might find that to accommodate Windows Server 2003 deployment testing you simply need to perform minor hardware and software upgrades. For example, you might need to upgrade your servers so that they all have the same amount of memory and hard disk capacity and use the same processor type and speed as the servers you plan to deploy.

If upgrading is not feasible, you will need to seek approval for creating a new test lab. To justify the investment to your project sponsors, take a broad view of the associated costs. Testing in a suitably equipped lab leads to cleaner implementations and reduced support costs. By using the test lab to develop operational efficiencies, such as automated administrative tools and remote installation procedures, you can reduce your organization's total cost of ownership. When viewed over time, therefore, the costs of building and maintaining a test lab dedicated to Windows Server 2003 deployment are likely to be dramatically lower than the costs of fixing problems in production, redeploying poorly developed or poorly tested solutions, or managing the production environment with resource-intensive processes.

In organizations that build separate test labs for different projects, economies of scale often can be realized by consolidating labs. This way, several projects can share in the reduced cost of a single test lab. If your team decides to share a lab, however, do so with a project that has compatible scheduling and equipment requirements.

# Ad Hoc Test Lab vs. Permanent Test Lab

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Many organizations build an ad hoc test lab every time they need test facilities for a new project. Other organizations build a permanent test lab that is scalable for various projects and, after the original project is deployed, use it for change management.

**Ad Hoc Test Lab**
An *ad hoc test lab* is set up for a specific project only. When the project is over, the equipment is redeployed for a different use. For example, lab equipment might be used in the production environment, become part of inventory, or be returned to the vendor from whom it was leased.

Because all the lab equipment is eventually redeployed for other uses, the short-term costs of creating and using ad hoc test labs might be a fraction of those for creating and running a permanent test lab. This view of cost is shortsighted, however, because a new test lab must be built for every project that requires one.

There are additional disadvantages of using ad hoc labs:

- When a new test lab is required for each new project, time becomes a critical factor. Because teams need the test lab early in a project, issues such as the following arise:
    - Can you obtain the appropriate hardware and software licenses in time?
    - Will hardware or software substitutions lead to inadequate testing?
    - Can you locate the representative equipment from each vendor, including the exact models and versions, needed to adequately test the production mix of hardware and software?
    - Can you reserve the physical space needed for building the network configuration and performing the tests?
    - Will the time spent building and debugging the test lab reduce the time available for actual testing, possibly resulting in incomplete testing?
- When many teams are searching for hardware and software licenses, it becomes difficult to track who is using what and who authorizes purchases. The resulting lack of accountability can lead to excess expenditures and increased costs.

If you have an ad hoc test lab and have adequate space and funding, consider converting it to a permanent test lab. You might be able to reduce your team's cost for creating a permanent lab by seeking funding from other groups that would benefit from having a dedicated test lab.

**Permanent Test Lab**
The problems associated with creating and using an ad hoc test lab present compelling reasons for building a permanent, formalized lab. A permanent lab has the additional advantage of providing a place to test changes to your production environment after you have deployed Windows Server 2003 or Windows XP Professional, and, as such, it becomes a change management tool. After deployment, your organization could use the lab to test:

- Network upgrades.
- Service pack additions and software patches.
- New business applications that might pose compatibility problems.
- New desktop configurations.
- New hardware platforms.

- New administrative and support processes.
- New client computer management tools.

A fully equipped, permanent test lab that is used for change management:

- Helps keep the test lab adequately equipped.

  By maintaining a permanent lab and using it for change management, your organization might be able to justify the purchase of equipment you need for specific testing requirements. You are also more likely to maintain the mix of equipment that accurately reflects your production environment when you have a permanent lab. Maintaining the proper mix of equipment in the test lab allows thorough regression testing during the change management process.

- Reduces risk to your business.

  Solid testing in a lab that mimics the production environment leads to cleaner implementations.

- Saves time for the project.

  Setup and debugging time are minimized because a lab can be upgraded faster than a new lab can be assembled. The time saving is critical if your lab will be used for ongoing developmental prototyping or for general development.

- Helps establish consistent methodologies.

  With a permanent test lab and continuity in lab management, your team can establish testing processes and techniques that produce consistent results, which can be compared over time.

- Saves costs in the long run.

  When viewed across projects, the cost of a permanent test lab is likely to be more reasonable than that of an ad hoc test lab for which purchases are not tracked or financial accountability is diluted.

# Centralized Test Lab vs. Distributed Test Lab

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A test lab can be centralized in one location or distributed across numerous physical, or even geographical, locations.

**Centralized Test Lab**
A *centralized test lab* is located in one site. Consolidating all lab resources allows you to develop a more complex and complete lab. Configuring and managing a centralized lab is also easier. However, if your organization is decentralized and you choose to establish a centralized test lab, testers from other areas or regions will need to travel to the lab to perform tests, which is not always practical or cost effective.

If you choose to create a centralized test lab, you might decide to develop several independent, labs within your site for different testing purposes. For example, you might build one test lab for network infrastructure and server testing and another test lab for client computer and application testing. Or, you might have a network infrastructure test lab with multiple locations connected by a WAN for testing the effects of using various link speeds.

If you are deploying Windows Server 2003 and Windows XP Professional at the same time, many factors will influence your decision about whether to develop separate test labs for each or a shared lab. Factors include:

- The complexity of your deployment (such as the need to make changes in your production environment and the new features you plan to implement).
- The size, location, and structure of your project teams.
- The size of your budget.
- The availability of physical space.
- The location of testers.
- The planned use of the test lab(s) after deployment.

**Distributed Test Lab**
A *distributed test lab* consists of several individual labs. Often, the labs are located near the testing team or application developers; because of this proximity to development and testing, more resources are available to address problems that arise during testing. Some organizations distribute their labs across their various business or functional sites, which allows testing to be performed on location. The disadvantage of the distributed lab model is that the cost of maintaining multiple test labs can be substantial.

The following case studies describe two organizations that have chosen to build distributed test labs and how they use them.

**Case study 1: Functional test lab sites**
A large, high-technology hardware manufacturer is organized along functional lines. Its regional offices are located at various geographical sites, selected for proximity to the suppliers and vendors who support each region's particular function. This manufacturer developed a distributed test lab that spans three of its major United States sites, ranging across Southwestern and Western states. Each lab is designed to test the functions and configurations used for that site's business. Each one is a permanent lab that is used for managing change in the production environment.

Eventually the organization plans to expand the test lab to encompass international locations, such as cities in Asia, the Middle East, Eastern Europe, and the United Kingdom. The organization will use these remote sites to design and test factors or solutions for the challenges of operating a global enterprise, such as:

- Connectivity in controlled countries/regions.
- Slow links.
- Intermittent links.

- Multiple languages.
- Multiple time zones.
- International currencies.
- Variations in computer and networking hardware.

**Case study 2: Contingency test lab sites**

A large financial lending organization needs to be prepared in case of a disaster. This organization wants each of its geographically separated sites to be ready to function in the role of a centralized IT department, if necessary. In this organization, each test lab is a permanent change management lab that is also used for disaster-recovery testing.

In the event of a disaster, production computers at the alternative sites would be used to perform IT department functions. To maintain a state of readiness, the organization performs tests in each lab to ensure that all the needed hardware and software components are available and function properly at all the sites. Processes that are tested include:

- Loading applications and databases.
- Setting configurations.
- Running applications.

# Selecting a Test Lab Location

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

our decisions about the type of test lab your organization needs and its location are likely to be interrelated. The location of a permanent test lab to be used by a wide variety of groups requires more consideration than the location of an ad hoc lab to be used by a few groups. And, if you plan to use the lab long term for change management, room for growth will be an important issue. As you weigh all available options, consider the following:

- What test lab facilities already exist? How adequate are they? How easily can you modify them to fit test requirements?
- Can you consolidate existing test labs?
- What is the scale and complexity of the implementation?
- Does the test lab need to connect to the production network or to other test labs? If it needs to connect to the production network, how will you regulate the connection and configure routers to protect the production network?

  For more information about connecting the test lab to the production network, see "Simulating the Proposed Server Environment" later in this chapter.

Additional issues to consider when selecting a test lab location or locations include how much space and how many sites you need and whether the sites are accessible, secure, and appropriate for housing valuable testing equipment.

**Space** The complexity of your organization's production environment influences the complexity of the test lab and, therefore, its space requirements. Factors in your current and proposed production environment that can determine the complexity — and, therefore, the space requirements — of your test lab include:

- The number and combination of functions and features that you plan to implement.
- Whether you plan to implement a domain that spans multiple sites.
- Whether you plan to implement a virtual private network (VPN).
- The amount of variability in your production environment.
- Whether you have — and plan to deploy — standard equipment, applications, and configurations in your production environment or whether you will use equipment from several vendors or several models, versions, and configurations.
- The level of complexity in your network configuration.
- Whether you have more than one type of topology in your production network. For example, do you plan to have interfaces between Windows Server 2003 and mainframe, Macintosh, UNIX, or Linux systems?

In addition to factors in your production environment, some test situations also can affect the complexity of your test lab. For example, you might want additional servers so that you can isolate certain types of testing. For more information about isolating tests, see "Designing Domains for Testing" later in this chapter.

Space requirements also influence the number of people that are able to participate in testing. Consider how many testers you need to accommodate at one time, and configure the test lab accordingly.

**Number of locations** Your test lab might need to consist of multiple interconnected locations so that you can test the effect of geographically separated network segments. For example, if you plan to implement Microsoft® Active Directory® directory service with multiple Active Directory sites, you might want to test replication over a WAN or Internet connection similar to your production environment. For more information about Active Directory sites and replication, see "Designing the Site Topology" in *Designing and Deploying Directory and Security Services* of this kit.

In other cases, you might want to maintain multiple independent test labs for different uses. For example, you might want a separate test lab for application testing or perhaps separate test labs for Windows Server 2003 and Windows XP Professional testing.

**Accessibility** The test lab should be accessible to all of the groups using it. If you implement a program in which people from outside the project team come to test their own applications, the test lab should have facilities, such as parking, to accommodate visitors.

**Security** Ensure that you can physically secure the test lab to protect your equipment from unauthorized use. You can restrict access to your test lab by installing a keypad that requires a Personal Identification Number (PIN) or a smart card reader.

**Environmental conditions** Any site you consider for your test lab should be clean and should be able to maintain temperature and humidity levels appropriate for your team and your valuable equipment. The lab site also should be able to accommodate your power, cabling, and network connectivity requirements.

# Designing the Test Lab

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The lab planning process includes documenting the proposed test lab configuration. To design a lab that mimics your future production environment, you will need to simulate the proposed server and client environments as closely as possible. You also need to design domains for testing.

Figure 2.5 illustrates the test lab design process.

**Figure 2.5 Designing the Test Lab**

# Gathering Information About the Current and Proposed Environments

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you begin designing your test lab, you need to gather detailed information about both your current and proposed environments.

For your current environment, you need:

- The network design (logical and physical).
- An inventory of existing hardware (servers, client computers, and portable computers).

You can use the hardware inventory that you conducted to assess your current IT environment, as described in "Planning for Deployment" in this book. Or, you can use SMS to collect this information.

For your proposed environment, you need to compile the following from the master project plan:

- The proposed Windows Server 2003 design.
- A list of features to evaluate and explore.
- A list of hardware required for use with Windows Server 2003. Though this list might evolve during testing, you need a fairly complete list to equip the lab initially.
- A list of administrative tools required (Windows Server 2003, third-party, and custom built).
- A list of the upgrades, such as service packs, drivers, and BIOSs, that you need to install to be ready for a Windows Server 2003 deployment.

You also will need a high-level understanding of the Windows Server 2003 features and functions that you intend to include in your proposed design.

# Documenting the Test Lab Configuration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Design the test lab in a way that allows you to test as much of the proposed logical and physical production environment as possible, including computer hardware, network topology, WAN connections, domain architecture, services, databases, business applications, administrative tools, security model, application deployment methodology, and network server storage methods.

Design the client computer portion of the test lab so that you can test the same functions and features that you currently use and that you plan to use in your production environment. Include the same types of hardware, applications, and network configurations.

As you design the test lab, document it with both a text description and a diagram. Post the diagram in the lab to provide easy access to lab information and to keep lab users up-to-date on design changes.

For additional information about components that you might need to include in your test lab to fully test Windows Server 2003 and Windows XP Professional, see "Simulating the Proposed Server Environment" "Simulating the Proposed Client Computer Environment" and "Designing Domains for Testing" later in this chapter.

# Test Lab Description

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Include information about the following in your test lab description:

- The domain structure, including:
  - DNS structure
  - The forest and tree hierarchy
  - Group Policy objects (settings and where they apply)
  - The method you will use to populate user account data
  - The site layout
  - Trust relationships (transitive and explicit)

  For more information about domain structure considerations for testing Windows Server 2003, see "Simulating the Proposed Server Environment" and "Simulating the Proposed Client Computer Environment" later in this chapter.

- Domain controllers, including:
  - Primary domain controllers (PDCs) and backup domain controllers (BDCs), if you are migrating from Windows NT Server 4.0
  - Servers to be promoted to domain controllers, if you are migrating from any other operating system
  - Replication topology
  - Global catalog layout
- Member servers, including the services that will run on them. Examples of services include:
  - DHCP topology
  - WINS topology
- Client computers, including:
  - Computer make and model
  - Amount of memory
  - Processor type and speed
  - Hard disk capacity
  - Graphics cards (type, resolution, and color depth)
  - Network adapter (model and speed)

- Wireless network adapter

For more information about client computer configurations for testing Windows Server 2003, see "Simulating the Proposed Client Computer Environment" later in this chapter.

- Requirements for specific tests, including:

  - Side-by-side testing (tests performed on identical computers, one running the current operating system and one running the new operating system)
  - Mixed-mode testing (tests performed while migrating or transitioning from one domain to another)
  - Native-mode testing (tests performed while maintaining your existing domain structure)
  - Functional level testing (tests performed at levels of domain and forest functionality)
  - Dial-up and other remote testing
  - Interoperability testing (with UNIX, Linux, mainframes, and other operating systems)
  - Replication and Active Directory site testing
  - WAN link testing

For more information about Active Directory functional levels, see the *Active Directory Collection* of the *Windows Server 2003 Technical Reference* (or see the Active Directory Collection on the Web at http://www.microsoft.com/reskit).

# Test Lab Diagrams

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The test lab diagram should show both the logical and the physical structure of the lab. Depending on the complexity of your test lab network, the logical and physical diagrams can be combined into one diagram or they can remain separate.

**Logical Diagram**

Document the following in the logical diagram:

- The domain hierarchy, including forests and trees. For more information about domain structure considerations for testing Windows Server 2003, see "Simulating the Proposed Server Environment" and "Designing Domains for Testing" later in this chapter.
- Domain names.
- Active Directory sites.
- Special service servers (domain controllers, global catalog servers, DNS servers, DHCP servers, and WINS servers). For each server, include the following information:
  - Computer name
  - IP address
  - Server function
- Transitive trusts.
- Explicit or one-way trusts.

Figure 2.6 is an example of a logical diagram of a test lab. This test lab has one tree, which consists of a root and three child domains. Double-headed arrows indicate transitive trusts between Windows Server 2003 domains. The Windows NT Server 4.0/Microsoft® Windows® 2000 operating system domain has explicit one-way trust relationships with the Windows Server 2003 tree. This test lab does not have Active Directory sites. The test lab includes domain controllers (noted in the figure as DCs), some of which are also DNS servers supporting the dynamic update protocol, DHCP servers, and one global catalog server.

**Figure 2.6 Example of a Test Lab Logical Diagram**

**Physical Diagram**

Document the following in the physical diagram:

- Network components, such as:
    - Routers and bridges
    - Hubs
    - Link simulators
    - Proxy servers
    - Sniffers and traffic generators
    - Analog and Integrated Services Digital Network (ISDN) lines
    - LAN (local area network), WAN, and Internet connections and speeds
- Servers (include domain name, computer name, IP address, and server function)
- Client computers (include computer name and, if you use static addressing, IP address)

Figure 2.7 is an example of a physical diagram for the same test lab illustrated in the logical diagram in Figure 2.6. This diagram shows the three subnets for the three child domains. Each subnet has both a Windows XP Professional client computer and another type of client computer. The test lab uses simulated frame relay links and has a UNIX server.

**Figure 2.7 Example of a Test Lab Physical Diagram**

After you have completed the lab description and the logical and physical designs, expand your lab design to include all the components that you will need to fully simulate the Windows Server 2003 and the Windows XP Professional environments, as described in the following sections.

# Simulating the Proposed Server Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This section lists some components you might need to include in your lab to fully test Windows Server 2003. The recommendations presented here might not apply to all Windows Server 2003 implementations. Focus on the considerations that apply to your design.

**Server hardware and drivers**
Use the same type of hardware components and drivers that you use, or plan to use, on servers in the production environment. Be sure to obtain an updated BIOS that is compatible with Windows Server 2003.

**Services and configurations**
Use the same services and configurations that you will use in the actual deployment. For example, duplicate the Domain Name System (DNS), Dynamic Host Configuration Protocol (DHCP), and Windows Internet Names Service (WINS) configurations.

**User accounts**
If you are migrating from Windows NT Server 4.0, set up your domain controllers as replicas of your production domain controllers, using copies of the production user accounts. You can use the Clone Principal tool (Clonepr.dll) to copy production users to your test domain. For more information about the Clone Principal tool, see the Microsoft TechNet link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources, and then search for Tools. Coordinate with your IT security division whenever you copy production data to test lab databases. For more information about security, see "Planning a Secure Environment" in *Designing and Deploying Directory and Security Services* of this kit.

**Domain structure**
If you are implementing Active Directory, simulate the domain hierarchy; for example, include a forest with multiple trees, a tree with parent and child domains, and transitive and one-way trust relationships, as appropriate. Reflect your IT administration structure (either centralized or decentralized). Include Active Directory sites as appropriate. For more information, see "Designing Domains for Testing" later in this chapter.

**Group Policy settings**
Duplicate the Group Policy settings from your production environment in the test lab. Properly testing Group Policy settings in the lab helps you identify whether implementing new features or technologies will require that you make changes to your Group Policy settings.

**Server strategy**
Include domain controllers, file and print servers, application servers, Web servers, database servers, and other utility servers that are, or will be, included in your production environment. If you plan to use SMS to deploy Windows Server 2003, include it in the test lab.

**Mixed environments**
To accommodate both the mixed environment that exists during a phased rollout and the Windows Server 2003 environment that will exist after the completion of the rollout, plan to include some native-mode and mixed-mode domains.

By simulating the interim state, you can identify functional problems that might occur during the phased implementation. The servers running operating systems other than Windows Server 2003 should mirror the services they perform in the current production environment. For more information, see "Designing Domains for Testing" later in this chapter.

**Client computer configuration**
Client computers in the test lab should conform to the standard configuration that your organization has established. They should have the same components and peripherals found in your production environment.

Use the same mix of client computers that is present in your production environment. If you plan to deploy Windows Server 2003 first and Windows XP Professional later, include in your test lab the client computer operating system that you will be using until Windows XP Professional is deployed.

If you plan to deploy Windows XP Professional first, test to see how the extended server functionality will be introduced into your environment as the infrastructure is deployed.

If you plan to have a phased rollout, include the same mix of client computers in your test lab that will be present in your production environment. For example, have client computers with Windows NT Workstation 4.0 and client computers with Windows XP Professional.

**Network topology and protocols**
Mirror the network topology and protocols that you use in your production environment as closely as possible. For example, if your production network uses both Ethernet and Token Ring, the test lab should include both.

**WAN connections**
If you have a WAN, the test lab should include routers for testing network latency or for testing domain controller and global catalog replication across the WAN link. If you have the facilities and budget, you might want to set up a secondary test lab at a remote location to test network latency across the WAN link. If you have a multinational organization, place the secondary test lab in a different region to test actual latency problems.

If you do not have a secondary test lab located where you can test the WAN link, you can connect two routers in the same lab with a cable and use a link simulator to test the link.

**Remote connectivity**
In the test lab, provide the same types of remote connectivity — such as Routing and Remote Access service and VPN — that will be included in your production environment so that you can test the Point-to-Point Tunneling Protocol (PPTP), Internet Protocol security (IPSec), Layer 2 Tunneling Protocol (L2TP), and Demand Dial Routing.

**Peripherals**
Include a representative sample of the types of peripherals used in your production environment. For example, include the same types of printers and scanners, along with their associated drivers.

**Interoperability**
If you plan to implement Windows Server 2003 so that it operates with networks or computers using another operating system, mimic the interoperability infrastructure. For example, include connections to mainframe hosts, UNIX systems, or other network operating systems. To keep your test lab configuration manageable, decide which interoperability scenarios are most important to your organization and focus on those.

**Administrative tools**
Include the tools (Windows Server 2003, third-party, or custom built) that you currently use or plan to use for server-based administrative tasks. Test the tools for compatibility and effectiveness in the new environment.

**Fault tolerance techniques**
Test any fault tolerance techniques you plan to use in your production environment. For example, if you plan to use clustering, include a server cluster in the test lab.

**Terminal Services**
If you plan to implement Terminal Services, install the appropriate mix of applications on the server so that you can assess the effect of running applications in a multiuser environment. You might need to modify the default operating environment for some applications to obtain the desired functionality. For more information about hosting applications using Terminal Services, see "Hosting Applications with Terminal Server" in *Planning Server Deployments* of this kit.

**Protecting the production network**
Be sure you isolate the test lab from your corporate network. If you need to provide a connection from the test lab to the corporate network, plan how to regulate and control the connection and be sure to devise a way to quickly terminate the connection.

You can design router configurations to protect the production network. For example, consider using a multihomed router with two network adapters to connect the test lab to the production network for specific, controlled uses. Configure the router so that the production network can access the test lab network, but the test lab network cannot access the production network. This approach protects the production environment from events that might occur in the test lab, but allows a user in production to access test lab resources. For example, you could use this approach to test logon scripts on a test lab server with a limited number of users before moving the scripts to a pilot in the production environment.

# Simulating the Proposed Client Computer Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This section lists some components you might need to include in your lab to fully test Windows XP Professional. The recommendations presented here might not apply to all Windows XP Professional implementations. Focus on the considerations that apply to your lab design.

**Client computer hardware**
Include at least one client computer from each vendor and one of each model that will run Windows XP Professional in your production environment. If your organization uses laptops, docking stations, or port replicators, be sure to include components that fully represent the vendors and models. Be sure to obtain a BIOS update that is compatible with Windows XP Professional.

Develop a standard hardware configuration for Windows XP Professional as part of your deployment project. Lab testing can help you define and refine a standard configuration that is compatible with Windows XP Professional. Some of the components that need to be tested for compatibility include:

- Universal serial bus (USB) adapters.
- Compact disc (CD) and digital video disc (DVD) drives.
- Sound cards.
- Network adapters.
- Video adapters.
- Small computer system interface (SCSI) adapters.
- Mass storage controllers.
- Removable storage devices.
- Pointing devices (mouse or trackball).
- Keyboards.

To determine whether a device is compatible with Windows XP Professional, see the Windows Catalog link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources, and then look up the component. If a device is not included in the Windows Catalog list, contact the device vendor to find out if a driver is available.

Alternatively, you can use the Windows XP Professional CD to check hardware and software incompatibility. To obtain a report that indicates hardware and software incompatibilities and identifies device drivers that need to be updated, insert the Windows XP Professional CD in your drive and select Check System Compatibility. If updated drivers for your devices are not included with Windows XP Professional, contact the device vendors to obtain them.

On computers running Microsoft® Windows® 95 or Microsoft® Windows® 98 operating systems, you can check hardware and software incompatibility by using the log file called Upgrade.txt. Upgrade.txt is located in the Windows Installation folder. On systems running Windows NT Server, you can check hardware and software incompatibility by using the log file Winnt32.log. Winnt32.log also is located in the Windows Installation folder.

**Note**

- Windows XP Professional does not support 16-bit drivers. If your components use 16-bit drivers, you need to obtain 32-bit drivers for those components.

**Network connectivity**

Provide connectivity to the same types of networks that you use in the production environment, such as a LAN, a WAN, or the Internet.

If you plan to use Routing and Remote Access or a proxy network service in the production environment, include these types of connections in the test lab.

**Server-based services**
Configure servers for the services used in the production environment. For example, include services such as:

- DNS, WINS, and DHCP.
- Directory services, such as X.500 and Novell NetWare.
- File sharing.
- Network printing.
- Server-based line-of-business applications, both centralized and decentralized.
- IntelliMirror® management technologies.

Remember to account for administrative services or tools, such as:

- Remote operating system installation.
- Server-based application deployment.
- Tools for managing client computers (SMS, for example).

**Domain authentication**
If your organization uses, or plans to use, domain authentication, simulate your authentication configuration in the test lab. If you are migrating from Windows NT Server 4.0 to Windows Server 2003, plan for authentication in the mixed environment that will occur during the phase-in period.

**Network management services**
Include network services used in your environment, such as Simple Network Management Protocol (SNMP).

**Network protocols**
Use the protocols you plan to use in the production environment. Verify that the protocols you use on client computers work properly before connecting the client computers to the production network.

**Applications**
You need licenses for, and access to, the software for all applications, stand-alone or server-based, that is to be supported on Windows XP Professional client computers.

**Peripherals**
Include a representative sample of the types of peripherals, such as printers and scanners, used in the business environment.

**Server platform interoperability**
Simulate the server platforms to be accessed by Windows XP Professional client computers. You might need to establish connections with the following systems:

- Windows Server 2003
- Windows 2000 Server
- Windows NT Server 4.0
- Mainframes supporting 3270 emulation

- UNIX or Linux
- Other server operating systems

If you have a separate server test lab, consider connecting the client computer test lab to it, instead of installing servers in the client computer lab.

If you plan to deploy Windows XP Professional at the same time as Windows Server 2003, include every type of server that a client computer will be able to access during the deployment period.

**Desktop configurations**
As part of your Windows XP Professional deployment, your organization might decide to evaluate Standard Client configurations and Group Policy objects for managing them. Lab tests can provide information that will help you recommend specific configurations and Group Policy objects to management. If you decide to perform this type of evaluative testing, include side-by-side comparisons of different configurations and Group Policy object settings.

Plan to have enough computers of the same make and model to allow for the side-by-side evaluations. Evaluate client configurations based on performance, ease of use, stability, hardware and software compatibility, functionality, and security model. Evaluate Group Policy objects by verifying that they produce the desired result, particularly when more than one object applies to a configuration, and that the resulting logon time is acceptable.

**Performance**
Use the test lab to start evaluating the effect on your network traffic by testing for changes in baseline traffic patterns when there is limited user activity, for example, when conducting your pilot.

**Production network connectivity**
If you have separate test labs for clients and servers, you need to isolate them both from the corporate network. If you need to provide a connection from the test lab to the corporate network, plan how you will use routers to separate the two networks.

# Designing Domains for Testing

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Design the test lab domain structure to provide a consistent setup and configuration so that testers can rely on a standardized infrastructure. For example, allocate a single domain for migration and mixed-mode testing. If you do this, the domain should always be in the mixed-mode state except for scheduled periods when it is rolled back to the prior state to test the migration process. This way, test lab users always know what to expect.

Because some tests alter the lab environment, they can inadvertently affect other tests; for example, server upgrade tests change the services running on the server, which can affect any networking protocols that you are using. Care must be taken to isolate, coordinate, and manage these types of tests. Address issues such as these in the test lab domain design.

**Important**

- If you destroy the child domains and intend to reuse the same names upon reinstallation, you must clean up the metadata. To avoid this problem, use the Active Directory Installation Wizard and remove Active Directory from the domain controller prior to destroying the child domains.

Some of the types of testing that might require separate domains are:

- DNS
- Native-mode
- Mixed-mode
- Functional level
- Migration process
- Business data replication

**Case study: Designing test domains**

A large manufacturing company created a root domain with four child domains. This domain structure allowed the project team to use a separate domain to test:

- Windows Server 2003 functionality, including printing, in a native-mode domain.
- VPN.
- Mixed-mode interoperability and migration process.
- Microsoft® Exchange Server integration with Windows Server 2003.

In addition, an isolated domain allowed the team to test DNS without affecting other testing.

Figure 2.8 illustrates the logical domain structure of the test lab.

**Figure 2.8 Example of a Test Lab Logical Domain Design**

After you have designed and documented your test lab, have your project subteams review the plan to ensure that all the necessary requirements have been addressed.

# Developing the Test Lab

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you finish the test lab planning process and receive management approval, you can build the lab. To ensure smooth operation of the lab, assign a test lab manager and develop test lab guidelines and procedures.

Figure 2.9 illustrates the steps you take to develop the test lab.

**Figure 2.9 Developing the Test Lab**

If you plan to rebuild the test lab periodically as your testing focus changes, consider using tools or products such as SMS to manage test lab changes. Also consider using Remote Installation Services (RIS), Sysprep, or unattended installations to rapidly make changes to the client computer configurations in the test lab. Active Directory Service Interfaces (ADSI) and Windows Script Host can help you quickly create, delete, or change users, groups, and organizational units in your test lab environment.

For more information about using RIS to automate client computer installations, see "Designing RIS Installations" in *Automating and Customizing Installations* of this kit. For more information about using Sysprep to automate client computer installations, see "Designing Image-based Installations with Sysprep" in *Automating and Customizing Installations* of this kit. For more information about using unattended installations to automate client computer installations, see "Designing Unattended Installations" in *Automating and Customizing Installations* of this kit.

# Assigning a Test Lab Manager

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If your test lab will be permanent or will be used by many groups, you will need to assign someone to manage it. This is particularly important if the test lab is to be used by several groups for testing during the change management process.

Smaller test labs or labs used by a single team might not need a dedicated manager. For such a lab, consider the tradeoffs between — and the costs of — either hiring a dedicated lab manager or assigning the role to a project team member. Evaluate whether assuming lab management duties in addition to other project responsibilities might be too burdensome for a team member. Even if you decide not to assign a dedicated, full-time manager, select someone to be responsible for the test lab.

A test lab manager is responsible for:

- Establishing and enforcing test lab policies and procedures.
- Establishing a test lab budget for support costs.
- Scheduling any configuration changes to servers or clients that might be required by certain tests, and communicating these requirements to other test lab users.
- Developing a bug or problem escalation plan.
- Developing and managing an incident-tracking system.
- Developing and monitoring the change control process.

  The change control process defines who is allowed to make changes to the test lab environment. For more information about change control, see "Using the Test Lab After Deployment" later in this chapter.
- Setting up an inventory control system.
- Maintaining test lab documentation (such as test lab descriptions, diagrams, and guidelines and procedures).
- Managing network taps and server capacity and configurations.
- Managing hardware and software configurations and updates.
- Establishing physical security.

  The test lab manager takes measures to prevent unauthorized use of lab equipment and manages lab access with keys or electronic locks.
- Implementing a preventive maintenance program for equipment.
- Establishing an approval process for removing equipment (for lending it to another group, for example).
- Making periodic server backups.
- Ensuring the test lab is kept clean and orderly.

# Building the Test Lab

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**To build the test lab**

1. Acquire hardware and software, including administrative tools.

2. Install and configure routers, switches, wireless and optical devices. Label all network cables.

3. Install and configure all servers.

   If you are redeploying servers, you might need to upgrade them to accommodate Windows Server 2003. Use the same memory, disk capacity, and CPU speed that you plan to deploy. Be sure to check for viruses and to defragment the hard disks. Partition the hard disks in the same way you plan to partition them during deployment.

   Install the appropriate operating system, either Windows Server 2003 or the operating system from which you plan to upgrade.

   If you are upgrading your domain controllers, you should consider using a disk-imaging program to create images of the domain controllers before you upgrade them. Test the images and store them in a safe place. If necessary, you can use the disk images to restore the servers to their original state. By making reliable disk images, you avoid intruding on your production environment if your upgrade process changes or fails.

   If you are purchasing new equipment, burn in the components for two or three days to be sure that they are working properly.

4. Test all network connections.

   Testing the network before you install the servers makes it easier to locate and solve problems.

5. Install application software when you are ready to include it in testing. Install all server-based applications, such as SMS, and business applications that are included in your production environment.

   Build or load copies of the associated databases. Install tools for testing and administration. If you are planning to verify network traffic or test performance, you might want to include a hardware sniffer or a software sniffer.

   For more information about testing tools, see "Planning and Testing for Application Deployment" in this book.

6. Install and configure all client computers.

7. If you are implementing Terminal Services, install a representative set of applications so you can test concurrent users.

8. If you plan to create backups for restoring baseline configurations, set up the baseline configurations and make the backups.

   For example, if you plan to upgrade Windows NT Workstation 4.0 to Windows XP Professional instead of performing a clean installation, back up a Windows NT Workstation 4.0 client computer that is running your standard set of applications.

   The baseline configurations should include all the service packs that are supported in your environment. Be sure to test and document the restore process.

9. Test the individual components in the lab to isolate problems that are not related to Windows Server 2003 and Windows XP Professional deployment.

When testing starts, you will want to spend your time debugging deployment problems, not fixing problems with the test lab.

10. If you need to provide connectivity to the production network, configure and test routers to isolate the test lab from production.

**Important**

- As the team builds and rebuilds the test lab, be sure to document, in chronological order, every change made to servers and client computers. This documentation can help resolve problems that might arise later and help team members understand why a specific computer behaves as it does over time. It also can help you reverse recent changes to solve a short-term problem.

After your team has built the test lab, establish lab guidelines and procedures. Then your team can begin testing.

# Developing Test Lab Guidelines and Procedures

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Test lab users need to know when they can perform their tests, whether their testing will disrupt other tests, and what the current state of the lab is. For example, if a domain in the lab is used for testing the migration process, in addition to mixed-mode functionality, test lab users need to know if the computers are ready for an upgrade or if they already have been upgraded. Your lab manager or an assigned team member should establish a communication system to disseminate information about the availability and state of the test lab and should establish guidelines for lab use.

Guidelines should be easy to follow and to remember, and should address each of the following issues.

**Roles and responsibilities** Identify who is responsible for tasks such as scheduling test lab use and performing backups.

**Facilities and guidelines for special types of tests** Identify the domains and configurations team members should use for testing the migration process.

**Test lab change control procedures** Identify who is allowed to make configuration changes and define the approval process for change requests. For example, identify who can make schema changes and who should be notified when a change is made. Describe how changes to the lab should be made and identify who is responsible for documenting these changes.

**Server initialization procedures** Document the steps for installing, configuring, and populating domain controllers and member servers. Include DNS settings if you do not plan to use the DNS Server service in Windows Server 2003.

**Test lab restore procedures for testing the rollout** Document the steps for restoring domain controllers to their original state and for refreshing user account data. Document all server configurations. Test the refresh process before you begin migration testing.

**Client computer restore procedures** If you plan to rebuild client computers frequently to test various configurations, document the tools required to quickly restore the computers to a known state. For example, if you use RIS, note this in your guidelines.

As part of the lab guidelines and procedures, the lab manager or an appointed team member also should develop an escalation plan and an incident-tracking system.

# Developing an Escalation Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An *escalation plan* describes what testers need to do when problems arise during testing. The escalation plan should address the following issues:

- Where test failures and other test issues should be posted; for example, you might decide to post failures and problems in the incident-tracking system or on an intranet Web site.

  For information about the incident tracking system, see "Developing an Incident-Tracking System" later in this chapter.

- The steps to follow before posting an issue or problem; for example, you might want to indicate whether the problem should be reproduced and, if so, by whom.

- The information to include when posting an issue or problem:

  - Contact information (phone number, pager number, and e-mail address for the subteam lead and the external support person)

  - The status of the problem (new or ongoing)

  - The priority of the problem and the business objective that the problem jeopardizes

  - The sequence of events leading to the problem (include relevant information such as IP addresses and domain name)

  - The causes (known or suspected)

  - Troubleshooting information (traces, diagnostics)

- The procedure for notifying the development team of issues or problems.

- The notification hierarchy.

- The team members responsible for reviewing and resolving problems and issues.

# Developing an Incident-Tracking System

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An *incident-tracking system* is used for recording and reporting bugs and other testing problems, recording how they are resolved, and recording test results. A tracking system helps you monitor testing progress and evaluate the test success rate.

Your incident-tracking system should provide fields for recording:

- The tester's name and department.
- The date and time the test was performed.
- The Windows product name (Windows Server 2003 or Windows XP Professional).
- A full description of the test results.
- A description of any problem that was encountered, and its resolution.

Some organizations use a paper-based system to document test results, recording results on the page that describes the test case. With such a system, however, it is difficult to keep track of which tests have been performed and to create summary reports.

Alternatively, your organization can purchase a commercial product for tracking test cases. Or, your team can develop a database application specifically for this purpose. With either of these tools, you can create automated reports to monitor test results and progress.

Another alternative is to create an intranet site for posting test results. In this case, you can designate the level of detail displayed to a user depending on that user's credentials. For example, executives and test lab personnel could be permitted to view all test result information. Testers or technicians could be permitted to view only test results generated from within their group. By creating an intranet site, you can make test results available anywhere within your intranet, without requiring team members to install additional applications.

Regardless of the approach to documenting test results that you choose, it is important that test results be accessed easily.

# Designing Test Cases

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A *test case* is a detailed procedure that fully tests a feature or an aspect of a feature. Whereas the test plan describes what to test, a test case describes how to perform a particular test. You need to develop a test case for each test listed in the test plan. Figure 2.10 illustrates the point at which test case design occurs in the lab development and testing process.

**Figure 2.10 Designing Test Cases**

A test case includes:

- The purpose of the test.
- Special hardware requirements, such as a modem.
- Special software requirements, such as a tool.
- Specific setup or configuration requirements.
- A description of how to perform the test.
- The expected results or success criteria for the test.

Test cases should be written by a team member who understands the function or technology being tested, and each test case should be submitted for peer review.

Organizations take a variety of approaches to documenting test cases; these range from developing detailed, recipe-like steps to writing general descriptions. In detailed test cases, the steps describe exactly how to perform the test. In descriptive test cases, the tester decides at the time of the test how to perform the test and what data to use.

Most organizations prefer detailed test cases because determining pass or fail criteria is usually easier with this type of case. In addition, detailed test cases are reproducible and are easier to automate than descriptive test cases. This is particularly important if you plan to compare the results of tests over time, such as when you are optimizing configurations. Detailed test cases *are* more time-consuming to develop and maintain. On the other hand, test cases that are open to interpretation are not repeatable and can require debugging, consuming time that would be better spent on testing.

Table 2.1 provides an example of the first few steps of a detailed test case.

**Table 2.1 Sample Detailed Test Case**

| Step | Procedure | Success Criteria | Outcome |
|---|---|---|---|
| 1 | Log off the server, and return to the netlogon screen. | None. | |
| 2 | Click the domain list to open it. | The local server name does not appear in the list. | |
| 3 | Click the domain list to open it. | The root domain appears in the list. | |
| 4 | Log on to the server using an account with administrative credentials. | The account logs on to the server without errors. | |

When planning your tests, remember that it is not feasible to test everything. Instead of trying to test every combination, prioritize your testing so that you perform the most important tests — those that focus on areas that present the greatest risk or have the greatest probability of occurring — first. For example, you might choose to test the slowest client computer, the busiest server, or the least reliable network link. Then, if time allows, you can perform lower priority tests.

For more information about developing test cases, see "Planning and Testing for Application Deployment" in this book.

# Conducting Tests

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After your team has designed test cases, it can begin testing. Figure 2.11 illustrates the point at which this step occurs in the overall lab development and testing cycle.

**Figure 2.11 Conducting Tests**

When conducting tests, the tester must perform each test as described in the test case, evaluate the test results, escalate problems that arise until they are resolved, and document the test results. Figure 2.12 illustrates the testing process.

**Figure 2.12 The Testing Process**

**Note**

- Before testing begins, the tester might need to modify the test lab setup to meet the requirements specified in the test case.

When conducting a test, the tester needs to follow the written test cases carefully. To accurately assess results or to reproduce a test to compare results over time, team members need to know exactly which steps the tester took and the exact sequence in which those steps were performed.

When a test is complete, the tester must evaluate the results against the criteria in the test case to determine if the test passed or failed. Not all tests fail because there is a problem with your system implementation; tests can fail because there is a

problem with the test itself, with the test lab setup, or with the proposed design. If one of these problems causes a test to fail, the tester should take the appropriate measures to remedy it. Table 2.2 shows some typical test problems and solutions.

**Table 2.2 Test Problems and Solutions**

| Problem | Potential Solution |
|---|---|
| Test case problem | Revise the test case, taking care to document all the changes made, and then rerun the test. |
| Test lab setup problem | Following the change control process for the lab, reconfigure the lab, and rerun the test. |
| Design problem | Follow the escalation procedure to notify the appropriate individuals about the problem. Prioritize outstanding problems and track them until they are resolved and the corresponding tests have been rerun. To prioritize problems, consider the potential impact and the probability that they will occur. |

Record all test results in the incident-tracking system, so you can monitor test progress.

**Important**

- Remember that the lab will change frequently as tests are run and new tests are begun. Make backups of baseline configurations so testers can quickly restore a computer to its prior state. Be sure to test the restore process. Document the backup files and store them in a safe, accessible place.

# Using the Test Lab After Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The importance of testing changes to your computing environment after you have deployed Windows Server 2003 and Windows XP Professional cannot be overemphasized. Because of the potential effect changes can have in the production environment, many organizations test every update and service pack until the anticipated results are achieved before they set up a pilot or a rollout. Figure 2.13 shows that the lab can be used to manage post-deployment changes.

**Figure 2.13 Using the Test Lab After Deployment**

If you plan to use your test lab to manage changes to your production environment, you will need to develop appropriate guidelines. Describe, in a general way, how to prepare the lab for testing a change and identify procedures for conducting tests and reporting results. For each change that you test, you will need to identify:

- Components required before the change can be implemented in the test lab.
- Steps required to implement the change.
- Documentation to be produced in the test lab.
- Action to take if a lab test fails.
- Action to take if a lab test succeeds.

Remember to periodically evaluate test lab components to determine and counteract the effects that accumulated changes have on them. For example, a computer that has undergone many changes in the testing process might not behave in the same way that a computer that has been newly installed with the same configuration would.

# Additional Resources for Designing a Test Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information related to this chapter.

**Related Information**

- "Planning and Testing for Application Deployment" in this book for information about application compatibility testing.
- "Designing a Pilot Project" in this book for information about designing a pilot project.
- The *Networking Collection* of the *Windows Server 2003 Technical Reference* (or see the Networking Collection on the Web at http://www.microsoft.com/reskit) for more information about Dynamic Host Configuration Protocol (DHCP).
- "Designing the Active Directory Logical Structure" in *Designing and Deploying Directory and Security Services* of this kit for information about how to deploy DNS specifically for Active Directory.
- "Planning an Active Directory Deployment Project" in *Designing and Deploying Directory and Security Services* of this kit for information about how to plan and deploy Active Directory in your environment.

- The *Active Directory Collection* of the *Windows Server 2003 Technical Reference* (or see the Active Directory Collection on the Web at http://www.microsoft.com/reskit) for more information about Active Directory functional levels.

# Planning and Testing for Application Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Deploying applications to computers running the Microsoft® Windows® Server 2003 or Windows® XP Professional operating system requires that you first thoroughly analyze your applications and test them for compatibility with the operating system and your environment.

**In This Chapter**

Overview of Testing and Deploying Applications

Defining Application Deployment Project Scope and Objectives

Planning for Server Application Compatibility

Creating an Application Compatibility Test Plan

Preparing for Application Testing

Testing for and Resolving Compatibility Problems

Deploying and Distributing Applications and .Sdb Files

Additional Resources for Planning and Testing for Application Deployment

**Related Information**

- For more information about testing, see "Designing a Test Environment" in this book.
- For more information about piloting, see "Designing a Pilot Project" in this book.

# Overview of Testing and Deploying Applications

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you move from your current version of the Microsoft® Windows® operating system to Windows XP Professional or Windows Server 2003, you need to test your applications to ensure that they are compatible with the new operating system. An organization can have as many as several thousand applications installed across distributed networks. Compatibility problems with one or many of these applications can cause costly work stoppages.

Although most applications developed for earlier versions of Windows probably will perform well on the new versions, some applications might behave differently because of new technologies within the new versions. The applications that you need to test to ensure compatibility include core applications that are part of your standard desktop configurations, such as office productivity suites; line-of-business applications, such as enterprise resource-planning suites; administrative tools, such as antivirus, compression, backup, and remote-control applications; and custom tools, such as logon scripts. Low-level applications — such as antivirus applications, kernel-mode drivers, and filter drivers — are especially likely to pose problems. You also need to ensure that your server applications are compatible.

This chapter is designed to help IT professionals in medium to large organizations test and deploy applications. It explains primarily how to test and deploy desktop applications that run on client computers. However, many of the concepts and techniques for application compatibility testing and deployment apply whether an application runs on Windows XP Professional or Windows Server 2003. For specific information about server application compatibility, see "Planning for Server Application Compatibility" later in this chapter.

This chapter does not describe how to test applications that will run on Microsoft® Windows® XP 64-Bit Edition Version 2003 or the 64-bit versions of Windows Server 2003 family. Testing 16-bit and 32-bit applications on these 64-bit operating systems is beyond the scope of typical application compatibility testing. This is because the 64-bit versions of these operating systems do not support 16-bit applications, and because you must use the *x*86 emulator, known as WOW64 (Windows32 on Windows64), to run 32-bit applications on the 64-bit versions of these operating systems. For more information about porting 32-bit applications to 64-bit operating systems, see the Porting 32-bit Applications link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Application Testing and Deployment Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Application compatibility testing begins with identifying and prioritizing the applications in use throughout your organization, which helps you determine the objectives and scope of the project. After establishing priorities and examining special considerations for server applications, you can develop the test plan. As you encounter compatibility problems during testing, you need to develop solutions, test them, and then package them for deployment. Figure 3.1 illustrates this process.

**Figure 3.1 Application Testing and Deployment Process**

**Important**

- To create distributable application compatibility solutions for Windows XP Professional and Windows Server 2003, you need to download and install the Microsoft Windows Application Compatibility Toolkit. To download the current version of the toolkit, use the Windows Application Compatibility link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources. You can also find the toolkit on the Microsoft® Windows® Server 2003 Deployment Kit companion CD. The Windows Application Compatibility Toolkit cannot be installed on the 64-bit versions of the operating systems.

# Application Compatibility Testing Within the Project Life Cycle

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Application compatibility testing is an important part of your deployment project. Although application testing takes place during the developing phase of the project, related tasks occur throughout the project life cycle. Figure 3.2 shows the phase of the deployment project during which each of the application compatibility testing and deployment tasks might occur. The time frames are estimations and might vary from deployment to deployment.

**Figure 3.2 Application Compatibility Testing Within the Project Life Cycle**

# Application Compatibility Fundamentals

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To resolve application compatibility problems, perform the following tasks:

1. **Identify the applications that you need to test.** This includes creating an inventory of your applications (if you do not already have one) and determining the certification status, level of importance to your organization, and the priority of each application, to help determine the level of testing required.

2. **Identify application compatibility problems.** This includes testing, and possibly debugging, your applications.

3. **Resolve application compatibility problems.** This includes identifying and creating application compatibility solutions. It also can include modifying the source code and recompiling applications for which you have the source code.

4. **Deploy or distribute applications and solutions.** You can use various Windows XP Professional and Windows Server 2003 deployment and distribution tools.

To perform these tasks, you need to understand how application compatibility problems arise, what you can do to resolve the problems, and which tools you can use to plan your application compatibility testing project and to test, fix, and deploy applications.

# Common Compatibility Problems

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An application written specifically for a different version of Windows — especially for the Microsoft® Windows® 95, Windows® 98, or Windows® Millennium Edition (Windows Me) operating system — might manifest problems for several reasons. Most problems occur in the following areas.

**Setup and installation** Problems can occur when an application copies files and shortcuts to folders that exist on an earlier version of the Windows operating system, but not on Windows XP Professional or Windows Server 2003. Problems also can occur when a program:

- Writes entries directly to the registry without using the Windows Installer or the shell APIs.
- Checks for a specific version of the operating system.
- Does not support hard drives larger than 2 gigabytes (GB).
- Does not support long file names.
- Tries to access hardware directly rather than by calling the appropriate APIs.

**Kernel-mode drivers** Problems can occur when a driver tries to perform a task that is allowed in an earlier version of Windows but not in Windows XP Professional or Windows Server 2003. The most common types of programs that exhibit kernel-mode driver problems include antivirus programs, personal firewall programs, disk defragmenting programs, and CD burning programs.

**Permissions** Permissions problems can occur when an application tries to access areas of the file system or registry that are accessible by all users and applications in an earlier version of Windows but are no longer accessible in Windows XP Professional and Windows Server 2003. In Windows XP Professional and Windows Server 2003, user accounts can write only to the following locations:

- The registry key HKEY_CURRENT_USER, except its subkeys \Software\Policies and \Software\Microsoft\Windows\CurrentVersion\Policies
- The user's own user profile folders
- Shared Documents folders
- Any folder that the user creates from the root of the system hard disk

If a user tries to write to any other location, an error occurs.

**Heap management** Heap management problems can occur because Windows XP Professional and Windows Server 2003 immediately detect problems that frequently took some time to appear in earlier versions of Windows.

In addition, application compatibility problems can arise because of the following changes to existing features, and the addition of new features, in Windows XP Professional and Windows Server 2003:

- **Windows File Protection.** This feature prevents applications from replacing system files. Earlier versions of Windows allowed applications to replace shared system files during installation, which frequently caused problems ranging from application errors to an unstable operating system. Windows File Protection verifies that protected system files are the correct Microsoft version and restores the correct version when a file is replaced.
- **Enumeration of hardware devices.** Some hardware devices are no longer supported, which means they are not detected or enumerated during startup. This might cause problems for applications that expect a device to be present.
- **Enumeration of fonts.** The list of fonts has changed. Because registry keys have been added to support

internationalization, the operating system might not provide applications with the font choices that the application expects.

- **Windows Messaging Service.** Applications that expect the operating system to provide Windows Messaging Service (WMS) will not find it.

- **File input/output security.** Security has been enhanced for file input and output. Applications that use file filters, such as antivirus programs, might lose significant functionality.

- **Privileged instructions.** Use of privileged instructions is more restrictive. A *privileged instruction* is an operating system call that is executed in kernel mode rather than in user mode. An application might shut down unexpectedly if it uses privileged instructions such as **cli**, **sti**, **in**, or **out**. At other times, it might generate access violations that can be ignored, allowing the application to continue running without consequence.

# Application Compatibility Solutions

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows XP Professional and Windows Server 2003 resolve application compatibility problems by dynamically matching applications with solutions. The matching mechanism is controlled by a dynamic-link library (DLL) that starts and runs the matching mechanism whenever a user installs or runs an application. The matching mechanism is transparent and has a minimal effect on the performance of the operating system or installed applications.

To match applications with solutions, the matching mechanism relies on several databases. The databases contain a list of applications that have known problems and instructions for solving those problems. The databases are saved in the *systemroot*\AppPatch folder on Windows XP Professional and Windows Server 2003.

Three types of application compatibility databases are available: migration databases, prepackaged databases, and custom databases. The files containing the migration databases have an .inf extension; the files containing the prepackaged and custom databases have an .sdb extension. Throughout this chapter the term *.sdb file* is used to refer to prepackaged and custom application compatibility databases.

**Migration databases** These databases, which are provided by Microsoft, are used during an operating system upgrade to determine whether an application has compatibility problems, and to warn users about these compatibility problems if they prevent the application from running on the new operating system. Two migration databases are provided — one for checking applications that run on Windows 95, Windows 98, and Windows Me, and one for checking applications that run on the Microsoft® Windows NT® and Microsoft® Windows® 2000 operating systems. Migration databases have an .inf file name extension.

**Prepackaged databases** These databases also are provided by Microsoft, and are used when an application installs or runs, to determine whether the application has compatibility problems and to provide solutions to those problems. Prepackaged databases have the .sdb file name extension.

Prepackaged databases can contain any of the following solutions:

- **An application compatibility fix.** This is a segment of code that replaces a problematic function call with a function call that is compatible with Windows XP Professional or Windows Server 2003. This ensures that the operating system returns the result that the application expects.

- **An application compatibility mode.** This is a collection of application compatibility fixes that, together, emulate a specific operating system environment. For example, a Windows 95 application compatibility mode contains approximately 50 of the most common application compatibility fixes that applications designed to run on Windows 95 need in order to run on Windows XP Professional or Windows Server 2003.

- **An Application Help message.** This is a message that is displayed when a user installs or runs an application that is incompatible with the operating system, and an application compatibility fix or mode is not available or effective. An Application Help message can warn a user about an incompatibility but still let the user install or run the incompatible application, or it can block the user from installing or running the application.

**Custom databases** These databases are created by you, and can contain the same types of solutions as the prepackaged databases — application compatibility fixes, application compatibility modes, and Application Help messages. The difference is that these databases contain solutions for applications that are not addressed in the prepackaged databases. You can give a custom database any name, but it must have the .sdb file name extension. You also can save a custom database anywhere on a computer, but it is usually most convenient and efficient to save your custom databases in a subfolder in the *systemroot*\AppPatch folder (for example, *systemroot*\AppPatch\Custom).

In addition to the databases, the matching mechanism relies on several .dll files. These .dll files contain the code segments that run when an application requires an application compatibility fix or mode. These files begin with the letters "ac," and are installed by the operating system in the *systemroot*\AppPatch folder.

Table 3.1 describes all of the application compatibility databases that are prepackaged by Microsoft. The .inf files are stored on the Windows XP Professional and Windows Server 2003 operating system CDs. The .sdb files are stored in the *systemroot*\AppPatch folder.

**Table 3.1 Application Compatibility Databases**

| File | Description |
| --- | --- |
| MigDB.inf | Migration database that contains a list of Windows 95, Windows 98, and Windows Millennium Edition applications that are incompatible with Windows XP Professional or Windows Server 2003. |
| NTCompat.inf | Migration database that contains a list of applications that are designed to run on the Microsoft® Windows NT® Server 4.0 and Windows 2000 operating systems and are incompatible with Windows XP Professional or Windows Server 2003. |
| Apphelp.sdb | Prepackaged database that contains a list of third-party applications that have compatibility problems and associated Application Help messages. You can add third-party applications and custom Application Help messages to this database, but you cannot change or delete the existing list of names and Application Help messages. |
| Sysmain.sdb | Prepackaged database that contains a list of third-party applications that have compatibility problems and their associated application compatibility fixes and modes. You cannot change or delete the information in this database, but you can use the application compatibility fixes and modes that it contains to create custom databases. |
| Drvmain.sdb | Prepackaged database that contains a list of device drivers that have compatibility problems and their associated Application Help messages. |
| Msimain.sdb | Prepackaged database that contains a list of Windows Installer packages (.msi files) that have compatibility problems and their associated Application Help messages. |

# Application Compatibility Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Microsoft provides a variety of tools and features to help you to plan your application compatibility testing project and to test, fix, and deploy applications. These tools and features are provided for each of the four major phases in the overall application compatibility testing process: planning, testing, resolving, and deploying.

**Planning tools** These include Microsoft Application Compatibility Analyzer, Microsoft® Systems Management Server (SMS), Windows Catalog, and Windows Upgrade Advisor. Use Application Compatibility Analyzer, Windows Catalog, and Windows Upgrade Advisor to collect information about the applications in your organization and to identify applications that are known to have compatibility problems. Use SMS to create a software inventory.

**Testing tools** These include Microsoft Application Verifier and debugging tools. Use these tools to create a test environment for identifying hard-to-find application compatibility, stability, and security problems. Testing tools also include Windows Upgrade Advisor and the Windows Catalog, which identify applications that have already been tested and certified for use with Windows XP Professional and Windows Server 2003.

**Resolution tools** These include Microsoft Compatibility Administrator, the Program Compatibility Wizard, and the Compatibility property sheet. You can use Compatibility Administrator to apply compatibility modes and fixes to custom .sdb files, which you can distribute throughout your organization. The Program Compatibility Wizard and the Compatibility property sheet are ideal for resolving compatibility problems on a stand-alone computer (a computer that is not connected to a domain or a network).

**Deployment tools** These include automated installation tools, such as the System Preparation tool (Sysprep) and Remote Installation Services (RIS), and software management tools, such as Group Policy Software Installation and logon scripts. You can use these tools to deploy applications and .sdb files during an operating system rollout, or to distribute applications and .sdb files to computers that already have an operating system installed. Deployment tools also include the Application Compatibility Database Installer (Sdbinst.exe) and the Windows Installer program (Msiexec.exe), both of which are used in conjunction with the deployment and distribution tools to install applications and custom database (.sdb) files. You also can use the Windows Installer Software Development Kit to package applications, application updates, and .sdb files into Windows Installer packages (.msi files).

**Note**

- The Program Compatibility Wizard and the Compatibility property sheet are rarely used to address application compatibility issues in a large enterprise. In addition, you cannot use these two tools to resolve issues with kernel-mode drivers; doing so can result in system instability.

Table 3.2 provides a list of common tasks, the tools that you use to perform them, and where those tools can be found.

**Table 3.2 Tools for Performing Common Application Compatibility Tasks**

| To perform this task... | Use this tool or feature... | Available... |
|---|---|---|
| Create a software inventory that is adequate for general deployment planning tasks, including application compatibility testing. | SMS | For purchase from Microsoft. |
| Create a software inventory that is tailored for application compatibility testing. | Microsoft Application Compatibility Analyzer | In the Windows Application Compatibility Toolkit. |

| | | |
|---|---|---|
| Quickly check the compatibility of applications. | Windows Catalog<br>–or–<br>Windows Upgrade Advisor* | On the Microsoft Web site. Windows Upgrade Advisor is also included on the Windows XP Professional and Windows Server 2003 operating system CDs. |
| Test applications for hard-to-find stability, compatibility, and security problems. | Application Verifier | In the Windows Application Compatibility Toolkit. |
| Investigate and resolve complex application compatibility problems when you have access to the application's source code. | Microsoft Debugging Tools for Windows | On the Microsoft Web site. |
| Quickly resolve common application compatibility problems on a stand-alone computer. | Program Compatibility Wizard<br>–or–<br>Compatibility property sheet | In Windows XP Professional and Windows Server 2003. |
| Resolve application compatibility problems by creating a custom application compatibility database (.sdb file). | Compatibility Administrator | In the Windows Application Compatibility Toolkit. |
| Install and register custom application compatibility files and .sdb files on destination computers. | Application Compatibility Database Installer (Sdbinst.exe) | In Windows XP Professional and Windows Server 2003. |
| Create a Windows Installer package (.msi file). | Windows Installer Software Development Kit | On the Microsoft Web site. |
| Install a Windows Installer package (.msi file) on a destination computer. | Windows Installer tool (Msiexec.exe) | In Windows XP Professional and Windows Server 2003. |
| Deploy applications and .sdb files during an operating system rollout. | Windows System Preparation tool (Sysprep)<br>-or-<br>Unattended installation answer file (Unattend.txt)<br>-or-<br>Remote Installation Services (RIS) | On the Windows XP Professional and Windows Server 2003 operating system CDs. |

| | | |
|---|---|---|
| Distribute applications and .sdb files after an operating system rollout. | Group Policy Software Installation tool<br>-or-<br>Logon scripts<br>-or-<br>Software Update Services (SUS)<br>-or-<br>SMS | All tools except for SMS are included in Windows XP Professional and Windows Server 2003. SMS is available for purchase from Microsoft. |

*Windows Upgrade Advisor is used rarely in enterprise environments, although it is a viable method of checking the compatibility of an application.

For more information about planning tools, see "Generating an Application Inventory" later in this chapter. For more information about testing tools, see "Testing with Windows Application Verifier" later in this chapter. For more information about resolution tools, see "Applying and Testing Solutions with Compatibility Administrator" later in this chapter. For more information about deployment tools, see "Deploying and Distributing Applications and .Sdb Files" later in this chapter.

# Defining Application Deployment Project Scope and Objectives

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The fundamental objective of any application compatibility testing and deployment project is to successfully deploy applications that are compatible with the new operating system. To plan your application deployment project, you must first define the project scope and objectives. To do this, you need to conduct an inventory of the software currently in use in your organization, and then analyze this information to determine the constraints and risks of the compatibility testing project. You can use this information to begin creating the deployment project plan.

Figure 3.3 illustrates when this step occurs in the application compatibility testing process.

**Figure 3.3 Defining Application Deployment Project Scope and Objectives**

# Generating an Application Inventory

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To determine the scope of the project, you need to conduct an inventory of the applications used in your organization. If you do not already have a complete software inventory, gather information about both client and server applications that are installed on your computers. Include limited-use applications for special projects within the organization and nonapproved software that will inevitably be present. By having a complete inventory of the applications used in your organization, you can ensure that an otherwise overlooked application is not incompatible.

Several tools are available for creating a software inventory. The Application Compatibility Analyzer, included in the Windows Application Compatibility Toolkit, gathers data that can make your application compatibility testing project easier and more efficient to implement. You also can use SMS or third-party tools to inventory your software. SMS is a robust systems management tool, which, although not designed specifically for application compatibility projects, provides adequate inventory information for application compatibility testing.

Regardless of which tool you use to generate your software inventory, your inventory should include the following information:

- The application name, vendor, and version number
- Service packs or hot fixes that have been applied or are required
- An evaluation of how critical the application is to the success of your business
- The target platform for the application and a description of the client/server components
- The development platform used to create the application
- Historical data, including any known problems or bugs that were identified in previous testing

Some of this information is gathered by the tool that you use to generate the software inventory. You will need to manually collect any additional information that is required. For information about the type of data that a tool collects, see the documentation for the tool.

**Note**

- In addition to generating an inventory of the applications currently in use in your organization, be sure to account for applications that you plan to introduce with the new operating system. Because these applications cannot be inventoried, you need to collect information about them manually.

# Using the Application Compatibility Analyzer to Generate an Application Inventory

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Application Compatibility Analyzer helps you collect software-related information from the computers in your organization. The Application Compatibility Analyzer tool has two components:

- A console component, the Application Compatibility Analyzer, which you install on the administrator's computer.
- A command-line component, the Microsoft Collector, which you distribute to each computer from which you want to gather an application inventory. The Collector runs in the background on each computer to which it is distributed to collect data about every application on that computer. The Collector records the data in an XML-formatted log file for that computer.

You can compile the data gathered by the Collector into a Microsoft® SQL Server™ database or a Microsoft® Access database by using the Application Compatibility Analyzer console. Then, you can use the Application Compatibility Analyzer console to generate reports that describe the compatibility of the applications in your inventory. To do this, you use the Application Compatibility Analyzer console to compare your software inventory to a database of application compatibility information (known as the *application compatibility database*). The application compatibility database is maintained by Microsoft, and contains application compatibility information from the Windows Catalog, Microsoft internal testing, and outside parties. It is periodically updated by Microsoft. You can compare your inventory with information in the database directly over the Web, or you can download the compatibility information and add it to your database so you can use the compatibility information offline.

**Note**

- If you download the application compatibility database, you can modify the database to include the results of in-house application testing.

The Application Compatibility Analyzer is available for downloading from the Microsoft Web site. See the Windows Application and Customer Experience link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Installing and Using the Application Compatibility Analyzer**

You can install the Application Compatibility Analyzer on any computer that is running Windows 2000, Windows XP Professional, or Windows Server 2003. It requires Microsoft® Internet Explorer version 5.5 or later.

Install the Application Compatibility Analyzer on the administrator's computer on which you will review Application Compatibility Analyzer reports. Then, use Application Compatibility Analyzer to define the database that will store the information that Collector collects as either a SQL Server database or an Access database. If you are compiling Collector logs in an enterprise, a SQL Server database is recommended.

After installing the Application Compatibility Analyzer, distribute the Collector to your client and server computers. You can run the Collector on the Windows 95, Windows 98, Windows Me, Windows 2000® Professional, or Windows XP Professional operating system, and on servers running Windows NT Server 4.0, Windows 2000, or Windows Server 2003. The Collector need not run under an administrator account.

You can configure the Collector using command-line arguments or initialization (.ini) scripts. You can specify which drives, either network or local, and which paths the Collector should search, and whether the Collector should detect server functions. You also can configure the Collector to define the scope of the inventory, and you can specify where to save the log files (by default the log files are stored on the computer on which the Collector is run). For more information about customizing the Collector, see the Collector Help files.

**Important**

- Set up a secure share with write-only access on which to save your log files. The log files contain computer information that should be accessible only by administrators.

You can distribute the Collector manually on floppy disks or on CDs, over the network using a network distribution share or a hyperlink in e-mail, or through Group Policy. These distribution methods all require that end users actively install and run the Collector on their computers. Alternatively, you can automate Collector distribution by using logon scripts or SMS. For information about distributing the Collector, including sample logon scripts, see "Collection Scenarios" in Application Compatibility Analyzer Help.

**Note**

- If you plan to use logon scripts to run the Collector, use the **/CW** switch to configure the Collector to wait for five minutes before starting collection. This reduces the CPU load at startup.

When the Collector finishes collecting information from all of your computers, you can use the Application Compatibility Analyzer console to merge all of the Collector log files into the SQL or Access database that you defined earlier. For more information about merging Collector log files into a database, see "Merger" in Application Compatibility Analyzer Help.

**Example: Using the Application Compatibility Analyzer to Generate an Application Inventory**
The following example illustrates how the Application Compatibility Analyzer might be used in a network environment.

A midsized company is preparing to deploy Windows XP Professional to all desktop computers. The organization is divided among three physical locations connected by high-speed data connections. The organization uses the Active Directory® directory service within a single domain, and has created an organizational unit (OU) for each physical location (HQ, East, and West).

On Server1, the IT department creates a shared folder for storing all log files generated by the Collector, with the Universal Naming Convention (UNC) path \\Server1\Analyzer, and another shared folder for storing the Collector executable, with the path \\Server1\Collector. The IT department decides to use a logon script assigned through Active Directory to distribute and run the Collector. Because there are three physical locations represented by three separate OUs within the domain, the organization decides to gather data by OU. To accomplish this, the IT department adds the following lines to the logon script:

```
Copy \\server1\collector\collector.exe c:\
C:\collector.exe /O \\server1\analyzer /N /E HQ /CW
```

The first line of code copies the Collector executable program from the shared folder on Server1 to drive C on the client computer. The second line of the code instructs Collector to do the following: send log file output to the shared folder on Server1 that is specified for storing logs (with the **/O** switch); scan network drives that might be mapped (with the **/N** switch); mark the data with an "HQ" designation for the HQ OU (with the **/E** switch); and wait 5 minutes before starting the collection. The IT department can include similar lines for the logon scripts in the East and West OUs, with the exception that the **/E** switch would define the OU name in each case.

# Organizing and Analyzing Inventory Data

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After gathering your inventory data into a single database, you can analyze the applications currently installed in your organization. You can begin to determine which applications are compatible with the new operating system and which are not compatible or require special considerations, and you can make decisions about consolidating the application base in your organization.

**Checking Application Compatibility**

Using the Application Compatibility Analyzer, you can connect to the application compatibility database at Microsoft to determine whether the applications in your organization are compatible with Windows XP Professional or Windows Server 2003. When the Application Compatibility Analyzer tool generates a compatibility report, it automatically accesses the application compatibility database and updates your software inventory with compatibility information. If you use a different tool to generate an inventory, or if you want to check the compatibility of an application that you have not yet deployed, you can use the Windows Catalog instead.

You can use an application's compatibility rating to assess the level of testing that application requires. If your organization uses an application listed as compatible or as designed for Windows XP Professional or Windows Server 2003 without customization, you need only minimally test the product. However, if you customize applications with macros, templates, or custom tools, you need to thoroughly test those applications.

**Checking application compatibility using the Application Compatibility Analyzer**

When you use the Application Compatibility Analyzer tool to request compatibility information for an application from the application compatibility database, one of four levels of compatibility is returned:

- **Compatible.** The application has no known issues.
- **Compatible with Issues.** The application has one or more minor functionality issues.
- **Incompatible.** The application's general functionality fails.
- **Unknown.** The application's compatibility is unknown.

The compatibility levels returned by the application compatibility database are combined with the information in your inventory to create a local application compatibility database for your organization. The local compatibility database provides details about the operating systems and scenarios under which the applications were tested. It also contains other useful information, such as the number of computers on which each application is installed and which departments are using which applications. You can use this information to categorize your applications and prioritize them for testing.

For more information about checking application compatibility with the Application Compatibility Analyzer tool, see "Connecting to the Compatibility Database" in Application Compatibility Analyzer Help.

As you find out more about an application, either through your own testing or from the application vendor, you can update its compatibility information in your local compatibility database.

**Checking application compatibility using the Windows Catalog**

If you gathered your inventory using SMS or a third-party inventory tool, or if you have not yet deployed the application whose compatibility you want to check, you can use the Windows Catalog to check compatibility. In Windows XP Professional or Windows Server 2003, you can open the Windows Catalog by clicking **Start,** clicking **All Programs**, and then clicking **Windows Catalog**. Alternatively, you can use the Windows Catalog link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

If an application is listed as Compatible in the Windows Catalog, either Microsoft or its manufacturer has tested it for compatibility with Windows XP Professional, and it meets specific compatibility criteria. The Windows Catalog also highlights products that are part of the Designed for Windows Logo Program for Windows XP Professional. Products with the Designed for Windows XP logo are specifically created to take advantage of the features of Windows XP Professional, which reduces the number of problems that you might otherwise have in using these applications.

**Gathering Additional Application Information**

Regardless of which tool you use to generate your inventory, you need to manually collect information that is organization-specific or group-specific for each application. This type of information cannot be collected by an inventory tool, but it is important for creating your test plan.

Talk with representatives from the groups that use each application to document:

- A description of the application's function.
- The name of the application vendor (if applicable).
- The version number of the application.
- The importance of the application to your organization.
- The current status of the application (in production, under development, no longer used).
- The development platform for the application (if the application was developed internally).
- Contact names and phone numbers for internal contacts and vendors.
- Other information that pertains to the organization or group's unique use of the application.
- Additional certification or testing that might be necessary to meet government regulations. For example, certain applications used in the development and production of pharmaceuticals must meet certification requirements set by the Food and Drug Administration (FDA). In some cases, if you change the operating system on which the application runs, you might also have to recertify the application.

You can use this information to help prioritize your testing, especially if you have limited resources and are unable to fully test each application.

**Consolidating Your Application Base**

Review the inventory to see if you can consolidate your organization's application base. Limiting the applications used in your organization can minimize your testing effort, decrease configuration variability during deployment, and increase the likelihood of a successful deployment.

Look for the following in your inventory:

- **Several versions of the same application.** Consider updating older applications to newer versions or moving all users to a full-featured version of a particular application. For example, if some of your users use Microsoft® Office 2000 and others use Microsoft® Office XP, you might decide to support only Office XP in the future.
- **Redundant applications.** If groups in your organization are using different applications to accomplish the same tasks, consider moving everyone to the same application.
- **Obsolete applications.** Review your inventory for applications that are rarely or never used in your organization, and consider retiring them.

# Defining Project Constraints and Risks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Identify the project constraints and risks in order to help your team define the parameters of the application deployment project and develop the project plan.

**Defining Project Constraints**

To prioritize and define the scope of the application deployment project, gather information about the constraints of your project. Constraints often include:

- **Resources.** Identify the equipment, software, staff, and space that are available for the project.
- **Time.** Identify the date by which the application deployment project must be completed, and how the application testing process fits into the larger deployment project.
- **Organizational issues.** If the project will not involve the entire organization, identify which groups in your organization will be affected by it. Additionally, determine if a particular group in the organization needs the new operating system sooner than others. If so, you might decide to perform a staged rollout.
- **Access to developers.** Identify applications that were developed in-house or especially for your organization. Access to the developers of these applications is critical during the testing and issue resolution phases of the project. Such access also can be an invaluable aid with retail applications.

**Identifying Risk Factors**

By identifying risk factors, you can identify the potential barriers to a successful deployment and assess the cost of failure for each potential blocking issue. With this information in hand, you can create contingency plans to help mitigate or avoid blocking issues. For application compatibility testing, it is important to think about the project risks early in the project rather than later, during the test planning phase.

The main risk for any application testing and deployment project is the business impact of application failure. For business-critical applications, a failure in deployment could have severe financial repercussions for the organization, whereas the failure to properly deploy an application that is used infrequently by a few users might have very little effect. Assess the financial impact that could be caused by a failure at any time during the deployment project.

For information about assessing constraints and risks, see the Microsoft Solutions Framework link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Planning for Server Application Compatibility

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Assessing the compatibility of server applications with Windows Server 2003 presents some unique challenges. Because server applications tend to span several servers and to do so in several tiers, generating an application inventory, as well as deploying application compatibility fixes for server applications, can be challenging.

Figure 3.4 illustrates when the compatibility of server applications is assessed in the application compatibility testing process.

**Figure 3.4 Planning for Server Application Compatibility**

# Inventory Considerations for Server Applications

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Server applications are often tiered applications with different components running on different servers. This can make generating an inventory of these applications more difficult than doing so for client applications, because the various components of the application might not be associated in the inventory. Work with the owners of the servers in your network to manually associate the various components of the applications within your database.

The Application Compatibility Analyzer does not detect Internet Authentication Service (IAS) applications. If your organization has IAS applications, you must gather inventory data about them manually.

# Obtaining ISV Support for Server Applications

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In large organizations, it is often important to have your Independent Software Vendor (ISV) support all server applications that will be running on the new operating system. Commonly, large organizations check with the ISV to see if there is an update or upgrade that solves application compatibility problems, rather than create an application compatibility fix themselves.

Alternatively, you can obtain a statement of support from an ISV. A statement of support means that the ISV has designed and tested the application to work well with the new operating system. Microsoft continues to work with ISVs to encourage them to provide statements of support for widely used server applications. You can find ISV statements of support for application compatibility in the Windows Server Catalog, or through the online compatibility database that you can access through the Application Compatibility Analyzer. If no statement of support is posted for your application, contact the ISV and request that they publish one through the Windows Server Catalog.

The Windows Server Catalog also contains the names of applications that are certified for Windows Server 2003. Applications that are certified for Windows Server 2003 must pass a rigorous third-party testing process, which provides the highest assurance that they will run on Windows Server 2003.

For more information about the Windows Server Catalog, see the Windows Server Catalog link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

In some cases, you might find that an ISV does not support the version of the software that you are using in the production environment, but does support a later version. If this is so, consider upgrading to the supported version.

**Note**

- An ISV can submit information about an application through the Designed for Windows Logo Program. For more information, see the Designed for Windows Logo Program link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Special Considerations for Server Applications

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The following sections provide information about server application compatibility.

**Active Directory Considerations**
Several changes in the implementation of Active Directory between Windows 2000 and Windows Server 2003 might affect your applications.

**Anonymous LDAP operations**
In earlier versions of Windows, Active Directory accepted anonymous client requests. With Windows Server 2003, only authenticated users can initiate a Lightweight Directory Access Protocol (LDAP) request against Windows Server 2003–based domain controllers. For more information about anonymous LDAP requests, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources, and search for article number 326690 "Anonymous LDAP Operations to Active Directory Are Disabled on Windows Server 2003 Domain Controllers."

**Microsoft Exchange Server 2000 schema conflicts**
The Microsoft® Exchange Server 2000 schema defines several attributes differently from those defined in RFC 2798, "Definition of the inetOrgPerson LDAP Object Class." The attributes — **Secretary**, **labeledURI**, and **houseIdentifier** — also are defined by the base schema. This deviation can cause problems when you upgrade from Windows 2000 to Windows Server 2003. During the upgrade to Windows Server 2003, the **ldapDisplayNames** values for these attributes are renamed to permit the upgrade to succeed, causing duplicate names. This renaming does not cause problems with the functioning of Active Directory or the operating system, because the names are not used in this context. However, you might have an application that needs to access these values, which will be inaccessible.

This situation is not a problem if:

- You add the Windows 2000 InetOrgPerson Kit to a Windows 2000 forest before you run the Windows Server 2003 **adprep** command.
- You run the Windows Server 2003 **adprep** command in a Windows 2000 forest before you install Exchange Server 2000.
- You add Exchange Server 2000 to an existing Windows Server 2003 forest.

However, you may encounter problems if:

- You add the Exchange Server 2000 schema to a Windows 2000 forest before you add the InetOrgPerson class from the InetOrgPerson Kit.
- You add the Exchange Server 2000 version of the InetOrgPerson class to a Windows 2000 forest before you run the Windows Server 2003 **adprep** /**forestprep** command.
- A Windows 2000 domain controller that contains the Exchange Server 2000 definition of InetOrgPerson does not receive updates to Active Directory after you run InetOrgPerson-Fix.ldf from the Windows 2000 InetOrgPerson Kit.

For more information, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources and search for article number 314649 "Windows Server 2003 ADPREP Command Causes Mangled Attributes in Windows 2000 Forests That Contain Exchange 2000 Servers," and 328661 "XADM: Running Exchange 2000 Setup with /Forestprep Switch Produces Error 0XC1037AE6."

**Message Queuing**
Several features of previous versions of Microsoft® Message Queuing (MSMQ) have been removed from MSMQ version 3.0, which ships with Windows Server 2003. In addition, one feature has been changed. Consequently, you might need to modify applications that rely on features that are no longer relevant or useful, or that have been superseded by other features.

Feature changes include:

- The MSMQ Exchange connector is no longer supported in Windows XP Professional and Windows Server 2003. It continues to be available for Windows NT Server 4.0 and Windows 2000.

- The Internetwork Packet Exchange (IPX) protocol is not supported in MSMQ 3.0.

- The MSMQ 3.0-dependent client supports only the MSMQ version 2.0 level of functionality. This means that new MSMQ 3.0 features, such as distribution lists, are not available to MSMQ 3.0-dependent clients. The alternative is to deploy DCOM-based solutions instead.

If your applications use any of these features, verify that they work with MSMQ 3.0.

For more information about applications and MSMQ, see the "Programming Best Practices with Microsoft Message Queuing Services (MSMQ)" white paper, available through the Message Queuing link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Internet Information Services**
Windows Server 2003 includes Internet Information Services (IIS) version 6.0. Changes made in IIS 6.0 might affect your Web applications unless you address the following configuration issues during the installation of Windows Server 2003:

- IIS is not installed by default during a clean installation, except on the Microsoft® Windows® Server 2003, Web Edition, operating system. If you plan to run Web-based applications on other editions of the Windows Server 2003 operating system (Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003 Enterprise Edition; or Windows® Server 2003, Datacenter Edition), you must install IIS.

- Active Server Pages (ASP), ASP .NET, Server Extensions (installed and enabled) for the Microsoft® FrontPage® Server Extensions (installed and enabled), Web-based Distributed Authoring and Versioning (WebDAV), and all other Internet Server API (ISAPI) extensions and Common Gateway Interface (CGI) applications by default are not enabled when you enable the Application Server Role in **Add/Remove Windows Components**. You can install these by using **Add/Remove Windows Components**, and then enable them in the Web Service Extensions node in IIS Manager.

- If you perform a clean installation of IIS 6.0, IIS 6.0 runs in worker process isolation mode by default. To take advantage of the new security, availability, and scalability features in IIS 6.0, IIS 6.0 must be running in worker process isolation mode. However, for compatibility purposes, you can change the application isolation mode to IIS 5.0 isolation mode if the application must run in the Inetinfo.exe process or Dllhost.exe process, or when the application uses ISAPI filters that perform raw data reads.

For more information about IIS and compatibility problems for Web applications, see "Migrating IIS Web Sites to IIS 6.0" in *Deploying Internet Information Services (IIS) 6.0* of this kit (or see "Migrating IIS Web Sites to IIS 6.0" on the Web at http://www.microsoft.com/reskit).

**Terminal Server**
Because Terminal Server is available for multisession or multiuser use, and because display and keystroke information travels over the network, applications that have certain characteristics might perform poorly with Terminal Server. When planning to host applications with Terminal Server in your organization, establish a set of acceptable performance guidelines and determine through testing whether such applications run better on the user's local computer or over your intranet. For more information about application compatibility with Windows Server 2003 Terminal Server, see "Hosting Applications with Terminal Server" in *Planning Server Deployments* of this kit.

For more information about server application compatibility, see the Server Roles: The Application Server link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Enhanced Security Configuration in Internet Explorer

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To prevent security risks, the default configuration of Internet Explorer has changed in Windows Server 2003. This new default configuration, known as Internet Explorer Enhanced Security Configuration, restricts the ability of a Web site to download files and to run scripts and ActiveX® components. In addition, the Internet Explorer Enhanced Security Configuration disables Internet Explorer's ability to detect whether a Web site is in the Local intranet zone, which restricts access to such things as: intranet Web sites, Web-based applications that run over the intranet, and files or folders on network shares. The Local intranet zone is one of the four Web content zones, along with Internet, Trusted sites, and Restricted sites.

Prior to the implementation of the Internet Explorer Enhanced Security Configuration, anything that was in the Local intranet zone was considered trustworthy. For example, if Internet Explorer determined that a Web site was in the Local intranet zone, and the Web site requested a user's credentials, Internet Explorer would automatically pass the credentials to the Web site without prompting the user. Under the Internet Explorer Enhanced Security Configuration, intranet Web sites and universal naming convention (UNC) paths must be explicitly specified in the Local intranet zone or the Trusted sites zone to be considered trustworthy.

Because of the Enhanced Security Configuration settings, some applications might experience problems interacting with Web sites, network resources, and ActiveX components and scripts. These problems can occur when an application is being installed and when an application is running. For example, the Enhanced Security Configuration can prevent an application from being installed properly when the application attempts to download required files from a site that is restricted. Similarly, the Enhanced Security Configuration can prevent an application from running properly when it attempts to use an Internet Explorer feature that has been disabled. In addition, an application might not be able to use a UNC path to access a shared folder across the network.

To overcome these limitations, you can:

- Add trusted sites and UNC paths to the Trusted sites zone or to the Local intranet zone.
- Modify Internet Explorer security settings for a specific content zone or all content zones.
- Disable Internet Explorer Enhanced Security Configuration settings.

If you know that an application requires access to an Internet site that is restricted, you also can request that the application vendor change the application setup program so that the required Web site is added to the Trusted sites zone during installation.

**Caution**

- Do not disable the Enhanced Security Configuration settings unless you have no other alternative. Disabling the Enhanced Security Configuration increases the risk of security attacks.

For more information about Enhanced Security Configuration settings, see "Internet Explorer Enhanced Security Configuration" in Help and Support Center for Windows Server 2003.

# Testing Applications for Compatibility with the Enhanced Security Configuration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When a user or an administrator opens Internet Explorer for the first time on Windows Server 2003, a default home page that contains information about the Internet Explorer Enhanced Security Configuration is displayed in the browser window. If the user is not a member of the Administrators group, the home page describes the Enhanced Security Configuration and explains how the user can access a Web site that is not trusted. If the user is a member of the Administrators group, the home page describes the Enhanced Security Configuration in detail and explains how the administrator can modify it. Because OEMs can set a different default home page as part of their system configuration, a warning explaining that the Enhanced Security Configuration is enabled is also displayed in a separate dialog box. Users can permanently dismiss this dialog box.

When users start Internet Explorer directly — for example, by clicking a shortcut to Internet Explorer or by clicking Internet Explorer on the **Start** menu — these messages provide clear guidance for what to do if a Web site does not display properly or if a network resource cannot be reached. However, if an application starts Internet Explorer, the user might not receive these warnings and, consequently, will not understand why the application is failing or how to resolve the problem.

There are four primary types of problems to look for when you test server applications under the Internet Explorer Enhanced Security Configuration settings.

**Sites and UNC paths are not listed in the trusted Web content zone** Look for cases where an application starts Internet Explorer so that the user can view a Web site, download files, or run a Web-based application. If the application cannot access these Web sites, applications, or resources, see if you can resolve the problem by adding the Web site or UNC path to the Trusted sites zone or to the Local intranet zone (if appropriate).

**Use of client-side redirection** Look for cases where an application's online content relies on client-side redirection (for example, an application tries to open a Web page, but then gets routed automatically to a different URL). Client-side redirection is disabled under the Enhanced Security Configuration. For client-side redirection to work properly, the target Web site needs to be added to either the Trusted sites zone or to the Local intranet zone (if appropriate).

**Dependency on ActiveX components** Look for cases where an application accesses a Web site that relies on Active X components to display properly, such as a Web site that requires Macromedia Flash or Adobe Acrobat. You need to download and install these types of Web-based applications and ActiveX components on a per-computer basis, as you would do with any other application software.

**Use of Internet Explorer features** Although they are not obvious, look for cases where an application relies on Internet Explorer features and components — for example, Install on Demand or multimedia features.

While most applications that rely on Internet Explorer features will work properly, in some cases an application, or some extensible component within an application, might attempt to access an Internet Web site that relies on a script or an ActiveX component. In these cases, if the Web site is not listed in the Trusted sites zone, the script or ActiveX component will not run properly, and the user will be prompted to add the Web site to the Trusted sites zone. You can eliminate the need for user intervention by identifying the scripts and ActiveX components that an application relies on and by deploying those scripts and ActiveX components to your user base, just as you would any application.

# Modifying Enhanced Security Configuration Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can modify Enhanced Security Configuration settings manually by using **Add or Remove Programs** and **Internet Options** in Control Panel. Usually, you modify settings manually on a single machine when you are testing applications and trying to identify and resolve problems. You also can automate the modification of Enhanced Security Configuration settings during an unattended installation or during an image-based installation with Sysprep by changing answer file settings. Usually, you automate configuration tasks when you are deploying an operating system and applications to many computers.

**Manually Modifying Enhanced Security Configuration Settings**

When Enhanced Security Configuration settings are enabled, it reduces the exposure of your server to security attacks from Web sites that are not listed in the Local intranet zone or in the Trusted sites zone. By adding intranet Web sites and UNC paths that you trust to the Local intranet zone, or by adding Internet Web sites to the Trusted sites zone, you can maintain the security of your server computers while allowing access to trusted Web sites.

**To add Web sites and UNC paths to the Local intranet or Trusted sites zones**

1. In Control Panel, double-click the icon for **Internet Options**.
2. On the **Security** tab, click **Local intranet** or **Trusted sites**, depending on which Web content zone you want to add a Web site or a UNC path to.
3. Click **Sites**.
4. In the **Add this Web site to the zone** text box, type the URL of the Web site or UNC path that you want to add, and then click **Add**.

**Important**

- Do not add Internet Web sites to the Local intranet zone. User credentials can be passed to Web sites in the Local intranet zone without notifying the user.

When the Enhanced Security Configuration is enabled, several of the extensibility and security features of Internet Explorer are adjusted to decrease security risks. As a consequence, some scripts, ActiveX components, and other applications might not run. By changing these settings, you can maintain the security of your server computers and still allow certain scripts, ActiveX components, and applications to run.

**Important**

- Changing extensibility and security features requires in-depth knowledge and understanding of the consequences and is not recommended.

**To modify Internet Explorer extensibility and security features**

1. In Control Panel, double-click the icon for **Internet Options**.
2. On the **Advanced** tab, configure extensibility and security features by selecting or clearing the check box next to the feature.

The Enhanced Security Configuration can be enabled or disabled based on group membership. You can disable the Enhanced Security Configuration for members of the Administrators group (it is enabled by default), and you can enable Enhanced Security Configuration for members of the Users group (it is disabled by default). Usually, you disable the Enhanced Security Configuration for members of the Administrators group only when you are testing applications or when you are configuring a computer prior to putting the computer into a production environment. You should always enable the Enhanced Security Configuration for members of the Administrators group before you put a computer into a production environment.

**To enable or disable Enhanced Security Configuration**

1. In Control Panel, double-click **Add or Remove Programs**.

2. Click **Add/Remove Windows Components**.

3. Click **Internet Explorer Enhanced Security Configuration**, and then click **Details**.

4. Select the group for which you want to enable or disable Enhanced Security Configuration, and then click **OK**.

**Automating the Modification of Enhanced Security Configuration Settings**

There are two ways to modify Enhanced Security Configuration settings during an unattended installation or during an image-based installation with Sysprep: you can add trusted Web sites to the Local intranet zone or to the Trusted sites zone, or you can disable or enable the Enhanced Security Configuration.

Usually, during an automated installation, you do not need to disable the Enhanced Security Configuration. However, there is one case in which you might need to do so. If you are performing image-based installations with Sysprep, and you set up your master installation by performing an unattended installation, you might need to disable the Enhanced Security Configuration so that you can download and install ActiveX components, device drivers, and applications on the master installation. You can then enable the Enhanced Security Configuration during the Factory mode phase of the image-based installation. For more information about automated installations, see "Deploying and Distributing Applications and .Sdb Files" later in this chapter.

**Adding Web sites to Web content zones during automated installations**

You can add Web sites to the Trusted sites zone and the Local intranet zone by configuring the [IEHardening] section of the unattended installation answer file (Unattend.txt) and the Factory mode answer file (Winbom.ini). The unattended installation answer file is used to automate an unattended installation; the Factory mode answer file is used to automate the Factory mode phase of an image-based installation that uses Sysprep. The syntax is the same for both answer files.

You can add Web sites to the Trusted sites zone by using the following entry in the [IEHardening] section of Unattend.txt or Winbom.ini:

```
TrustedSites = url_1 [,url_2]…
```

You can add Web sites to the Local Intranet zone by using the following entry in the [IEHardening] section of Unattend.txt or Winbom.ini:

```
LocalIntranetSites = url_1 [,url_2]…
```

**Enabling or disabling Enhanced Security Configuration during automated installations**

You can enable or disable the Enhanced Security Configuration by configuring the [Components] section in the unattended installation answer file (Unattend.txt) and the Factory mode answer file (Winbom.ini). The syntax is the same for both answer files.

You can enable or disable the Enhanced Security Configuration for members of the Administrators group by using the following entry in the [Components] section of Unattend.txt or Winbom.ini:

```
IEHardenAdmin = On | Off
```

You can enable or disable Enhanced Security Configuration for members of the Users group by using the following entry in the [Components] section of Unattend.txt or Winbom.ini:

```
IEHardenUser = On | Off
```

# Creating an Application Compatibility Test Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you have gathered the preliminary information that you need, you can begin creating your application compatibility test plan. Your application compatibility test plan should address all of the issues that are typically addressed in a standard test plan — testing scope and objectives, testing hardware and software requirements, incident tracking procedures, testing scheduling, and so on. Most of these issues are discussed earlier in this chapter and in "Designing a Test Environment" in this book.

You can use this information to create the foundation of your application compatibility test plan. In addition, your application compatibility test plan should:

- Define your testing methodology.
- Identify which applications you need to test.

Figure 3.5 shows when these activities occur in the application compatibility testing process.

**Figure 3.5 Creating an Application Compatibility Test Plan**

For complete information about creating your overall test plan, see "Designing a Test Environment" in this book.

# Defining a Test Methodology

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Two testing methodologies are useful for testing application compatibility: Windows Fundamentals Test Methodology and Windows Applications Exploratory Test Methodology. Use Windows Fundamentals Test Methodology when your testing team thoroughly understands how an application works and how the groups who use the application expect it to perform. Use Windows Applications Exploratory Test Methodology, a more ad hoc form of testing, when this is not the case.

For more information about Windows Fundamentals testing and Windows Applications Exploratory testing, see "Developing Test Cases" later in this chapter.

# Identifying the Applications to Test

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Most medium-to-large organizations use so many applications that it is not possible to test them all thoroughly. Consequently, most organizations prioritize the applications they plan to test.

After you have consolidated your application base, so that only the applications that you plan to support with the new operating system are listed, you can prioritize your list based on factors such as whether applications are compatible with Windows Server 2003, how critical they are to your business operations, and the number of users who depend upon them. If the amount of time available for testing or your resources are limited, you can use this prioritized list to decide whether to perform a reduced set of tests on an application or set of applications or whether to not test certain applications at all.

**Important**

- If time and resources permit, full testing of all applications is recommended.

The ultimate goal of prioritizing inventoried applications is to identify the core group of applications that must function properly before you begin to roll out the new version of the Windows operating system. Whether you use existing priority categories — such as those you use for disaster recovery — or use the categories suggested here, the categories need to account for this core group of applications.

Use the information in the following sections and any other considerations unique to your particular situation to establish the testing priority for each application.

**Prioritizing Application Testing Based on Levels of Compatibility**

Using the compatibility information that you obtained through the Application Compatibility Analyzer or the Windows Catalog, you can begin to prioritize the level of application testing. Use the information in Table 3.3 to assist with this task.

**Table 3.3 Application Compatibility Priority Categories**

| Application's Compatibility | Priority Recommendation |
|---|---|
| **Compatible**. The application has been tested and is deemed compatible with Windows XP Professional or Windows Server 2003. | If the application is used without customization, you might assign it low priority. However, it is recommended that you test compatible applications with your organization's Active Directoryand Group Policy infrastructure, at a minimum, to ensure that there are no problems in your particular environment.<br><br>If you use the application with customizations such as templates or macros, at the very least test the customizations. |
| **Compatible with Issues**. The application typically is compatible, but might have problems when run in certain contexts. | Consult the Application Details section of the Application Compatibility Analyzer report to identify the situations under which the application has problems, and test the application in those situations. Also test compatible applications with your organization's Active Directory and Group Policy infrastructure to ensure that there are no problems in your particular environment. |
| **Incompatible**. The application is not compatible with Windows XP Professional or Windows Server 2003. | If the Application Details section of the Application Compatibility Analyzer report lists fixes for the application, fully test the fixes within your environment. |
| **Unknown**. Either the application or its compatibility with Windows XP Professional or Windows Server 2003 is unknown to Microsoft. | Fully test the application if you plan to use it in your production environment. |

**Prioritizing Application Testing Based on How Critical Applications Are to Your Business**

By using the information that you collected from the groups who use the applications, you can prioritize the testing of your applications based on how critical they are to your organization's business. Use the categories listed in Table 3.4 to prioritize

your applications for testing using this criterion.

**Table 3.4 Business Priority Categories**

| Category | Impact of Failure | Priority Recommendations |
|---|---|---|
| **Mission-critical**. Required in order to collect revenue or to fulfill legal obligations; must be first back online after a disaster occurs. | High | Thoroughly test the application in the proposed environment even if it is listed as compatible with the new operating system. Situations in your network or domain infrastructure might cause unforeseen compatibility problems with a mission-critical application, which must be fixed before you deploy the application and new operating system. |
| **Business-critical**. Required in order to run the business infrastructure; should be second back online after a disaster occurs. | Moderate | Thoroughly test the application in the proposed environment; however, if an application is listed as compatible, and it has not been customized, you might consider testing only the most important functionality if time is limited. |
| **Required**. Required in order to run the business, but can be offline longer. | Low | Thoroughly test the application in the proposed environment; however, if an application is listed as compatible, and it has not been customized, you might consider not testing it if time is limited. |
| **Other**. Not required in order to run the business. | Very low | Thorough testing is not necessary for the application. |

**Prioritizing Application Testing Based on Usage**

In prioritizing the applications that you plan to test, consider the impact of the failure of an application on the organization as well as the number of employees who use it.

The report generated by the Application Compatibility Analyzer can tell you how many desktops in the organization each application is installed on. You should test an application that is used by many employees, regardless of whether the application is listed as compatible with the operating system. An example of this type of application is antivirus software that runs on every desktop in the organization.

If only a few employees use an application, but its failure will affect a great number of employees, you should test the application. For example, only a few people in the accounting department use the payroll software. However, if that software does not work properly, all employees might receive their paychecks late.

# Preparing for Application Testing

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before application testing can begin, you must prepare your test environment. It is assumed that your organization has a test lab and has established standards and best practices for testing. If this is not the case, see "Designing a Test Environment" in this book for information about designing and setting up your test lab.

To prepare your test environment, you need to set up your test lab for application compatibility testing, install tools for testing applications and for debugging them, gather all of the information and components needed to install and test each application, and develop test cases. Figure 3.6 shows when these tasks occur within the application compatibility testing process.

**Figure 3.6 Preparing for Application Testing**

# Setting Up a Test Lab

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To determine whether your applications are compatible with Windows XP Professional or Windows Server 2003, you must test them in a lab environment on computers that represent the hardware and software configurations found in your organization. These hardware and software configurations include variables such as all of the operating systems that interoperate in your environment; a mix of clients; the mix of applications to be installed on a single computer; and all the supporting programs, hardware components, and required files. Therefore, the size and complexity of the test lab is determined by the complexity of the applications to be tested and by the network environment where you plan to deploy them.

In addition to duplicating hardware and software configurations, you need to simulate the way that you install and use the applications in your production environment. For example, one organization has a production environment that encompasses thousands of applications running on both Windows NT Server 4.0 and Windows 2000. This organization uses scripted application installations to control the application environment and to prevent unauthorized copying or installation of third-party products. In addition, it standardizes drive mappings for production applications. For example, drive F is reserved for authorized applications for which users have read-only access, drive G is reserved for authorized applications for which users have read and write access, and drive J is reserved for the users' customized and personal settings, which are retained across sessions.

The test lab includes separate network shares to simulate the drive mappings. Windows XP Professional is installed on all of the test lab computers, except for two baseline computers that have Windows NT Server 4.0 and Windows 2000 installed. Each computer is set up with a core set of applications that are common to all users — such as an office productivity suite, Internet browser, antivirus application, and administrative tools. This core set of applications is pretested for compatibility. Each additional application is then tested using the production application installation script in an environment where the core applications are installed.

# Determining a Lab Strategy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Depending on your circumstances and environment, you might decide to test applications in the same lab that you use to test your Windows Server 2003 family deployment. However, if you have the budget and the space, it might be more efficient to have a separate lab for testing applications. For example, if you have many applications, a lab that can be used full-time only for testing applications can make it easier for you to meet your schedule.

The lab that you use for testing applications can be centralized or distributed. If your application owners and testers are widely dispersed, a distributed lab can make resources more readily available during testing and also can help end users become involved in testing. Because distributed labs can require a greater investment in equipment and can be more complex to manage, you might combine both approaches. For example, you might use a large, centralized lab to test critical line-of-business applications that require specialized servers and configurations, and use smaller, distributed labs to test more independent workstation applications. A distributed lab in this case might be as simple as a workstation on a tester's desk.

When deciding your lab strategy, consider the following factors:

- The number and complexity of applications to be tested
- The location of application testers
- The location of application owners
- Budget and space constraints
- Hardware constraints
- Transportation time and costs

For more information about centralized and distributed testing facilities, see "Designing a Test Environment" in this book.

# Configuring the Lab

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In the test lab, configure test stations that can be independently managed and scheduled. If enough computers are available, include at least two workstations in each test station to support side-by-side testing. Configure one with the operating system that is currently deployed and one with the new operating system. If you do not have enough computers for each test station, provide a separate group of computers running the current operating system that you can assign as needed.

If you plan to deploy Windows XP Professional or Windows Server 2003 by performing system upgrades rather than clean installations, you need to test how applications behave on the new operating system without reinstalling them. To test, include a workstation that is running your current version of the operating system in each test station, so that you can install each application before you upgrade to the new operating system.

Provide each test station with its own dedicated monitor, keyboard, and mouse. To isolate problems that might occur at a test station, configure each one so that it can be detached quickly from the rest of the test network, for example, by unplugging a cable or making a programmatic change. Provide access to peripheral devices such as printers and scanners, so that testers can test the full functionality of applications.

To facilitate testing, configure the workstations with the following features:

- **Enable auditing to monitor permission failures.** Because the default settings for Windows XP Professional and Windows Server 2003 are more secure than those in earlier versions of Windows, it is not uncommon for an application to fail because permissions are invalid, especially when the application is installed or when it accesses files. Use the audit log and the event log to identify permissions that need to be changed to allow an application to be installed and to run. For more information about the event log and audit log, see Event Viewer overview in Help and Support Center for Windows Server 2003.

- **Enable crash dump files in Dr. Watson.** *Crash dump files* are binary files that capture the contents of memory when a fatal error occurs. Crash dump files can be loaded into a debugger. For information about configuring Dr. Watson to enable crash dump files, see "Using Dr. Watson" in Help and Support Center for Windows XP Professional.

Mirror the corporate domain structure in the lab, and duplicate user rights for both the domain and the workstations. If you plan to use Group Policy settings in your new environment, implement those policies in the lab.

As a rule, try to duplicate resources such as databases and client/server applications in the lab. If you cannot duplicate some resources, such as mainframe databases, and therefore need to access them over the corporate network, plan how to regulate and control the connection, and devise a quick way to terminate it if that becomes necessary.

As a best practice, rebuild the workstations and, possibly, the servers before testing each application. This approach minimizes the possibility of introducing problems that are not related to application compatibility and helps testers identify problems. To ensure a consistent starting point and to reduce setup time, use scripts or computer images to rebuild the workstations. Your baseline image should include your organization's core applications so that as you test each application, you also test for possible negative interactions between applications.

For more information about designing and configuring a test lab, see "Designing a Test Environment" in this book.

# Installing Application Testing Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After setting up the test lab, gather and install application testing tools. Be sure to install any testing tools that you use to automate tests, such as scripts and batch files, as well as the tools in the Windows Application Compatibility Toolkit that are used to apply application compatibility fixes.

**Testing Tools**
Some testing tools gather or define test data, others run tests, and still others monitor what happens to files and the registry when tests run. The following types of tools automate various steps in the testing process:

- Test automation tools, such as record and playback tools, or test case generators
- Custom scripts, such as installation scripts
- Data extraction tools, such as data warehouse tools
- Test databases, such as those created for regression testing
- Comparison and monitoring tools, such as tools that track file and registry changes

**Windows Application Compatibility Toolkit**
The Windows Application Compatibility Toolkit, provided by Microsoft, contains Windows Application Verifier, a tool that helps uncover heap problems and other problems that are difficult to locate, and Compatibility Administrator, a tool that applies application compatibility fixes to an application when it runs in order to resolve compatibility problems. The application compatibility fixes help resolve compatibility problems when you do not have access to the source code or when you do not have sufficient time to debug, modify, and implement code changes. Because application compatibility fixes do not modify source code, you must apply them whenever you install an application on a workstation.

# Installing Debugging Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If the source code for an application is available, and you want to resolve the underlying cause of compatibility problems by modifying the source code, use a debugging tool to investigate the problem. You can use your own debugging tools, or you can use Debugging Tools for Windows.

Debugging Tools for Windows is a collection of kernel-mode and user-mode debuggers provided by Microsoft. Applications run in one of two modes: *kernel mode* or *user mode*. Operating system services and some low-level programs, such as device drivers and antivirus applications, run in kernel mode. Kernel-mode applications can access any part of the system. User-mode applications are limited to their allocated area in memory and have restricted access to system interfaces and system data. Most end-user applications run in user mode.

Choose a tool based on the type of application that you need to debug (a kernel-mode or user-mode application) and whether you will use a local or remote computer for debugging. Most of the applications that you need to test for compatibility with Windows XP Professional are user-mode applications; however, you might need to test kernel-mode applications if you develop device drivers or other kernel-mode applications in-house. If you have kernel-mode applications that have been developed by third-party vendors, contact those vendors for upgrades.

Table 3.5 lists each debugger included in Debugging Tools for Windows, telling the processing mode for which it is designed and whether it must be used from the local computer or a remote computer.

**Table 3.5 Debugging Tools for Windows**

| Tool | Processing Mode | Debugging Computer |
|---|---|---|
| Microsoft Console Debugger (CDB) | User mode | Local or remote |
| Microsoft NT Symbolic Debugger (NTSD) | User mode | Local or remote |
| Microsoft Windows Debugger (WinDbg) | User mode and kernel mode | Local or remote |
| Microsoft Kernel Debugger (KD) | Kernel mode | Remote |

**Important**

- Debugging information for all system applications, drivers, and DLLs resides in separate files known as *symbol files*. By separating debugging information from the application, symbol files allow applications to be smaller and faster, but still permit them to be debugged if the symbol files are installed. If you use a Microsoft debugger on a third-party application that has no symbol file, the debugger tries to extract symbolic information from the executable file and indicates that the characters are export symbols. These are not actual symbols, and they should not be used for debugging analysis.

In addition to the debuggers, Debugging Tools for Windows provides some other tools that can help you during debugging. The Logger and LogViewer, in particular, can help you debug application compatibility problems. Logger and LogViewer can help you analyze the API calls made by an application. If an application worked on an earlier version of Windows, differences in API implementations probably are causing the incompatibilities. One of the most effective ways to debug a third-party application is to examine the Win32 APIs that it calls.

**CDB and NTSD**

Microsoft Console Debugger (CDB) and the Microsoft NT Symbolic Debugger (NTSD) are console debuggers that allow you to analyze user-mode memory and constructs on target applications that are either console or graphical Windows applications. CDB and NTSD have the same functionality, except that NTSD opens a second command window when it is started. When you use these tools to debug an application that has failed, they can obtain a stack trace or display invalid parameters. You also can use them to observe the behavior of an application that is functioning properly.

By using CDB or NTSD, you can display and execute program code, set breakpoints, and examine and change values in memory. CDB and NTSD can disassemble binary code and display assembly instructions. They also enable you to analyze source code directly.

**Note**

- A copy of NTSD is installed in the \Windows*system32* directory when Windows XP Professional or Windows Server 2003 is installed, but the version included with Debugging Tools for Windows is the most recent version. The version of NTSD installed with Windows XP Professional or Windows Server 2003 can be used only for local debugging.

**WinDbg**

WinDbg is a graphical interface debugger that supports full source-level debugging for the Windows kernel, kernel-mode drivers, and system services, as well as user-mode applications and drivers. WinDbg is the most versatile debugger in Debugging Tools for Windows. It can monitor variables, CPU registers, and parameters passed in function calls. You also can use it to review a crash dump file from Dr. Watson, which captures the state of the system when a failure occurs. By using WinDbg, you can view source code, set breakpoints, and view variables (including C++ objects), stack traces, and memory.

**Logger and LogViewer**

Logger monitors the actions of a user-mode application and records all of its API calls. You can display the resulting information in a debugger, save it as a text file, or display it in an interactive format in the LogViewer.

You can start Logger by using the stand-alone Logger.exe program, or by starting NTSD or WinDbg, and using the LogExts.dll debugger extensions. Both methods produce the same type of log output. By starting Logger with NTSD or WinDbg, however, you have access to all the functionality of both a debugger and Logger.

After logging the API calls, you can use LogViewer to view the log file. You can view the list of all the API calls in the order in which they were logged, filter the list, export the list to a text file, and view the values of parameters sent to or received from each API call.

**Obtaining Debugging Tools for Windows**

Debugging Tools for Windows are available for downloading. To use the tools, you should also install the appropriate symbol files for the version of Windows that is running the application that you need to debug. Symbol files contain a variety of information that is not required to run a program, but that is useful for debugging. This information is contained in a symbol file instead of in the executable file for performance purposes. To download the most recent version of Debugging Tools for Windows and the appropriate symbol files, see the Debugging Tools link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources. For more information about debugging, including information about debugging tools, see *Using Debugging Tools for Windows*, which is installed when you install the Debugging Tools for Windows. To open *Using Debugging Tools for Windows* on Windows XP Professional, click **Start**, click **All Programs**, click **Debugging Tools for Windows**, and then click **Debugging Help**. To open *Using Debugging Tools for Windows* on Windows Server 2003, click **Start**, click **Programs**, click **Debugging Tools for Windows**, and then click **Debugging Help**.

# Gathering Application Information

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you begin testing, gather everything that you need for testing each application. Microsoft customers have found that the more effort they put into preparation and information gathering before beginning to test, the faster and more easily testing progresses. Having all related information readily available also makes it easier to resolve any problems that testing uncovers.

For each application, gather its software and documentation along with supporting components required to install and run the application, and find out whether the application is dependent on the network basic input/output system (NetBIOS).

**Gathering Software and Supporting Information**

Work with the application owners within your organization to locate each application and its documentation. Before installing each application in the test lab, gather the supporting information and components that are required to run it. For example, gather the following information:

- Required security clearances, such as user IDs, passwords, database permissions, group memberships, and so on.
- Required servers and IP addresses.
- Accurate installation instructions, installation media, and contact information for application experts.
- Service packs or patches that have been applied or are required.
- Software dependencies, such as the need for SQL Server or third-party components.
- Whether the application is client-based or server-based, and where each component resides — on the client or on the server.
- The version of Windows on which the application currently runs.
- Application configuration information, such as search paths and working directories.
- The directory path where the application files are installed.
- Registry settings that the application creates or modifies.
- The location where user data is stored.
- URLs for Web applications.
- The location of symbol files that were created when the application was compiled, for use with debuggers.

**Identifying NetBIOS Dependencies**

Determine whether any applications require NetBIOS. If any do, ensure that NetBIOS is included in the new Windows environment.

On computers running Windows 95, Windows 98, and Windows NT, NetBIOS is enabled by default. On computer running Windows 2000, Windows XP Professional, and Windows Server 2003, NetBIOS is disabled by default. If an application runs on a system without NetBIOS and calls functions that use NetBIOS, the functions return errors. In such a situation, you must either enable NetBIOS or change the application to use functions that do not depend on NetBIOS.

# Developing Test Cases

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before starting to test, develop and document *test cases*, which describe the tests to be performed and, if possible, the expected results. The number and complexity of test cases that you need depends in part on how extensively you need to test an application. The extent of testing required for an application depends on several factors, including the application's level of compatibility, how critical the application is to your business, and how often the application is used. In addition, the extent of testing required depends on whether the application is a third-party product, has been customized, or was developed in-house. For third-party applications, the extent of testing also depends on whether the application is known to be compatible with the new version of Windows that you are deploying.

Applications that require limited testing fall into the following categories:

- Applications that are listed as Compatible in the Windows Catalog
- Applications that are not required to run the business
- Applications that are required to run the business, but can be offline for long periods of time without impacting the business
- Applications that do not impact the organization severely if they fail

Usually, you do not need to develop complex or wide-ranging test cases for these types of applications.

Applications that require in-depth testing fall into one or more of the following categories:

- Applications that have been developed in-house
- Applications that have been customized for your organization
- Applications whose compatibility is listed as Unknown by the Application Compatibility Analyzer
- Applications that are listed as Compatible with Issues by the Application Compatibility Analyzer
- Applications that are not listed in the Windows Catalog

For these applications, you need to develop a wide range of test cases that encompass all the functionality required in your environment.

Applications that are listed as Compatible by the Application Compatibility Analyzer or in the Windows Catalog or that are listed as Designed for Windows XP in the Windows Catalog do not need to be tested as extensively as those in the preceding list. Even so, you should perform general testing to ensure that these applications perform as expected, given the way they are used with your hardware and software configuration. Develop test cases for the functions that are used most frequently and for any atypical functions or unique techniques that are used. For example, if your organization uses scripts to manage the desktop environment, test the applications with those scripts. If your organization hosts applications with Terminal Server, remember to include test cases to test the applications with Terminal Server.

The testing methodology that you choose for each application determines how you develop the test cases. Many testing methodologies exist, and you might already have one that you use. If you do not already have a methodology for developing test cases, use one of the following methodologies:

- Windows Fundamentals Test Methodology, which helps you develop test cases when you have an in-depth understanding of the application
- Windows Applications Exploratory Test Methodology, which helps you develop test cases as you learn about an application that is unfamiliar to you

# Using Windows Fundamentals Test Methodology

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Windows Fundamentals Test Methodology provides guidelines for developing test cases when you are familiar with an application, its end users, and its use in your environment. When you have this level of knowledge about an application, you can develop test cases based on the way your organization uses it.

When using the Windows Fundamentals test method, define the test cases ahead of time, before you start testing the application. Develop test cases for the following four areas: installation, operating system interaction, application functionality, and uninstallation. For a checklist to help you track your Windows Fundamentals tests, see the "Windows Fundamentals Testing Checklist" (PDP_APPA_2.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see the "Windows Fundamentals Testing Checklist" on the Web at http://www.microsoft.com/reskit).

**Developing Test Cases for Installation**

Even if you plan to upgrade from an earlier version of Windows to Windows XP Professional or Windows Server 2003, you need to test application installation. This phase of testing verifies that an application can be installed correctly — whether by a user, a power user, or an administrator account — and that the various installation methods — typical, network, full, and minimal — work correctly. If you use Windows Installer, you should also test the application's advertising and publishing functions.

Develop test cases to verify that the application:

- Installs successfully with the types of user account to be used in your environment (user, power user, or administrator).
- Installs successfully with the types of installation to be performed in your environment (minimal, typical, full, or custom).
- Installs successfully with the methods to be used in your environment (network installation or a local installation using **Add or Remove Programs**).
- Is listed correctly in **Add or Remove Programs**.
- Checks the Windows version correctly.
- Installs on a partition that has more than 2 GB of free disk space.
- Is listed on the **Start** menu, and has desktop shortcuts for all users (if applicable).

If you use Windows Installer, develop test cases to verify that the application:

- Advertises and publishes correctly.
- Uses system variables for the locations of user data settings.
- Respects Windows File Protection.
- Supports DLL redirection of shared components.
- Does not use outdated techniques such as placing .ini files in the system folder.

**Developing Test Cases for Operating System Interaction**

Tests of operating system interaction verify that an application works correctly with the fundamental features of the operating system. These tests use standard Windows operations, such as opening and closing files, manipulating windows, printing, and viewing Help and Support Center topics.

The following lists provide a starting point for identifying test cases that verify an application's interaction with the operating system. This list is not exhaustive; it merely provides an idea of the scope of features to test. The "Windows Compatibility

Checklist" white paper, which is included in the Windows Application Compatibility Toolkit, is oriented toward applications under development and might provide additional ideas. If an application uses peripherals such as scanners or digital cameras, you might also need test cases to verify the application's interaction with these devices.

**Basic application testing**

Develop test cases to verify that the application:

- Interacts with the other applications used in your environment.
- Starts successfully in a variety of ways (from the **Start** menu, from shortcuts, from the autorun file on the application CD, from the console, and from the Quick Launch bar).
- Starts successfully when you double-click a file that has the file name extension associated with the application, if applicable.
- Starts successfully when another instance of the application is running (if applicable; some applications do not allow multiple instances).
- Has associated shortcuts on its **Start** menu, such as for documentation or related programs, that work correctly, if applicable.
- Handles copy, paste, and edit functions correctly.
- Handles changes to the monitor resolution correctly (such as a change from 640 × 480 pixels to 1024 × 768 pixels).
- Works correctly with Windows display themes.
- Starts successfully when you open an application document by using the wheel on a wheel mouse, if applicable.
- Scrolls correctly when you use the wheel on a wheel mouse, if applicable.
- Opens Help from the **Help** menu and with the F1 key, if applicable.

**Testing file system interaction**

Develop test cases to verify that the application can successfully:

- Handle long file names and universal naming convention (UNC) paths.
- Save a file to, and open a file from, an NTFS file system folder that has restricted access permissions.
- Save a file to, and open a file from, a disk partition that has more than 2 GB of free disk space.
- Save a file that has a 255-character file name to a UNC path and to a mapped drive, and open the file from both locations.
- Save a file that has a 255-character file name to the My Documents folder, and open it from that folder.
- Save and open a file that has supported special characters — such as a plus sign, a comma, a semicolon, an equal sign, or brackets ([]) — in the file name.
- Save and open all document types supported by the application.
- Import and export files of all formats that are supported by the application, such as JPG, GIF, or BMP.
- Open documents on the NTFS file system, even when they were created on the FAT16 or the FAT32 file system.
- Open and save a document on both a drive formatted for the FAT16 file system and a drive formatted for the NTFS file

system.

- Open and save a document on both a drive formatted for the FAT32 file system and a drive formatted for the NTFS file system.
- Save and open a file on a distributed file system (DFS).
- Open documents that were copied from Windows NT Server 4.0–based or Windows 2000–based NTFS computers to Windows XP Professional–based NTFS computers.

**Testing printing**
Develop test cases to verify that the application can successfully:

- Print a document to a printer that has a long name.
- Print a document to a printer by using a UNC path.
- Print a document to a local printer and to a network printer.
- Print a document to a PostScript printer.
- Print to a file on a generic text printer.
- Print to a file on a color inkjet printer.
- Handle a print command when no printer drivers are installed.
- Print a document from an LPT port other than LPT1 or LPT2.
- Handle a print command when the printer is turned off while a document is printing.
- Print a document in both portrait and landscape orientations.

**Testing Advanced Configuration and Power Interface (ACPI) support**
Develop test cases to verify that the application:

- Handles ACPI notification and events correctly.
- Allows the monitor to turn off correctly when turn-off time is set to 1 minute.
- Allows the hard drive to turn off correctly when turn-off time is set to 2 minutes.
- Goes into standby and hibernation, and then resumes without loss of functionality.
- Wakes from standby and hibernation — whether triggered by normal time-out or by a low battery alarm — without losing data.

**Testing support for multiple monitors**
Develop test cases for configurations with multiple monitors, if appropriate, to verify that the application handles the following correctly:

- Monitor placement, left and right
- Monitor placement, top and bottom
- Different monitor resolutions on both monitors

- Different monitor color depths on both monitors
- Spanning across monitors, both from left to right and from top to bottom
- Mouse movement, back and forth from left to right and up and down from top to bottom, on both monitors
- Windows set to maximum size and minimum size on both monitors

**Developing Test Cases for Application Functionality**

Tests for application functionality validate that the application features used in your environment work as expected and that known input yields expected results. You need to test application functionality whether or not you have access to source code.

If you have developed or customized an application internally, you might have test scripts and data you can use to verify the application's compatibility with the new operating system. If you do not have test scripts, work with the people in the organization who are familiar with the application to develop test cases that exercise all essential functions.

**Developing Test Cases for Uninstallation**

Tests for removing an application verify that all components are removed from the computer without causing problems.

Develop test cases to verify the following:

- The application is removed from **Add or Remove Programs**.
- All shortcuts are removed from the **Start** menu.
- All files in the installation directory are removed.
- No system files or shared components are removed.
- All application-specific registry entries are removed.

# Using the Windows Applications Exploratory Test Methodology

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Windows Applications Exploratory Test Methodology defines a process for learning about an application so that you can identify the most important aspects to test when no one who is knowledgeable about the application is available for testing.

When you use the exploratory test methodology, you do not define the test cases in advance. Rather, you define the test cases and execute the tests as you explore and learn about the application.

**Exploratory Testing Overview**
The purpose of exploratory testing is to determine, in a limited amount of time, whether an application works well on the new version of Windows for the majority of users. Exploratory testing addresses both application functionality and stability. This method is not a comprehensive test method, and it is not a substitute for a more formal method if application experts are available.

Exploratory testing is an interactive process during which you concurrently explore the application, design the tests, and execute the tests. Although the method is freeform in many respects, the process includes specific tasks, objectives, and deliverables, making it a systematic process with auditable results.

This method is based on the *General Functionality and Stability Test Procedure* developed by James Bach. For more information about the exploratory test methodology, see the "Windows Applications Exploratory Test Procedure" white paper in the Application Compatibility Toolkit.

**Exploratory Testing Process**
The exploratory testing process consists of five tasks:

1. Identify the purpose of the application.
2. Identify the functions that the application supports.
3. Identify potential areas of application instability.
4. Document issues and questions that arise about the application during the exploration process.
5. Create a test outline, and use it to execute the tests.

As you identify the purpose, functions, and areas of potential instability, you create a test case outline and use it to test each function and to record problems. The results of the exploratory testing process are notes and documented application failures.

Because it is not possible to test all functions of an application in a limited amount of time, you can simplify the testing process by making risk-based decisions about how much attention to give each function. To help you make these decisions, the methodology categorizes functions as *primary* or *contributing*.

To determine which functions are primary and which are contributing, you must understand the purpose of the application. A *primary function* is associated with the purpose of the application and is essential to that purpose. Any function that contributes to the utility of the application, but is not essential to it, is a *contributing function*. Typically, primary functions warrant the most testing. Sometimes a group of contributing functions might be considered a single primary function, or a single primary function might be separated into primary and contributing subfunctions. For more information about how to classify a function, see the "Windows Applications Exploratory Test Procedure" white paper in the Application Compatibility Toolkit.

After identifying and categorizing the functions, test all of the primary functions that you can reasonably test in the time available. Then test a sample of significant contributing functions. Many contributing functions probably will be tested as you test the primary functions.

Also test areas where application instability is most likely to occur, especially in primary functions. Functions that are potentially unstable include:

- Functions that interoperate with other applications.
- Functions that handle events that are external to the application, for example, waking up a sleeping computer when a fax arrives.
- Functions that make intensive use of memory.
- Functions that interact extensively with the operating system.
- Functions of unusual complexity.
- Functions that change operating parameters, such as preference settings.
- Functions that modify the operating system configuration.
- Functions that intercept or recover from errors.
- Functions that replace basic operating system functions.
- Any function or set of functions that involves multiple simultaneous processes.
- Functions that manipulate multiple files simultaneously.
- Functions that open files over a network.

# Testing for and Resolving Compatibility Problems

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After developing your test cases, you can start to test applications and record the results. Perform your basic testing first, using either the Windows Applications Exploratory Test Methodology or the Windows Fundamentals Test Methodology. Then, if you have access to source code, use Application Verifier to test for subtle problems that are difficult to find. As you detect compatibility problems, use Compatibility Administrator to apply and test application compatibility fixes to resolve the problems. For some special cases in which application compatibility fixes do not resolve the problem, you might need to try special techniques. Figure 3.7 shows when these testing and problem resolution tasks occur during the application compatibility testing process.

**Figure 3.7 Testing for and Resolving Compatibility Problems**

# Testing Applications

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As you conduct tests, evaluate and record the results. Before you assume the problem is a Windows compatibility issue, always perform the following two steps:

- **Verify that the problem is not a test environment issue**. The problem might be the result of a hardware, software, or network configuration issue rather than an application compatibility problem.

- **Verify that the problem does not occur on the version of Windows you currently use**. Perform exactly the same test on the version of Windows on which the application currently runs to see if it works correctly there. If the same error occurs on the current platform, the problem is not a compatibility issue specific to Windows XP Professional or Windows Server 2003.

The testing process is an iterative process of testing, identifying problems, resolving problems, and retesting. The steps in the process vary depending on the nature of the problem encountered and the nature of the resolution. Problems that are resolved by applying an application compatibility fix, for example, are managed differently from problems resolved by modifying source code or obtaining vendor upgrades.

For problems that can be resolved by applying an application compatibility fix, the resolution phase can be built into the testing phase: As you encounter problems, you apply application compatibility fixes and retest until the application is ready to deploy.

If you modify source code, the iterative process is the more traditional cycle of testing, debugging, coding and recompiling, and retesting. If you cannot identify an application compatibility fix to resolve the problem, and you do not have access to source code, you need to contact the application vendor for an application upgrade.

Figure 3.8 illustrates the testing process.

**Figure 3.8 Testing Applications**

# Testing with Windows Application Verifier

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you have access to source code, Windows Application Verifier can help you uncover subtle stability, reliability, compatibility, and security problems. Windows Application Verifier is not an automated test tool. To use it, you must run an application with Application Verifier enabled and exercise all of your test cases.

Windows Application Verifier helps you to identify code that needs to be modified by running in either of two modes of operation: debugging or logging. In *debugging mode*, it detects problems in the application and transfers the results to a debugger. In *logging mode*, it writes all of the output that it generates to a text file for later review.

Figure 3.9 shows the main window of Application Verifier.

**Figure 3.9 Application Verifier Main Window**

To start Application Verifier on Windows XP Professional, click **Start**, click **All Programs**, click **Microsoft Windows Application Compatibility Toolkit**, and then click **Windows Application Verifier**. On Windows Server 2003, click **Start**, click **Programs**, click **Microsoft Windows Application Compatibility Toolkit**, and then click **Windows Application Verifier**.

To use Application Verifier, you must be logged on as an Administrator. Click **Add** to add the applications that you want to test in the left pane. To test an application, select it in the left pane, select the tests that you want to apply to it in the right pane, and then start the application in your normal way and run the test cases. After you add an application to the list, Application Verifier is enabled for that application, whether you start the application from this tool, from a shortcut, or from the command line. The tests that you select are applied whenever you run the application on that computer until you remove the application from the list in Application Verifier.

**Note**

- Application Verifier tests require the symbol files for the version of Windows and the application that you are testing.

The tests detect the most common application problems, such as incorrect version checking, bad registry usage, and hard-coded file paths. You can view a list of the detected problems in the Application Verifier log, which is located in the \Documents and Settings\All Users\Shared Documents\AppVerifierLogs folder with a file name corresponding to the name of the

executable file for the application. You also can export the log to a text file so that you can send it to others.

Some of the test options provided by this tool are designed to cause the application to stop responding when it encounters a problem. These problems are not written to the Application Verifier log. To determine the cause of the problem in such a case, run the application under a debugger with Application Verifier running. When using a debugger, you can set Application Verifier so that it breaks into the debugger for any event that is written to the Application Verifier log.

For more information about the Application Verifier tool, see Windows Application Compatibility Toolkit Help.

Table 3.6 describes the tests that you can perform with Application Verifier.

**Table 3.6 Application Verifier Tests**

| Test | Description |
|---|---|
| **PageHeap — Detect heap corruptions** | Performs regular checks of the heap and adds guard pages at the end of each allocation to catch possible heap overruns. |
| **Locks — Check lock usage** | Looks for common errors with locks, and displays the output in a separate debugger application. This test can cause access violations if an error is found. |
| **Handles — Detect invalid handle usage** | Checks for common problems with handles, and displays the output in a separate debugger application. This test can cause access violations if an error is found. |
| **Stacks — Check for adequate stack** | Disables stack growth, causing a stack overflow exception if the initial allocation is too small. |
| **LogStartAndStop — Logs start and stop** | Enters log information when the application starts or stops, making it easier for you to review test data. |
| **FilePaths — Checks system path usage** | Monitors the application's attempts to obtain file path information to determine if the application uses hard-coded paths or a nonstandard method of gathering the path information. This test can cause the application to stop responding if the application uses an improper method for determining file paths. |
| **HighVersionLie — Checks version handling** | In the past, many applications were written to run on a specific version of Windows. This test returns a very high version number to test how the application handles a version that does not yet exist. |
| **RegistryChecks — Checks registry usage** | Checks how the application uses the system registry to determine whether the application uses any inappropriate or dangerous calls. Logs any problems that it detects. |
| **WindowsFileProtection — Logs changes to Windows File Protection files** | Verifies that applications are not improperly replacing files that are protected by Windows File Protection. |
| **DXFileVersionInfo — Logs DirectX file checks** | Logs information about any attempt that the application makes to check the version of Microsoft® DirectX® application programming interface installed on the local computer. |
| **LogRegistryChanges — Logs registry changes** | Logs any changes that the application makes to the registry. |
| **LogFileChanges — Logs file system changes** | Logs information about any change that the application makes to the file system. |
| **ObsoleteAPICalls — Logs calls made to obsolete APIs** | Logs any attempt to use a *deprecated API*, which is an API that is still supported but is likely to be unsupported in the future. |

| | |
|---|---|
| **KernelModeDriveInstall — Logs installation of kernel-mode drivers** | Logs data about any kernel-mode driver that is installed for use by the application. |
| **SecurityChecks — Logs potential security problems** | Identifies many common security problems. |

# Applying and Testing Solutions with Compatibility Administrator

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Compatibility Administrator is an all-purpose tool that you can use to apply and test application compatibility fixes and compatibility modes, and then package them for deployment. Application compatibility fixes are prepackaged solutions provided by Microsoft to resolve known compatibility problems. Compatibility modes are collections of application compatibility fixes that resolve problems that commonly occur under certain circumstances. By using Compatibility Administrator, you can fine-tune the solutions to be applied to an application by mixing and matching application compatibility fixes and compatibility modes.

To simplify distribution, you can create custom databases that consolidate all of the solutions that are required in order to support multiple applications. For example, you can create one custom database for each standardized desktop in a managed environment and then deploy those databases to the computers running Windows XP Professional and Windows Server 2003 in your environment.

In addition, use Compatibility Administrator to:

- Create custom compatibility modes.
- Create custom Application Help messages.
- Search the computer's hard disk for applications whose compatibility problems are resolved with application compatibility fixes, compatibility modes, or Application Help messages.
- Query compatibility databases for solutions that meet specified criteria.
- Temporarily disable or enable application compatibility fixes.

Use this tool whether or not you have access to the source code for your applications. You do not need to log on under an Administrator account to run Compatibility Administrator, but you do need to log on under an Administrator account to install a custom database.

# Strategies for Using Compatibility Administrator

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you have determined that an application has compatibility problems, you can use the Compatibility Administrator to apply one or more application compatibility fixes to resolve the problems. The steps that follow are a suggested approach to isolating the appropriate resolution.

To resolve compatibility problems for an application by using the Compatibility Administrator:

1. Follow the suggestions contained in Application Help messages that appear for the application. For example, an Application Help message might indicate where you can obtain an update.

2. To quickly determine whether application compatibility fixes resolve the problems, try a prepackaged compatibility mode. Start with the compatibility mode that targets the environment in which the application currently runs. For example, if the application currently runs on Windows 98, use the Windows 98/Windows Me compatibility mode, or, if you are testing as a restricted user, try Limited User Access (LUA) mode. You might need to try several compatibility modes until you find one that works. Include the color, resolution, and visual themes compatibility modes, if necessary.

3. If a compatibility mode does not resolve all of the problems, try a combination of a compatibility mode and application compatibility fixes. When you apply a compatibility mode, you can add or remove any combination of application compatibility fixes. For information about which application compatibility fixes to apply for different types of problems, see "Determining the Application Compatibility Fix to Apply" later in this section.

If you resolve compatibility problems by applying a compatibility mode, you should then determine the precise mix of application compatibility fixes required for the application by iteratively deleting application compatibility fixes and retesting. Doing so can prevent introducing new problems with application compatibility fixes that are not necessary. However, you might need to balance the very low risk of introducing new problems against the time you have available for testing applications.

Follow these guidelines as you apply and test application compatibility fixes and modes:

- Do not use compatibility modes to bypass version warnings for the installation programs of kernel-mode applications such as antivirus, firewall, CD burning, disk management, or backup applications. Some of these applications are designed for a specific operating system and, therefore, they intentionally prohibit the use of later versions. Installing such applications can potentially cause system instability. Replace such applications with ones designed specifically for Windows XP Professional or Windows Server 2003.

- Before you start testing your applications, be sure that you have installed the most current critical updates and operating system updates. Critical updates and operating system updates can contain application compatibility fixes. You can use Windows Update or Software Update Services (SUS) to obtain critical updates and operating system updates. To access the Windows Update Web site, click the Home button in Help and Support Center for Windows Server 2003, and then, under **Pick a Task,** click **Keep your computer up-to-date with Windows Update**. For more information about SUS, see "Deploying and Distributing Applications and .Sdb Files" later in this chapter.

- If you find a combination of application compatibility fixes that you think will work for multiple applications, create a custom compatibility mode. If you need to include a custom compatibility mode in a different custom database, copy it. For information about how to create a custom compatibility mode and copy it to a different database, see "Creating Custom Compatibility Modes" later in this chapter.

- For simplicity in deployment, create as few custom databases as possible. Even if you create several custom databases during the testing process, you can consolidate them into a single database by using Compatibility Administrator. For information about how to copy to a database, see "Creating Custom Compatibility Modes" later in this chapter.

# Applying and Testing Application Compatibility Fixes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you encounter an application that has a compatibility problem, use Compatibility Administrator, shown in Figure 3.10, to select application compatibility fixes, either singly or in combination, and then test the application to see if the fixes resolve the problem. To find application compatibility fixes for a wide range of problems, use the "Compatibility Solutions Spreadsheet" (PDP_APP_1.xls) on the Windows Server 2003 Deployment Kit companion CD (or see the "Compatibility Solutions Spreadsheet" on the Web at http://www.microsoft.com/reskit) or, see Table 3.9 through Table 3.31.

**Figure 3.10 Compatibility Administrator**

To start Compatibility Administrator on Windows XP Professional, click **Start**, click **All Programs**, click **Microsoft Windows Application Compatibility Toolkit**, and then click **Compatibility Administrator Tool**. On Windows Server 2003, click **Start**, click **Programs**, click **Microsoft Windows Application Compatibility Toolkit**, and then click **Compatibility Administrator Tool**.

The left pane displays the contents of all the application compatibility databases on the computer. When you select an application that is listed in a database, the right pane displays detailed information. For example, if you select an application in a custom database in the left pane, the right pane displays the application file name, the compatibility mode or application compatibility fixes that apply to the application, and the application matching information.

**To select and test application compatibility fixes**

1. On the **File** menu, click **New** to create a new custom database.

2. On the **Database** menu, click **Create New,** and then click **Application Fix**.

3. Follow the steps in the Create New Application Fix Wizard to select the application to test and the compatibility mode or application compatibility fixes to apply, and then click **Test Run** to test the application from the wizard.

4. Continue selecting application compatibility fixes and retesting them until the problem is resolved.

5. Continue following the steps in the wizard to select the type of information that you want to use to match the application to the application compatibility fix.

6. Click **Finish** to save the application compatibility fixes in the database.

7. On the **File** menu, click **Save** to save the custom database. Provide a descriptive name for the database; the system appends an .sdb file name extension. Then save the database in the *systemroot*\AppPatch\Custom folder (or any other folder that you choose).

Alternatively, you can use this procedure to add more applications, with their associated application compatibility fixes, to an existing custom database. You also can copy application compatibility fixes from other application compatibility databases by using the **Copy** command on the shortcut menu, which is displayed by right-clicking the application name in the left pane of Compatibility Administrator.

This procedure saves the custom database but does not install it on the test computer. This means that the next time you run the application on the test computer without Compatibility Administrator running, the application compatibility fixes will not be applied to the application. To apply the application compatibility fixes to an application every time that you run it, you must install the custom database on the computer on which the application will run.

**To install a custom database on the test computer**

1. In Compatibility Administrator, select the custom database that you want to install.

2. On the **File** menu, click **Install**.

### Note

- You can run Compatibility Administrator in expert mode by typing **compatadmin.exe /x** at the command line. Expert mode provides more than 200 additional fixes, many of which are application-specific, that you can apply to a custom database. For more information about expert mode, see the Application Compatibility Toolkit version 3.0 or later.

For information about deploying and installing custom databases on Windows XP Professional or Windows Server 2003 computers, see "Deploying and Distributing Applications and .Sdb Files" later in this chapter.

# Applying and Testing Compatibility Modes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Sometimes you might want to get an application to work quickly by applying all of the application compatibility fixes that are commonly required by applications written for a specific computing environment, instead of testing for the specific application compatibility fixes needed by the application. In this case, you can apply a prepackaged compatibility mode. A *prepackaged compatibility mode* is a group of application compatibility fixes that resolve problems that commonly occur in certain environments. For example, one prepackaged compatibility mode includes application compatibility fixes that address problems typically found in applications that are run by users with limited user rights.

Table 3.7 lists the prepackaged compatibility modes that Compatibility Administrator provides and describes what they do.

**Table 3.7 Prepackaged Compatibility Modes**

| Prepackaged Compatibility Mode | Description |
|---|---|
| Windows 95 | Resolves the most common Windows 95 incompatibilities. |
| Windows 98 / Windows Me | Resolves the most common Windows 98 and Windows Millennium Edition incompatibilities. |
| Windows NT 4.0 SP 5 | Returns version credentials for Windows NT Server 4.0 with Service Pack 5. |
| Windows 2000 | Returns version credentials for Windows 2000. |
| 256 Color | Sets the screen to 256 colors; this is most useful for games and educational titles. |
| 640 x 480 Screen Resolution | Sets the screen resolution to 640 x 480 pixels; this is most useful for games and educational titles. |
| Disable Visual Themes | Disables Windows XP Professional or Windows Server 2003 visual themes. |
| International | Handles double-byte character sets. |
| Limited User Access | Redirects file-system and registry write requests to nonrestricted areas when the user has insufficient access permissions; useful for applications written for versions of Windows that have no security-related user accounts. |
| Profile Setup Support | Installs the application for all users of a computer rather than only for the current user. |

You can apply a prepackaged compatibility mode in two ways:

- Use Compatibility Administrator to add a prepackaged compatibility mode to a custom application compatibility database.
- Use a batch file or script to apply a prepackaged compatibility mode directly to an application.

**Applying Prepackaged Compatibility Modes by Using Compatibility Administrator**

You can use Compatibility Administrator to add any of the prepackaged compatibility modes to an application compatibility database. The procedure for doing this is identical to the procedure described in "Applying and Testing Application

Compatibility Fixes" earlier in this chapter. However, instead of adding application compatibility fixes to an application compatibility database, you add one of the prepackaged compatibility modes listed in Table 3.7.

**Applying Compatibility Modes in Batch Files and Scripts**

If you have a batch file or script that executes programs that have compatibility problems, you can apply prepackaged compatibility modes from the script or batch file instead of packaging them in a custom database and deploying the database to the computer where the programs run. When you apply compatibility modes in a batch file or script, you can ensure that they are recursively applied to processes initiated by any command in the batch file.

The syntax for applying compatibility modes in a script or batch file is:

```
set __COMPAT_LAYER=[!]CompatModeName1 [CompatModeName2]
```

The keyword **set** is followed by a space and then two underscores (__). *CompatModeName* represents the short name for the compatibility mode to be applied, as defined in Table 3.8. For example, the Windows 98 compatibility mode is "Win98." The parameter "!" specifies that a compatibility mode is not to be applied if other application compatibility fixes are already being applied to the application.

**Table 3.8 Scripting Short Names for Compatibility Modes**

| Prepackaged Compatibility Mode | Scripting Short Name |
|---|---|
| Windows 95 | Win95 |
| Windows 98/Windows Me | Win98 |
| Windows NT 4.0 SP 5 | NT4SP5 |
| Windows 2000 | Win2000 |
| 256 Color | 256Color |
| 640 x 480 Screen Resolution | 640x480 |
| Disable Visual Themes | DisableThemes |
| International | International |
| Limited User Access | LUA |
| Profile Setup Support | ProfilesSetup |

For example, to apply the Windows 98 and Disable Visual Themes compatibility modes, use this command:

```
set __COMPAT_LAYER=Win98 DisableThemes
```

You can disable the compatibility mode after applying it in this way by using the same command without specifying the compatibility mode. For example, you can cancel the compatibility mode if it is no longer needed at a certain point in the batch file. Any processes that start while the compatibility mode is in effect continue to run with the compatibility mode activated until they terminate. The syntax for canceling a compatibility mode in a script or batch file is:

```
set __COMPAT_LAYER=
```

To see a simple example of the **set** command in a batch file, see article Q286705, "HOW TO: Script Compatibility Layers in Windows XP," in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Creating Custom Compatibility Modes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As you identify the application compatibility fixes that are needed for your applications, you might find a group of them that are needed for several applications, or you might want to customize a prepackaged compatibility mode by adding or removing application compatibility fixes. In this case, you can create a custom compatibility mode and include it in multiple custom databases.

**To create a custom compatibility mode**

1. In the Compatibility Administrator, select the custom database to which you want to add the custom compatibility mode.
2. On the **Database** menu, click **Create New**, and then click **Compatibility Mode**.
3. Give the custom compatibility mode a descriptive name, and select the application compatibility fixes to include in it.
4. On the **File** menu, click **Save** to save the updates to the custom database.

Include the new custom compatibility mode in other custom databases by using the **Copy** and **Paste** commands on the shortcut menu, which is displayed by right-clicking the compatibility mode name.

# Creating Custom Application Help Messages

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When a compatibility problem cannot be resolved with an application compatibility fix, an Application Help message is the last option. Application Help messages can prevent users from running an application that might cause system instability or that might affect other applications adversely. An *Application Help message* either blocks the application from running or displays an informative message before allowing the application to run. For example, an Application Help message might notify the user that the application requires an update and provide the URL to the vendor's Web site.

Microsoft, in conjunction with ISVs, has developed prepackaged Application Help messages for some third-party applications that have compatibility problems. The prepackaged Application Help messages are most commonly used to block the installation of low-level programs — such as antivirus programs and disk access utilities — that were not designed to run on Windows XP Professional or Windows Server 2003. The messages are displayed when a user attempts to install or run one of these applications.

You also can create custom Application Help messages. Because Application Help messages do not resolve compatibility issues, but instead only notify or stop the user, use this type of solution only when you can find no other solution. Whether or not you choose to use an Application Help message that blocks the application from running, provide an informative message that describes possible results or provides instructions about where to find an update.

**To create a custom Application Help message**

1. In the Compatibility Administrator, select the custom database to which you want to add the custom Application Help message.

2. On the **Database** menu, click **Create New**, and then click **Apphelp Message**.

3. Follow the steps in the Create a Custom AppHelp Message Wizard to select the application to test and the type of information to use to match the application to the Application Help message.

4. Follow the steps in the wizard to specify whether you want the application to run or not to run after the message is displayed, and to specify the message text.

5. Click **Test Run** to test the application with the new Application Help message.

6. After resolving any problems, on the **File** menu, click **Save** to save the updates to the custom database.

# Determining the Application Compatibility Fix to Apply

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The tables in this section include descriptions of some compatibility problems that might occur in applications written for earlier versions of Windows, along with the application compatibility fixes that resolve them. As you test applications and encounter compatibility problems, these tables can help you isolate the most appropriate application compatibility fix to apply. If you are still in the planning phase, skip to "Identifying Strategies for Resolving Special Problems" later in this chapter for additional information on resolving problems.

In some cases, you might need to look at multiple tables to find the application compatibility fix that resolves your compatibility problem. For example, you might want to review both color palette issues (Table 3.12) and display issues (Table 3.13) if elements in the application window are not displayed correctly.

Table 3.9 identifies the application compatibility fixes that you can apply for 16-bit applications that have compatibility problems.

**Table 3.9 Application Compatibility Fixes for 16-Bit Application Problems**

| Symptom | Application Compatibility Fix |
|---|---|
| The installation program or application expects to find Microsoft Windows 95 or Microsoft Windows 98 running. | WOWCFEX_PLATFORMVERSIONLIE |
| The installation program or application expects to find Microsoft Windows NT running. | WOWCF2_HACKWINFLAGS |
| The installation program or application expects to find Service Pack 2 installed. | WOWCFEX_SP2CSDVERSIONLIE |
| The application window is hidden by a second window. | ForceSeparateVDM |
| The application becomes unresponsive. | WOWCF_NOWAITFORINPUTIDLE |
| The application behaves unpredictably. | WOWCF_USER_DDENOSYNC |
| A minimized application cannot be restored. | WOWCF2_FIXLUNATRAYRECT |
| Messages are displayed behind the application. | WOWCF2_SETFOREGROUND |
| A message indicates that a file has not been found. | WOWCF2_SYNCSYSFILE |
| A message indicates that the application requires 256 colors. | WOWCFEX_DISPMODE256 |
| A message indicates that the application requires 256 colors. | WOWCFEX_EATDEVMODEMSG |
| A general protection fault (GP fault) occurs. | WOWCFEX_FORCEINCDPMI |
| The application returns a divide-by-zero error. | WOWCF2_DELAYTIMEGETTIME |
| The Help file does not open. | WOWCFEX_USEWINHELP32 |

Table 3.10 identifies the application compatibility fixes that you can apply when the application cannot be removed successfully.

**Table 3.10 Application Compatibility Fixes for Application Removal Problems**

| Symptom | Application Compatibility Fix |
| --- | --- |
| The application returns the "<DirName> refers to a location that is unavailable" error message when an application is removed. | DelayShowGroup |
| During uninstallation, the application returns an error message stating that registry entries cannot be removed. | LUARedirectReg_Cleanup |
| Files are left behind after an application has been uninstalled. | LUARedirectFS_Cleanup |
| Files are left behind after an application has been uninstalled. | MoveWinInitRenameToReg |

Table 3.11 identifies the application compatibility fixes that you can apply when problems occur with the Clipboard when you perform copy and paste operations.

**Table 3.11 Application Compatibility Fixes for Clipboard Problems**

| Symptom | Application Compatibility Fix |
| --- | --- |
| The application does not perform copy or paste operations correctly. | EmptyClipboardtoSet |
| When bitmaps are copied to or from the Clipboard, the application returns the "Access violation" error message. | EmulateClipboardDIBFormat |

Table 3.12 identifies the application compatibility fixes that you can apply when the color palette is distorted or when components of the application window are displayed in the wrong color.

**Table 3.12 Application Compatibility Fixes for Color Palette Problems**

| Symptom | Application Compatibility Fix |
| --- | --- |
| The application window does not display as expected at startup and during execution. | IgnoreHungAppPaint |
| The application changes the system colors. | IgnoreSysColChanges |
| After the application switches tasks or modes, colors change. | PaletteRestore |
| A palette error occurs. | EmulateGetDeviceCaps |
| A palette error occurs when you quit the application, and it returns the "PM_free():Allocation 001B4498 failed integrity check! (InitPalette)" error message. | EmulateGetDeviceCaps |
| The application returns the "Unhandled Error: User Category 10 Fatal Error: Code 2 Palette Error" message. | EmulateDeleteObject |
| The palette is distorted. | ForceDefaultSystemPaletteEntries |
| After the application switches tasks or modes, images appear corrupted. | PaletteRestore |
| After the application switches tasks or modes, the background turns black. | PaletteRestore |
| After the application switches tasks or modes, buttons disappear. | PaletteRestore |

Table 3.13 identifies the application compatibility fixes that you can apply when the application has problems with the screen display, such as incorrect screen resolution and color quality settings.

**Table 3.13 Application Compatibility Fixes for Display Problems**

| Symptom | Application Compatibility Fix |
|---|---|
| The application starts up in a 640 x 480 pixel window and does not switch to a full screen. | Force640x480 |
| The application starts up in a 640 x 480 pixel window and does not switch to a full screen. | Force640x480x16 |
| The application starts up in a 640 x 480 pixel window and does not switch to a full screen. | Force640x480x8 |
| Most of the application window runs off the desktop. | LazyReleaseDC |
| The application returns a message that indicates that the display is corrupted. | Force8BitColor |
| Graphics are corrupted in full-screen mode. | ForceDirectDrawEmulation |
| The application returns a message that indicates that 256 colors are required. | Force8BitColor |
| The application returns a message that indicates that 256-color mode is required. | ForceDisplayMode |
| Introductory videos do not play. | ForceDirectDrawEmulation |
| The taskbar is visible when the application is in full-screen mode. | HideTaskBar |
| When the application switches modes, the screen becomes blank. Pressing ALT+TAB restores the video display. | IgnoreNoModeChange |
| When the application closes, the system display mode changes. | ForceTemporaryModeChange |
| When the application closes, the display mode is not restored. | EmulateUSER |

Table 3.14 identifies the application compatibility fixes that you can apply when the application fails during execution.

**Table 3.14 Application Compatibility Fixes for Execution Problems**

| Symptom | Application Compatibility Fix |
|---|---|
| Access violations occur regularly during application execution. | DisableBoostThread |
| The application shuts down unexpectedly during execution. | HeapIgnoreMoveable |
| The application shuts down unexpectedly during execution. | HeapLookasideFree |
| The application shuts down unexpectedly during execution. | HeapPadAllocation |
| The application shuts down unexpectedly during execution. | HeapValidateFrees |
| The application shuts down unexpectedly when it accesses configuration or user settings. | LUARedirectFS |
| The application periodically shuts down unexpectedly, typically at the same interval at which the screen saver is set to activate. | DisableScreenSaver |

| | |
|---|---|
| Access violations occur during normal functioning as the heap becomes corrupted, causing the application to become unresponsive. | EmulateHeap |
| An access violation occurs when the application switches contexts. | HeapForceGrowable |
| The application returns a "Runtime error 6" message when you install add-ons to the application. | IgnoreVBOverflow |
| The application returns a "Runtime error 6" message when you attempt to use Help. | IgnoreVBOverflow |
| Executable programs designed to run at Windows startup, such as application toolbars, do not run for all users. | LUARedirectReg |
| A default screensaver cannot be applied. | MoveIniToRegistry |

Table 3.15 identifies the application compatibility fixes that you can apply when access violations occur while an application is exiting.

**Table 3.15 Application Compatibility Fixes for Exit Problems**

| Symptom | Application Compatibility Fix |
|---|---|
| Access violations occur when the application is closed. | EmulateHeap |
| Access violations occur when the application is closed. | IgnoreFreeLibrary |
| Access violations occur when the application is closed. | IgnoreLoadLibrary |
| Access violations occur when the application is closed. | IgnoreCRTExit |
| Access violations occur when the application is removed. | IgnoreCRTExit |
| Access violations occur when dialog boxes are canceled. | IgnoreCRTExit |

Table 3.16 identifies the application compatibility fixes that you can apply when the application has file access problems.

**Table 3.16 Application Compatibility Fixes for File Input/Output Problems**

| Symptom | Application Compatibility Fix |
|---|---|
| During installation or operation, the application reports the incorrect amount of available disk space. | EmulateGetDiskFreeSpace |
| When a user with a DBCS (double-byte character set) name starts the application, the application returns an error message indicating that there are problems with the user's temp path. | RedirectDBCSTempPath |
| The application returns the "The system file does not exist" error message. | RedirectWindowsDirToSystem32 |
| When you attempt to open certain Audio Video Interleaved (.avi) files, the application returns the "Access violation" error message. | EmulateWriteFile |
| When you attempt to open a file, the application stops responding. | RemoveOverlappedFlagFromCreateFile |
| When you attempt to open a file, the application says that the file is read-only. | RemoveReadOnlyAttribute |
| When you attempt to open a folder, the application says that the folder is read-only. | RemoveReadOnlyAttribute |

| | |
|---|---|
| When you move files or projects, the application returns the "Access violation" error message. | ChangeAuthenticationLevel |
| The application returns the "File mapping not created" error message. | CorrectCreateEventName |
| The application returns the "File mapping not created" error message. | EmulateCreateFileMapping |
| When accessing a CD, the application returns either the "Unable to locate files" or the "Unable to install" error message. | EmulateCDFS |
| When accessing a CD, the application quits without generating an error message. | RemoveNoBufferingFlagFromCreateFile |
| The application returns the "Files do not exist" error message. | EmulateEnvironmentBlock |
| Files are not found or error messages or paths are truncated. | EmulateGetCommandLine |
| The Uninstall command fails to remove files and folders from program files. You need to use this fix with the CorrectFilePaths compatibility fix (in Table 3.26). | CorrectFilePathsUninstall |

Table 3.17 identifies the application compatibility fixes that you can apply when focus within an application is not maintained correctly.

**Table 3.17 Application Compatibility Fixes for Focus Problems**

| Symptom | Application Compatibility Fix |
|---|---|
| When the application starts, the configuration window is minimized. | ForceKeepFocus |
| The application window becomes inactive. | ForceApplicationFocus |
| A message box becomes inactive. | ForceMessageBoxFocus |

Table 3.18 identifies the application compatibility fixes that you can apply when graphical elements in the application are not displayed correctly.

**Table 3.18 Application Compatibility Fixes for Graphics Control Problems**

| Symptom | Application Compatibility Fix |
|---|---|
| When the application loads, the graphics become corrupted. | EmulateBitmapStride |
| When a minimal installation of the application is performed, graphics are missing and video clips do not play. | ForceCDStop |
| When the application starts, the screen becomes blank. | ForceSimpleWindow |
| When the application starts, the screen becomes blank. | EmulateDirectDrawSync |
| When the application starts, the screen becomes blank. | WinExecRaceConditionFix |
| Either the introductory video does not appear, or the application won’t play in hardware mode. | ForceSimpleWindow |
| Inactive windows do not display as expected. | AlwaysActiveMenus |

| | |
|---|---|
| Clicking on an active bitmap image causes the application to become unresponsive. Bitmap images do not load. | CorrectBitmapHeader |
| Instead of an icon, a shadowed block appears. | CorrectCreateIcon |
| When the application loads bitmaps, they do not display as expected. | CorrectCreateSurface |
| The characters of Asian fonts do not display correctly. | CorrectFarEastFont |
| Pressing ESC returns you to a blank window rather than to the application menu. | DelayWin95VersionLie |
| Menu or list box contents do not appear or they do not appear as expected. | DisableAnimation |
| When you enable the FilterKeys option, the graphics do not display as expected. | DisableFilterKeys |
| The application alternates between the currently applied themed view and the nonthemed view. | DisableThemes |
| When the application runs under new themes, the standard message boxes do not appear. | DisableThemes |
| The system buttons (Minimize and Close) do not work. | DisableThemes |
| The title bar of the application window hides the toolbars. | DisableThemes |
| Dialog boxes are truncated. | DisableThemes |
| Buttons overlap. | DisableThemes |
| When the application window is resized, it does not display as expected. | DisableThemes |
| Text does not appear in the menu or in message boxes. | EmulateDrawText |
| The application fails when it attempts to display the menu or message boxes. | EmulateDrawText |
| Bitmaps in the Autorun dialog boxes do not display as expected. | EmulateGetProfileString |
| The application scrolls text too rapidly. | EmulateGetStringType |
| Typed text or text that should be displayed on the menu buttons or on labels does not appear. | EmulateTextColor |
| The application does not display graphics. | EnlargeGetObjectBufferSize |
| A file cannot be inserted as an icon into another file. Attempting to do so produces an "Out of memory or system resources" error. | ExtractAssociatedIcon |
| An application’s attempts to access menus, specifically the File menu, produces an "Access violation" error. | FailObsoleteShellAPIs |
| The menu and toolbar buttons are the wrong color. | FakeThemeMetrics |
| Typed text or text that is displayed on the menu buttons or in labels is the wrong color. | EmulateTextColor |
| Menu commands are replaced with black boxes. | ForceDefaultSystemPaletteEntries |

| | |
|---|---|
| The application fails when it returns to the main menu. | HeapDelayLocalFree |
| The mouse pointer appears unexpectedly. | HideCursor |
| A button or other control is corrupted. | LoadComctl32Version5 |
| Resizing a window causes the icons and other visual elements to disappear. | NoGdiBatching |
| The application window flickers and is repeatedly refreshed. | NoShadow |
| The user interface is unresponsive. | RemoveInvalidW2KWindowStyles |
| After you quit the application, the system cursor is not restored. | RestoreSystemCursors |
| Images, and the text associated with them, are displayed backwards. | UnMirrorImageList |
| When you insert an image file, the application returns an "Access violation" error message. | IgnoreLoadLibrary |
| When you modify an image, an access violation occurs. | DisableThemes |

Table 3.19 identifies the application compatibility fixes that you can apply when the application fails to install.

**Table 3.19 Application Compatibility Fixes for Installation Problems**

| Symptom | Application Compatibility Fix |
|---|---|
| When you attempt to install the application, the application returns the "ComponentMoveData" error message. | CorrectOpenFileExclusive |
| When you attempt to perform a default installation, text in the Destination Directory dialog box is unreadable. | EmulateGetProfileString |
| When you attempt to install the application, the application returns "The application or DLL <drive>:\<%windir%>\system32\ole2.dll is not a valid Windows image" error message. | CorrectVerInstallFile |
| When you attempt to install an application using an Autorun file, the installation fails. | EmulateCreateProcess |
| Attempts to install the application with InstallShield version 5.0 fail when user names with East Asian characters are used. | IgnoreOemToChar |
| The application appears to become unresponsive during setup because a dialog box containing an error message occupies space beyond the visible desktop. | KeepWindowOnMonitor |
| The application fails to install. | RedirectEXE |
| Setup fails unexpectedly. | EmulateLZHandles |
| On a dual processor machine, an application fails during installation or when you attempt to start it. | SingleProcAffinity |
| The application returns the "<x> not installed correctly, please install again" error message, where x is an application component. | SyncSystemAndSystem32 |

| | |
|---|---|
| The application cannot find a path during installation when a double-byte character set (DBCS) user name is used. | HandleDBCSUserName |
| The application cannot find a path during installation when a DBCS user name is used. | HandleDBCSUserName2 |
| Access violations occur during installation. | FileVersionInfoLie |
| During installation, when the application is searching for the presence of previous versions, an access violation occurs. | LimitFindFile |
| When the application is installed, an access violation occurs. | RemoveBroadcastPostMessage |
| When the application is installed, an access violation occurs. | IgnoreFreeLibrary |
| The application does not install from an Autorun file, causing an access violation. | HideDisplayModes |
| During installation, the application returns the "Cannot open files" error message. | FailOpenFile |
| After you run the setup program, the application returns the "Access violation" error message. | DuplicateHandleFix |
| The application returns the "Setup32: This product does not support Windows NT" error message. | DeRandomizeExeName |
| The application returns the "Unknown button state" error message. | DisableW2KOwnerDrawButtonStates |
| You are notified that a certain DLL is required for installation. | EmulateGetProfileString |
| The application returns the "Must be an administrator to install" error message. | ForceAdminAccess |
| The Configuration menu is blank. After the application's setup program finishes, InstallShield fails. | ForceWorkingDirectoryToEXEPath |
| If you do not register the application, the application does not start. | HeapLookasideFree |
| The application fails to start. | RedirectEXE |
| When the application is started, an access violation occurs. | RemoveBroadcastPostMessage |
| The system fails to restart after you confirm the application's restart request. | EnableRestarts |
| The application fails to register services. | RedirectEXE |
| The Readme.txt file cannot be opened. | HandleRegExpandSzRegistryKeys |

Table 3.20 identifies the application compatibility fixes that you can apply when entering data with the keyboard or using certain key sequences causes problems.

**Table 3.20 Application Compatibility Fixes for Keyboard Input Problems**

| Symptom | Application Compatibility Fix |
|---|---|

| | |
|---|---|
| When you attempt to type in logon information, the application returns the "Unexpected error" message. | AliasDXDC |
| The application does not correctly display the shortcut keys. | DisableKeyboardCues |
| Using the ALT+TAB key combination causes the application window to become blank. | IgnoreAltTab |
| The application becomes unresponsive when you use the ALT+TAB key combination. | IgnoreAltTab |
| The application stops responding when you use the SHIFT key, the CTRL key, or the ALT key 5 times or more in succession. | DisableStickyKeys |
| The keyboard locks up during normal operation. | EmulateUSER |
| The keyboard is sluggish or doesn't function at all, and the system becomes generally unresponsive. | LowerThreadPriority |

Table 3.21 identifies the application compatibility fixes that you can apply when the application has problems with sound, graphics, animation, or video.

**Table 3.21 Application Compatibility Fixes for Multimedia Problems**

| Symptom | Application Compatibility Fix |
|---|---|
| Sounds do not play. | DelayWinMMCallback |
| No sound or limited sound plays. | CorrectACMStreamOpen |
| Sounds do not play because the application does not detect sound devices. | AddWritePermissionsToDeviceFiles |
| The application cannot use the sound hardware, so it returns the "Sound hardware already in use" error message. | AddWritePermissionsToDeviceFiles |
| Sounds do not play with Audio Compression Manager drivers. | CorrectACMArgs |
| The application returns the "Active Movie Control: An object or name was not found" error message. | CorrectActiveMoviePath |
| A message indicates that the sound device driver failed to load. | CorrectSoundDeviceId |
| The sound loops perpetually, and the application does not always respond to shutdown requests. | EmulatePlaySound |
| Audio Video Interleaved (.avi) files continue to run behind the menu screen. | ForceAVIWindow |
| The cursor freezes momentarily during background music changes. | IgnoreMCISTOP |
| The application attempts to send sound to the wrong device (usually to an audio card instead of to the desired USB devices). | WaveOutUsePreferredDevice |

Table 3.22 identifies the application compatibility fix that you can apply when network connections cannot be set up correctly.

**Table 3.22 Application Compatibility Fix for a Network Connection Problem**

| Symptom | Application Compatibility Fix |
|---|---|

| | |
|---|---|
| The application automatically selects Serial Connection when you attempt to select a network connection. | DirectPlayEnumOrder |

Table 3.23 identifies the application compatibility fix that you can apply when permission problems occur.

**Table 3.23 Application Compatibility Fix for a Permissions Problem**

| Symptom | Application Compatibility Fix |
|---|---|
| Insufficient user rights produce errors. | LUATrackFS |

Table 3.24 identifies the application compatibility fixes that you can apply when printing does not work correctly.

**Table 3.24 Application Compatibility Fixes for Printing Problems**

| Symptom | Application Compatibility Fix |
|---|---|
| Access violations occur when the application starts or when it searches for printers. Consequently, the application returns error messages when you attempt to find, select, or print to a printer. | EmulatePrinter |
| The application shuts down unexpectedly when you attempt to print. | ForceAnsiWindowProc |

Table 3.25 identifies the application compatibility fixes that you can apply when invalid registry entries cause problems.

**Table 3.25 Application Compatibility Fixes for Registry Problems**

| Symptom | Application Compatibility Fix |
|---|---|
| The application makes a call to a statically loaded .dll file that has not yet been loaded. | InjectDll |
| When you use a limited user account (LUA), the application returns the error message "Failed to update system registry. Please try using RegEdit." | LUARedirectFS |

Table 3.26 identifies the application compatibility fixes that you can apply when **Start** menu entries or shortcuts are not created correctly or do not work correctly.

**Table 3.26 Application Compatibility Fixes for Start Menu and Shortcut Problems**

| Symptom | Application Compatibility Fix |
|---|---|
| Shortcuts are not created for all users. | CorrectFilePaths |
| Shortcuts are not created for all users. | LUARedirectReg |
| A desktop shortcut is not created. | ForceAnsiGetDisplayNameOf |
| Shortcuts are not removed for all users. | CorrectFilePathsUninstall |
| A valid and an invalid shortcut appear in the Start menu during application installation. | DelayShowGroup |
| The application does not appear on the Start menu. | ProfilesEnvStrings |
| The application does not appear in the Start menu. | ProfilesGetFolderPath |
| The application does not appear in the Start menu. | ProfilesRegQueryValueEx |

| | |
|---|---|
| Shortcuts do not appear on the desktop. | ProfilesEnvStrings |
| Shortcuts do not appear on the desktop. | ProfilesGetFolderPath |
| Shortcuts do not appear on the desktop. | ProfilesRegQueryValueEx |

Table 3.27 identifies the application compatibility fixes that you can apply when problems occur during application startup or during the startup of a process initiated by the application.

**Table 3.27 Application Compatibility Fixes for Startup Problems**

| Symptom | Application Compatibility Fix |
|---|---|
| The setup program fails to install the application. | HandleWvsprintfExceptions |
| The application cannot load. | IgnoreDebugOutput |
| The application does not start after it is installed. | EmulateGetStdHandle |
| The application does not start, but displays error messages or indicates that an access violation has occurred. | StackSwap |
| When starting, the application causes an access violation. | HeapPadAllocation |
| When you attempt to start the application, it returns an error message indicating that the application is not installed. | FailGetStdHandle |
| When you attempt to start the application, it returns an error message indicating that the application must be installed. | EmulateGetStdHandle |
| The application fails to start, and returns an error message. | EmulateVerQueryValue |
| When the application is started directly after setup is complete, it returns the "No Disc Inserted" error message because it does not detect the CD drive. | AddWritePermissionsToDeviceFiles |
| An access violation occurs when the application starts. | EmulateGetDeviceCaps |
| When you start the application, it returns the "Computer memory full" error message. | GlobalMemoryStatusLie |
| When you attempt to start the application, it returns the "Component failed to be located" error message. | VirtualRegistry |
| The application stops responding immediately after starting. | HideDisplayModes |
| The application quits immediately after starting. | HeapClearAllocation |
| The application becomes unresponsive after starting. | AddWritePermissionsToDeviceFiles |
| The application becomes unresponsive or closes unexpectedly shortly after starting. | EmulateFindHandles |
| When the application starts, it returns an exception error. | IgnoreCoCreateInstance |
| When the application starts, it returns the ".dll not compatible with the application" error message. | LoadLibraryCWD |

| | |
|---|---|
| A component or file is not correctly registered or is missing, or the application returns an "Invalid" error message. | CorrectFilePathInSetDlgItemText |
| When the application starts, a window containing only a cursor opens. | IgnoreException |
| The application returns the "Component failed to initialize" error message. | DelayDllInit |
| When you start the application, it automatically minimizes, but sound effects continue to play. The application might or might not run when selected from the taskbar. | NoGhost |
| Runtime errors occur when you start the application or when you start specific components. | SetEnvironmentVariable |
| When the application expects to find a joystick, it quits unexpectedly. | EmulateJoystick |
| When you attempt to start executable programs, such as Scandisk, Disk Defragmenter, or Help, the application displays an error message. | EmulateMissingEXE |
| When the application runs on a high-end machine, its window is blank or it displays an "Access violation" error message. | EmulateSlowCPU |
| When you attempt to start two instances of the application, the application returns an error message. | EmulateToolHelp32 |
| Starting a Safedisk program causes access violations. | FailCloseProfileUserMapping |
| Logging on and starting services take a long time. | FixServiceStartupCircularDependency |
| The application returns a message asking that the correct CD be put in the drive or stating that there is no CD in the drive. | ForceCDStop |
| The application fails to run its startup movie (.avi file) and shuts down. | ForceCoInitialize |
| The application returns the "DirectX does not support the Windows version on the system" error message. | ForceDXSetupSuccess |
| The application does not run in hardware mode. | ForceSimpleWindow |
| The **Autorun** menu does not appear. | CorrectBitmapHeader |
| The **Autorun** dialog box does not get refreshed after the application is installed, so that the option to start the application is still disabled. | HandleAPIExceptions |
| The application becomes unresponsive immediately after starting. | IgnoreException |
| The application displays message boxes that give debugging or other extraneous information. | IgnoreMessageBox |
| The application fails to start or performs slowly. | IgnoreScheduler |
| The application does not start, and it returns the "Desktop is running in 0 bit color mode" error message. | LazyReleaseDC |
| The application does not start, or you get error messages when you attempt to start it. | MapMemoryB0000 |

| | |
|---|---|
| When the application is run by a user other than the user who installed it, it displays error messages such as "Cannot find <X>" (where x is a folder or file that does exist on the system) or "<X> components were not found or are corrupt, run setup." | PopulateDefaultHKCUSettings |
| When you start the application, it returns the "Not a valid Win32 application" or "Unable to run the command" error message. | RecopyExeFromCD |
| An access violation occurs when you attempt to start another program through the application by linking to Windows components (Internet Explorer Web Links or Windows Explorer folders, for example). | RemoveDDEFlagFromShellExecuteEx |
| When the application attempts to start Windows components (such as Microsoft Paint), it returns the "File or program cannot be found" error message. | SearchPathInAppPaths |
| The application returns the "Files cannot be found or do not exist" error message. | SetEnvironmentVariable |
| Entry-point errors occur for functions within earlier versions of Cryptsys and DirectX DLLs. | TerminateExe |
| The application returns the error message "WinG32.dll has been incorrectly installed in the system folder. Please move it to the System32 folder." | WinG32SysToSys32 |

Table 3.28 identifies the application compatibility fixes that you can apply when the telephone dialer does not work correctly.

**Table 3.28 Application Compatibility Fixes for Telephony Application Programming Interface (TAPI) Problems**

| Symptom | Application Compatibility Fix |
|---|---|
| A runtime error occurs in Mfc40.dll when the call is disconnected. | IgnoreTAPIDisconnect |
| The phone dialer does not hang up. | IgnoreTAPIDisconnect |

Table 3.29 identifies the application compatibility fixes that you can apply when the application expects a version of Windows that is not available.

**Table 3.29 Application Compatibility Fixes for Versioning Problems**

| Symptom | Application Compatibility Fix |
|---|---|
| The application requests that Windows 95 be installed. | Win95VersionLie |
| The application requests that Windows 98 be installed. | Win98VersionLie |
| The application requests that Windows NT 4.0 Service Pack 5 be installed. | WinNT4SP5VersionLie |
| The application requests that Windows 2000 be installed. | Win2000VersionLie |
| The application requests that Windows 2000 Service Pack 1 be installed. | Win2000SP1VersionLie |
| The application requests that a previous version of DirectX be installed. | Win2000VersionLie |
| The application requests that a previous version of DirectX be installed. | WinNT4SP5VersionLie |
| The application requests that a previous version of DirectX be installed. | Win2000SP1VersionLie |
| The application reports that it will not function on a Windows NT system. | Win95VersionLie |

| | |
|---|---|
| The application reports that it will not function on a Windows NT system. | Win98VersionLie |

Table 3.30 identifies the application compatibility fixes that you can apply when application windows do not work correctly.

**Table 3.30 Application Compatibility Problems for Window Management Problems**

| Symptom | Application Compatibility Fix |
|---|---|
| An unexpected dialog box appears. | ForceShellLinkResolveNoUI |
| A dialog box does not come to the foreground; you must press ALT+TAB to see it. | GiveupForeground |

Table 3.31 includes miscellaneous application compatibility fixes that do not fit within any other category.

**Table 3.31 Application Compatibility Fixes for Miscellaneous Problems**

| Symptom | Application Compatibility Fix |
|---|---|
| A spawned process fails to operate properly, although the parent process functions normally. For example, Setup.exe works correctly, but the spawned process, Setup2.exe, fails. | PropagateProcessHistory |
| The application does not display system information properly when you use the System Info button in the **About** dialog box. | RemoveIpFromMsInfoCommandLine |

# Identifying Strategies for Resolving Special Problems

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Some special problems cannot be resolved by applying application compatibility fixes or by debugging and modifying source code. If application compatibility fixes do not resolve an application problem, try one of the following solutions.

**Reinstall the application by using an Administrator account**
If the problematic application was written for Windows 95, Windows 98, or Windows Millennium Edition, use an Administrator account to install the application. These versions of Windows did not differentiate between Administrator and limited user accounts, so an application that runs on these versions might write to a location that is not allowed by Windows XP Professional.

**Use the current Microsoft Virtual Machine**
Use the most current version of the Microsoft Virtual Machine, which enables Java programs to run on Windows.

**Remove and reinstall the application after upgrading to Windows XP Professional**
If you upgraded the computer to Windows XP Professional, and the application is listed in the Windows Catalog as compatible with Windows XP Professional, try to remove and then reinstall the application after performing the upgrade. If removing and reinstalling the application on Windows XP Professional does not solve the problem, the application might not have been entirely removed. Contact the application vendor for specific instructions on how to remove the application manually. For example, it might be necessary to remove certain folders or registry entries in order to fully reinstall the application.

**Verify MDAC and DirectX versions**
If the application uses Microsoft Data Access Components (MDAC) or DirectX, ensure that you are using the correct versions. Windows XP Professional with Service Pack 1 and Windows Server 2003 support MDAC version 2.7 with Service Pack 1 and DirectX version 9.0. Some older applications attempt to install an earlier version of MDAC or DirectX, but Windows File Protection replaces the earlier version with the newer version. If the application requires the earlier version, errors can occur. In this case, you might need to create a redirection file, as described in the following section, to ensure that the required version is loaded when the application runs.

**Load earlier versions of .dll files**
Some older applications require earlier versions of .dll files than are supplied by Windows XP Professional or Windows Server 2003. If a newer version of a .dll file is loaded when an application runs, problems can occur. To ensure that the application uses the version of the .dll file that it requires, create a redirection file. The redirection file must be created in the same directory as the .dll files and the application.

A redirection file contains no data or information (the contents of the redirection file are ignored), but its name must have the format *ApplicationExecutable.local*. For example, if an application's name is Editor.exe, the redirection file must be named Editor.exe.local.

Even if you do not use a redirection file, always install the .dll files for an application in the same directory as the application. Doing so ensures that the application does not overwrite copies of the .dll files, which might be used by other applications. Doing so also ensures that the application loads the .dll files that it requires.

Placing a redirection file in the directory with an application ensures that all the .dll files in that directory are loaded when the application runs, instead of the .dll files supplied by the operating system. Without a redirection file, the .dll files supplied by the operating system are loaded when the application runs.

### Important

- You do not need to use a redirection file with Windows XP Professional with Service Pack 1 or higher, or with Windows Server 2003. You do need to use a redirection file with Windows XP Professional without Service Pack 1.

**Create application manifest files**
As you migrate applications to Windows XP Professional or Windows Server 2003, you should write an application manifest, a .man file, for each application. The *manifest* is a text file in XML format that lists the dynamic-link libraries that the application should be executed with, along with their version numbers. In the manifest, list the DLL versions with which the application was originally built and tested. When Windows XP Professional or Windows Server 2003 runs an .exe file for which a manifest exists, it loads only the DLL versions specified in the manifest. For more information about specific DLLs, see the DLL Help Database link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Change the short date format**

Some applications that were designed for Windows 95 do not handle short dates correctly when they run on Windows XP Professional. If an application does not accept short dates that are entered by a user, try changing the short date format in **Regional and Language Options**. For example, if the short date format is M/d/yyyy (the default), try changing the format to MM/dd/yyyy.

**To change the short date format on Windows Server 2003**

1. Open **Regional and Language Options** in Control Panel.
2. On the **Regional Options** tab, click **Customize**.
3. On the **Date** tab, next to **Short date format**, select a short date format.

**To change the short date format on Windows XP Professional**

1. Open Control Panel, and then click **Date, Time, Language, and Regional Options**.
2. Click **Regional and Language Options**.
3. On the **Regional Options** tab, click **Customize**.
4. On the **Date** tab, next to **Short date format**, select a short date format.

**Verify that the Kodak Image Edit control is not required**

Ensure that the application does not depend on the Kodak Image Edit control. This control has been removed from Windows XP Professional and Windows Server 2003.

**Verify the length of network printer names**

Some older applications fail when they attempt to print to a network printer with a name longer than 31 characters. To prevent this problem, create a local connection to the network printer for the application.

**To create a local printer connection**

1. Start the Add Printer Wizard.
2. On the Local or Network Printer page, select **Local printer attached to this computer**,and clear **Automatically detect and install my Plug and Play printer**.
3. On the Select a Printer Port page, select the port if it is listed. Otherwise, select **Create a new port,** and then for **Type of Port**, select **Local Port**.
4. Click **Next** to display the **Port Name** window, and enter the port name for the printer in the format *PrintServer**PrinterName*.
5. On the Install Printer Software page, select the printer manufacturer and the appropriate printer.
6. On the Use Existing Driver page, select **Keep existing driver**, if there is one.
7. On the Name Your Printer page, type a name using fewer than 31 characters and finish the wizard as appropriate for your environment.

# Deploying and Distributing Applications and .Sdb Files

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After adding application compatibility fixes and modes to your custom application compatibility databases (.sdb files), you must deploy or distribute the .sdb files to destination computers in your organization. Usually, you also must deploy or distribute the applications to which the fixes apply. In this context, *deploying* means you are installing .sdb files and applications during an operating system rollout. *Distributing* means that you are installing .sdb files and applications as part of your ongoing operations after rolling out an operating system.

Typically, an automated installation method, such as image-based installation or unattended installation, is used to deploy .sdb files and applications to destination computers during an operating system rollout. By contrast, a software management mechanism, such as Group Policy Software Installation, logon scripts, or Software Update Services (SUS), is typically used to distribute .sdb files and applications to destination computers that already have an operating system installed.

Your deployment team is usually responsible for deploying applications and .sdb files during an operating system rollout. Your operations team is usually responsible for distributing applications and .sdb files on destination computers that already have operating systems installed.

Figure 3.11 shows where the deployment and distribution tasks fit into the overall application compatibility planning, testing, and deployment process.

**Figure 3.11 Deploying and Distributing Applications and .Sdb Files**

This section describes how to use various tools to deploy and distribute applications and .sdb files. This section does not help you choose a deployment or distribution tool. That choice depends on several factors, including your deployment design, your IT standards and practices, and your operational procedures. It is assumed that you have already chosen a deployment or distribution tool based on these factors. For more information about choosing an automated deployment tool, see "Choosing an Automated Installation Method" in *Automating and Customizing Installations* of this kit. For more information about choosing an application distribution tool, see the "Application Deployment Using Microsoft Management Technologies" white paper, available through the Application Deployment link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Reviewing Application Deployment and Distribution Tools

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Microsoft provides several tools to help you deploy or distribute applications and .sdb files. These tools include:

- Deployment tools, such as the System Preparation (Sysprep) tool and Remote Installation Services (RIS). You use these automated installation tools to deploy applications and .sdb files during an operating system rollout.

- Distribution tools, such as SUS, Group Policy Software Installation, logon scripts, and SMS. You use these tools to distribute applications and .sdb files to computers that already have an operating system installed.

In addition, Microsoft provides two tools that you use in conjunction with the deployment tools and the distribution tools to package and install applications and .sdb files. These tools are:

- Application Compatibility Database Installer (Sdbinst.exe), which you use to install and register .sdb files.

- Windows Installer, which consists of two tools: a software packaging tool that you use to package application installation files and .sdb files, and an installer tool that you use to install the packages.

This section provides you with an overview of these tools.

**Deployment Tools**

There are three primary methods of deploying applications and .sdb files during an operating system rollout: unattended installation, image-based installation, and RIS installation. Each method requires one or more tools.

**Unattended installation** Unattended installation is a method of automating the Windows Setup program so that no user input is required when you install an operating system or applications. To perform unattended installations, you need to create an answer file that contains answers to the questions that Windows Setup normally prompts for during an installation. By using an answer file to control Windows Setup, you can automate the entire installation process, including the installation of applications and .sdb files. Unattended installation is the most flexible method of deploying applications and .sdb files: It can be used to perform operating system upgrades or clean installations on computers with different hardware and software configurations.

**Image-based installation** Image-based installation is a method of copying, also known as *cloning*, preconfigured operating systems and software applications onto clients and servers. To perform image-based installations, you need the Sysprep tool, which can be found on the Windows XP Professional or Windows Server 2003 operating system CD, and you need a third-party disk-imaging tool. Image-based installation is the fastest method of installing operating systems and applications, but you cannot use it to perform operating system upgrades.

**RIS installation** RIS installation is a method of cleanly installing an operating system and applications across a network with minimal end-user interaction. RIS uses Pre-Boot eXecution Environment (PXE) technology to enable client computers without an operating system to start up and connect remotely over a TCP/IP network connection to a RIS server, which installs a supported operating system. RIS installations require substantial planning and design, but are an efficient deployment method if you need to install clean operating systems and preconfigured applications onto a large number of clients.

To obtain the unattended and image-based installation tools, open the Support\Tools folder on any Windows XP Professional or Windows Server 2003 operating system CD, and then open Deploy.cab. The Readme.txt file in Deploy.cab explains how to install and use the tools. The RIS installation tools are built into Windows Server 2003. For more information about unattended installations, image-based installations, and RIS installations, see "Designing Unattended Installations," "Designing Image-based Installations with Sysprep," and "Designing RIS Installations," respectively, in *Automating and Customizing Installations* of this kit.

**Distribution Tools**

The four most commonly used methods of distributing applications and .sdb files are the use of Group Policy Software Installation, logon scripts, the Software Update Services (SUS), and SMS.

**Group Policy Software Installation** You can use Group Policy Software Installation to centrally install and manage software applications throughout an organization. Using this management system, you can distribute applications and .sdb files to

groups of users and computers. It is the most common method of distributing applications and .sdb files to computers that already have an operating system installed. Active Directory is required in order to use Group Policy Software Installation.

**Logon scripts** Logon scripts run when a user logs on to a computer. Logon scripts typically are written as command (.cmd) files, batch (.bat) files, or Microsoft® Visual Basic® Scripting Edition (.vbs) files.

**Software Update Services (SUS)** You can use SUS to download updates for Windows XP Professional and Windows Server 2003. The updates can include updated versions of the prepackaged application compatibility databases and updated versions of the corresponding code segments that run when an application needs an application compatibility fix, application compatibility mode, or Application Help message. SUS provides dynamic notification of updates to computers, and it provides a simple, automatic solution for distributing updates to networked clients and servers.

**SMS** You can use SMS to distribute applications and .sdb files. SMS includes features such as software metering and software distribution-point population and maintenance. SMS does not require Active Directory.

**Note**

- You also can use a third-party software management program to distribute applications and .sdb files.

Group Policy Software Installation and SUS are built into Windows Server 2003. For more information about Group Policy, see "Group Policy" in Help and Support Center for Windows Server 2003 and "Deploying a Managed Software Environment" in *Designing a Managed Environment* of this kit. For more information about SUS, see the "Software Update Services Deployment" white paper, available through the Software Update Services link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources, and the Deploying Software Update Services White Paper on the Microsoft Web site.

SMS is a Microsoft product available for purchase. For more information about SMS, see the SMS Product Information link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Application Compatibility Database Installer**

The Application Compatibility Database Installer (Sdbinst.exe) installs and registers your .sdb files on destination computers. Sdbinst.exe is a command-line program that is installed by default into the *systemroot*\System32 folder on computers running Windows XP Professional or Windows Server 2003. Although you can use Compatibility Administrator to install and register .sdb files, using Sdbinst.exe is the only way to automate this task on a large number of computers.

To use Sdbinst.exe, you first copy your .sdb files to the destination computers, and then run Sdbinst.exe on each destination computer. Usually, you copy your .sdb files to a subfolder in the *systemroot*\AppPatch folder (for example, *systemroot*\AppPatch\Custom) on each of the destination computers. This keeps all of the .sdb files in one place, because the prepackaged databases are stored in the *systemroot*\AppPatch folder on Windows XP Professional and Windows Server 2003. If you prefer, you can copy your application compatibility database files to a different folder, but if you do this you must set permissions on the folder granting the Everyone group Read & Execute access and the Administrators group Full Control access. This ensures that your application fixes get implemented regardless of who runs an application. It also ensures that only those users with Administrator credentials can register or alter your application compatibility database files.

Sdbinst.exe requires the following syntax:

```
          sdbinst [-?] [-q] [-u] [-g] [-n] ApplicationCompatibilityDatabase.sdb |
{GUID} | "InternalApplicationName"
```

The parameters are defined in Table 3.32.

**Table 3.32 Command-Line Parameters for Sdbinst.exe**

| Parameter | Description |
|---|---|
| **-q** | Runs Sdbinst.exe in quiet mode, which suppresses message boxes during the database installation process. Use this parameter if you are using an automated installation method to install application compatibility databases. |
| **-u** | Uninstalls an application compatibility database. To identify the application compatibility database that is to be uninstalled, you must specify a file name, a globally unique identifier (GUID), or an internal name. |

| | |
|---|---|
| **-g** | Specifies the GUID of the application compatibility database that you want to uninstall. Use only with the **-u** parameter. You must specify a GUID if you use this parameter. |
| **-n** | Specifies the internal name of the application compatibility database to be uninstalled. This is the name assigned internally to the database when it was created in Compatibility Administrator. Use only with the **-u** parameter. You must specify the internal name of the database if you use this parameter. |
| *ApplicationCompatibilityDatabase* | Specifies the name of the .sdb file that you want to install or uninstall. |
| *GUID* | Specifies the globally unique identifier of the application compatibility database that you want to uninstall. Use only with the **-g** parameter. |
| *InternalApplicationName* | Specifies the name of the application compatibility database that you want to uninstall. This is the name assigned internally to the database when it was created in Compatibility Administrator. Use only with the **-n** parameter. |
| **-?** | Displays the Help documentation for Sdbinst.exe. |

**Windows Installer**

Windows Installer consists of several tools and features, two of which are useful for deploying and distributing applications and .sdb files: Windows Installer packages (.msi files), and the Windows Installer tool (Msiexec.exe). As a stand-alone tool, Msiexec.exe is not a solitary solution for deploying and distributing applications and .sdb files. You use Msiexec.exe in conjunction with your deployment or distribution tools. Likewise, you use .msi files in conjunction with your deployment or distribution tools.

**Windows Installer packages**

A Windows Installer package (.msi file) contains all of the information that the Windows Installer service requires to run an application's setup program and to install and configure the application. In addition, a Windows Installer package can contain any files that are required by the application's setup program, such as dynamic-link library (.dll) files, information (.inf) files, executable (.exe) files, or cabinet (.cab) files. Packaging your applications and your .sdb files into Windows Installer packages makes application deployment and distribution easier and more efficient, and prevents you from having to manage numerous installation files for each of your applications. Application developers usually create Windows Installer packages at the end of the software development process, but you can create a Windows Installer package after an application has been developed.

You can use either Microsoft® Visual Studio® .NET development system or a third-party software program to create Windows Installer packages. For more information about creating Windows Installer packages, see the Windows Installer Software Developer's Kit (SDK) link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Windows Installer tool (Msiexec.exe)**

Msiexec.exe carries out the instructions that are contained in a Windows Installer package. Msiexec.exe performs all installation-related tasks, including copying files onto the hard disk, modifying the registry, and creating shortcuts on the desktop. Msiexec.exe is a command-line tool that is built into Windows XP Professional and Windows Server 2003.

For more information about Msiexec.exe command-line syntax and usage, see "Msiexec (command-line options)" in Help and Support Center for Windows Server 2003.

# Deploying Applications and .Sdb Files

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use any of the following automated installation methods to deploy applications and .sdb files during an operating system rollout: unattended installation, image-based installation with the Sysprep tool, and RIS installation. The method that you use depends on several factors, such as the operating system that you are installing, your organization's network and hardware configuration, and the applications that you are deploying. With a few exceptions, no single factor determines which installation method you should use.

This section does not provide guidance for choosing an automated installation method. It is assumed that you have evaluated all of the factors that affect your choice of an automated installation method already, and that you have determined which automated installation method best suits your needs. It is also assumed that you understand how to use the tools associated with each of these automated installation methods.

**Note**

- For more information about unattended installation and image-based installation with Sysprep, see the *Microsoft® Windows® Server 2003 Corporate Deployment Tools User's Guide* (Deploy.chm and Ref.chm). Deploy.chm and Ref.chm are included in the Deploy.cab file in the Support folder on the Windows Server 2003 operating system CD. Deploy.chm and Ref.chm must be stored in the same folder. You can open these files on the operating system CD, or open them on your computer by installing Deploy.cab in a folder on your computer.

# Deploying Applications and .Sdb Files During Unattended Installations

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To deploy applications and .sdb files during an unattended installation, you need to configure the following items.

**Your distribution share** Add your applications and .sdb files to your distribution share so that they can be installed on your destination computers.

**Your Cmdlines.txt file** Add the appropriate commands to your Cmdlines.txt file so that Sdbinst.exe runs and installs your .sdb files after an operating system is installed on a destination computer, but before the destination computer restarts and a user logs on.

**The [GuiRunOnce] section of your answer file** Add the appropriate commands to the [GuiRunOnce] section of your answer file so that your applications are installed on each of your destination computers after the computer restarts and a user logs on.

Your unattended installation must adhere to the following guidelines:

- You cannot perform an unattended installation from a Windows XP Professional or Windows Server 2003 operating system CD. You must use a distribution share.
- You cannot name your answer file Winnt.sif. You must name it Unattend.txt or another name. You can use the name Winnt.sif only if you are starting your destination computers from a Windows XP Professional or Windows Server 2003 operating system CD, which you cannot do if you are deploying applications or .sdb files.
- You cannot install applications or .sdb files during an unattended upgrade. This is because you cannot use a distribution share during an unattended upgrade, and you need to use a distribution share to install applications and .sdb files.

#### Configuring Your Distribution Share

You need to add the following files to your distribution share to deploy applications and .sdb files during an unattended installation.

**.Sdb files** Add your .sdb files to your distribution share so that the .sdb files are copied to every destination computer. Although you can save .sdb files in any folder on a destination computer, the most commonly used location is a folder named *systemroot*\AppPatch\Custom. To copy your .sdb files to the *systemroot*\AppPatch\Custom folder on each of your destination computers, save your .sdb files in the $OEM$\$$\AppPatch\Custom folder of your distribution share. To save your .sdb files to another folder on your destination computers, save your .sdb files in a corresponding folder in the $OEM$ folder of your distribution share. For example, if you want to save your .sdb files in *systemdrive*\Myapps\Sdbfiles, save your .sdb files in the $OEM$\$1\Myapps\Sdbfiles folder of your distribution share.

**Installation files for applications** Add the installation files for your applications to your distribution share. This ensures that the installation files are copied to every destination computer, and that the files are available during your unattended installation. You can save installation files, such as .msi files, in any folder that you choose on a destination computer. For example, if you are installing an application called Myapp, you might save the installation files for Myapp in *systemdrive*\Apps\Myapp. To create this folder structure on every destination computer, add $OEM$\$1\Apps\Myapp to your distribution share.

For more information about structuring your distribution share, see "Designing Unattended Installations" in *Automating and Customizing Installations* of this kit.

#### Configuring Your Cmdlines.txt File

To install .sdb files during an unattended installation, you need to configure your Cmdlines.txt file. If you are not already using a Cmdlines.txt file to perform other installation and configuration tasks during an unattended installation, you need to create a Cmdlines.txt file.

**To create a Cmdlines.txt file**

1. Use Notepad, or any text editor, to create a text file named Cmdlines.txt.

2. Add the following section to the Cmdlines.txt file:

```
[Commands]
```

3. Save the Cmdlines.txt file in the $OEM$ folder of your distribution share.

4. Add the following section, entry, and value to your unattended installation answer file:

```
[Unattended]
OemPreinstall = Yes
```

**To configure a Cmdlines.txt file to install .sdb files**

- Add the **Sdbinst.exe** command, with the appropriate parameters, to the [Commands] section of your Cmdlines.txt file. The command and associated parameters must be enclosed in quotation marks.

Be sure to use the **/c** parameter with the Cmd.exe command. This terminates Cmd.exe when Sdbinst.exe has finished running. Also, be sure to use the **-q** parameter with the **Sdbinst.exe** command, which instructs Sdbinst.exe to run in quiet mode. For example, to install *systemroot*\AppPatch\Myapp.sdb, create the following entry in your Cmdlines.txt file, below the [Commands] section heading:

```
" cmd.exe /c sdbinst -q %systemroot%\AppPatch\Myapp.sdb"
```

**Configuring the [GuiRunOnce] Section in Your Answer File**

To install applications on a destination computer during an unattended installation, you need to add commands to the [GuiRunOnce] section in your answer file. The commands that you use depend on how you are installing the application. If you are installing an application that is packaged into an .msi file, use the **Msiexec** command to start the Windows Installer tool. If you are installing an application that is not packaged into an .msi file, use whatever command is necessary to run the application's setup program (usually, the command is **Setup**).

For example, to install an application that is packaged into an .msi file, add the following command to the [GuiRunOnce] section of your answer file:

```
" cmd.exe /c msiexec /qn /i Myapp.msi"
```

The **/c** parameter instructs the command console program to close when Msiexec.exe stops running. The **/i** parameter instructs the Windows Installer program to install the .msi package, and the **/qn** parameter instructs the Windows Installer program to run without displaying a user interface.

Likewise, to install an application that is not packaged into an .msi file and that has its own setup program named Setup.exe, add the following command to the [GuiRunOnce] section of your answer file:

```
" cmd.exe /c Setup.exe"
```

Regardless of whether you install applications with the Windows Installer program or with an application's setup program, you must adhere to the following guidelines in setting up an unattended installation.

**Installation programs cannot require a restart** You can automate installation tasks only if you can prevent the installation program from restarting the computer. When a computer restarts, all remaining commands in the [GuiRunOnce] section are lost. If the system restarts before running the commands listed in the [GuiRunOnce] section, the remaining commands will not run. Therefore, you need to suppress restarts. If you cannot suppress a restart within the installation program, you can try to repackage the application into a Windows Installer package by using a third-party application. For more information about Windows Installer packaging, see the Windows Installer Software Developer's Kit (SDK) link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Installation programs cannot rely on the Windows Explorer shell** The Windows Explorer shell is not loaded when the operating system starts running commands, programs, scripts, or batch files that are listed in the [GuiRunOnce] section of an answer file. In some cases, the application vendor can give you an updated installer program that does not rely on the Windows Explorer shell. If the vendor cannot provide this, you might be able to repackage the application as a Windows Installer package (.msi file).

**Installation programs might need to be run from a batch file** Installation programs often start and stop several different

processes. In some cases when you are installing multiple applications, this can inadvertently cause the next command listed in the [GuiRunOnce] section to start before the previous command finishes running. When this occurs, the second installation program usually fails. To prevent this, you can run the installation programs from batch files by using the **Start** command with the **/wait** parameter. This forces each installation program to run until it is completed before the next command listed in [GuiRunOnce] runs. For more information about using the **start** command to run installation programs in batch files, in Help and Support Center for Windows Server 2003, click **Tools**, and then click Command-line reference A-Z.

# Deploying Applications and .Sdb Files During Image-based Installations

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Three primary methods are available for deploying applications and .sdb files during an image-based installation:

- You can install and configure your applications and .sdb files on the master installation and then create a disk image of the master installation. The *master installation* is the reference computer that contains the operating system, software applications, and configuration settings that you plan to install on destination computers in your organization. When you copy the disk image to a destination computer, and then start the destination computer, the applications and .sdb files will be installed, configured, and ready for use by an end user on the destination computer.

- You can install applications and .sdb files by using a Sysprep.inf file to automate Mini-Setup. Mini-Setup is a subset of Windows Setup that gathers and configures user-specific information when a user starts a destination computer for the first time. This method uses a Cmdlines.txt file and the [GuiRunOnce] section of the Sysprep.inf file.

- You can use the Factory mode feature of Sysprep, and a Winbom.ini file, to attach or detach applications and run Sdbinst.exe on each destination computer. When you attach or detach applications, your application files and .sdb files exist on your disk image, but the applications and .sdb files are not installed. Then, when you copy the disk image to a destination computer and start the destination computer, you can use a Winbom.ini file to attach (install) or detach (remove) your application files and .sdb files.

The first and second methods are used most commonly in corporate environments in which a single standard software configuration is deployed. The Factory mode method is most often used in factory environments or corporate environments where several different software configurations are being deployed.

**Installing and Configuring Applications and .Sdb Files on a Disk Image**
To deploy installed and configured applications and .sdb files on a disk image:

1. Install and configure your applications on your master installation.

2. Copy your .sdb files to your master installation. Usually, .sdb files are saved in the *systemroot*\AppPatch\Custom folder, but you can save the files in any folder.

3. Run Sdbinst.exe on your master installation to install and register your .sdb files.

4. Run the Sysprep tool on your master installation.

5. Run your disk imaging program, and save the disk image in a shared folder or on some type of removable media.

6. Use your disk imaging tool to copy the disk image to your destination computers.

This is only a summary of the tasks that you need to perform to deploy installed and configured applications and .sdb files on a disk image. For more information about designing and performing an image-based installation, see "Designing Image-based Installations with Sysprep" in *Automating and Customizing Installations* of this kit.

**Installing and Configuring Applications and .Sdb Files During Mini-Setup**
To install and configure applications and .sdb files during Mini-Setup:

1. Copy your application files to the Sysprep folder on your master installation. Do not install the applications.

2. Copy your .sdb files to your master installation. Usually, .sdb files are saved in the *systemroot*\AppPatch\Custom folder, but you can save the files in any folder.

3. Create and configure your Cmdlines.txt file as described in "Deploying Applications and .Sdb Files During Unattended Installations" earlier in this chapter. Save the file in the Sysprep folder on your master installation.

4. Specify the path to your Cmdlines.txt file by configuring the InstallFilesPath entry in the [Unattended] section in your Sysprep.inf file.

5. Create and configure the [GuiRunOnce] section of your Sysprep.inf file in the same way you created and configured the [GuiRunOnce] section of your unattended installation answer file. For more information about configuring the [GuiRunOnce] section of Sysprep.inf, see "Deploying Applications and .Sdb Files During Unattended Installations" earlier in this chapter.

6. Configure any other sections and entries in your Sysprep.inf file, and save the file in the same location as Sysprep.exe and Setupcl.exe, which are usually in the *systemdrive*\Sysprep folder on your master installation.

7. Run the Sysprep tool on your master installation.

8. Run your disk imaging program, and save your disk image in a shared folder or on some type of removable media.

9. Use your disk imaging tool to copy the disk image to a destination computer.

This is only a summary of the tasks that you need to perform to deploy applications and .sdb files during Mini-Setup. For more information about designing and performing an image-based installation, see "Designing Image-based Installations with Sysprep" in *Automating and Customizing Installations* of this kit.

**Installing and Configuring Applications and .Sdb Files in Factory Mode**
To install and configure applications and .sdb files by using the Factory mode feature of Sysprep:

1. Copy your application files to your master installation. Do not install the applications.

2. Copy your .sdb files to your master installation. Usually, .sdb files are saved in the *systemroot*\AppPatch\Custom folder, but you can save the files in any folder.

3. Create a Winbom.ini file by using Notepad or any other text editor, and save the Winbom.ini file on a floppy disk, on a CD, or in the same folder as the Factory.exe program (usually, the *systemdrive*\Sysprep folder).

4. Configure the [OEMRunOnce] section of the Winbom.ini file. This section contains the list of commands to be run while the computer is running in Factory mode. For example, you can attach (install) or detach (remove) applications, and run Sdbinst.exe.

5. Configure the WinbomType entry in the [Factory] section of the Winbom.ini file. This entry specifies how the Winbom.ini file is processed; it is required.

6. Run the Sysprep tool, with the **/factory** parameter, on your master installation.

7. Run your disk imaging program, and save your disk image in a shared folder or on some type of removable media.

8. Use your disk imaging tool to copy the disk image to a destination computer.

9. Start the destination computer.

10. After the computer processes your Winbom.ini file and installs your applications and .sdb files, run Sysprep with the **/reseal** parameter.

This is only a summary of the tasks that you need to perform to deploy applications and .sdb files by using the Factory mode feature of Sysprep. Although Factory mode lets you install and configure applications quickly and efficiently, using it requires substantial planning and design. For more information about planning, designing, and implementing image-based installations with Factory mode, see "Designing Image-based Installations with Sysprep" in *Automating and Customizing Installations* of

this kit.

# Deploying Applications and .Sdb Files During RIS Installations

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Two methods are available for using a Remote Installation Services (RIS) server to deploy applications and .sdb files: the Risetup method, which uses Remote Installation Services setup (Risetup.exe), and the Riprep method, which uses Remote Installation Preparation Wizard (Riprep.exe). With either method, you can deploy an operating system, applications, and .sdb files across your network to destination computers throughout your organization.

**Risetup** In the Risetup method, a distribution share is used to deploy an operating system, applications, and .sdb files. The distribution share is similar in structure to the distribution share that is used during an unattended installation. You can add applications and .sdb files to the distribution share, and use answer files to install the applications and .sdb files.

**Riprep** In the Riprep method, disk images are used to deploy an operating system, applications, and .sdb files. The disk images are similar to the disk images that are used during an image-based installation with Sysprep, but instead of using Sysprep to prepare the master installation, you use Riprep. Riprep converts the master installation into a remote installation image that you can install on multiple destination computers.

Using the Riprep tool is the most common way to use RIS to deploy an operating system, applications, and .sdb files. It is faster than the Risetup method, and it requires less configuration after an image is copied to a destination computer.

**Deploying Applications and .Sdb Files Using Riprep**

To deploy applications and .sdb files using Riprep:

1. Install and configure the operating system and applications on your master installation.

2. Copy your .sdb files to your master installation. Usually, .sdb files are saved in the *systemroot*\AppPatch\Custom folder, but you can save the files in any folder.

3. Run Sdbinst.exe on your master installation to install and register your .sdb files.

4. Test the master installation to verify that the applications function properly and that the configuration is correct.

5. Run Remote Installation Services setup (Riprep.exe) on your master installation.

   Riprep converts the master installation into a remote installation image that you can install on multiple destination computers. It also replicates the image to a RIS server, where the image is available for installation on remote-boot-enabled client computers.

   Riprep configures various operating system settings on the master installation to ensure that every copy of the master installation's disk image is unique when you install it on destination computers. For example, Riprep resets the security identifiers (SIDs). Riprep also configures the master installation so that every destination computer starts in Mini-Setup mode.

6. Use RIS to copy the disk image to your destination computers.

   Before a RIS server can deploy an operating system image to a client computer, the client computer must initiate a remote network boot. When a client computer initiates a remote network boot, it is assigned a RIS server, which downloads the disk image to the client computer.

   After the disk image is downloaded to the client computer and the client computer is restarted, Mini-Setup starts. Mini-Setup then uses Plug and Play to detect hardware differences between the master installation and destination computers. This enables you to use a single master installation to deploy an operating system, applications, and .sdb files to destination computers that have different hardware configurations.

This is only a summary of the tasks that are required in order to deploy installed and configured applications and .sdb files using RIS. For more information about designing and performing a RIS installation, see "Designing RIS Installations" in *Automating and Customizing Installations* of this kit.

# Distributing Applications and .Sdb Files

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To distribute applications and .sdb files to computers that already have an operating system installed, you can use any of the following tools: the Group Policy Software Installation tool, logon scripts, SUS, and SMS. The tool that you use depends on several factors, such as the operating systems that you are running, your Active Directory configuration, and the design of your managed environment. With a few exceptions, no single factor determines which distribution tool you should use. This section does not provide guidance for choosing a distribution tool. It is assumed that you have already evaluated all of the factors that affect your choice of an application distribution tool, and that you have determined which tool best suits your needs.

**Tip**

- You can also distribute applications and .sdb files by writing stand-alone scripts that can be run any time (as opposed to logon scripts), and then running the scripts remotely with Windows Script Host. For information about Windows Script Host, see the Windows Script Host link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Distributing Applications and .Sdb Files Using Group Policy Installation

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can distribute applications and .sdb files to remote computers in managed environments by using Group Policy Software Installation to assign Windows Installer packages to computers. This is the most common method of distributing applications and .sdb files in managed environments. Windows Installer packages are deployed and managed within a Group Policy object, which is, in turn, associated with an Active Directory container — either a site, a domain, or an organizational unit. Therefore, you need either to create a new Group Policy object and link it to one of these Active Directory containers or to edit an existing Group Policy object and link it to a site, domain, or organizational unit.

**Important**

- To complete this procedure, you must log on as a member of the Domain Administrators security group, the Enterprise Administrators security group, or the Group Policy Creator Owners security group.

**To deploy software to remote computers**

1. Open the Group Policy Object Editor.
2. Do one of the following:
   - To assign or publish software applications to computers, in the console tree, double-click **Computer Configuration**.
   - To assign or publish software applications to users, in the console tree, double-click **User Configuration**.
3. Double-click **Software Settings**, and then click **Software Installation**.
4. Right-click **Software Installation**, click **New**, and then click **Package**.
5. Click the Windows Installer package that you want to assign, and then click **Open**.
6. In **Deploy Software,** click **Assigned**.

For information about using Group Policy, see "Group Policy" in Help and Support Center for Windows Server 2003.

# Distributing Applications and .Sdb Files Using Logon Scripts

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

*Logon scripts* are batch files, programs, or scripts that can be assigned to user accounts. Logon scripts run automatically when a user logs on. A logon script can be used to configure a user's working environment when the user logs on. It allows an administrator to influence a user's environment without managing all aspects of it. You also can use a logon script to install applications, application updates, and .sdb files.

A logon script can be assigned to a user account or to a security group in two ways: You can assign a logon script to run on a stand-alone computer by using Group Policy, or you can assign a logon script to run on a group of computers in a site, organizational unit, or domain by using Active Directory.

If you use Group Policy to assign logon scripts on a stand-alone computer, the scripts are saved locally in the *systemroot*\System32\GroupPolicy\Machine\Scripts\Logon folder on each stand-alone computer. If you use Active Directory to assign logon scripts to a group of computers, the scripts are saved in the *systemroot*\SYSVOL\sysvol*DomainName*\Scripts folder on your domain controllers. This folder is shared using the share name NETLOGON. Computers running Windows XP Professional or Windows Server 2003 look for logon scripts in this folder on the authenticating domain controller when a user logs on.

To assign a logon script to a user or group, you must be a member of the Administrators group on the local computer, or you must have been delegated the appropriate authority.

**To assign a logon script to a local user account or security group**

1. In Control Panel, double-click **Administrative Tools**, and then double-click **Computer Management**.
2. In the console tree, double-click **Local Users and Groups**.
3. In the console tree, click **Users** or **Groups**.
4. Double-click the name of the user or group to whom you want to assign a logon script.
5. Click the **Profile** tab.
6. In the **Logon script** text box, enter the path and name of the logon script that you want to assign to the user or group, and then click **OK**.

**To assign a logon script to a user in Active Directory**

1. In Control Panel, double-click **Administrative Tools**, and then double-click **Active Directory Users and Computers**.
2. In the console tree, click **Users**.
3. Double-click the name of the user to whom you want to assign the logon script.
4. Click the **Profile** tab.
5. In the **Logon script** text box, type the path and name of the logon script that you want to assign to the user, and then click **OK**.

For more information about configuring logon scripts, see "Logon Scripts" in Help and Support Center for Windows Server 2003.

# Distributing Patches and .Sdb Files Using SUS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

SUS replaces Corporate Windows Update. It provides a means for medium-sized enterprises to manage and distribute critical Windows patches. These patches resolve security vulnerabilities and stability problems with the Windows XP Professional and Windows Server 2003 operating systems. The patches also can include updates to the prepackaged databases that are installed in the *systemroot*\AppPatch folder. Although SUS is well suited to an Active Directory environment, Active Directory is not required in order to use SUS.

SUS provides dynamic notification and automatic distribution of critical updates to computers that are running Windows XP Professional or Windows Server 2003. In addition, only one of your computers needs to be connected to the Internet for SUS to function.

An SUS solution has three components: an SUS server, an Automated Updates client, and an Intranet-hosted Windows Update server.

**An SUS server** The server component of an SUS solution is installed inside the corporate firewall. With SUS installed, the internal server can synchronize with the Windows Update Web site whenever critical updates are available. The synchronization can be automatic, or the administrator can perform it manually. After the updates are downloaded to the server that is running SUS, the administrator can decide which updates to publish. All clients that are configured to use the server that is running SUS can then install the updates.

**An Automatic Updates client** The client component of a SUS solution is installed on client computers running Windows XP Professional or Windows Server 2003 so that they can connect to the internal server that is running SUS. The administrator can control which server each client computer connects to, and schedule when the client performs all installations of critical updates.

**An intranet-hosted Windows Update server** This server acts as the virtual Windows Update server for client computers. It contains the synchronization service and administrative tools for managing updates. It services requests for approved updates by the client computers connected to it using the Hypertext Transfer Protocol (HTTP). This server can also host critical updates downloaded from the synchronization service and refer client computers to those updates.

For more information about configuring and deploying SUS, see the "Software Update Services Deployment" white paper, available through the Software Update Services link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources, and the Deploying Software Update Services White Paper on the Microsoft Web site.

# Distributing Applications and .Sdb Files Using SMS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

SMS includes a software distribution feature that can automate the distribution of applications and .sdb files. By using the software distribution feature, you can centrally manage and monitor the installation of applications and .sdb files on remote computers. SMS is a Microsoft product available for purchase. For more information about SMS, see the SMS Product Information link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Additional Resources for Planning and Testing for Application Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information related to this chapter.

# Designing a Pilot Project

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Conducting the pilot is the last major step before deployment of the Microsoft® Windows® Server 2003 operating system. During the pilot, your release management team tests your design in a controlled environment in which users perform their normal business tasks using the new features. This demonstrates that the design works in the production environment as expected and that it meets the organization's business requirements.

**In This Chapter**

Overview of Designing a Pilot Project

Creating a Pilot Plan

Preparing for the Pilot

Deploying and Testing the Pilot

Evaluating the Pilot

Preparing for Production Deployment

Additional Resources for Designing a Pilot Project

**Related Information**

- For more information about Microsoft Solutions Framework, see the Microsoft Solutions Framework link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.
- For more information about deployment project planning, see "Planning for Deployment" in this book.
- For more information about testing your implementation design prior to conducting the pilot, see "Designing a Test Environment" in this book.
- For more information about how to pilot specific technologies, such as Microsoft® Active Directory® directory service, see the related books in this kit.

# Overview of Designing a Pilot Project

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A *pilot* release is a deployment of your Windows Server 2003 or Microsoft® Windows® XP Professional operating system to a subset of the live production environment or user group. The primary purposes of a pilot are to demonstrate that your design works in the production environment as you expected and that it meets your organization's business requirements. Conducting a pilot reduces your organization's risk of encountering problems during full-scale deployment. To further minimize your risk during deployment, you might want to conduct multiple pilots consisting of separate pilots for different technologies or operating systems, or you might want to conduct a full-scale pilot in phases.

Depending on the context of the project, the pilot release can take the following forms:

- In a general business enterprise, a pilot can be conducted with a group of users on a set of servers in a datacenter.
- In a Web development enterprise, a pilot can be conducted by hosting site files on a staging server or servers or in folders that are live on the Internet, using a test Web address.
- Commercial software vendors, such as Microsoft, often conduct a pilot with a special group of early adopters.

The pilot participants provide feedback about how well the design and features are working. The release management team uses this feedback to resolve issues that arise or to create a contingency plan. Ultimately, the pilot leads to a decision to proceed with a full deployment or to slow down so you can resolve problems that could jeopardize your deployment.

The Microsoft Solutions Framework (MSF) training course offers in-depth instruction on the practical use of MSF for planning and conducting a deployment project. For more information about the MSF training course, see the Microsoft Training and Certification link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources, and search for MSF.

# Process for Designing a Pilot Project

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The pilot process is iterative. You deploy Windows Server 2003 on a limited number of servers in a controlled environment, evaluate the results, fix problems, and deploy an updated release of your pilot, repeating this process until you are satisfied that you are ready for a full deployment.

If you are deploying more than one operating system, or if you are deploying into an environment that contains more than one operating system, you might want to conduct multiple pilots. This allows you to isolate problems more quickly, because you do not have to research problems on multiple platforms. For example, if you are deploying both the Windows XP Professional and Windows Server 2003 operating systems, you can conduct separate pilots for the client operating system and for the server operating system, and then conduct a final pilot in which the two operating systems are deployed at the same time.

Figure 4.1 illustrates the process of planning and conducting a pilot project.

**Figure 4.1 Designing a Pilot Project**

# Pilot Planning and Deployment Within the Project Cycle

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The pilot is conducted during the stabilizing phase of the MSF project cycle. However, planning for the pilot occurs during the envisioning and planning phases of the deployment project, and preparing for the pilot occurs during the developing phase. Figure 4.2 illustrates the tasks involved in planning for and conducting a pilot and shows the MSF phase during which each of these activities might occur. The time frames are estimations, and they might vary from deployment to deployment.

**Figure 4.2 Role of the Pilot in the Project Life Cycle**

# Creating a Pilot Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

During the planning phase of the deployment project, product management, program management, and release management teams collaborate to create the pilot plan. The pilot plan defines the scope and objectives of the pilot and identifies pilot participants and where the pilot will be conducted. It includes a schedule for deploying and conducting the pilot and plans for training and communicating with pilot participants, evaluating the pilot, identifying risks and contingencies, and other key activities that occur during a pilot deployment.

You have various options for how to conduct your pilot. For example, you might have multiple pilots, with a separate pilot for Windows XP Professional and one for Windows Server 2003, or you might introduce your implementation progressively with a staggered rollout, gradually adding more user groups to your pilot.

If you plan to conduct multiple pilots, develop a pilot plan for each. For example, if the subteam responsible for deploying a particular operating system plans to conduct its own pilot, that subteam should write a pilot plan. Even if you do not plan to conduct multiple pilots, each subteam can contribute to the overall pilot plan.

Figure 4.3 illustrates where creating a pilot plan occurs in the deployment pilot process.

**Figure 4.3 Creating a Pilot Plan**

When the pilot plan is ready for review, have project team members, necessary support personnel, and management representatives read and approve the plan. Be sure that the supervisors of everyone directly affected by the pilot have a chance to review the plan. For example, if the schedule allots time for a particular user group to participate in the pilot, have the supervisor of that group review the schedule.

# Defining the Pilot Scope and Objectives

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The first step in planning your pilot is to define what you want to accomplish (the objectives, or goals) and what you plan to include and exclude (the scope). Be sure to align the pilot objectives and scope with those for the deployment project as a whole, as defined in the master project plan. Ensure that the pilot plan includes an opportunity for the team to evaluate features identified in the project plan as high priority, to ascertain that they successfully meet all of your business objectives.

If you plan to conduct multiple pilots, define the scope and objectives of each by using these guidelines.

# Defining Pilot Objectives

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Explicitly state the objectives of the pilot. Use the objectives to identify criteria for measuring the success of your pilot.

Many organizations have primary pilot objectives, such as:

- Ensure that the system works properly in the business environment.
- Ensure that the design meets the business requirements.
- Build user support for the Windows Server 2003 deployment project.

Many organizations have additional objectives, such as:

- Test the deployment process.
- Train the installation team.
- Create documentation for the full deployment.
- Train the support and Help desk teams.
- Train the administrative teams.
- Gather information for estimating future support requirements.
- Gather information for estimating actual hardware requirements.

  **Note**

  - Sometimes a pilot reveals that there is a greater amount of data in the production environment than anticipated and that storage requirements exceed those that were proposed in the test lab. As a result, hardware requirements might exceed those previously estimated.

- Meet the baseline requirements for functionality that were established in testing.
- Develop and test end-user training materials.

You might need to define objectives that are related to specific technologies, such as Active Directory, or to your network infrastructure. If you plan to conduct multiple pilots, define the objectives for each.

If possible, use the objectives to develop metrics for evaluating the pilot. For example, if your team's objective is to gather information for estimating future support requirements, establish baseline metrics for current system functionalities, such as system availability, performance, and reliability, and collect similar metrics for the system after the pilot is complete. These metrics can then be used to evaluate the success of the pilot and to estimate the level of support required.

# Defining Pilot Scope

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Define the scope of the pilot by clearly stating which services and features will be included and which will not. When you list the services and features you plan to include in the pilot, also state how you expect them to perform. Describe the areas of functionality that the pilot implementation affects, and note to what extent they are affected, and in which situations they are affected.

Avoid the mistake of making pilot testing too easy. Test as many situations that might arise in production as you possibly can.

If certain technologies have particular requirements, include those specific requirements in your pilot. For example, if you are going to deploy Windows Server 2003 on an international scale in which users do not all speak one language, be sure to address international language issues in the pilot.

Do not expect to test every feature or service during the pilot. Focus on processes that present the greatest risk and events that are most likely to occur. Prioritizing the features to be tested in the pilot is particularly important if your team plans to conduct multiple pilots. When multiple pilots are planned, start small and gradually increase the scope of successive pilots.

If certain aspects of your design cannot be covered by the pilot, describe them. For example, if your organization plans to upgrade your domain using your existing architecture without any restructuring, and then restructure the architecture later, you might choose to exclude the restructuring process from the first pilot.

Also specify the duration of the pilot, in terms of either time or of the criteria to be met.

Be sure to describe how you expect to proceed after the pilot is complete. If you plan to keep some functions in place and remove others for the full production rollout, identify the features that will be removed. For example, if you are redesigning your namespace, you might want the option of changing it after the pilot concludes. Indicate how to back out features that will be removed.

# Defining the Pilot Group

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Carefully select the pilot participants and the sites where the pilot will be conducted. First establish the selection criteria for participants, and then select candidates based on these criteria.

**Selecting the Pilot Group and the Pilot Sites**
The pilot group should include end users who are typical of those in your organization. This might include a wide range of users, some of whom are technically proficient and others who are less comfortable with technology. If you plan to conduct multiple pilots, the type of user you select might vary as the pilots progress. For an early pilot, however, good candidates have some of the following traits:

- Are able to derive tangible benefit from Windows Server 2003.
- Play a noncritical role in day-to-day operations.

  The group should be able to absorb some downtime or reduction in performance if problems occur.
- Represent the target environment.

  Choose groups or sites that do not have unique requirements or operating environments, because the pilot should predict how your design and rollout will work in your organization at large. Most pilot participants should have the same technical expertise as the average user in your organization.
- Perform a variety of activities using a variety of computer hardware.
- Are enthusiastic about the Windows Server 2003 project.
- Are comfortable with technology.

  This is not an essential attribute for pilot participants. However, if participants are comfortable with technology, they tend to be more patient with problems that occur during a pilot, and they are more likely to test the limits of the Windows Server 2003 operating system. This type of participant, however, might accept problems that should be reported. Encourage participants to report every problem they encounter.

You can identify candidates by conducting interviews, issuing and evaluating questionnaires, or requesting volunteers. Volunteers, in particular, can be very helpful, because their offer to participate indicates an interest in the Windows Server 2003 technology. You might also consider soliciting recommendations for users who might be good candidates for the pilot; for example, you might ask supervisors to identify power users of a particular technology that is going to be deployed.

The selection of a pilot site or sites often depends on the type and location of the pilot participants who have been selected and the number of support staff available to help them. Determine the number of pilot sites and the size of the pilot users group based on:

- The objectives of the pilot.
- The number of functions and features you are testing.
- The size of your support staff.
- Specific technology requirements that can be piloted only by using particular sites or user groups.

Choosing suitable pilot groups and sites helps to ensure a successful pilot project.

**Using the IT Group as a Pilot Group**

Many organizations use their IT group for the first pilot. Because this group is familiar with testing software and hardware changes, they are adaptable and can report issues quickly. After problems with the first pilot have been resolved, you can begin your full-scale pilot in the production environment.

**Selecting a User Liaison**

After you select your participants, choose one as your user liaison. Select someone who has good communication skills and a good relationship with both the pilot group and the project team.

Work with the user liaison as you plan the pilot. The liaison can provide you with information about the type of work the pilot group performs and can prepare the group for its role in the pilot.

# Creating Pilot Plan Documents

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The pilot plan includes a number of documents that provide procedures for successfully rolling out the pilot in a business environment. The pilot plan should include:

- A training plan that describes what the pilot participants need to know before they begin the pilot and describes how you plan to train them.
- A support plan that describes how problems that arise for participants during the pilot will be resolved.
- A communication plan that explains how you will keep participants informed about what is happening in the project.
- An evaluation plan that describes how you plan to obtain feedback from participants.

  This can be used to assess design changes that might be required before the pilot is rolled out to the rest of the organization.
- A risk and contingency plan that describes potential risk factors and how you plan to assess and diffuse them.
- A backup and recovery plan that describes how to back up data and system configurations, how to test those backups, and how to roll back to previous configurations if problems arise that might affect business operations or participants' access to data.

  Having a backup and recovery plan is particularly important because the pilot is a rollout in a business environment.
- A schedule that includes milestones at which you plan to evaluate and make necessary changes to the pilot.

The pilot plans you create help to ensure the smooth deployment and completion of your pilot project by clarifying the tasks and roles of the release management team and the pilot participants.

# Creating a Pilot Training Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Well before you begin the pilot, your team needs to decide which features of the new system the participants need to be trained on, the form training will take, and when training will occur.

Training for pilot participants should be limited to the features that they must understand to do their work. Include a plan to provide training for the support and operations teams, which might need to be more detailed than the training presented to pilot participants.

How you train participants depends greatly on your facilities and your budget. Options include hiring an external trainer, holding brown-bag seminars, developing a "train-the-trainer" program, or using media technology to broadcast training. You might also consider using the test lab for training after testing is complete.

After you have determined what the training should cover and how it will be accomplished, estimate how long it will take and decide when to begin. Many organizations find that it works best to provide training just prior to pilot installation. Remember to include training in the pilot plan schedule.

# Creating a Pilot Support Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The support plan identifies who will provide support for pilot participants, the level of support required, and how users can report problems. Be sure to develop your support plan early, because doing so will help you identify the type of training the support staff requires.

**Defining Support Team Roles**
For each pilot, identify who will support participants: project team members such as developers and testers, Help desk personnel, or outside resources. Even if the project team will not be providing primary support for the pilot, decide what the role of the team will be. If the project team is divided into subteams for different technologies, such as Active Directory or network infrastructure, determine whether the subteams should play a role in supporting participants and, if so, what that role should be.

If Help desk personnel will provide support, or if one of your pilot objectives is to train Help desk personnel, determine how they will be trained. If external resources are required, ensure that they are aware of the schedule and have been properly trained.

Develop a contact list for support staff that includes the names, phone numbers, and e-mail addresses of all support staff members and other key contacts. For example, provide the contact name and information for a manufacturer who supplies key equipment.

**Service Levels for Support**
Determine the level of service that the support team can provide during the pilot. The level of service depends on the number of support personnel available and the number of problems they can support. For example, if support staff can install upgrades to 20 client computers, but can provide support to only five participants if they all have problems, plan to upgrade only five client computers, so the team can provide the appropriate support level.

When determining support requirements, some typical questions to ask include:

- Must critical problems be resolved within a specific number of hours? If so, what is that number?
- During which hours must support be available to the users?

The level of service your support team can provide dictates the size of your pilot and the timeline for its deployment. In addition, determining the level of service helps you establish a baseline for a level of service that can be used to create final Service Level Agreements (SLAs) for the organization.

**Problem Tracking and Resolution**
When problems arise during pilot testing, participants must have a way to report them to the team. The incident tracking system, problem escalation process, and issue resolution process your team develops should identify:

- Where participants post their problems.

  Can they report problems to an existing incident-tracking system, or does the team need to develop a new mechanism, such as a Web site, for participants to use to log their problems?

  If your testing team set up an incident-tracking system to record and report testing problems, you can use the same system to report and track problems that arise during the pilot. If your organization has not developed an incident-tracking system, set one up before the pilot begins. Be sure that the incident-tracking system is well documented so pilot participants can easily enter problems into the system.

- How problems will be reviewed, prioritized, and fixed.

  For example, support staff can review reported problems on your incident-tracking system daily, and a problem can be assigned to the support staff personnel responsible for the applicable technology or functional area. After a problem has been assigned, the support team member responsible for it can prioritize the problem and estimate the amount of time required to fix it. If this information is entered into the incident-tracking system, participants who report problems can

track the status of their problems.

- The escalation process the team will use to notify the appropriate team members.

  The incident-tracking process should have a procedure for escalating problems that can not easily be resolved to the appropriate team for resolution. Determine who is responsible for deciding when a problem must be escalated, and who should contact the team who can resolve the issue.

  During a pilot, problems must be escalated and resolved much more quickly than during the testing phase, because pilot participants are working in a business environment. How quickly problems will be resolved after the escalation process has begun should be spelled out and understood by both the pilot participants and the team. Set reasonable expectations for issue resolution so both support staff and pilot participants are comfortable with the time allowed for the escalation and resolution of problems.

- How change requests are submitted, approved, tested, and implemented.

  Your change management plan should address these issues. The way your team handles change management can vary depending upon when the change is requested: during testing, during the pilot, or when Windows Server 2003 has been rolled out to the business environment.

Note that the procedures for resolving a problem that arises during the pilot might vary significantly from those used during full production deployment. For example, a bug in the pilot might be discovered and fixed, and an updated release deployed to participants very quickly. Depending on the severity of a problem, when a bug is discovered in production, the team might be required to go through a lengthy change management and deployment process before the bug is resolved and an update to the system is made available in the production environment.

# Creating a Communication Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In the communication plan, describe how you will communicate with participants both before the pilot begins, to prepare them for the pilot, and during the pilot, to exchange status reports. Use the communication plan to identify:

- The type of information you will communicate, to whom it will be communicated, by what means, and how often.

  If you provide too much information too often or to too many people, participants might start ignoring your communications. Remember that it is important to report successes, too.

- Mechanisms for communicating information about the pilot, such as Web sites, frequently asked questions (FAQ) pages, procedures, and status reports. As you determine how you will communicate with participants during the pilot, begin creating the required mechanisms.

  For example, set up e-mail distribution lists for the various groups that need to receive specific types of information. Note the types of information you plan send to those on each distribution list. For example, from time to time you might want to communicate information about the pilot to others in the organization to keep them informed about the progress of the pilot and to encourage their support for the change when it is their turn to upgrade.

- What you need participants to do to prepare for the pilot. In your instructions to pilot participants, include the ramifications of failing to comply with the instructions. For example, if you need participants to log off at night so you can update user logon settings, tell them that failure to log off might result in their inability to log on at all because their settings could not be updated.

**Tip**

- Use links in your e-mail correspondence to pilot participants to provide detailed information without specifying it in the e-mail. For example, if you have users of varied technical competency, provide a link to a Web site that contains additional technical information for those who need the detail, instead of providing it in the e-mail. This approach also allows you to update instructions and details on the Web site as the need arises without having to resend the information.

# Creating an Evaluation Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The evaluation plan describes the way you plan to obtain and assess feedback from the team and pilot participants. This feedback can be used to evaluate design changes that might be required before the deployment is rolled out to the rest of the organization. In addition, it helps your team decide whether the deployment project should proceed and, if so, how.

In the evaluation plan, define the process you plan to use to solicit feedback from participants and the team. Determine the types of questions the evaluation will ask. Decide on a review process, and determine who is responsible for making the decision about the next step to be taken.

# Creating a Risk and Contingency Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The risk and contingency plan describes the risk factors that could prevent the pilot from being deployed successfully. Risks might include the test lab being behind schedule, required hardware or software being unavailable, or participants working on other projects or needing additional training.

Properly addressing risk factors that could prevent a successful deployment in a pilot environment reduces the likelihood of encountering those same problems when you deploy into your production environment.

# Creating a Backup and Recovery Plan

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The backup and recovery plan establishes guidelines and procedures to prevent problems that might cause data loss or interruptions to your organization's operations, and to allow recovery as quickly as possible if such events do occur.

Consider planning downtime or outages for the pilot in order to test rollback procedures, and, if applicable, disaster recovery and business continuity plans.

**Creating a Backup Plan**

The importance of a backup plan cannot be overstated. When you begin rolling out Windows Server 2003 in the business environment, problems might arise that even the most thorough testing could not reveal. By making regular and reliable backups, you ensure that the team can restore the system to its original state if your pilot rollout process changes or fails.

The backup plan should define procedures for:

- Backing up baseline configurations (the state of a computer before it is upgraded) so a computer can quickly be restored to its prior state.
- Backing up servers before they are upgraded.
- Backing up the most recent system and user data before you begin switching systems.
- Testing the restore process for each of the above processes using the backup files.

In addition, the backup plan should identify who is responsible for performing backups, and should include the schedule for all periodic backups and periodic testing of backups, as well as instructions for labeling and storing all backup files.

For more information about creating backup plans, see the *Storage Technologies Collection* of the *Windows Server 2003 Technical Reference* (or see the Storage Technologies Collection on the Web at http://www.microsoft.com/reskit).

**Creating a Recovery Plan**

The recovery plan describes the recovery and rollback process, which allows you to return your production system to whatever earlier state you require. Depending on the severity of a problem encountered in the pilot, you might need to return your production system to a baseline configuration or just roll it back to the state it was in at a particular point in time.

Include the following elements in the recovery plan:

**A list of scenarios** Analyze all of the systems involved in the rollout and identify the situations, or scenarios, under which problems are likely to occur. Determine which systems might be affected and the functional dependencies among them so you have a clear understanding of the larger impact that a single failure might have. Use these scenarios to create strategies that identify when and how to run backups and the types of recovery for which you need to plan.

**A definition of acceptable downtime** Define how much downtime your organization can accommodate. If your organization cannot afford for systems to go down during normal business hours, you might plan to roll out the pilot, or parts of it, at night or over a weekend. If systems must be operational at all times, you might plan to deploy servers and desktops on new computers and then quickly replace the old ones, instead of upgrading computers.

**A list of critical systems and processes** In the event that a failure does occur, you need to know which systems are the most critical and must be brought back online first. If resources such as bandwidth are limited, you need to know which systems have the highest priority and which should not take up network traffic. When evaluating how critical a system or process is, consider factors such as its effect on human health and safety, the legal liability it exposes, the risk to corporate confidentiality, and the cost of replacement.

**A recovery strategy** Your recovery strategy should define how you will recover data or systems in each of the scenarios you define in the recovery plan. This might include restoring data from backup tapes, switching over to redundant systems, rolling back to previous configurations, or other strategies. Include an additional procedure for recovering from severe data corruption in your directory service if that becomes necessary. By having your recovery strategy in place, you can quickly restore your production environment to the required state so that work can continue with minimal interruption.

**A rollback strategy** The rollback strategy defines how you plan to use backup and recovery procedures to return your pilot or production environment to the state it was in before changes were made. Specify the criteria that a problem should meet to warrant rolling the environment back to its previous state. For example, you might establish a system for classifying the severity of problems and describe which type of response is warranted by certain levels of severity. Also decide whether you need to have different rollback strategies for different types of problems. For example, you might develop one procedure for backing out the entire pilot if the problem is pervasive and another procedure for backing out specific components if the problem is isolated.

**The roles and responsibilities for team members** Make sure that every task in the plan is assigned to an appropriate team member, and that that person has the information needed to successfully perform required tasks. Consider including training in the plan.

Have the backup and recovery plan reviewed by the project team and by those responsible for potentially affected systems. After the plan has been approved, test it to ensure that the processes you put in place work as expected.

# Creating a Pilot Schedule

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

One of the earliest activities in planning a pilot is to draft a schedule, which is usually included in the master project schedule. When drafting the pilot schedule, be sure to schedule time for:

- Planning the pilot.
- Training participants, support staff, and the installation team.
- Creating an inventory of pilot sites.
- Upgrading hardware.
- Developing the support and communication mechanisms you identified during planning.
- Deploying the pilot.
- Testing by pilot participants during the pilot.
- Evaluating the pilot.

To accurately schedule pilot deployment, you need to know:

- How many computers or servers need to be upgraded and the approximate time it will take to upgrade each one.

  After you have gathered this information, determine how many machines can be upgraded per day and the sequence in which they should be upgraded.

- Which hours of the day and which days of the week are best for upgrading servers and client computers. Questions to ask include:

  - Should computers be upgraded during off hours to avoid disrupting users?
  - Should client computers be upgraded during working hours so that the users can attend training during that time?

- The types of upgrades that are required.

  If you are upgrading servers, the pilot might require a longer period than if you are upgrading only client computers, because some server processes occur on a monthly, rather than a daily, schedule.

- Whether participants should receive training before Windows Server 2003 is upgraded or installed on their computers. If so, the training schedule is a dependency for your pilot deployment.

After you have drafted the pilot schedule, review it with management and all affected users. After you deploy the pilot, update the master schedule based on your installation experience so that it more accurately reflects the time that will be required for installation during the full deployment.

# Preparing for the Pilot

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Preparation for the pilot deployment begins in the developing phase of the project. The release management team sends communications to the participants about their role in the pilot and prepares an inventory of the software and hardware that will be used with Windows Server 2003. Finally, the testing team prepares procedures and tests to aid in the rollout and the validation of the success of the rollout.

Figure 4.4 illustrates what is involved in preparing for the pilot and when this step occurs in the deployment pilot project.

**Figure 4.4 Preparing for the Pilot**

# Preparing Pilot Sites

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Prepare the pilot sites in advance so that the installation team can begin to install upgrades when the pilot begins. If you have not already done so, inventory the computers and network equipment that are used at the pilot site. Then determine whether the following hardware or software upgrades are required:

- Client computer upgrades to meet your minimum supported hardware configuration (including memory, hard disk capacity, processor speed and type, and network adapters). Your minimum supported hardware configuration is based on the baseline configuration metrics established in your pilot objectives.
- Server upgrades for optimal hardware configurations.
- Network upgrades to meet design requirements.
- Client and server upgrades (hardware, applications, or drivers) to provide compatibility with Windows Server 2003.

For more information about compiling an inventory of your network equipment, see "Planning for Deployment" in this book.

At the very least, identify the required upgrades and acquire the required components. If possible, have the new components installed and tested before the pilot is scheduled to begin.

In addition, use the inventory of computers and system components to identify the following:

- All applications in use at the pilot site
- Any special security measures required at the site
- All special connectivity requirements for the site
- Minimum system requirements as determined by your baseline functionality metrics

This information allows the release management team to plan for the types of testing that might be necessary during the pilot, such as tests that push the limits of available network connectivity for a site.

Ensure that the testing team has tested all the hardware and software present at the pilot site to verify that they are compatible with Windows Server 2003. Also make certain that the installation team is aware of any special requirements and is equipped to handle them.

# Preparing Pilot Participants

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Establish communication with the pilot group as early in the pilot planning process as possible. Your initial contact should open the channel of communication and set participants' expectations. Then, as the start date for the pilot approaches, prepare participants for their role by keeping them apprised of pilot deployment plans and target dates and by providing necessary training.

**Establishing Early Communication**
Soon after you select the participants, meet with them to:

- Obtain their commitment to the pilot.
- Select a user liaison.
- Provide them with a timeline for the pilot.
- Clarify participants' responsibilities.
- Describe the type of testing they are to perform.

  Although pilot participants will continue to perform their daily business tasks, you might want to specify certain areas they should focus on. Provide test plans for any special tasks they are to perform.
- Discuss communication mechanisms that have been established and how they should be used by participants.
- Discuss the level of support you plan to provide.
- Clarify problem reporting and issue resolution procedures.
- Discuss rollback plans.

Pilot participants need to understand what the pilot entails. Ensure that they understand how the pilot might affect their work. Be sure to address any concerns they might have about the pilot or their role in the deployment process.

**Keeping Participants Informed**
As the pilot plans develop, the user liaison can keep the release management team informed of the participants' concerns and the participants informed about new developments.

As the training plan progresses, tell participants about the type of training they will receive and when they can expect it. When the support plan is finalized, explain to participants how and when they should request support. Also explain the mechanisms provided for reporting problems or issues.

As the pilot deployment date approaches, the release management team should provide participants with the following information:

- Scheduled dates for training and for upgrading computers
- Procedures they need to follow before their computers are upgraded
- Contact names and numbers for support

Regular and comprehensive communication with pilot participants helps to ensure that participants are committed to the success of the pilot project.

**Training the Pilot Participants**

Train pilot participants just before the pilot is scheduled to start. The duration and type of training you provide depends on the scope of the pilot, as determined in the training plan.

Training might be required for both support staff and pilot participants. If so, train the support staff before the pilot participants, so that the participants can have assistance as soon as the pilot begins if they need it.

# Testing the Rollout Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Although the test lab is a good place to debug problems with the proposed deployment of Windows Server 2003, the pilot provides an opportunity to assess the accuracy and efficiency of deployment procedures in the actual production environment. If one of your pilot goals is to test the Windows Server 2003 rollout process, schedule time during the testing phase for the installation team to develop, document, and test the rollout procedures. Preparing the pilot site also can provide valuable information about the rollout process, such as the time required to upgrade each computer and the number of concurrent upgrades your support team can accommodate, and information about other upgrade tasks.

Procedures and resources required for deploying Windows Server 2003 on various types of computers should be carefully documented throughout the planning, testing, and developing phases of the project. These documents will form the core of the installation guidelines and should include:

- A list of the required tools and supplies.
- A list of automated installation scripts and where they are stored.

  Ensure that any scripts and tools for automating installations obtained from the testing team are appropriate for the computers in the pilot environment. For more information about automating installations, see "Choosing an Automated Installation Method" in *Automating and Customizing Installations* of this kit.
- A list of backups that installers must make before and during deployment.

  Include backups of user data on client computers.
- Procedures for performing both automated and manual computer installations and upgrades.

  If the automated installation method does not work properly, you can install the operating system manually. For more information about automating installations, see "Choosing an Automated Installation Method" in *Automating and Customizing Installations* of this kit.
- The acceptance tests that the installers must perform during pilot deployment and immediately after it to verify that the deployment works as expected. These tests are developed by the testing team during the developing phase. For more information, see "Designing a Test Environment" in this book.
- The operational procedures that installers and administrators must perform (for example, resetting permissions, changing passwords, and restoring user data).
- Procedures for backing out if the pilot fails. Review the backup and recovery plan for information about to how to back out system changes. For more information about creating the backup and recovery plan, see "Creating a Pilot Plan" earlier in this chapter.

Most of this documentation, including a list of automated installation scripts and operational procedures, can be obtained from the testing team. Use the documentation to create a checklist of deployment tasks that can be used to ensure that all necessary steps have been completed.

# Deploying and Testing the Pilot

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you deploy your pilot, you begin testing your Windows Server 2003 implementation under live conditions. Start the pilot deployment process with a trial run of the pilot to identify problems with the deployment and the pilot plan. Then, when the full pilot begins, keep track of which deployment tasks have been completed so that the team can monitor the progress of the pilot.

As participants use the system, have the release management team track the progress of the pilot, and pinpoint areas of concern. Encourage all participants to use the incident-tracking system to report problems and to use the escalation plan when immediate problem resolution is not possible.

In MSF, the pilot is conducted during the stabilizing phase. Figure 4.5 illustrates the steps involved in deploying and testing a pilot.

**Figure 4.5 Deploying and Testing the Pilot**

**Conducting a Trial Run of the Pilot**

Before you deploy the pilot, perform a trial run of the process. A trial run is a rehearsal of all the elements of the deployment that allows your team to identify problems prior to deploying the pilot.

To perform a trial run, schedule a time during nonbusiness hours to perform the entire upgrade process, to test the new setup thoroughly, and then to back out all components of the implementation. Use the same deployment task checklist that you plan to use for deploying the pilot, as described in the next section.

**Deploying the Pilot**

As the installation team deploys the pilot, they need to:

- Validate all backups, clearly label them, and store them in a safe place.
- Record how long installation takes so the team can update the schedule.
- Identify and document inefficiencies, and use this information to refine the rollout process.
- Update the production deployment documents to reflect all changes that have been made during the pilot.
- Ensure that a system administrator who has full security administrative credentials, including rights to administer mail

and database server passwords, is available during the pilot deployment.

Instruct the installation team to check off each of the above steps in the deployment tasks checklist as it is completed.

**Resolving Issues During the Pilot Deployment**
During the pilot, the participants perform their regular, daily work and report any problems by using the incident-tracking system.

Problems that are reported are reviewed, prioritized, and fixed according to procedures outlined in the issue resolution plan. Problems can be resolved either by further development, by documenting resolutions and workarounds for the installation teams and support staff, or by incorporating the resolution or workaround as supplemental material in training courses.

Depending on your team's rollback strategy, resolving problems might require rolling back the pilot. Clear communication with participants is essential when a rollback is required.

If multiple pilots are scheduled, evaluate the results of the current pilot to determine if it meets the success criteria before beginning the next pilot.

**Monitoring the Pilot**
During the pilot, the release management team should continually monitor the pilot system, including the network used by the pilot group, looking for bottlenecks and areas that need to be fine-tuned. The more information you collect during the pilot, the more accurately you can evaluate its success and recommend how to proceed with the full deployment to the entire business environment.

Have the team check problem reports frequently and look for trends and for problems with traffic flow and application performance, such as:

- Degradation in performance, such as slower response time.
- Improvement in performance, such as quicker response time.
- Tasks that could be performed before, but not after, the upgrade.
- Tasks that can be accomplished only by using a workaround.

It is important that release team members visit the pilot site periodically. Talking with users frequently reveals issues or problems that might otherwise go unnoticed.

As the release management team receives feedback, they will need to assess problems that pose risk to the overall project. Specifically, they should look for situations that might result in:

- Scope changes
- Cost increases
- Interoperability problems
- Unanticipated downtime

Assessing the severity of these issues allows the release management team to make informed decisions about whether to proceed with the deployment.

# Evaluating the Pilot

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When the pilot is complete, obtain feedback from a variety of sources, including participants, pilot release management and support teams, and other observers, to evaluate the pilot's success.

Figure 4.6 illustrates when pilot evaluation occurs in the pilot deployment process.

**Figure 4.6 Evaluating the Pilot**

# Obtaining Feedback

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Have your incident-tracking system in place when the pilot begins, and encourage pilot participants to use it to report problems. Participants often neglect to report problems, either because they think a problem is insignificant or because they find a way to work around it. To accurately assess your pilot, however, you need participants to report every problem.

**Tip**

- To encourage participants to offer feedback, consider developing an incentive program. For example, you might give away prizes or have managers give recognition to participants who make a special effort to contribute during the pilot.

Gather feedback from a variety of sources and through a variety of means, including:

- Web site feedback forms
- Sessions with business managers
- Problem reports
- Participant surveys
- IT project team observations

Try to obtain information about both the Windows Server 2003 design and the deployment process, including information about:

- Training
- The rollout process
- Support
- Communications
- Problems encountered
- Problems that were fixed without the need for incident-tracking
- Potential improvements

Review the parts of the pilot that were successful and the types of problems that were reported so that you can revise and improve your plan. Determine whether the pilot met the success criteria you defined before the pilot began. If you established metrics to measure your success, evaluate how the pilot measured up. Use the feedback to evaluate whether the delivered design meets the design specification, as well as the business requirements.

# Deciding the Next Step

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Once enough pilot data has been collected and participant feedback has been evaluated, the team must decide how to proceed. Depending on how well the pilot meets the success criteria, there are a number of strategies that your team can employ at this point in the pilot deployment:

- **Stagger the pilot forward.** If the pilot was deemed partially successful, deploy the pilot to the next pilot group or, if your team has planned to conduct multiple pilots, proceed with the next pilot.

- **Roll back the pilot.** When the pilot is not completely successful, it is often necessary to roll it back so that issues can then be resolved. Typically, a rollback is required when:

    - The production environment contains invalid or problematic data that was not discovered in testing and that caused the deployment to fail. Roll back the pilot to the configuration used before the pilot began, clean up the data, and redeploy the pilot so that the pilot group can continue with its work.

    - Production configurations and settings, such as Group Policy settings or security restrictions, cause problems with the deployment that could not be detected in the test lab. After rolling the pilot back to the configuration used before the pilot began, resolve the problems with the conflicting configurations or settings and redeploy the pilot.

- **Suspend the pilot.** If the pilot is not successful and issues cannot be resolved easily, suspend the entire pilot, halting all pilot testing until the issues have been resolved and the pilot can be redeployed. This requires rolling the pilot back to the configuration used before the pilot began.

- **Update the pilot and continue.** If the pilot is not successful, but the issues raised are easily fixed, issue the same pilot group an update to existing code.

- **Proceed to the production deployment phase.** If the pilot is deemed successful and ready for production, you can proceed with your plans for full deployment.

The pilot is not complete until the team ensures that the proposed solution is viable in the production environment and that every component of the solution is ready for deployment.

# Preparing for Production Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After your team has agreed that the pilot has been successfully completed and has obtained management approval for proceeding, the next step in your deployment project is to fully deploy the system to the entire organization. During this phase, the release team deploys the core technology and site components, stabilizes the deployment, transitions the management of the project to the operations and support teams, and obtains final management approval of the project.

Before the actual deployment begins, ensure that the production deployment plan is complete. The production deployment plan contains many of the same types of documents as the pilot plan. For a discussion of pilot plan documents, see "Creating a Pilot Plan" earlier in this chapter.

Keep in mind that your production deployment plan must include a strategy for deploying the Windows Server 2003 implementation across your entire organization, and, as such, must address such issues as how to manage specific requirements for particular sites, how to train all users, and how the deployment schedule will affect work in various departments. The production deployment plan is a living document that should continually be updated to reflect changes that are made when testing of the release components and processes reveals a deficiency.

Many of the tools that your team developed for the pilot deployment also can be used for the production deployment. These include the list of tasks that must be performed to deploy Windows Server 2003, the issue resolution process your team established, and the mechanism for monitoring your system.

MSF contains information about deployment that your team might find helpful for planning your production deployment. For more information about MSF, see the "MSF Process Model" white paper, available through the Microsoft Solutions Framework link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Additional Resources for Designing a Pilot Project

Updated: March 28, 2003

# Planning Server Deployments

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Welcome to *Planning Server Deployments* of the *Microsoft Windows Server 2003 Deployment Kit*.

This book provides comprehensive information about planning server storage and designing and deploying file servers, print servers, and terminal servers in medium and large organizations. You can also use the guidelines in this book to maximize the availability and scalability of your servers by planning for remote server management, designing and deploying server clusters, and designing and deploying Network Load Balancing clusters.

This book contains the following chapters:

Planning for Storage

Designing and Deploying File Servers

Designing and Deploying Print Servers

Hosting Applications with Terminal Server

Planning for Remote Server Management

Planning for High Availability and Scalability

Designing and Deploying Server Clusters

Designing Network Load Balancing

Deploying Network Load Balancing

# Planning for Storage

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For many organizations today, data is their most important asset. Losing data can mean losing thousands or even millions of dollars in revenue. Organizations can help protect valuable data by ensuring adequate, available, and secure storage. To manage and secure data, you can use a number of technologies with the Microsoft® Windows® Server 2003 operating system, including direct-attached storage, storage area networks (SANs), network-attached storage, Windows server clusters, Volume Shadow Copy service, Distributed File System (DFS), and Automated System Recovery (ASR).

**In This Chapter**

Overview of Storage Planning

Determining Organizational and Application Requirements

Reviewing Storage Architectures

Planning for Storage Scalability

Planning for SAN Deployment

Planning to Protect User Data

Planning for Fault Tolerance

Planning for Disaster Recovery

Additional Resources for Planning for Storage

**Related Information**

- For information about file servers, Distributed File System (DFS), File Replication service (FRS), Windows server clusters, NTFS file system permissions, disk quotas, shadow copies, and redundant array of independent disks (RAID) levels, see "Designing and Deploying File Servers" in this book.

- For information about high availability planning, see "Planning for High Availability and Scalability" in this book.

- For information about backup and recovery, see the *Storage Technologies Collection* of the *Windows Server 2003 Technical Reference* (or see the Storage Technologies Collection on the Web at http://www.microsoft.com/reskit).

# Overview of Storage Planning

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Several factors have contributed to the growth of both online and offline organizational storage requirements. Among these factors are:

- Increasing amounts of data
- Increasing needs for high availability and fast recovery
- Declining costs of storage

These developments have caused many organizations to place increased priority on storage planning and design. Planning and designing a storage solution involves defining the specific requirements of your organization and carefully evaluating how those requirements can work with or benefit from operating system services and features. Windows Server 2003 includes support for critical storage technologies such as direct-attached storage, network-attached storage, and SANs, as well as features such as Automated System Recovery (ASR), shadow copies, and open file backup that should be considered as you plan to meet your organization's storage requirements. If your storage plan includes using additional storage management or backup tools, you will also need to plan for integration of the operating system's storage features with these tools.

You can use the information in this chapter to assess your organization's specific storage needs, and consider the storage technologies and operating system features that are available to meet those needs. You can then follow the processes defined here to develop a storage plan that meets your needs for scalability, security, availability, and recoverability. While this chapter does discuss how to plan for and work with various storage architectures and technologies, you should already have a working knowledge of each of these technologies.

# The Storage Planning Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A properly implemented storage infrastructure will meet your organization's needs if it is sufficiently scalable, protects valuable data, is fault tolerant, and is recoverable in the event of disaster. With this in mind, you need to address both your organizational needs and specific methods for achieving these requirements when planning for storage. Figure 1.1 shows the steps involved in planning for storage.

**Figure 1.1 Planning for Storage**

# New Storage Features in Windows Server 2003

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 provides many new features that aid in the planning and deployment of storage within your organization. Table 1.1 describes these features.

**Table 1.1 Windows Server 2003 Storage Improvements**

| Feature | Description |
|---|---|
| Automated System Recovery (ASR) | ASR allows you to initiate *bare metal restores* of a system. With bare metal restores, you can boot a failed system by using the installation CD, insert an ASR floppy disk (created during an ASR backup), and recover the system state and required operating system files on the boot and system volumes from a backup. ASR can be combined with Remote Installation Services (RIS) to automate the recovery of several systems on your network. |
| Volume Shadow Copy service | The Volume Shadow Copy service provides an infrastructure for creating a volume that is a point-in-time image of the original volume. This image is known in the storage industry as a volume snapshot. The shadow copy can be used for the purpose of backing up the files within the volume; the copy is identical to the files at the instant the shadow copy was taken.<br><br>Solutions built on the Volume Shadow Copy service can produce much higher quality snapshots than other technologies because of the ability to integrate with business applications and coordinate with storage hardware. As a result, high-fidelity backup recovery and data mining are possible without significantly affecting performance. |
| Shadow copies | You can give users access to previous versions of files by enabling shadow copies, which provide point-in-time copies of files stored on servers running Windows Server 2003. Because users can restore or roll back their files to a previous state, you can reduce the administrative burden of restoring previously backed up files for users who accidentally delete or overwrite them. |
| Open file backup | By integrating with the Volume Shadow Copy service, the Backup program (NTBackup.exe) available in Windows Server 2003 can now back up open files that are locked by a user or application. Previously, files had to be closed in order to be successfully backed up. |
| Distributed File System (DFS) | Servers running Microsoft® Windows® Server 2003, Enterprise Edition and Windows® Server 2003, Datacenter Edition support multiple DFS roots on a single server. Other new DFS features include the ability to configure DFS to choose an alternate target based on cost if no same-site targets are available. |
| File Replication service (FRS) | You can use the Distributed File System snap-in to configure the FRS replication topologies (ring, hub and spoke, and custom), and configure connection priorities. FRS suppresses excessive replication and provides better staging directory management. |
| SAN support | Windows Server 2003 provides many new features that make it easier to work with data and devices on a SAN. These features include improved support for booting a system from a storage device on a SAN, greater control of mounting and unmounting volumes on the SAN, including the ability to suppress the automatic mounting of volumes, and improved handling of Fibre Channel host bus adapters (HBAs) for easy SAN integration and interoperability. |
| Virtual Disk service (VDS) | VDS provides a standard set of application programming interfaces (APIs) to storage hardware and storage management programs that makes it easy for storage applications to work with storage hardware that includes a VDS provider. The new command-line tool DiskRaid (which is available in the *Microsoft® Windows® Server 2003 Deployment Kit* ) allows you to manage hardware devices that have VDS hardware providers without the need for other management applications. |

| | |
|---|---|
| Multipathing | Multipathing provides for high availability data access by allowing a host to have up to 32 paths to access an external storage device, which facilitates failover and load balancing. Multipathing is not a feature of the operating system, but is supported through the MPIO Driver Development Kit (DDK), which provides a means for storage vendors to create interoperable multipathing solutions. |
| Disk Defragmenter | Disk Defragmenter performs faster and is more efficient than in the Microsoft® Windows® 2000 operating system, also now supports online defragmentation of the master file table (MFT), and can defragment NTFS volumes with any cluster size. |

# Determining Organizational and Application Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Determining your organization's storage requirements not only involves considering your company's business needs, but also any requirements related to your line of business applications. For example, a client application might need to access data on file servers by using a single UNC path, but your storage plan calls for providing fault tolerance by storing the data on two servers. The requirements of this client application could be met by implementing DFS. The first step in planning for storage, consequently, involves determining both the needs of your organization and the needs of your applications. Collectively, they will define your storage requirements. This process is shown in Figure 1.2.

**Figure 1.2 Determining Organizational and Application Requirements**

# Determining Organizational Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Organizational storage requirements go beyond having sufficient capacity for the data stored on each server and workstation. You must also satisfy redundancy and replication requirements. For example, to provide fault tolerance, you might decide to replicate data between two different file servers at two sites. In this case, you will need to ensure that there are sufficient storage resources at each site to store the replicated data.

To determine your organizational requirements, it will be helpful to answer the following questions.

**What are your current priorities?** You should focus on prioritizing which systems to address in what order. For example, mission-critical servers are more important than individual workstations. Prioritizing systems will help to define where you should begin when defining storage requirements, and is also important when budget concerns limit the amount of storage that you can immediately upgrade. When prioritizing, focus on maximizing return on investment and distributing the benefit of improvements to the largest possible number of individuals in your organization.

**What is the expected growth of data?** Do not plan only for your current volume of data. Your plan should also include estimates of the size and expected growth rate of your organization's data.

**What are your budget constraints?** Budget is always a limiting factor. Understanding your budget constraints reduces wasted design efforts and helps focus on improvements that can actually be delivered. You might consider a solution that technically addresses all of your needs, but you will need to find a compromise or an alternative if the necessary funds are not available.

**Can you consolidate storage?** Consolidating storage reduces the cost of managing storage on multiple servers and increases the efficiency of storage allocation and backup tasks. However, consolidation also introduces risk, because more users depend on fewer servers; so an outage affects more users than in a more distributed installation. If you plan to consolidate storage, you should also investigate ways to increase storage availability.

**Will training be needed?** It might be necessary for your administrators to get additional training. For example, administrators might be comfortable with planning simple clusters, but they should not attempt state-of-the-art Fibre Channel solutions without specific training. Make plans to build necessary training into your project and budget if you plan to implement storage solutions with a high degree of complexity, or with complex management interfaces.

**Will your storage needs change?** Your storage needs are probably growing. It is easier to manage a flat growth rate than an explosive one, but in either case it is best to build flexibility into your storage plan at the outset. Implementing flexible Windows storage features now lets you adapt your plan later with little or no disruption to users. For example, DFS allows you to add servers transparently to your environment, and SAN-based storage arrays and network-attached storage appliances let you achieve higher storage utilization than direct-attached storage. Look for any upcoming projects or other business changes that might require additional storage.

**How many copies of data are maintained?** You need to plan adequate storage not only for primary copies of data, but also for any additional copies of the data that you need. Be sure to plan for the appropriate amount of backup media, and for sufficient online disk storage for shadow copies and replication.

**What are your performance requirements?** Your choice of storage solutions is normally influenced by performance considerations. For example, your local area network (LAN) and wide area network (WAN) network components will likely need to be considered when planning for replication or data recovery between two systems in the same site, or between two or more systems in remote sites. Other considerations regarding performance include the type of server disks used, such as Enhanced Integrated Drive Electronics (EIDE) or Small Computer System Interface (SCSI), storage interfaces, and the speed of backup storage devices, such as tape drives.

**What are your backup scheduling requirements?** You might have a backup window that must be met for nightly backups, or you might be able to run backups over their own network during the day. In addition to impacting the network, even backups made to direct-attached storage devices consume CPU cycles. Your backup plan should ensure that servers are available for clients and applications when they are needed most, and that backup activity does not impact network traffic during peak usage periods.

**How important is ease of backup and recovery?** You might have the resources to manually back up your data nightly, and, in case of a system disaster, you might be able to bring in additional staff on an overtime basis to recover the information. Alternatively, you might require an automated approach that relies on high-end enterprise level backup software. Your plan for backup and recovery of data must balance your need for automation against the increased costs of various automated solutions.

**How long can data recovery take?** Some critical systems must be continuously available. For example, an online banking enterprise might require that its system experience zero downtime. Other organizations might be able to tolerate a one-hour window of downtime. Your plan needs to take into account your organization's specific tolerance for downtime during data recovery.

**Will you use legacy equipment?** Budget considerations sometimes dictate that you not replace existing equipment as you build your new storage environment. This is especially true for expensive storage libraries. The presence of older servers, disk arrays, cabling, and other equipment might save your organization money, but it might also dictate compromises in your storage plan. Also, if your plan calls for keeping existing technology, you might need to budget for any additional hardware needed to allow you to use the technology in your new storage environment.

# Determining Application Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When determining storage requirements, start at the application and operating system level, noting the storage and disk requirements for each system. For example, you might decide that your Microsoft® Exchange Server requires 500 gigabytes (GB) of total storage, but you also need fault-tolerance. To configure a 500 GB RAID 0+1 disk array to provide fault-tolerance, you would need 1 terabyte (TB) of physical disk storage. You would also need to allocate drives for the Exchange transaction log files.

Taking this approach server-by-server and application-by-application, you can determine the number of physical disks that you require, as well as the amount of total storage you need. When you estimate your total storage requirements, do not forget to include backup requirements. For example, you might plan to back up your Exchange server to a magnetic storage array for very fast backup and recovery performance, and then copy the backup data to tape for offsite storage. To keep a single full backup onsite would require that you double your storage estimate for the Exchange server. You will also need to estimate the growth rate of each database so that your storage meets both your immediate and future needs for a period of time as defined by your organization.

When considering storage requirements for the operating system, you should note which servers require disk mirroring to protect their boot and system volumes, and note the number of required disks along with the amount of required storage for each.

Estimating application storage requirements can be difficult without in-depth knowledge of all the applications that run in an organization. If your organization has designated specialists for your applications, consult with them to arrive at a proper estimate. The documentation for each application can also serve as an excellent source for compiling storage planning information

# Reviewing Storage Architectures

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you plan a new storage configuration or reengineer your existing configuration, you will need to make decisions about the types of storage architecture to use. These architectures are direct-attached storage, network-attached storage, and storage area networks. The different storage architectures are not necessarily exclusive, but are actually complementary and often coexist on the same network. Because these architectures are well known, the discussion that follows includes only a brief overview of each architecture, and focuses on the planning considerations related to using each architecture with Windows Server 2003. The process for reviewing the storage architectures is shown in Figure 1.3.

**Figure 1.3 Reviewing Storage Architectures**

**Direct-Attached Storage**

Direct-attached storage refers to a storage device, such as a hard drive or tape drive, that is directly connected to a single computer. These connections are usually made by one of the following methods:

- Enhanced Integrated Drive Electronics (EIDE)
- Small Computer Systems Interface (SCSI)
- Fibre Channel

EIDE connects internal Advanced Technology Attachment (ATA) storage to a computer, SCSI provides a means to connect both internal and external storage to a computer, and Fibre Channel connects external storage to a computer. Fibre Channel is most often used with external storage in a SAN. Although Fibre Channel can be used for direct-attached storage, less expensive SCSI storage can offer similar performance, but works only over limited distances due to the physical limitations of the SCSI bus. When external direct-attached storage devices are located more than twelve meters away from a server, then Fibre Channel must be used.

Direct-attached storage retains its high popularity because of its low entry cost and ease of deployment. The simple learning curve associated with direct-attached storage technologies is also a factor many organizations consider. Direct-attached storage also makes it easy to logically and physically isolate data, because the data can only be directly accessed through a single server.

Although it is simple to deploy, there are other management considerations to take into account with direct-attached storage:

- Direct-attached storage can be more expensive to manage because you cannot redeploy unused capacity, which results in underutilization.

- Having storage distributed throughout the organization makes it difficult to get a consolidated view of storage across the organization.

- Disaster recovery scenarios are limited because a disaster will cause both server and storage outages.

- For data backup and recovery, you need to choose whether to attach local backup devices to each server, install dual network adapters in each server and back up the data over a separate LAN, or back up the server over the corporate LAN. Large organizations have found that placing stand-alone tape drives in individual servers can quickly become expensive and difficult to manage, especially when the number of servers in the organization grows into the hundreds. In this situation, it is often best to back up servers over a network to a storage library, which offers backup consolidation and eases management.

**Network-Attached Storage**

Network-attached storage solutions are ideal for both addressing immediate storage needs and storage consolidation projects. Their high capacity and ease of deployment allow you to implement network-attached storage with little planning. With network-attached storage, you can fulfill your storage requirements with a single purchase. This is because many network-attached storage devices are built to be *appliances*. Like home appliances, such as a refrigerator or microwave oven, you can literally purchase a network-attached storage appliance and plug it into your network. This is possible because network-attached storage appliances come prepackaged with network interfaces, storage interfaces (SCSI, Fibre Channel, or both), internal or external magnetic storage, and an operating system. Only the services required for file serving, security, and management are installed on the appliance, thus making it a high-performance file server. A network-attached storage implementation is shown in Figure 1.4.

**Figure 1.4 Network-Attached Storage Implementation**

Network-attached storage has risen in popularity primarily due to the quick-and-easy nature of its implementation: Many Windows Powered Network Attached Storage appliances can be installed and running within minutes, and easily integrate into any enterprise environment.

The operating systems on Windows Powered Network Attached Storage appliances are either Windows 2000 or Windows Server 2003. Windows Powered Network Attached Storage appliances offer the file system, security, reliability, and scalability features common to all Windows operating systems, and come preconfigured with network file system (NFS), File Transfer Protocol (FTP), AppleTalk, Hypertext Transfer Protocol (HTTP), Web Distributed Authoring and Versioning (WebDAV), and NetWare protocol support. Because Windows Powered Network Attached Storage appliances support other operating system environments such as UNIX and Linux, you can seamlessly integrate them into any existing computer infrastructure, whether it uses Windows or not. They also support standard Web protocols, which allows you to manage Windows Powered Network Attached Storage appliances from a Web browser.

Windows Powered Network Attached Storage appliances are well suited for use as both departmental file servers and enterprise file servers. Network-attached storage solutions built on Windows offer data protection and high availability features like clustering and snapshots. In addition, network-attached storage appliances offer a highly scalable solution that can grow with the business. For example, storage can be added on the fly to address growing business needs.

To summarize, the key benefits of Windows Powered Network Attached Storage are:

- **Ease of deployment.** Windows Powered Network Attached Storage appliances can be installed in a heterogeneous environment within minutes.

- **Active Directory integration.** Windows Powered Network Attached Storage appliances can be integrated with the Active Directory® directory service to take advantage of features such as Kerberos authentication, Internet Protocol security (IPSec), Encrypting File System (EFS), and Group Policy objects (GPOs).

- **ISV utility support.** You can install several independent software vendor (ISV) utilities on Windows Powered Network Attached Storage appliances, including quota, backup, antivirus, and replication utilities. This is not possible with many

other network-attached storage appliances.

- **Simple management.** Remote management is supported through Terminal Services sessions as well as through a Web interface. Administrators do not have to learn a new operating system to operate a network-attached storage appliance, because it uses Windows 2000 or Windows Server 2003.

- **Enhanced snapshot support.** Windows Powered Network Attached Storage appliances maximize the availability of data by supporting up to 250 snapshots, which provides an advantage compared to other network-attached storage solutions. *Snapshots* are similar to the shadow copy feature in Windows Server 2003.

- **DFS and FRS integration.** You can use DFS to build and manage a single, hierarchical view of multiple file servers and their shares. To provide redundancy and load balancing, you can store shares with identical data on multiple servers, and DFS will automatically redirect clients to alternate servers if a server becomes unavailable. To keep these shares synchronized, you can use FRS.

For more information about Windows Powered Network Attached Storage appliances, see the Windows Powered Network Attached Storage link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Storage Area Networks**

Unlike direct-attached or network-attached storage, SANs require careful planning before implementation. SANs differ from network-attached storage in that they store and access data at the block level, whereas network-attached storage appliances store data at the file level. File level access is preferable for users and applications needing to access a particular file, whereas block level data access is better for applications that need to quickly access data. SANs also differ from other storage architectures in that they are dedicated storage networks, and use their own network protocols and hardware components.

A simple SAN configuration is illustrated in Figure 1.5.

**Figure 1.5 SAN Implementation**

For more information about specific considerations for deploying SANs with Windows Server 2003 see "Planning for SAN Deployment" later in this chapter.

# Planning for Storage Scalability

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A properly planned storage infrastructure should meet both your current and future needs. It is crucial to understand the storage design and implementation limitations of your existing systems, as well as methods to overcome those limits. The general process for storage scalability planning is shown in Figure 1.6.

**Figure 1.6 Planning for Storage Scalability**

# Reviewing Storage Limits

Updated: August 3, 2011

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2008 R2 with SP1

To accurately plan for storage scalability, you must take into account the physical and logical design limits of your servers. The following sections describe these limits.

**Reviewing the physical storage limits**

From a hardware perspective, your choice of storage bus will determine the physical limits of your storage scalability. For example, local storage with two Integrated Device Electronics (IDE) controllers will allow a system to have up to four IDE storage devices; with SCSI storage, the SCSI bus type will determine the maximum amount of allowable storage devices on each bus. If you need to extend a system's local storage beyond the limitations of IDE or SCSI, you can use Fibre Channel–based storage or use SCSI protocol over TCP/IP (iSCSI), a new IP-based storage networking standard that carries SCSI commands over IP networks. However, these newer, more flexible architectures are more expensive than traditional IDE or SCSI buses.

| **Important** |
|---|
| Unless otherwise noted, all storage limits discussed in the following sections apply to Windows Server® 2003, Windows Server® 2008, and Windows Server® 2008 R2 operating systems. |

**Reviewing the limits for basic and dynamic Disks**

In addition to reviewing the physical storage limits, you also need to keep in mind the volume types in Windows Server 2003, Windows Server 2008, and Windows Server 2008 R2 and their limits. All versions of these operating systems provide enhanced volume management capabilities. You can plan for both basic disks and volumes and dynamic disks and volumes.

*Basic disks* use the same disk structures as those used in Microsoft® Windows NT® version 4.0 and Windows 2000. When you use basic disks, you are limited to creating four primary partitions per physical disk, or three primary partitions and one extended partition that can contain multiple logical drives. Primary partitions and logical drives on basic disks are known as *basic volumes*. As shown in Table 1.2, basic volumes are limited to 2 TB. Even if you create multiple volumes on a single logical unit, the combined size of all those volumes cannot exceed 2 TB. If you want to use volumes larger than 2 TB, you must use dynamic spanned, striped, or RAID-5 volumes.

Dynamic disks, which offer features not available in basic disks, were introduced in Windows 2000. Dynamic disks contain *dynamic volumes*, including simple volumes, spanned volumes, striped volumes, mirrored volumes, and RAID-5 volumes. Dynamic disks offer greater flexibility for volume management because they use a hidden database, instead of the disk's partition table, to track information about dynamic volumes on the disk and about other dynamic disks in the server. This flexibility allows you to create spanned, striped (RAID-0), and RAID-5 volumes that exceed the 2-TB size limit of basic volumes. Simple and mirrored volumes cannot exceed 2 TB.

Table 1.2 lists the contrasts between basic and dynamic Master Boot Record (MBR) disks.

**Table 1.2 Comparison of Basic and Dynamic MBR Disks**

| Storage Capabilities | Basic Disks | Dynamic Disks |
|---|---|---|
| Volume size (maximum) | 2 TB | 2 TB for simple and mirrored volumes.<br><br>Up to 64 TB for spanned and striped volumes. (2 TB per disk with a maximum of 32 disks per volume.)<br><br>Up to 62 TB for RAID-5 volumes. (2 TB per disk with a maximum of 32 disks per volume and 2 TB used for parity.) |
| Supported RAID implementation | Hardware RAID only | Hardware or software RAID |
| Storage of boot and system volumes | Yes | Simple or mirrored volumes only |

| | | |
|---|---|---|
| Shared cluster storage in server clusters | Supported | Not supported* |

* For more information about using dynamic disks on shared cluster storage, see article 237853, in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?linkid=99316).

Use the following guidelines to choose between basic disks and dynamic disks.

Use basic disks if:

- You do not need to create volumes that exceed 2 TB.
- You are configuring shared cluster storage on a server cluster.
- The server runs other operating systems that cannot access dynamic disks. The only server operating systems that can access dynamic disks are Microsoft® Windows® 2000 Server and Windows Server 2003.

Use dynamic disks if:

- You want to create RAID-0 volumes or fault-tolerant volumes (RAID-1 or RAID-5) and the server does not contain hardware RAID.
- You want to combine logical units (LUNs) in a RAID array to create a volume larger than 2 TB.
- You want to extend a volume, but the underlying hardware cannot dynamically increase the size of LUNs, or the hardware has reached its maximum LUN size.

**Reviewing the limits for NTFS and the number of volumes per server**
When you configure storage in Windows operating systems, it is important to understand NTFS limits and volume limits for server storage.

Table 1.3 describes the NTFS and volume limits.

**Table 1.3 NTFS and Volume Limits**

| Description | Limit |
|---|---|
| Maximum size of an NTFS volume | $2^{32}$ clusters minus 1 cluster<br><br>Using a 64-kilobyte (KB) cluster (the maximum NTFS cluster size), the maximum size of an NTFS volume is 256 TB minus 64 KB.<br><br>Using a 4-KB cluster (the default NTFS cluster size), the maximum size of an NTFS volume is 16 TB minus 4 KB. |
| Maximum number of dynamic volumes per disk group | 1,000<br><br>A disk group is collection of dynamic disks. Windows Server 2003 supports one disk group per server. |
| Maximum volumes per server | Approximately 2,000 volumes<br><br>Up to 1,000 of these volumes can be dynamic volumes; the rest are basic volumes. Boot times increase as you increase the number of volumes. In addition, the use of multipathing can reduce the number of volumes per server. |

**Reviewing the number of supported disk drives**
When you select the number of disk drives in Windows operating systems, it is important to understand the number of drives supported in different types of file systems. The number of disk drives you can use for each server is limited only by the available memory for FAT16, FAT32, NTFS, and UDF files systems.

**Reviewing methods for adding storage space to volumes**
If you create volumes smaller than the maximum sizes listed earlier, and you later want to add storage space to those volumes, you can do so by increasing the size of the volume or by creating a mounted drive.

**Extending volumes**
When a defined volume begins to reach its allocated capacity, but there is still free unallocated space on a hard disk or hardware RAID array, you can use the DiskPart command-line tool (Diskpart.exe), available in the Windows Server 2003 operating system, to extend the volume size without any loss of data. When using DiskPart, consider the following guidelines:

- You cannot use DiskPart to extend system or boot volumes; DiskPart can only be used to extend data volumes. This is not applicable for Windows Server 2008.
- The volume to be extended must be formatted with the NTFS file system.
- For basic volumes, the unallocated disk space used for the extension must be the next contiguous space on the same disk. (The disk can be a single physical disk or a group of physical disks presented by a RAID adapter to the operating system as a single disk, often referred to as a LUN.)
- For dynamic volumes, the unallocated disk space can be any empty space on any dynamic disk on the system.
- If you upgraded from Windows 2000 to Windows Server 2003, you cannot extend a simple or spanned volume that was originally created as a basic volume and converted to a dynamic volume on Windows 2000. For more information about basic and dynamic volumes, see Storage Technologies Collection (http://go.microsoft.com/fwlink/?linkid=4681).

For more information about using DiskPart, see "DiskPart" in Help and Support Center for Windows Server 2003. For more information about choosing volume sizes based on Chkdsk and recovery times, see "Designing and Deploying File Servers" in this book.

**Using mounted drives**
Mounted drives are useful when you want to add more storage to an existing volume without having to extend the volume. A mounted drive is a local volume attached to an empty folder on an NTFS volume. Mounted drives are not subject to the 26-drive limit imposed by drive letters, so you can use mounted drives to access more than 26 drives on your computer. For more information about mounted drives, including information about creating mounted drives on server clusters, see "Using NTFS mounted drives" in Help and Support Center for Windows Server 2003.

# Planning for Storage Virtualization by Using DFS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Storage virtualization is a means to organize storage virtually instead of physically. With virtualized storage, the user sees all available storage, but is insulated from the actual physical structure and processes of storage, such as the configuration, location, and capacity of the individual devices that make up the storage system. At the network level, you can achieve virtualization by using DFS. DFS allows you to move data between servers, load balance data access among servers, and change or expand your storage configuration without impacting users.

Even if your network incorporates only a single file share, you should still build your shared storage infrastructure to use DFS. This way, as your storage needs expand, the infrastructure is already in place to support that growth. With the transparency that DFS provides, you can configure and reconfigure storage at any time with no downtime or interruption to users or applications.

The benefits of using DFS include:

**Unified namespace** A DFS namespace links together shared folders on different servers to create a hierarchical structure that behaves like a single high-capacity hard disk. Users can navigate the logical namespace without having to know the physical server names or shared folders that host the data.

**Location transparency** DFS simplifies migrating data from one file server to another. Because users do not need to know the name of each physical server or shared folder that contains the data, you can physically move files to another server without having to reconfigure applications and shortcuts, and without having to reeducate users about where they can find their data.

**Storage scalability** You can deploy additional or higher-performance file servers and present the storage on the new servers as new folders within an existing namespace.

**Increased availability of file server data** When multiple servers running Windows Server 2003 host a domain-based DFS root, clients are redirected to the next available root server if any of these servers fail, which provides fault-tolerant data access. To ensure the availability of stand-alone DFS namespaces, you can create the root on a clustered file server.

**Load sharing** DFS provides a degree of load sharing by mapping a single logical name to shared folders on multiple file servers. For example, suppose that \\Company\StockInfo is a heavily used shared folder. By using DFS, you can associate this location with multiple shared folders on different servers, even if the servers are located in different sites.

**Simplified maintenance** Using multiple copies of shared folders also allows administrators to transparently perform preventive maintenance or upgrades on servers. A server that hosts one target can be taken offline without affecting users, because DFS automatically routes requests to a target that is online.

For more information about DFS, see "Designing and Deploying File Servers" in this book.

# Planning for SAN Deployment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If your organizational and application requirements can best be satisfied by using a SAN, you need to follow the steps in this section to adequately plan for your SAN implementation. Several new or enhanced storage features are included with Windows Server 2003 to better support storage devices located on a SAN. Planning for optimal SAN deployment in a Windows Server 2003 network includes careful consideration of these SAN-related features so that you can seamlessly integrate your SAN with your Windows network. You can then plan how to configure Windows for your specific SAN implementation, and how to integrate additional storage technologies from other vendors. The process of planning for SAN deployment in a Windows network is shown in Figure 1.7.

**Figure 1.7 Planning for SAN Deployment**

# Planning to Use Windows Storage Features with SANs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As you plan your SAN implementation, consider which operating system features you can use to optimize the storage located on your SAN. Windows Server 2003 adds several services, components, and capabilities to better support storage devices located on a SAN. These include:

- Virtual Disk service (VDS)
- Volume Shadow Copy service
- Volume Automount
- Multipath Input/Output (MPIO)

**Virtual Disk Service**

Until recently, storage applications managed storage by directly interfacing with storage devices, based on the hardware vendor's device-specific applications. In Windows Server 2003, the Virtual Disk service (VDS) provides a standard set of APIs that storage software can use to communicate with VDS, which then sends the necessary queries or commands to the storage hardware. VDS simplifies storage management by providing a single management interface for multivendor storage devices, whether in direct-attached storage or on SANs. By using VDS, you can configure a mixed storage environment without needing to use the individual management tools supplied by each hardware vendor. To support VDS, hardware vendors must supply a VDS *provider* for the storage hardware. The provider translates the VDS APIs into instructions specific to the hardware.

VDS insulates applications from the complexities associated with storage implementations, making query and configuration operations common across all managed devices. The specific scope of VDS functionality depends on the capabilities of the underlying hardware.

Windows Server 2003 components that work with VDS as management applications include the Disk Management snap-in, the DiskPart command-line tool, and the DiskRaid command-line tool (Diskraid.exe), which is available in the *Windows Server 2003 Deployment Kit*. DiskRaid requires at least one VDS provider supplied by a storage vendor. For more information about DiskRaid, click **Tools** in Help and Support Center for Windows Server 2003, and then click Windows Resource Kit Tools Help.

Because of the advantages of using VDS, you should consider making VDS support a criterion when evaluating hardware or software for use in your storage infrastructure. Devices with VDS providers will be compatible with Windows Server 2003 and with other storage applications that are written for VDS. If your plan calls for storage devices that are not VDS compliant, check to ensure that the devices are compatible with Windows Server 2003 and are supported by your storage applications. For more information about device compatibility with Windows Server 2003, see the Windows Server Catalog link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources

**Volume Shadow Copy Service**

The Volume Shadow Copy service adds new features for direct-attached storage and external storage arrays, including arrays that are SAN-based. It provides an infrastructure that makes possible high-fidelity backup, recovery, and data mining without significantly affecting performance.

The Volume Shadow Copy service is not a user-accessible feature, but an operating system service that works by creating a volume that can be accessed by other applications. This volume appears as a read-only point-in-time copy of the original volume. By default, the shadow copy does not appear to the server as an additional volume, but other applications can mount it and read from it. Following the creation of a shadow copy, the original volume continues to be used by the system in the same way it was used before the shadow copy was created.

The Volume Shadow Copy service can be extended with providers supplied by storage vendors, so that backup and data management applications can leverage the advanced capabilities of different storage arrays without having to deal directly with the complexities of a particular array. This allows storage management applications to more easily support a number of different hardware devices.

The Volume Shadow Copy service also enables additional capabilities in Windows Server 2003, including the following:

- **Open-file backups.** Backup applications that work with Volume Shadow Copy service, such as the Backup program in Windows Server 2003, can back up open files. For more information about backing up open files, see "Planning to Back Up Open Files" later in this chapter.

- **Shadow copies.** After an administrator has configured and enabled shadow copies, users themselves can restore earlier versions of files from point-in-time copies stored on file servers that are running Windows Server 2003. For more information about shadow copies, see "Protecting User Data by Using Shadow Copies" later in this chapter.

**Volume Automount**

By default, volumes automatically mount when discovered in Microsoft® Windows® Server 2003, Standard Edition and Windows® Server 2003, Web Edition operating systems. In the Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition operating systems, automount is suppressed by default to prevent these servers from aggressively mounting all volumes attached to the SAN. Automount can be enabled or disabled by using the DiskPart command-line tool. When volumes are not automounted, you can mount them and assign drive letters to them by using DiskPart.

For more information about using DiskPart, see "DiskPart" in Help and Support Center for Windows Server 2003.

**Multipath Input/Output**

Multipathing increases availability by providing multiple paths from the host to the external storage device. The Multipath Input/Output (MPIO) Driver Development Kit (DDK) allows storage vendors to create interoperable multipathing solutions that work with Windows Server 2003. Up to 32 paths to each logical unit are supported. For devices that can support multiple active paths, a vendor can improve performance by implementing load balancing.

To take advantage of MPIO on your SAN, you must ensure that your storage uses multipath drivers that support Microsoft MPIO technology. For more information about compatibility with Windows Server 2003, see the Windows Server Catalog link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Configuring Windows Server 2003 for SANs

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As you create your plan for deploying servers running Windows Server 2003 that use SAN-based storage, you need to resolve several configuration issues. In particular, consider the following:

- Is the SAN topology compatible with Windows Server 2003?
- Can the SAN storage be configured to be shared between server cluster nodes?
- Can Windows Server 2003 boot from the storage connected to the SAN?
- How will zoning and LUN masking be configured?

The sections that follow assume that you understand the basic concepts of SANs, including Fibre Channel SAN topologies and hardware components.

# SAN Configurations

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Your SAN configuration directly affects the speed and reliability with which your systems can access storage devices on the SAN. Two critical considerations are your choice of a Fibre Channel SAN topology and the use of redundant components in the access path to storage devices.

**Supported Fibre Channel Topologies**
Windows Server 2003 supports all Fibre Channel SAN topologies (point-to-point, loop, and fabric). For attaching single storage devices to Windows Server 2003 systems using a Fibre Channel host bus adapter (HBA), the point-to-point topology is ideal. There are, however, some limitations with respect to the loop (FC-AL) topology. Loop topologies are inherently limited in operation and scalability, because they often require full loop reinitialization when devices are added or removed from the SAN. This can cause data to be inaccessible for periods ranging up to minutes. Also, loops can only scale to support up to 127 devices, and, like token ring networks, only allow a single device on the SAN to transmit data at one time, which might not make full use of the available bandwidth on the SAN.

Windows Server 2003 supports FC-AL topologies when a single server is connected to storage. However, the only multiserver configuration supported on a loop is a single two-node cluster. This limitation also applies to the derivatives of FC-AL topologies: Fibre Channel Private Loop SCSI Direct Attachment (FC-PLDA), Fibre Channel Fabric Loop Attachment (FC-FLA), and Fibre Channel Private Loop Attachment (FC-PLA). This means that your SAN design should incorporate a true fabric, or switch-based fabric topology, using a fabric SAN switch (hubs or loop switches should not be used) for any SAN implementation that contains more than two components (servers or storage devices).

**Important**

- Placing new devices on an FC-AL–based SAN causes Loop Initialization Primitives (LIPs), which appear to the operating system as storage bus resets. LIPs can result in data unavailability and even data loss, if a LIP interrupts a write operation that is only partially committed to the storage device. LIPs can also disrupt backup operations to tape devices and can cause your devices to be assigned new addresses. Therefore, you should use persistent binding. You can limit the propagation of LIPs by using only fabric-based SAN topologies and compatible devices.

For more information about supported Fibre Channel topologies, see article 317162, "Supported Fibre Channel Configurations." To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Redundant Components**
Although storage data on a SAN offers many benefits, it also introduces additional components whose failure can result in loss of access to data. As on a LAN, the failure of an adapter, switch, or cable can interrupt or remove access to a storage device. The best means to provide for highly available storage is to implement a SAN that uses redundant storage (such as hardware RAID), redundant data access paths (including cables and switches) and server HBAs, and MPIO storage drivers.

# Server Cluster Integration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For server clusters of three or more nodes, each node must connect to shared storage over a fabric-based SAN. When planning an SAN storage solution that uses server clusters, ensure that your plan meets the following requirements:

- Each cluster on a SAN should be deployed in its own zone if possible. The mechanism the cluster uses to protect access to the disks can adversely affect other clusters or servers in the same zone. You can prevent this by using zoning to separate the SAN cluster traffic from other traffic.

- All HBAs in a single cluster must be the same type and have the same firmware, driver versions, and driver parameters. Many storage and switch vendors require that all HBAs on the same zone (and, in some cases, on the same fabric) share these features.

- All other storage drivers in the same cluster must have the same software versions.

- Only one node on a cluster should access the disks that are to be managed by the cluster when you first create the cluster, otherwise resource contention might cause the installation to fail.

  This is a requirement because, when the volume automount option is enabled, Windows Server 2003 mounts any volumes it can detect when the operating system boots (this is disabled by default on Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition).

  **Caution**

  - If multiple nodes that are not in the same cluster access the same disk, data corruption results.

- Tape devices must not be located in the same zone as cluster disk storage devices unless Storport miniport drivers are used. A tape device will interpret a bus reset as an instruction to rewind and possibly dismount the tape, which will disrupt any backup operation. If this occurs, the backup must be restarted.

For a white paper that provides more information about using SANs with server clusters, see the Windows Clustering: Storage Area Networks link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresourceson the Web Resources page at http://www.microsoft.com/windows/reskits/webresources

# SAN Boot Considerations

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If your plan requires servers attached to a SAN to boot from disks located on the SAN, you must verify with the disk vendor that the disks can be used to boot a Windows server. When a server's system and boot volumes are stored on a SAN, the SAN vendor must ensure that the disks are accessible during system startup. Make sure that the vendor provides specific configuration information, including needed firmware revisions and setup instructions. You will also need to ensure that each server's HBA is configured according to the disk vendor's guidelines for booting from a SAN.

Additional requirements for successfully booting servers from a SAN are:

- Proper fiber channel topology is used.

  The SAN should be configured in a fabric topology, or the host can be directly attached to the Fibre Channel storage device. For more information about Fibre Channel topologies, see "SAN Configurations" earlier in this chapter.

- Multipathing and redundant SAN links are used.

  You can avoid single points of failure in your SAN design by implementing redundant paths to the critical storage on the SAN, redundant HBAs, and MPIO-compliant drivers.

  Finally, use of the new Storport port driver and appropriate miniports from your HBA vendor will allow more flexibility in configuring your SAN. With Storport miniports, it is possible to have the boot disk and cluster disks on the same Fibre Channel connection. For more information about this configuration, see the Windows Clustering: Storage Area Networks link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

- The boot disk LUN is dedicated to a single host.

  A server that boots from the SAN must have exclusive access to the disk that it is booting from. Exclusively associating a storage device with a server can be accomplished either through zoning or LUN masking, which is configured at the SAN switch, HBA, or storage subsystem level. Storage-based LUN masking is the best choice when you cannot use switch zoning to isolate systems. For more information about LUN masking and zoning see "LUN Masking vs. Zoning" later in this chapter.

For more information about booting from SANs, see article 305547, "Support for Booting from a Storage Area Network (SAN)." To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# LUN Masking vs. Zoning

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The potential for any server on a SAN to mount and access any drive on the SAN can create several problems. The two most prominent ones are disk resource contention and data corruption. To deal with these problems, you can isolate and protect storage devices on a SAN by using zoning and LUN masking, which allow you to dedicate storage devices on the SAN to individual servers.

**Zoning**

Many devices and nodes can be attached to a SAN. When data is stored in a single *cloud*, or storage entity, it is important to control which hosts have access to specific devices. Zoning controls access from one node to another. Zoning lets you isolate a single server to a group of storage devices or a single storage device, or associate a grouping of multiple servers with one or more storage devices, as might be needed in a server cluster deployment.

Zoning is implemented at the hardware level (by using the capabilities of Fibre Channel switches) and can usually be done either on a port basis (hard zoning) or on a *World-Wide Name* (WWN) basis (soft zoning). WWNs are 64-bit identifiers for devices or ports. All devices with multiple ports have WWNs for each port, which provides more detailed management. Because of their length, WWNs are expressed in hexadecimal numbers, similarly to MAC addresses on network adapters. Zoning is configured on a per-target and initiator basis. Consequently, if you need to attach multiple nonclustered nodes to the same storage port, you must also use LUN masking.

**LUN masking**

LUN masking, performed at the storage controller level, allows you to define relationships between LUNs and individual servers. Storage controllers usually provide the means for creating LUN-level access controls that allow access to a given LUN by one or more hosts. By providing this access control at the storage controller, the controller itself enforces access policies to the devices. LUN masking provides more detailed security than zoning, because LUNs provide a means for sharing storage at the port level.

When properly implemented, LUN masking fully isolates servers and storage from events such as resets. This is critical for preventing the problems previously noted. It is important to thoroughly test your design and implementation of LUN masking, especially if you use LUN masking in server clusters.

# Integrating Vendor Features

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is likely that your SAN will include applications and services from various vendors. For optimal performance and reliability, you should ensure that all devices and applications on the SAN are fully compatible with Windows Server 2003. Use the following guidelines for all applications on your SAN:

- Device drivers for SAN components should conform to Plug and Play specifications. Failure to use Plug and Play drivers can unexpectedly prevent the operating system from recognizing a device and installing the correct device drivers, which can lead to data loss.

- Drivers for all devices on the SAN, such as HBA and multipathing drivers, should have a digital signature from Microsoft or the storage vendor. Device drivers that contain a digital signature assure you that the product was tested for compatibility with Windows, comes from the specified source, and has not been altered since testing. If the driver does not contain a digital signature from Microsoft or the storage vendor, contact the vendor directly and ask for a driver that meets the Designed for Microsoft Windows Server 2003 logo requirements.

  You can use the Windows Server Catalog to check for software and hardware compatibility with Windows Server 2003. To find the Windows Server Catalog, see the Windows Server Catalog link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources. Windows Server Catalog also provides information about additional compatibility requirements for software that qualifies for the Supported & Certified for Windows Server 2003 program and hardware that qualifies for the Designed for Windows Server 2003 program. Qualifying products are specifically created to take advantage of the new features in Windows Server 2003.

- Add VDS and Volume Shadow Copy service providers for storage devices that have them. This significantly improves the compatibility of the devices with Windows Server 2003 and gives applications from various vendors the ability to use the capabilities of the devices.

- Contact your storage vendor for a Microsoft MPIO-based multipath solution.

- Make sure that all device drivers are qualified by the storage vendor for use with the specific storage products from that vendor (disk, tape or software) that you will use in your SAN.

- If you are implementing Windows Clustering, it is extremely important that you select hardware configurations that have been approved by Microsoft for Windows server clusters. Microsoft supports only complete server clusters systems chosen from the Windows Server Catalog. For more information about approved hardware configurations, see the Windows Server Catalog link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

For more information about using SANs with server clusters, see "Designing and Deploying Server Clusters" in this book.

# Planning to Protect User Data

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 provides new features that allow you to automate protecting and recovering user data. Most notably, using shadow copies provides a high level of user data protection, and also frees administrators or help desk personnel from dealing with user requests to restore single files. You will also want to consider including folder redirection in your data protection plan. The process of planning to protect user data is shown in Figure 1.8.

**Figure 1.8 Planning to Protect User Data**

# Protecting User Data by Using Shadow Copies

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Shadow copies increase the availability of data and reduce the administrative burden of restoring files. After an administrator has configured and enabled shadow copies, users themselves can restore earlier versions of files from point-in-time copies stored on general-purpose file servers that are running Windows Server 2003. Shadow copies are also available on server clusters running Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition.

You can enable shadow copies by using Windows Explorer, the Disk Management snap-in, or Shared Folders extension to the Computer Management snap-in. You can also automate administrative tasks that involve making shadow copies by using the command-line tool Vssadmin.exe.

Shadow copies work by making a block-level copy of any changes that have occurred to files since the last shadow copy. Only the changes are copied, not the entire file. As a result, previous versions of files do not usually take up as much disk space as the current file, although the amount of disk space used for changes can vary depending on the application that changed the file. For example, some applications rewrite the entire file when a change is made, whereas other applications append changes to the existing file. If the application rewrites the entire file to disk, the shadow copy contains the entire file. Therefore, you should consider how the applications in your organization manage changes to files, as well as the frequency and number of updates to files, when you plan how much disk space to allocate for shadow copies.

Shadow copies are designed for volumes that store user data, and are best suited for protecting user data stored on servers from the following problems:

- Accidental deletion of files
- Accidental overwriting of files (for example, when a user forgets to use **Save As** to create a new version of a file)
- File corruption

Although shadow copies are made for an entire volume, users must use shared folders to access shadow copies. This is because shadow copies are designed to be accessed using the Common Internet File Sharing (CIFS) protocol. If you or your users want to access a previous version of a file that is not located in a shared folder, you must first share the folder. If you want to access shadow copies on a local server, you must use the *servername**sharename* path to access shadow copies.

The method of providing access to shadow copies from a given computer differs depending upon the operating system installed on the computer. Shadow copies can be accessed by computers running Windows Server 2003 and by computers running Microsoft® Windows® XP Professional on which you have installed the Previous Versions Client pack by running Twcli32.msi. This file is located in Windows Server 2003 in *windir*\system32\clients\twclient. You can install this file manually on clients or deploy the file by using the software distribution component of Group Policy. For more information about software distribution, see "Deploying a Managed Software Environment" in *Designing a Managed Environment* of this kit.

To access shadow copies from previous versions of Windows, including Windows 2000 and Windows XP Professional, you can download and install the Shadow Copy Client. For more information and to download the Shadow Copy Client, see the Shadow Copy Client Download link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Note**

- The Previous Versions Client and the Shadow Copy Client provide the same functionality, but the Shadow Copy Client can be installed on multiple operating systems, such as Windows 2000 and Windows XP Professional, whereas the Previous Versions Client can only be installed on Windows XP Professional.

If you have not yet deployed these operating systems or client packs on your clients, you can deploy one or more computers from which users can restore previous versions of files. You can also distribute the client pack on a case-by-case basis to users who request that files be restored.

For more information about shadow copies, see the following sources:

- For more information about designing a shadow copy strategy, see "Designing and Deploying File Servers" in this book.

- For more information about using shadow copies on server clusters, see "Using Shadow Copies of Shared Folders in a server cluster" in Help and Support Center for Windows Server 2003.

- For more information about using Vssadmin.exe to create shadow copies, see "Vssadmin" in Help and Support Center for Windows Server 2003.

# Protecting User Data by Using Folder Redirection

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If users store their data on their local workstations, you can protect it by using folder redirection. With folder redirection, user folders, such as the My Documents folder, can be redirected to a Windows Server 2003 file server. With all files located on a central server, you can configure shadow copies on the server so that users can recover earlier versions of their files, and you can back up their files in accordance with your organizational standards. You can easily implement folder redirection in your organization by using Group Policy.

Folder redirection offers the following advantages:

- Centralized user data for ease of backup
- Excellent integration and transparency with roaming user profiles
- Easily enforced disk quotas

To redirect special folders, in the Group Policy Object Editor snap-in to Microsoft Management Console (MMC), select the Group Policy object (GPO) that is linked to the site, domain, or organizational unit (OU) that contains the users whose folders you want to redirect. In the **User Configuration\Windows Settings\Folder Redirection** node of the Group Policy Object Editor, double-click **Folder Redirection**, right-click the special folder to redirect, and select **Properties**. Then you can configure redirection as either Basic or Advanced. With Basic redirection, the specified folders of all users are redirected to the same network share. With Advanced redirection, you can specify network share locations for redirection by user group.

If you have mobile users who travel with portable computers, working exclusively with folder redirection might not be feasible. To provide the benefits of folder redirection to mobile users while still making their data available to them when they travel, you can combine Offline Files with folder redirection. Offline Files allows users to download copies of their files from a server when they are connected to the network. If they modify files when they are not connected to the network, those files can be resynchronized with the server the next time the system is connected to the network. You can configure Offline Files options in a Group Policy object in the **Computer Configuration\Administrative Templates\Network\Offline Files** node of the Group Policy Object Editor.

For more information about redirecting folders, see "Implementing User State Management" in *Designing a Managed Environment* of this kit.

# Planning for Fault Tolerance

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Organizations are increasingly finding that any downtime that results in mission-critical data being unavailable is unacceptable. Windows Server 2003 offers several solutions to increase the availability of data. Solutions that use RAID and clustering technologies are especially suited to providing fault-tolerant storage. The process for analyzing and selecting among these solutions is illustrated in Figure 1.9.

**Figure 1.9 Planning for Fault Tolerance**

# Achieving Fault Tolerance by Using RAID

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

RAID is commonly implemented for both performance and fault tolerance. With RAID, you can choose to assemble disks to provide fault tolerance, performance, or both, depending on the RAID level that you configure. Table 1.4 summarizes commonly available RAID levels.

**Table 1.4 RAID Comparison**

| RAID Level | Description | Minimum Disks Required | Effective Capacity |
|---|---|---|---|
| 0 | Disk Striping. Two or more disks appear to the operating system as a single disk. Data is striped across each disk during read/write operations. Potentially increases disk access speeds 2X or better. Not fault tolerant. | 2 | S*N<br>*N* = # of disks in array<br>*S* = Size of smallest disk in array |
| 1 | Disk mirroring. Data is mirrored on two or more disks. Provides fault tolerance, but at a higher cost (space required is double the amount of data). Read performance is increased as well. | 2 | S<br>*S* = Size of smallest disk in array |
| 0+1 | Combines RAID 0 and RAID 1; offers the performance of RAID 0 and the protection of RAID 1. | 4 | S*N/M<br>*N* = # of disks in array<br>*S* = Size of smallest disk in array<br>*M* = Number of mirror sets |
| 5 | Disk striping with parity. Provides slower performance than RAID 0, but provides fault tolerance. A single disk can be lost without any data loss. Parity bits are distributed across all disks in the array. | 3 | S*(N-1)<br>*N* = # of disks in array<br>*S* = Size of smallest disk in array |

From a design perspective, your choice of a RAID solution should be dictated by the type of data being stored. Although RAID 0 offers the fastest read and write performance, it does not offer any fault tolerance, so that if a single disk in a RAID 0 array is lost, all data is lost and will need to be recovered from backup. This might be a good choice for high performance workstations, but might not be suited to mission-critical servers.

RAID 1 allows you to configure two or more disks to mirror each other. This configuration produces slow writes, but relatively quick reads, and provides a means to maintain high data availability on servers, because a single disk can be lost without any loss of data. When more than two disks make up the mirror, the RAID 1 array can lose multiple disks so long as a complete mirrored pair is not lost. When planning a RAID 1 solution, remember that the amount of physical disk space required is twice the space required to store the data.

RAID 0+1 combines the performance benefit of striping with the fault tolerance of mirroring. Compared to RAID 0, writes are

slower, but reads are equally fast. Compared to RAID 1, RAID 0+1 offers faster writes and reads but also requires additional storage to create the mirrored stripe sets. This configuration is often ideal for mission-critical database storage, because it offers both fast read access and fault tolerance.

RAID 5 provides fault tolerance: you can lose a single disk in an array with no loss of data. However, RAID 5 operates much more slowly than RAID 0 because a parity bit must be calculated for all write operations. RAID-5 volumes are well suited for reads and also work well in the following situations:

- In large query or database mining applications where reads occur much more often than writes. Performance degrades as the percentage of write operations increases. Database applications that read randomly work well with the built-in load balancing of a RAID 5 volume.

- Where a high degree of fault tolerance is required without the cost of the additional disk space needed for a RAID 1 volume. A RAID 5 volume is significantly more efficient than a mirrored volume when larger numbers of disks are used. The space required for storing the parity information is equivalent to 1/Number of disks, so a 10-disk array uses 1/10 of its capacity for parity information. The disk space that is used for parity decreases as the number of disks in the array increases.

**Choosing Between Hardware and Software RAID**

An additional consideration with RAID implementations is the choice between hardware-based and software-based RAID. With hardware RAID, a hardware RAID controller allows you to configure the RAID level of attached disks. With software RAID, the operating system manages the RAID configuration, along with data reads and writes.

Windows Server 2003 supports the following software RAID types:

- RAID 0: Up to 32 disks striped

- RAID 1: Two disks mirrored

- RAID 5: Up to 32 disks striped with parity

To configure software RAID, a disk must be configured as a dynamic disk. Although software RAID has lower performance than hardware RAID, software RAID is inexpensive and easy to configure because it has no special hardware requirements other than multiple disks. If cost is more important than performance, software RAID is appropriate. If you plan to use software RAID for write-heavy workloads, use RAID-1 instead of RAID-5. Using software-based RAID with Windows Server 2003 dynamic disks is a good choice for providing fault tolerance using SCSI or EIDE disks to non-mission-critical servers that require fault tolerance and can accommodate the added CPU load imposed by software RAID. This solution is ideal for small to medium organizations that need to add a level of fault tolerance while avoiding the cost of hardware RAID controllers.

For more information about software RAID and disk management, see Storage Technologies Collection (http://go.microsoft.com/fwlink/?linkid=4681).

**Using Dynamic Disks with Hardware RAID**

You can also use dynamic disks with hardware-based RAID solutions. Using dynamic disks with hardware RAID can be useful in the following situations:

- You want create a large volume by using software RAID, such as RAID-0, across hardware RAID LUNs.

- You want to extend a volume, but the underlying hardware cannot dynamically increase the size of LUNs.

- You want to extend a volume, but the hardware has reached its maximum LUN size.

Before converting hardware RAID disks to dynamic disks, review the following restrictions:

- You cannot use dynamic disks on shared cluster storage. However, you can use the DiskPart command-line tool to extend basic volumes on shared cluster storage. For more information, see "Extend a basic volume" in Help and Support Center for Windows Server 2003.

- If you create a software RAID-0 volume across multiple hardware arrays, you cannot later extend the RAID-0 volume to increase its size. If you anticipate needing to extend the volume, create a spanned volume instead.

**Preparing to Upgrade Servers That Contain Multidisk Fault-Tolerant Volumes**

Servers running Microsoft® Windows NT® Server version 4.0 can contain volume sets, mirror sets, stripe sets, and stripe sets with parity created by using the fault-tolerant driver Ftdisk.sys. To encourage administrators to begin using dynamic volumes, Windows 2000 offers limited support for Ftdisk volumes. Completing this transition, Windows Server 2003 does not support multidisk volumes. If you plan to upgrade a server that contains multidisk volumes, review the following issues:

- If you are upgrading from Windows NT Server version 4.0 to Windows Server 2003, back up and then delete all multidisk volumes before upgrading. This is necessary because Windows Server 2003 cannot access these volumes. Be sure to verify that your backup was successful before deleting the volumes. After you finish upgrading to Windows Server 2003, create new dynamic volumes, and then restore the data from your backup.

- If you are upgrading from Windows NT Server 4.0 to Windows Server 2003, and the paging file is located on a multidisk volume, you must use **System** in Control Panel to move the paging file to a primary partition or logical drive before beginning Setup. For more information about moving the paging file, see article 123747 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?linkid=99315).

- If you are upgrading from Windows 2000 Server to Windows Server 2003, you must use the Disk Management snap-in to convert all basic disks that contain multidisk volumes to dynamic disks before beginning Setup. If you do not do this, Setup does not continue. For information about converting basic disks to dynamic disks, see "Change a basic disk into a dynamic disk" in Help and Support Center for Windows Server 2003.

For more information about multidisk volumes, see Storage Technologies Collection (http://go.microsoft.com/fwlink/?linkid=4681).

# Achieving Fault Tolerance by Using Clustering

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Many organizations require that critical data be continuously available. Cluster technology provides a means of configuring storage to help meet that goal. Simply put, a cluster is two or more computer systems that act and are managed as one. Clients access the cluster by using a single host name or IP address; their request is answered by one of the systems in the cluster.

The purpose of cluster technology is to eliminate single points of failure. When availability of data is your paramount consideration, clustering is ideal. Using a cluster avoids all of these single points of failure:

- Network card failure
- Processor failure
- Motherboard failure
- Power failure
- Cable failure
- Storage adapter failure

With a cluster, you can essentially eliminate nearly any hardware failure associated with using a single computer. If hardware associated with one system fails, the other system automatically takes over. Two types of clustering solutions that accomplish this are *server clusters* and *Network Load Balancing clusters*. Both types of clustering are available on Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition. In addition, Network Load Balancing clusters are available on Windows Server 2003, Web Edition and Windows Server 2003, Standard Edition.

**Server Clusters**

Server clusters are often implemented to offer high availability solutions to applications that need both read and write access to data, such as database, e-mail, and file servers. Server clusters can be configured with up to eight computers, or nodes, participating in the cluster. To share the same data source, server cluster nodes connect to external disk arrays by using either a SCSI or Fibre Channel connection. Fibre Channel is required for interconnecting clusters of three or more nodes to shared storage. For the 64-bit versions of Windows Server 2003, you must always use Fibre Channel hardware to connect the nodes to shared storage.

When planning to deploy server clusters in your storage solution, you must take into account the following considerations:

- The boot and system disks of each cluster node must not be located on the same storage bus as the shared storage devices, unless you use a Storport driver for your HBAs.
- Shared cluster disks cannot be configured as dynamic disks.
- Shared cluster disks must be formatted as basic disks with the NTFS file system.
- For the 64-bit versions of the Windows Server 2003 family, the shared cluster disks must be partitioned as master boot record (MBR) and not as GUID partition table (GPT) disks.
- You cannot use Remote Storage with shared cluster storage.
- You should not enable write caching on shared cluster disks unless they are logical units on an external RAID subsystem that has proper power protection (such as multiple power supplies, multiple feeds from the power grid, or adequate battery backup).
- Because cluster disks must be basic disks, you cannot use software RAID. For disk fault tolerance, you must use a hardware-based RAID solution.

For more information about server clusters, see "Designing and Deploying Server Clusters" in this book.

**Network Load Balancing Clusters**

Network Load Balancing clusters maintain their own local copy of data and are ideal for load balancing access to static data, such as Web pages. Up to 32 computers can participate in a Network Load Balancing cluster. Because they manage their own local data, Network Load Balancing clusters are much easier to plan and implement. By using the Network Load Balancing Manager, you can quickly configure all Network Load Balancing clusters in your enterprise from a single server.

Using Network Load Balancing clusters is the best choice for several data availability needs. For any server that has difficulty meeting the load demands of its clients, Network Load Balancing is an ideal solution, and is commonly used to provide fault tolerance and load balancing for:

- Web Servers
- FTP Servers
- Streaming Media Servers
- VPN Servers
- Terminal Servers

For each of these, Network Load Balancing is ideal, not only because it is easy to implement, but also because of how easily a Network Load Balancing cluster can scale as your company grows. Because of their simple scalability, your initial estimates of the number of servers you will require need not be perfect with Network Load Balancing clusters. As the load on a Network Load Balancing cluster grows, you can balance the increased load by simply adding additional hosts to the cluster.

Because each Network Load Balancing cluster host maintains its own local copy of storage, storage planning with Network Load Balancing clusters is not as complex as with server clusters. Many of the disk restrictions of server clusters do not apply to Network Load Balancing clusters. The general storage considerations for Network Load Balancing cluster planning are:

- Network Load Balancing cluster hosts can use any local storage space, including space on boot or system volumes.
- Local storage can consist of basic and dynamic disks.
- Hardware or software RAID can be used to add additional fault tolerance. If the Network Load Balancing cluster services a high level of traffic and you need disk fault tolerance, you must use hardware RAID.

For more information about Network Load Balancing clusters, see "Designing Network Load Balancing" and "Deploying Network Load Balancing" in this book.

# Planning for Disaster Recovery

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A number of technologies are available that provide fault tolerance in the event of a failure, such as fault tolerant disk configurations with hot swappable drives, server clusters, and uninterruptible power supplies, However, all of these high availability technologies cannot substitute for having a reliable backup of mission-critical data.

In a complete site disaster, for example, it is possible that both online and offline availability technologies are destroyed (for example, all cluster nodes and all disks in a RAID array). Following such a system failure or disaster at a particular site, you must be able to recover data and systems from backup. Recovering systems or sites from failure is a daunting task, unless you have thoroughly planned and prepared by implementing scheduled backups, providing for backups of open files, and configuring for Automated System Restore. You must also thoroughly test your ability to restore data. The tasks involved in planning for disaster recovery are shown in Figure 1.10.

**Figure 1.10 Planning for Disaster Recovery**

# Planning a Backup Schedule

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The backup schedule is perhaps the most important consideration when planning for disaster recovery. It is critical to plan your backups around your restore requirements. For example, you run only incremental backups of a file server over an extended period of time. This approach delivers very fast backups that use little network bandwidth. However, to restore the server, you would need to restore all of the incremental backups, which could take days to complete. A backup plan presumes a restore plan: Your backup plan should always be based on your requirements for restoring data. You should carefully test and document all of the processes and time required to fully recover your servers from backup data. Use the results of this testing to establish the requirements for your backup schedules.

# Backup Decision Points

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To plan an effective backup schedule that meets your organization's data protection and recovery requirements, consider both the available backup types and your restore plan. When considering backup types, remember that your choice must accommodate restoring a system within the time specified in your restore plan. Available backup types can be categorized as fundamental and advanced.

**Fundamental Backup Types**

The fundamental backup types available are:

- **Full.** Full backups are the baseline for all other backups, and contain all the data on a system (or all the data in the folders or volumes that are defined to be backed up). Because full backups secure all server data, frequent full backups can provide you with greater guarantees as to the speed and success of restore operations. Remember that when you add additional backup types to the backup set, restore jobs are prolonged.

- **Incremental.** An incremental backup stores all files that have changed since the last backup, regardless of the backup type. The advantage of incremental backups is that they take the least time to complete. However, during a restore operation, each incremental backup in the backup set is applied, which could result in a lengthy restore job.

- **Differential.** Differential backups contain all data that has changed since the last full backup. The advantage of differential backups is that they can shorten restore time compared to a backup set that includes just full and incremental backups. However, if you perform too many differential backups within a single backup set, the size of the differential backup might grow to be as large as the baseline full backup.

- **Copy.** Copy backups are identical to full backups, with the exception that they do not mark files as backed up, and thus do not impact any other backup types. A full backup marks the beginning of a new backup cycle, while a copy backup does not. Copy backups are most frequently used to create offsite copies of backup data. In this way, you can maintain a local full backup for quick restore purposes, and keep an offsite copy backup for use in the event that your local backup copy is lost.

Your backup schedule should probably include some combination of all backup types. Regular full backups take the longest to complete, but offer the quickest restore performance. Because full backups copy all files defined in the backup job, they also consume the most backup media. Incremental backups consume the least backup media and take the shortest time to complete; however, they result in lengthier restores. Consequently, it is best to balance each of the backup types so as to satisfy your organizations restore needs. For example, you might elect to perform weekly full backups of a crucial file server, and supplement that with daily differential backups, and incremental backups every two hours. This approach gives you a high degree of data protection, while keeping restore time within reasonable boundaries.

**Advanced Backup Types**

Advanced backup types include:

- **Backup applications that leverage the Volume Shadow Copy service.** Backup applications that support the Volume Shadow Copy service can back up open files, and all the backed-up files are from a single point-in-time. For more information about backing up open files, see "Planning to Back Up Open Files" later in this chapter.

- **Server-free backups.** In a server-free backup, a *data mover* on a SAN copies data on a SAN disk to another storage device, such as a library on the SAN. A data mover is software that can reside on a SAN device, such as a switch or router, or on a server connected to the SAN. Because the data mover performs the copy operations, the server can maintain a high level of performance for clients. Server-free backup applications must have a way of creating a point-in-time snapshot, such as by leveraging the Volume Shadow Copy service or by using some other technology.

- **Hardware-based shadow copies.** External storage arrays that support hardware-based shadow copies (also called *snapshots*) can implement Volume Shadow Copy service providers to fully utilize advanced storage array features.

Your choice of how to integrate advanced backup types into your backup schedule will be dictated by your restore requirements. Some systems might require hourly shadow copies, while other, low priority systems might only warrant weekly full backups and daily incremental backups. Your best strategy is to align your backup plan for each system with the restore plan for that system. If the system requires quick recovery of user files, frequent shadow copies are ideal. If the data on the same system is required to be retained for seven years, then you will also need to perform frequent full backups of the system to media that can be stored in an offsite location.

For more information about backup and recovery planning, see the *Storage Technologies Collection* of the *Windows Server 2003 Technical Reference* (or see the Storage Technologies Collection on the Web at http://www.microsoft.com/reskit).

# Planning to Back Up Open Files

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Open files are files that are normally skipped during the backup process. This is usually because the files are locked by a service or application, such as an operating system, word processing program, or application database. In Windows 2000 and Windows NT 4.0, if the operating system could not back up a file that was locked by an application, the file was skipped, and thus not backed up. In Windows Server 2003, open files are backed up by using the Volume Shadow Copy service.

When a backup is initiated by an application that can use the Volume Shadow Copy service, such as the Backup program in Windows Server 2003, the Volume Shadow Copy service makes a shadow copy of the volume to be backed up. The shadow copy constitutes a read-only copy of the volume data that is read by the backup application during the backup job. Applications can continue to access the files on the volume itself, uninterrupted by the backup. After the backup is completed, the shadow copy of the volume is deleted, because it is no longer needed. The backed-up data is stored on the backup media.

By default, Windows Server 2003 temporarily consumes free disk space on a volume for the shadow copy. The amount of disk space consumed depends on the amount of data that changes on the volume during the backup.

In the event that a shadow copy is unsuccessful, for example, when there is not enough temporary disk space available on the volume, Backup continues without using shadow copy techniques and, as in previous versions of Windows, reads files from the original volume and does not back up any open files.

To take advantage of open-file backups, purchase a backup application that works with the Volume Shadow Copy service.

# Planning for Bare Metal Restores with ASR

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Automated System Recovery (ASR) is a new tool for use with Backup (NTBackup.exe) and other programs created by ISVs. It has a limited but critical purpose: to help you automatically restore your system after a system failure. Previously, restoring the complete system required that you first reinstall the operating system and then restore the data. With a bare metal restore, you can boot a system from the operating system CD, and then use an ASR floppy disk to recover the system directly from a backup.

ASR works with Windows Setup to rebuild the storage configuration of the physical disks and writes the critical operating system files to the boot and system partitions in order to allow the system to boot successfully. This process is referred to as a *bare metal restore*, because the system is restored to hardware that has no installed software. The process uses an ASR floppy disk that defines the state of the storage prior to the disaster and the process to be used for restoring the server. After an ASR restore completes, you can restore any needed user or application files.

# How ASR Works

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

ASR represents a new approach to backup and recovery. Prior to ASR, after a large-scale failure, you needed to reinstall Windows, configure all physical storage to the original settings, and then perform a complete restore of the data. The process of rebuilding the operating system could be lengthy, and you needed to perform many of these tasks at the local computer. ASR significantly automates this process. In addition to automating the restore of a single system, ASR can be used with Remote Installation Services (RIS) to automate the system state recovery of several systems across the network.

To prepare for ASR recovery, you must run the Automated System Recovery Wizard, which is part of Backup. To access this wizard when you are running Backup in Advanced Mode, click **Tools** and select **ASR Wizard**. You can start Backup in Advanced Mode by clearing the **Always start in Wizard Mode** check box when Backup starts.

The wizard backs up the operating system boot volumes and system volumes, but does not back up other volumes, such as program or data volumes. To secure data on other volumes, you must back up those volumes separately by using Backup or another backup tool. You can, however, choose to back up **All information on this computer** when running Backup. This option creates a full backup of your entire system, including ASR data. This means that you can recover the entire system through the ASR process in the event of failure.

When an ASR restore is initiated, ASR first reads the disk configurations from the ASR floppy disk and restores all disk signatures and volumes on the disks from which the system boots. In the ASR process, these are known as *critical disks*, because they are required by the operating system. Noncritical disks — disks that might store user or application data — are not backed up as a part of a normal ASR backup, and are not included in an ASR restore. If these disks are not corrupted, their data will still be accessible after the ASR restore completes. If you want to secure data on noncritical disks from disk failure, you can do so by backing it up separately.

After the critical disks are recreated, ASR performs a simple installation of Windows Server 2003 and automatically starts a restore from backup using the backup media originally created by the ASR Wizard. During an ASR restore, any Plug and Play devices on the system are detected and installed.

Before performing an ASR restore, ensure that the target system to which the restore will be made meets the following requirements:

- The target system hardware (except for hard disks, video cards, and network adapters) is identical to that of the original system.
- There are enough disks to restore all the critical system disks.
- The number and storage capacity of the critical disks are at least as great as those of the corresponding original disks.

**Caution**

- Do not depend on ASR to back up and recover user data files stored on the boot and system volumes. In addition, because your system volume is formatted during the ASR recovery process, any user files or directories located on those volumes are lost.

You normally access the ASR state file (Asr.sif) through a local floppy disk drive. If the computer does not have a floppy disk drive, or you want to perform an ASR restore over a network or remotely, you can use a Remote Installation Services (RIS) server to fully automate the ASR process. RIS uses Pre-boot eXecution Environment (PXE) technology to enable client computers without an operating system to boot remotely to a RIS server that performs installation of a supported operating system over a TCP/IP network connection. Consequently, the remote installation client computer must have a PXE-enabled network adapter.

For more information about using RIS to perform remote installations, see "Designing RIS Installations" in *Automating and Customizing Installations* of this kit.

**Note**

- ASR behaves differently from the Emergency Repair Disk feature in Windows 2000 Server, which ASR replaces. Emergency Repair Disk replaces missing or corrupt system files without formatting drives or reconfiguring storage. ASR,

by contrast, always formats the boot volume and might format the system volume.

# Guidelines for Using ASR

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To successfully use ASR in your disaster recovery plan, you should include the following guidelines:

- Run ASR backup regularly, preferably by using automatic settings.
- Plan for making the required resources, including tape backup drives and removable and hard disks, available for ASR recovery.
- Perform any needed file system conversions before running your first ASR backup.
- Plan for conditions that might prevent a fully successful ASR restore.

  Under the following conditions, ASR might not be able to restore all disk configurations

  - If a critical volume is not accessible during an ASR restore, the restore will fail.
  - Noncritical disks that are a part of the ASR backup are not restored if they are not found during the ASR restore, but the balance of the restore will complete successfully. Disk types that might not appear to the restore process include IEEE 1394, USB, or Jaz disks.
- Plan to protect the critical files Asr.sif and Asrpnp.sif generated by Backup and copied to your ASR floppy disk.

  If the ASR floppy disk that contains these files is lost, you can recover the files from the *systemroot*\Repair folder on the host system. If these files are not accessible on the original host, you can recover them from the ASR backup media by using another system. By storing these files in three locations — the ASR floppy disk, the Repair folder, and on ASR backup media — you have three levels of protection against their loss.

For more information about ASR, see the *Storage Technologies Collection* of the *Windows Server 2003 Technical Reference* (or see the Storage Technologies Collection on the Web at http://www.microsoft.com/reskit) and see "Automated System Recovery (ASR) overview" in Help and Support Center for Windows Server 2003.

# Testing Restores

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The single most overlooked aspect of disaster recovery planning is testing restores. Receiving confirmation that a backup completed successfully does not guarantee that a backup can be restored. To prepare for recovery and to validate backup data, you should periodically test your backups of mission-critical servers. If a server cannot be taken offline for testing restores, you can instead restore its backup data to a test server. Practicing restore operations allows you to prepare for problems that you might encounter when recovering a complete system after a failure. These problems include the following:

- When restoring to a new server with different hardware — for example, if the original server used SCSI storage and the server where you restore the data uses IDE storage — you might need to filter files such as Boot.ini from the restore job. If the restored data replaces the Boot.ini file, the system might not be able to boot following the restore, and the parameters in the restored Boot.ini file would need to be modified.

- When restoring to a new server with different hardware, you might need different drivers, such as drivers for the network adapter or video adapter. Make sure that these drivers are available during the restore.

- The time required to restore data might exceed the time allotted in your recovery plan, which means you must change your backup schedule, your process, or your equipment to improve the speed of the restoration.

- Backup media might be corrupt. Your disaster recovery plan should specify preventive measures (such as redundant backups), and indicate the procedures to follow in the event of corrupt media (such as the location of any redundant backups, or whether out-of-date backups are to be used).

Testing restores can help you plan how to deal with such problems. For example, if your organization requires that a critical file server be returned to full operation within a four hour window, but your test restore took six hours to complete, you can plan to either adjust your backup schedule or else justify the purchase faster backup media drives or network components. Without thoroughly testing your restore procedures, you cannot conclusively document recovery procedures or recovery time, both of which are crucial to your organization's disaster recovery plan.

# Additional Resources for Planning for Storage

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Related Tools**

- Diskraid.exe

  Use Diskraid.exe to manage and configure RAID subsystems that have the necessary VDS hardware providers. For more information about Diskraid.exe, in Help and Support Center for Windows Server 2003 click **Tools**, and then click Command-line reference A-Z.

- Diskpart.exe

  Use Diskpart.exe to manage disks and volumes from the command line. For more information about Diskpart.exe, in Help and Support Center for Windows Server 2003 click **Tools**, and then click Command-line reference A-Z.

# Designing and Deploying File Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

File servers running the Microsoft® Windows® Server 2003 operating system are ideal for providing access to files for users in medium and large organizations. Windows Server 2003 offers a number of file server solutions, such as Distributed File System (DFS), File Replication service (FRS), Windows server clusters, NTFS permissions, disk quotas, and shadow copies, for enhancing the manageability, scalability, availability, and security of file servers.

**In This Chapter**

Overview of Designing and Deploying File Servers

Identifying File Services Goals

Designing DFS Namespaces

Planning File Server Availability

Designing a Standard File Server Configuration

Planning File Server Security

Deploying File Servers

Additional Resources for Designing and Deploying File Servers

# Overview of Designing and Deploying File Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

File servers provide users a way to access shared data within their department or organization. The simplest way to create a file server is to share a folder on a server. However, this solution does not provide file server manageability, scalability, availability, or security. To achieve these goals, you can deploy the following Windows Server 2003 solutions:

**Shadow copies** If users frequently require administrators to restore deleted or overwritten files from tape, shadow copies provide point-in-time copies of files in shared folders, allowing users to recover files that were accidentally deleted or overwritten.

**DFS** If users need to access files on multiple file servers without having to keep track of all the server names, you can use DFS to logically group physical shared folders located on different servers by transparently connecting them to one or more hierarchical namespaces. DFS also provides fault-tolerance and load-sharing capabilities.

**FRS and Windows server clusters** Windows Server 2003 provides two independent solutions, FRS and server clusters, to ensure that important business data is always available, even if a server fails or is taken offline for maintenance.

**Disk quotas** By using the disk quotas feature in Windows Server 2003, you can track files on a per-volume, per-user basis to monitor disk space use and to prevent file servers from filling to capacity without warning.

**NTFS permissions** To prevent unauthorized users from accessing folders, you can use NTFS file system permissions to specify the groups and users whose access you want to restrict or allow and then select the type of access.

You can use the following information to design your organization's file services. Or, if your organization already has file servers running Microsoft® Windows® NT 4.0 or Microsoft® Windows® 2000 operating systems, you can use the following information to improve the design of your existing file services to take advantage of the new and enhanced features in the Microsoft® Windows® Server 2003, Standard Edition; Windows® Server 2003, Enterprise Edition; and Windows® Server 2003, Datacenter Edition operating systems.

# File Server Design and Deployment Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Figure 2.1 outlines the general process of file server deployment. This process consists of a design phase and a deployment phase. A file services designer or design team performs the design process. The file services deployment team implements the design by deploying file servers running Windows Server 2003 and configuring the file services solutions described in this chapter. Because some features of DFS and FRS require the Active Directory® directory service, this process assumes that your organization already has an existing Active Directory infrastructure.

**Figure 2.1 Designing and Deploying a File Server**

# New and Enhanced File Server Features in Windows Server 2003

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The following sections summarize the new and enhanced features in Windows Server 2003 that are described in this chapter.

**Shadow copies**
The shadow copy feature provides point-in-time copies of files on a volume, allowing users to view the contents of shared folders as they existed at points of time in the past. After you enable this feature, users can recover files that they accidentally delete or overwrite.

**DFS enhancements**
Windows Server 2003 includes the following DFS enhancements:

- You can create multiple DFS roots on servers running Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition.
- You can configure DFS to choose an alternate target based on the lowest connection cost if no same-site targets are available.
- You can use the Distributed File System snap-in to choose replication topologies that complement your network infrastructure.
- You can move a root target or a link target from one Active Directory site to another, and DFS will update the root or link information for the new site within 25 hours.
- To reduce network traffic to the server acting as primary domain controller (PDC) emulator master, you can configure DFS to get namespace updates from the closest domain controller, instead of from the server acting as the PDC emulator master. This mode is known as *root scalability mode*.
- By using the Offline Files feature, you can make shared folders that correspond to DFS link targets available offline to clients running Microsoft® Windows® XP Professional and Windows Server 2003. (You cannot make DFS link targets available offline to clients running Windows 2000.)

**FRS enhancements**
Windows Server 2003 includes the following FRS enhancements:

- FRS detects and suppresses excessive replication.
- FRS manages the staging directory to prevent it from becoming full.
- FRS supports connection priorities, which allow you to control the sequencing of the initial synchronization that occurs when you add a new member to the replica set or when you perform a *nonauthoritative restore*, which is used to bring a failed replica member back into synchronization with its partners.

**Security enhancements**
When you share a folder, the default permission is the Read permission for the Everyone group. This default is different from the default share permission in Windows 2000, which was the Full Control permission for the Everyone group.

**Server cluster enhancements**
Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition include the following server cluster enhancements:

- You can store encrypted files by using Encrypting File System (EFS) on cluster storage.

- You can create multiple stand-alone DFS roots on a clustered file server, and the roots can reside on any of the nodes in the cluster.

- You can enable client-side caching to cache files from a cluster file share onto client computers. Clients can then access these files even when the client computer is disconnected from the network.

# Identifying File Services Goals

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Some of the major steps for designing and deploying file servers might not apply to your organization. Therefore, the first step in the design process is to identify the goals that you want to achieve by deploying file servers running Windows Server 2003, as shown in Figure 2.2. These goals determine the design and deployment steps that are necessary for your organization.

**Figure 2.2 Identifying File Services Goals**

The following sections describe common goals for file services. Use the information in these sections to identify the goals for your organization and to find the relevant sections in this chapter or other sources of information to help you achieve those goals.

**Improving the way users access files on file servers**

If you want to improve how users access files on file servers, you might have the following goals:

- Providing an intuitive way for users to access multiple file servers throughout the organization.
- Making data on multiple file servers appear as though it were available on a single file server.
- Making data available in multiple sites so that users in each site use fast, inexpensive bandwidth to access the data.
- Reducing delays that occur when users access heavily used shared folders.
- Providing fault-tolerant access to shared folders.
- Consolidating file servers or migrating data without affecting how users locate data.

For more information about improving how users access files on file servers, see "Designing DFS Namespaces" later in this chapter.

**Managing applications and user data and settings**

If you are managing applications, user data, and settings, you might have the following goals:

- Enabling users to access files even when they are not connected to the network.
- Storing application files on file servers so that users can install the applications from the network to their local workstations.
- Using Group Policy–based software management to deploy, upgrade, update, and remove users' applications without

going to individual workstations.

- Allowing users to run applications from the file server.

For more information about managing applications and user data and settings, see "Implementing User State Management" and "Deploying a Managed Software Environment" in *Designing a Managed Environment* of this kit. For more information about hosting applications in a central location, see "Hosting Applications with Terminal Server" in this book.

**Adding storage to file servers**
If you plan to add storage to file servers, you might have the following goals:

- Transparently adding more storage to a file server.
- Making data on multiple volumes or disks in a file server appear within a single volume or drive letter.
- Creating more than 26 volumes on a server without being limited by the 26-drive letter limit.

For more information about adding storage to file servers, see "Using NTFS mounted drives" in Help and Support Center for Windows Server 2003.

**Planning for file server availability and reliability**
If you are planning for file server availability and reliability, you might have the following goals:

- Choosing file server hardware for reliability and availability.
- Ensuring data availability if a file server fails or is taken offline for maintenance.
- Making data available in multiple sites to provide inexpensive access to users within each site.

For more information about planning for file server availability and reliability, see "Planning File Server Availability" later in this chapter.

**Choosing file server hardware and settings**
If you are choosing file server hardware and settings, you might have the following goals:

- Choosing compatible file server hardware that meets your performance and storage requirements.
- Increasing file server performance.
- Consolidating file servers to reduce management costs and increase storage allocation efficiency.
- Enabling users to access previous versions of files on the file server.
- Monitoring and controlling disk space use.

For more information about choosing file server hardware and settings, see "Designing a Standard File Server Configuration" later in this chapter.

**Planning for file server security**
If you are planning for file server security, you might have the following goals:

- Protecting file servers from viruses.
- Preventing unauthorized users from accessing data on file servers.
- Allowing users to store encrypted files on a file server.

For more information about planning for file server security, see "Planning File Server Security" later in this chapter.

# Designing DFS Namespaces

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Users might have difficulty finding information in shared folders that are located on numerous file servers. Because shared folders are usually associated with physical servers, the user must first determine which physical server is hosting the shared folder. For example, a user might need to access product information about a server named \\Building 4\Marketing2\Prod_Info and on a server named \\Corporate\Floor 4\Sales\Prod_Info.

You can use DFS to address this challenge by consolidating a large set of physical shared folders into one or more virtual namespaces. You do not need to modify the shared folders to add them to the namespace, and users can navigate the namespace without having to know the physical server names or shared folders hosting the data.

Figure 2.3 outlines the general process of designing one or more DFS namespaces. For an Excel spreadsheet to assist you in documenting your DFS namespace design decisions, see "DFS Configuration Worksheet" (Sdcfsv_1.xls) on the *Microsoft® Windows® Server 2003 Deployment Kit* companion CD (or see "DFS Configuration Worksheet" on the Web at http://www.microsoft.com/reskit).

**Figure 2.3 Designing DFS Namespaces**

For more information about DFS security, see "Planning DFS and FRS Security" later in this chapter. For in-depth technical and troubleshooting information about DFS, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

# Deciding Whether to Implement DFS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Organizations of any size, with any number of file servers, can benefit from implementing DFS. DFS is especially beneficial for organizations in which any of the following conditions exist:

- The organization plans to deploy additional file servers or consolidate existing file servers.
- The organization has data that is stored in multiple file servers.
- The organization wants to replace physical servers or shared folders without affecting how users access the data.
- The organization has data located on servers in multiple sites and wants clients to connect to the closest servers.
- Most users require access to multiple file servers.
- Users experience delays when accessing file servers during peak usage periods.
- Users require uninterrupted access to file servers.

Even if you are busy planning your organization's migration to Windows Server 2003, you can make plans to implement DFS without immediately designing your entire namespace. You do not need to deploy DFS all at one time; you can choose to add as much or as little of your organization's physical storage as you need to the DFS namespace, at a pace that works with your overall migration schedule.

When deciding whether to implement DFS, do the following:

1. Review DFS terminology.
2. Review the benefits of using DFS.
3. Evaluate clients and servers for compatibility.

The following sections describe each of these steps.

# Reviewing DFS Terminology

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you are not familiar with DFS, review the following terms and definitions to understand the important elements of a DFS configuration. For visual examples of these concepts, see Figure 2.4 through Figure 2.7 later in this section.

**DFS namespace** A virtual view of shared folders on different servers as provided by DFS. A DFS namespace consists of a root and many links and targets. The namespace starts with a root that maps to one or more root targets. Below the root are links that map to their own targets.

**DFS root** The starting point of the DFS namespace. The root is often used to refer to the namespace as a whole. A root maps to one or more root targets, each of which corresponds to a shared folder on a separate server. The DFS root must reside on an NTFS volume. A DFS root has one of the following formats: *servername**rootname* or *domainname**rootname*.

**Root target** A physical server that hosts a DFS namespace. A domain-based DFS root can have multiple root targets, whereas a stand-alone DFS root can only have one root target.

**Stand-alone DFS namespace** A DFS namespace whose configuration information is stored locally in the registry of the host server. The path to access the root or a link starts with the host server name. A stand-alone DFS root has only one root target. Stand-alone roots are not fault tolerant; when the root target is unavailable, the entire DFS namespace is inaccessible. You can make stand-alone DFS roots fault tolerant by creating them on clustered file servers.

**Domain-based DFS namespace** A DFS namespace that has configuration information stored in Active Directory. The path to access the root or a link starts with the host domain name. A domain-based DFS root can have multiple root targets, which offers fault tolerance and load sharing at the root level.

**DFS path** Any Universal Naming Convention (UNC) path that starts with a DFS root.

**Link** A component in a DFS path that lies below the root and maps to one or more link targets.

**Link target** The mapping destination of a link. A link target can be any UNC path. For example, a link target could be a shared folder or another DFS path.

Figure 2.4 illustrates the elements of a stand-alone DFS namespace in the Distributed File System snap-in. These elements include a stand-alone DFS root, a single root target, and multiple links.

**Figure 2.4 Elements of a Stand-Alone DFS Namespace**

Figure 2.5 illustrates the elements of a domain-based DFS namespace in the Distributed File System snap-in. Notice that the \\Reskit.com\Public root has two root targets on different servers.

**Figure 2.5 Elements of a Domain-based DFS Namespace**

Figure 2.6 illustrates multiple link targets for the Software link. Notice that the link targets exist on three different servers and that the administrator has disabled referrals to the link target on \\dfs-03. DFS will not refer clients to the link target on \\dfs-03 until the administrator enables referrals.

**Figure 2.6 Multiple Link Targets**

The roots and links displayed in the Distributed File System snap-in also appear on each root server's local storage as follows:

- When you create a DFS root, you specify a shared folder to use as the root folder. If you add multiple root targets to a domain-based DFS root, you specify a shared folder on each of those root targets. (The shared folder names should always match the root name.)

- When you add links to the root, DFS creates special folders under each root folder. These folders, called *link folders*, are actually reparse points, and they display the following error message if you try to access them on the local server:

  E:\Public\GroupData is not accessible. The network location cannot be reached.

  Users who access the link folders from across the network are redirected to the appropriate link target.

Figure 2.7 illustrates volume E:\ on the local storage of one of the root targets. The volume contains root and link folders for the \\Reskit.com\Public namespace.

**Figure 2.7 Root and Link Folders**

# Reviewing the Benefits of Using DFS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you evaluate DFS for your organization, it is helpful to understand the benefits that your organization can gain after designing and implementing a DFS namespace. The following list describes the benefits of using DFS:

**Unified namespace** A DFS namespace links together shared folders on different servers to create a hierarchical structure that behaves like a single high-capacity hard disk. Users can navigate the logical namespace without having to know the physical server names or shared folders hosting the data.

**Location transparency** DFS simplifies migrating data from one file server to another. Because users do not need to know the name of each physical server or shared folder that contains the data, you can physically move data to another server without having to reconfigure applications and shortcuts, and without having to re-educate users about where they can find their data.

**Storage scalability** You can deploy additional or higher-performance file servers and present the storage on the new servers as new folders within an existing namespace.

**Namespace scalability** Servers running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition can host multiple domain-based DFS roots and stand-alone DFS roots. This feature improves the scalability of DFS, enabling you to build many large namespaces without having to add file servers to host the roots.

**Increased availability of file server data** When multiple servers running Windows Server 2003 host a domain-based DFS root, clients are redirected to the next available root server if any of these servers fail, providing fault-tolerant data access. To ensure the availability of stand-alone DFS namespaces, you can create the root on a clustered file server.

**Alternate site selection based on cost** By default, if a target in the same site as the users fails, or if no same-site target exists, DFS refers clients to a random target. If you configure the optional site costing feature, DFS can use the site information in Active Directory to locate an alternate target that has the lowest-cost network connection as defined by the administrator in the Active Directory Sites and Services snap-in. After site costing is enabled, clients can access data on DFS targets over the optimum network connection.

**Load sharing** DFS provides a degree of load sharing by mapping a given logical name to shared folders on multiple file servers. For example, suppose that \\Company\StockInfo is a heavily used shared folder. By using DFS, you can associate this location with multiple shared folders on different servers, even if the servers are located in different sites.

**Intelligent client caching** When a user requests access to a target that is a part of a DFS namespace, a referral containing the target's information is cached on the client. The next time the client requires access to that portion of the namespace, the client uses the cached referral instead of obtaining a new referral, and connects directly to one of the target computers. For more information about client caching in DFS, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

**Support for offline folders** If your clients are running Microsoft® Windows® XP or Windows Server 2003, you can make DFS link targets available offline by using the Offline Files feature. You can also use this feature to automatically cache programs so that users can run the programs locally instead of from the server. Using this feature for link targets that host applications can reduce network traffic and improve server scalability.

**Simplified maintenance** If a link has multiple link targets, administrators can perform preventive maintenance, repairs, or upgrades on servers by disabling referrals to specific link targets. While the referral to the link target is disabled, DFS automatically routes new requests to the remaining link targets that are online.

**Dynamic site discovery** DFS now supports dynamic site discovery. In Windows 2000, DFS maintained static site information. After the site information for a particular network resource was known, DFS used that information indefinitely, regardless of any changes in the site information of the resource. In Windows Server 2003, when you move a resource from one site to another, the information used by DFS converges to the new site information within 25 hours.

**Security integration** You do not need to configure additional security for DFS namespaces, because file and folder access is enforced by existing NTFS and share permissions on each link target. For example, a user navigating a DFS namespace is permitted to access only the files or folders for which he or she has appropriate NTFS or share permissions. If you use FRS to replicate content among multiple targets, FRS also replicates access control lists (ACLs) for each file and folder. For more information about DFS and FRS security, see "Planning DFS and FRS Security" later in this chapter.

# Evaluating Client and Server Compatibility

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you implement a DFS namespace, review the types of clients and servers in your organization to make certain that the servers can host targets and that the clients can access targets in the DFS namespace. For example, if you have UNIX clients, they cannot access the DFS namespace and must instead access the files by using the UNC path to the various file servers. Table 2.1 summarizes DFS interoperability.

**Table 2.1 DFS Interoperability**

| Platform | Act as DFS Clients? | Host DFS Roots? | Act as a Link Target? |
|---|---|---|---|
| Microsoft® Windows® Server 2003, Web Edition | Yes | Yes. Can host one stand-alone DFS root or one domain-based DFS root per server. | Yes |
| Windows Server 2003, Standard Edition | Yes | Yes. Can host one stand-alone DFS root or one domain-based DFS root per server. | Yes |
| Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition | Yes | Yes. Can host multiple stand-alone DFS roots and multiple domain-based DFS roots per server. | Yes |
| Windows XP | Yes | No | Yes |
| Windows Preinstallation Environment (WinPE) | Yes | No | No |
| Microsoft® Windows® 2000 Server family* | Yes | Yes, one stand-alone DFS root or domain-based DFS root per server. | Yes |
| Microsoft® Windows® 2000 Professional | Yes | No | Yes |
| Microsoft® Windows NT® Server 4.0 with Service Pack 6a | Yes | Yes, a single stand-alone DFS root per server. | Yes |
| Windows NT Workstation 4.0 with Service Pack 6a | Yes | No | Yes |
| Microsoft® Windows® Millennium Edition (Me) | Yes, client for stand-alone DFS included. Because Windows Me is designed specifically for home use, no domain-based DFS client is provided. | No | Yes |

| | | | |
|---|---|---|---|
| Microsoft® Windows® 98 | Yes, client for stand-alone DFS included; install the Active Directory client extension for Microsoft® Windows® 95 or Microsoft Windows 98 to access domain-based DFS namespaces. | No | Yes |

* Applies to general-purpose servers and Windows Powered Network Attached Storage solutions running Windows Server 2003.

**Note**

- The Active Directory client extension for Windows 95 or Windows 98 is available on the Windows 2000 operating system CD, or see the Active Directory Client Extensions link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

When evaluating client compatibility, review the following important considerations:

- Clients must be members of a domain before they can access a domain-based DFS namespace.

- Link targets can use other protocols, such as NetWare Core Protocol (NCP) for NetWare and Network Filesystem (NFS) for UNIX, but clients must have the appropriate redirector installed to access those link targets.

- In organizations that have a large number of domains, clients might have difficulty accessing link targets in other domains or forests. In addition, clients running Windows 98 might not be able to access any domain-based DFS namespace and might also have difficulty accessing links that point to other DFS namespaces. For more information about clients running Windows 98, see "Designing a DFS Namespace" later in this chapter.

# Choosing the DFS Namespace Type

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When creating a DFS namespace, you create either a stand-alone DFS root or a domain-based DFS root. Table 2.2 describes the differences between domain-based DFS namespaces and stand-alone DFS namespaces.

**Table 2.2 How DFS Namespace Types Differ**

| Characteristic | Domain-based | Stand-Alone |
|---|---|---|
| Path to DFS namespace | *domainname**rootname*<br>*Netbiosdomainname**rootname*<br>*DNSdomainname**rootname* | *servername**rootname* |
| Group memberships required to create and administer namespaces | For DFS administrators who are not members of the Domain Admins group, it is recommended that you delegate permissions so that administrators can create new domain-based DFS namespaces. Administrators must also be members of the local Administrators group on each of the root targets to be able to add and delete links and add and remove the root targets. | DFS administrators must be members of the local Administrators group on the local server to create new stand-alone DFS roots and add or delete links. |
| Where DFS root information is stored | In Active Directory. DFS root information is replicated to all servers that host domain-based DFS roots. | In the registry of the root server. |
| DFS namespace size restrictions | Large domain-based DFS namespaces might cause significantly increased network traffic due to the size of the DFS Active Directory object. As a result, Microsoft recommends using fewer than 5,000 links in domain-based DFS namespaces. | The largest recommended namespace size for a stand-alone root is 50,000 links. |
| Supported methods to ensure DFS root availability | Create multiple DFS root targets in the same domain. | Create a stand-alone DFS root on a clustered file server. |
| Supported methods to ensure link target availability | Create multiple link targets and replicate files by using one of the following methods:<br>• Enabling FRS<br>• Copying files manually or by using scripts<br>• Using a third-party replication tool | Create multiple link targets and replicate files by using one of the following methods:<br>• Copying files manually or by using scripts<br>• Using a third-party replication tool |

**Note**

- For information about DFS namespace size restrictions, see "Reviewing DFS Size Recommendations" later in this chapter.

Use the following guidelines to choose a DFS namespace type.

Choose stand-alone DFS namespaces if:

- Your organization does not use Active Directory.
- You need to create a DFS namespace and are not part of the Domain Admins group, or company policy prevents you from delegating authority to manage a domain-based DFS namespace.
- You need to create a single namespace with more than 5,000 links. (If you can divide your links among two or more namespaces, domain-based DFS is an option.)
- You want to ensure the availability of the namespace by using a clustered file server.

Choose domain-based DFS namespaces if:

- You plan to use FRS to replicate data and you want to use the Distributed File System snap-in to configure and administer replication.
- You want to ensure the availability of the namespace by using multiple root targets.

As described in Table 2.2, you can increase the availability of roots and links in both types of DFS namespaces. For more information and specific guidelines about increasing the availability of roots and links, see "Increasing the Availability of DFS Namespaces" later in this chapter.

# Reviewing DFS Size Recommendations

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As you design your DFS namespace, use the guidelines in Table 2.3 to avoid potential performance problems that can arise when size recommendations are exceeded.

**Table 2.3 DFS Size Recommendations**

| Description | Recommendation* | Explanation |
|---|---|---|
| Path limit | Less than 260 characters | Win32 application programming interfaces (APIs) have a maximum path limit of 260 characters, so applications will fail when trying to access a namespace that goes beyond that limit. If the path length of the DFS namespace exceeds the Win32 API limit of 260 characters, users must map part of the namespace to a drive letter and access the longer namespace through the mapped drive letter. |
| Number of DFS roots per server running Windows Server 2003, Standard Edition | One | Windows Server 2003, Standard Edition is limited to one root per server. |
| Number of DFS roots per server running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition | Varies | There is no limit to the number of DFS roots you can create on a server running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition. However, as you increase the number of roots per server, the Distributed File System service takes longer to initialize and uses more memory. |
| Number of root targets per domain-based DFS root | No fixed limit | If you do not enable root scalability mode, Microsoft recommends using 16 or fewer root targets to limit traffic to the server acting as the primary domain controller (PDC) emulator master. |
| Number of links per DFS namespace | 5,000 for domain-based DFS<br>50,000 links for stand-alone DFS | When the number of links exceeds the recommended limit, you might experience performance degradation when making changes to the DFS configuration. For stand-alone DFS, namespace initialization after server startup might also be delayed. |
| Size of each DFS Active Directory object (applies to domain-based DFS namespaces only) | 5 megabytes (MB) | The size of the DFS Active Directory object is determined by the number and path length of roots, links, comments, and targets in the namespace. Microsoft recommends using no more than 5,000 links in a domain-based namespace to prevent the DFS Active Directory object from exceeding 5 MB. Limiting the size of the Active Directory object is important because large domain-based DFS configurations can cause significantly increased network traffic originating from updates made to those roots, links, and targets. |

* The figures in this table are based on information gathered in a test environment. The numbers in an operational DFS configuration might exceed the numbers described here and still provide acceptable performance.

**Notes**

- You can check the size of an existing DFS namespace by using the following syntax in Dfsutil.exe:
- dfsutil /root:\\domainname\rootname /view (for domain-based DFS)
- dfsutil /root:\\servername\rootname /view (for stand-alone DFS)

- The command output displays the number of links and, for domain-based DFS namespaces, the size of the DFS Active Directory object (described as *blob size*).

If your organization plans to create large namespaces, there are a number of strategies you can implement to work within the size recommendations shown in Table 2.3.

**Keep comments to a minimum**
When you add a root target or link target in the Distributed File Systems snap-in, you can enter comments that describe the target. If you plan to create a large namespace, use minimal comments, if any, because they can increase the overall size of the namespace.

### Note

- Comments are visible only within the DFS administration tools, and they are not visible to users when they navigate the namespace.

**Create multiple namespaces**
If you need to create more than 5,000 links in a domain-based DFS namespace, you can create multiple DFS namespaces that meet the recommended sizes and then link them together. For more information about creating multiple namespaces, see "Designing a DFS Namespace" later in this chapter.

**Enable root scalability mode**
You enable root scalability mode by using the /RootScalability parameter in Dfsutil.exe, which you can install from the \Support\Tools folder on the Windows Server 2003 operating system CD. When root scalability mode is enabled, DFS root servers get updates from the closest domain controller instead of the server acting as the PDC emulator master. As a result, root scalability mode reduces network traffic to the PDC emulator master at the expense of faster updates to all root servers. (When you make changes to the namespace, the changes are still made on the PDC emulator master, but the root servers no longer poll the PDC emulator master hourly for those changes; instead, they poll the closest domain controller.) With this mode enabled, you can have as many root targets as you need, as long as the size of the DFS Active Directory object (for each root) is less than 5 MB. For more information about the 5-MB limit, see the entry describing the size of the DFS Active Directory object in Table 2.3 earlier in this chapter.

Do not use root scalability mode if any of the following conditions exist in your organization:

- Your namespace changes frequently, and users cannot tolerate having inconsistent views of the namespace.

- Domain controller replication is slow. This increases the amount of time it takes for the PDC emulator master to replicate DFS changes to other domain controllers, which, in turn, replicate changes to the root servers. Until this replication completes, the namespace will be inconsistent on all root servers.

### Note

- After you enable root scalability mode in a mixed domain, root servers running Windows Server 2003 can obtain updates from the closest domain controller; however, root servers running Windows 2000 Server still obtain updates from the PDC emulator master.

For information about installing Windows Support Tools, see "Install Windows Support Tools" in Help and Support Center for Windows Server 2003.

**Migrate root servers running Windows 2000 Server to Windows Server 2003**
Root servers running Windows Server 2003 do not add site information to the DFS Active Directory object. As a result, if all root servers run Windows Server 2003, DFS can store more root and link information to the DFS Active Directory object before reaching the recommended 5-MB limit. For more information about using a mix of root servers running Windows 2000 Server and Windows Server 2003, see "Designing a DFS Namespace" later in this chapter.

# Planning the Number of DFS Namespaces

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Your next step is to plan the number of namespaces you want in your domain. For an Excel spreadsheet to assist you in documenting your namespace decisions, see "DFS Configuration Worksheet" (Sdcfsv_1.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "DFS Configuration Worksheet" on the Web at http://www.microsoft.com/reskit).

Medium organizations might require only a single namespace, while large organizations might need multiple DFS namespaces. You can determine the number of namespaces you require by reviewing the following factors.

**Scope of your domain**
If your domain has a broad scope — geographically, organizationally, or functionally — you should plan for multiple DFS namespaces so that administrators in the geographical, organizational, or functional departments can define their own namespaces. On the other hand, if the domain has a narrow scope geographically, organizationally, or functionally, you might want to define a single DFS namespace.

**Size of your DFS namespace**
If your DFS namespace exceeds the recommended number of links per namespace, as discussed earlier in "Reviewing DFS Size Recommendations" create multiple DFS namespaces, each of which does not exceed the recommended size. In this way, you can provide a single namespace to users by creating a single DFS namespace with links that point to other DFS namespaces. For more information about linking from one namespace to another, see "Designing a DFS Namespace" later in this chapter.

**Administrative boundaries**
How DFS namespaces are administered can also affect the number of DFS namespaces your organization requires. For example, your organization might have the following administrative boundaries:

- **Geographic.** Geographically diverse sites can each have an administrator who creates and manages the DFS namespace located in that site.
- **Departmental or group ownership.** Individual departments or groups can create and manage a DFS namespace that is used by members of that department or group.
- **Political.** Individual departments or groups can create and manage a DFS namespace that is used by members of that department or group.

If groups in your organization will create and manage their own DFS namespaces, you can build an extensive DFS namespace out of smaller, more focused DFS namespaces. One benefit of this method is that you can present specific DFS roots to some users as the true top of the hierarchy and also present a set of those DFS roots to other users as the only DFS links in a larger hierarchy. By using a hierarchy of DFS roots, you can scale the namespace as your organization grows and tailor the namespace for distributed management.

For more information about linking from one namespace to another, see "Designing a DFS Namespace" later in this chapter.

**DFS namespace depth**
Limit the depth of DFS namespaces to 260 characters. The 260-character limit includes the fully qualified domain name (FQDN) of the domain hosting the DFS root as well as the DFS root name. If you exceed this limit, applications will fail when trying to access the namespace. To work around this issue, users must map part of the namespace to a drive letter and then access the longer namespace through the mapped drive letter.

# Developing Root and Link Naming Standards

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you roll out DFS, you have the opportunity to implement consistent namespace designs. Developing naming standards first — and ensuring that you adhere to the naming standards during implementation — makes it easier to use and manage any DFS namespace, both from a user perspective and an administrative perspective. Even if you do not expect to implement DFS until a later phase of your Windows Server 2003 deployment, it is important to begin thinking about namespace design early in the planning process. For an Excel spreadsheet to assist you in documenting your DFS namespace design decisions, see "DFS Configuration Worksheet" (Sdcfsv_1.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "DFS Configuration Worksheet" on the Web at http://www.microsoft.com/reskit).

**Creating DFS Root Names**

A DFS root name, significant primarily to users, is the point beyond the server name or domain name that is at the top of the hierarchy of the logical namespace. Standardized and meaningful names at this level are very important, especially if you have more than one DFS namespace in a domain, because the DFS root name is where users enter the namespace. The contents of a DFS namespace must be as clear as possible to the users so that they do not follow the wrong path, possibly across expensive WAN connections, and have to backtrack.

When creating the DFS root names for servers that will contain multiple roots, review the following restrictions:

- Each root requires its own shared folder.
- When you create a domain-based DFS root, the share name in the UNC path *servername**sharename* must be the same name as the DFS root name in *domainname**rootname*. For example, if you want to create a domain-based DFS root \\Reskit.com\Public on Server1, the UNC path to the shared folder must be \\Server1\Public.
- A root cannot be nested within another root. For example, if C:\Root is a shared folder that uses the share name Public, and you use this shared folder as a stand-alone DFS root (*servername*\Public) or domain-based DFS root (*domainname*\Public), you cannot create another root in the folder C:\Root\Software. Similarly, if you create a root by using the root folder C:\, you cannot create another root at C:\Root.
- On server clusters, do not create clustered DFS roots that have the same name as nonclustered DFS roots or shared folders.
- Shared folders on domain controllers must not have the same name as any domain-based DFS roots in the domain. If they do, clients who try to access the shared folder on the domain controller are redirected to the domain-based DFS root. For example, if Reskit.com has a domain controller named DC1 that contains a shared folder named Tools (\\DC1\Tools), do not create a domain-based DFS namespace using a root named Tools (\\Reskit.com\Tools). Otherwise, when users attempt to access \\DC1\Tools, they are redirected to \\Reskit.com\Tools.

**Creating DFS Link Names**

A DFS link is a component in a DFS namespace that lies below the root and maps to one or more link targets. Because DFS link names are exposed to users, it is important to develop standardized, meaningful names for DFS links. Another important design goal is to develop a DFS namespace that provides intuitive navigation within the hierarchy that the namespace represents. Keep in mind that comments entered in the Distributed File System snap-in are not visible to users. For this reason, the namespace must be as clear as possible at all levels.

Designing a clear naming scheme is even more important for a DFS namespace than for a physical namespace, because a user might jump to a shared folder on a different file server when he or she selects a link in the DFS namespace. As a result, a session has to be set up with that physical server (if one does not already exist), which might delay access. Therefore, you want to minimize the number of times that users traverse a wrong path. Clear and meaningful naming standards can help.

Try to keep links at the same level in the DFS namespace consistent in context. For example, you probably would not want to have links named New York, Seattle, and Milan mixed with other links named Sales, Marketing, and Consulting. To help you create a consistent namespace, DFS supports adding one or more folder names to the link name so that you can create a meaningful hierarchy of link names. In the previous example, you could create links such as the following:

- Branches\New York, Branches\Seattle, and Branches\Milan

- Departments\Sales, Departments\Marketing, and Departments\Consulting

When users browse this namespace, they will see a folder called Branches and another called Departments, which they can use to navigate to folders for branch offices (New York, Seattle, and Milan) and departments (Sales, Marketing, and Consulting).

**Note**

- If you want to encourage users to access the DFS namespace instead of going to individual servers, you can use a dollar sign ($) at the end of the shared folder name to hide it from casual browsers. The shared folder will still appear in the DFS namespace with the link name you specify. Doing so prevents users from accessing the shared folders by specifying individual server names. Instead, users must access the shared folders by using the namespace, which enables DFS to load share requests across multiple link targets and allows clients to be directed to another link target if the previously used target is unavailable.

# Designing a DFS Namespace

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As you design one or more DFS namespaces for your organization, you need to make a number of decisions about the structure and capacity of the namespaces. For an Excel spreadsheet to assist you in documenting your DFS namespace decisions, see "DFS Configuration Worksheet" (Sdcfsv_1.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "DFS Configuration Worksheet" on the Web at http://www.microsoft.com/reskit).

**Determining Who Can Manage the Namespace**

You can delegate administrative authority to individual users so that they can manage a DFS namespace. Table 2.4 describes the permissions and group memberships that you must delegate before users can manage a namespace on a member server. Administering DFS namespaces on a domain controller or configuring FRS replication requires membership in the Domain Admins group.

**Table 2.4 Permissions or Group Memberships Required to Administer DFS Namespaces**

| Task | Permissions or Group Membership Required |
|---|---|
| Creating or removing a domain-based DFS root on a member server. | One of the following:<br>• Membership in the Domain Admins group.<br>• Full Control permission on the DFS-Configuration container in Active Directory and membership in the local Administrators group on the root server. |
| Adding or removing a root target from an existing domain-based DFS root on a member server. | One of the following:<br>• Membership in the Domain Admins group.<br>• Full Control permission on the DFS-Configuration container in Active Directory and membership in the local Administrators group on the root server. |
| Creating or deleting a stand-alone DFS root on a member server. | Membership in the local Administrators group on the root server. |
| Adding a link to a domain-based DFS namespace or adding a target to an existing link on a member server. | Membership in the local Administrators group on each of the root target servers. |
| Removing a link from a domain-based DFS namespace or removing a target from an existing link on a member server. | Membership in the local Administrators group on each of the root target servers. |
| Changing root-related or link-related information, such as comments, referral status, and cache limits on a member server. | Membership in the local Administrators group on each of the root target servers. |
| Performing any of the tasks in this table on a domain controller. | Membership in the Domain Admins group. |
| Enabling replication on links in a domain-based DFS namespace. | • Membership in the Domain Admins group. |

You can also limit delegated authority to just one domain-based DFS namespace on a member server by granting a user or group Full Control permission on the DFS root object contained in the DFS-Configuration container. Doing so allows the administrator to add or remove root targets from a specific namespace. For more information about how to delegate

permission to manage a DFS namespace, see "Deploying DFS" later in this chapter.

**Selecting Servers to Host Roots**

Table 2.5 describes the guidelines for servers hosting stand-alone DFS roots and domain-based DFS roots.

**Table 2.5 Guidelines for Servers That Host DFS Roots**

| Server Hosting Stand-Alone DFS Roots | Server Hosting Domain-based DFS Roots |
|---|---|
| • Must contain an NTFS volume to host the root.<br>• Can be a member server or domain controller.<br>• Can be a general-purpose server or Windows Powered Network Attached Storage.<br>• Can be a clustered file server. | • Must contain an NTFS volume to host the root.<br>• Must be a member server or domain controller in the domain in which the DFS namespace is configured. (This requirement applies to every root target for a given domain-based DFS namespace.)<br>• Can be a general-purpose server or Windows Powered Network Attached Storage.<br>• Cannot be a clustered file server unless you host the domain-based DFS root on the local storage of a node in the server cluster. |

The following sections provide other factors to consider when selecting root servers.

**Restrictions for servers running Windows Server 2003, Standard Edition**

If you are using servers running Windows Server 2003, Standard Edition, you can create only one DFS root per server, which means that you need one server for each root you plan to host.

**Root servers that have the RestrictAnonymous registry value**

Before you create a DFS root on a server, verify that the RestrictAnonymous registry value is not set on the server. This registry value restricts anonymous access and causes DFS referral failures. For more information about this registry value, see "Planning DFS and FRS Security" later in this chapter.

**Root server performance**

When evaluating the hardware specifications of the servers that host roots, note that clients access the root server to get referrals, and then the clients cache the referrals locally. Therefore, root servers do not typically experience high CPU usage. However, as the size of the namespace grows, the DFS service uses more memory, so consider using more than the minimum recommended RAM for servers that host large DFS namespaces and for servers that host multiple DFS namespaces. For more information about choosing RAM and CPU speed for file servers, see "Determining RAM and CPU Specifications" later in this chapter.

**Important**

- Servers running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition can host multiple roots of any type (stand-alone or domain-based). However, as you increase the number of roots (namespaces) on a server, you also increase the number of namespaces that will be unavailable if the server fails. Therefore, devise a plan that allows you to increase the availability of the namespaces. For more information, see "Increasing the Availability of DFS Namespaces" later in this chapter.

**Hosting roots on domain controllers**

When deciding whether to host a DFS root on a domain controller, consider the following factors:

- Only members of the Domain Admins group can manage a DFS namespace hosted on a domain controller.
- If you plan to use a domain controller to host a DFS root, the server hardware must be sized to handle the additional load. As described earlier, root servers that host large or multiple namespaces require additional memory. For information about capacity planning for domain controllers, see "Planning Domain Controller Capacity" in *Designing and Deploying Directory and Security Services* of this kit.

**Using root servers running Windows 2000 Server and Windows Server 2003**

If you plan to host a domain-based DFS root on servers running a mix of Windows 2000 and Windows Server 2003, you need

to understand how DFS handles site information in each of these operating systems. These differences are important because Windows Server 2003 does not store site information in the DFS Active Directory object; instead, root servers running Windows Server 2003 obtain site information directly from Active Directory. If you have root servers running Windows 2000 Server, those servers try to obtain site information from the DFS Active Directory object, and unless you use Dfsutil.exe to manually update the site info in the DFS Active Directory object, the root servers running Windows 2000 Server might provide referrals that lead to a target outside of the client's site.

Table 2.6 describes how DFS root servers handle site information.

**Table 2.6 How Root Servers Handle Site Information**

| Site Difference | Windows 2000 Server | Windows Server 2003 |
|---|---|---|
| Where DFS stores and retrieves site information for root and link targets | DFS stores a copy of site information for root and link targets in the DFS object in Active Directory. | DFS uses IP addresses of root and link targets to obtain site information directly from Active Directory. By default, DFS does not store site information in the Active Directory object. |
| Characteristic of site information | Static | Dynamic |
| Method for updating site information after moving a link target to a different site | Remove the link target from the namespace, and then add it back. | By default, site information automatically updates every 25 hours. |
| How root servers use site information for referrals | Root servers running Windows 2000 Server use the link target's site information only if the link target was created by using Windows 2000 Server. If the link target was created by using Windows Server 2003, no site information is stored, which means that the referral could lead to a target outside of the client's site. | Root servers running Windows Server 2003 ignore any site information in the Active Directory object; instead, they use site information directly from Active Directory. |

Running Windows Server 2003 on every root server is recommended for a number of reasons:

- Site information is always up to date because DFS obtains site information directly from Active Directory instead of storing a copy of site information in the DFS Active Directory object.
- The DFS Active Directory object can hold additional root and link targets because it does not contain site information.

If you want referrals from root servers running Windows 2000 Server to be ordered according to site information, you can use the /UpdateWin2kStaticSiteTable parameter in Dfsutil.exe to update the static site information for all root and link targets in the DFS Active Directory object. If you plan to use this parameter, review the following issues:

- Using this parameter increases the size of the DFS Active Directory object, possibly making it exceed the 5-MB recommended size limit.
- You need to run this parameter each time you want to update site information.
- Root servers running Windows Server 2003 continue to get site information directly from Active Directory, and they ignore all site information in the DFS Active Directory object.

When all root servers are running Windows Server 2003, you can use the /PurgeWin2kStaticSiteTable parameter in Dfsutil.exe to remove site information from the DFS Active Directory object, providing you additional space for creating root and link targets.

**Important**

- If you are using a mix of root servers running Windows 2000 Server and Windows Server 2003, use the version of the Distributed File System snap-in available in either Windows Server 2003 or the Windows Server 2003 Administration Tools Pack to manage the namespace. Do not use the version of the Distributed File System snap-in available in Windows 2000 Server.

**Determine the Root and Link Referral Time to Live Values**

You can use the Distributed File System snap-in to specify the length of time that clients cache referrals to DFS root targets and link targets by adjusting the Time to Live value for each DFS root or link. When a client receives a referral to a target, the client will continue to access that target (either a particular root target or link target) until one of the following occurs: the client computer is restarted, the user clears the cache, or the Time to Live value for the root or link expires. The client will then obtain a new referral the next time it attempts to access the target. However, if the client continues to access the root or link within the Time To Live value, the Time to Live value is renewed each time and the client never requests a new referral. Clients that resume from hibernation do not request new referrals either.

Windows Server 2003 uses a default Time to Live value of 300 seconds (5 minutes) for DFS roots and 1800 seconds (30 minutes) for DFS links. The default Time to Live values work well in organizations where the namespace changes frequently and it is important that clients have up-to-date referrals. When using these values, make sure that your network has adequate bandwidth and your root servers have adequate resources to handle the traffic generated when clients contact the root servers for referrals.

Consider increasing the Time to Live value in the following situations:

- An established root or link has a single link target. In this case, you do not need to load balance requests among multiple servers, so it is appropriate to have a longer Time to Live value for that root or link.

- Your organization has clients in multiple Active Directory sites, but you do not have root servers in all sites. In this situation, you can increase the Time to Live value for the root to ensure that the client does not have to go out of its site for a root referral if more than 5 minutes have passed since the client last accessed the namespace. If your root information is static, you can set this value to be several hours.

For more information about Time to Live values, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

**Determining the Contents of the Root Folder**

The root folder of a DFS namespace is a launch point into the namespace — that is, a placeholder for the namespace. Keep the root folder as uncluttered as possible. For example, you might place a single file in the root folder (a readme file) that describes the contents and purpose of the namespace. When users access the namespace, they will see the readme file and the links that point to one or more link targets. For more information about the root folder, see "Reviewing DFS Terminology" earlier in this chapter.

**Choosing Shared Folders to Add to the Namespace**

Add shared folders to your namespace only if they are well established and unlikely to be retired in the near future. If you have targets whose underlying physical name is dynamic, include them in the DFS namespace only if you can tolerate the added administrative overhead or develop automated scripts to update the DFS links.

To secure files and folders, use NTFS as the underlying file system for shared folders that you add to a DFS namespace. You can add shared folders residing on file allocation table (FAT) volumes in Windows-based servers and shared folders residing on servers running other operating systems, such as UNIX or Novell NetWare servers; however, you cannot use NTFS security features to secure these folders. In addition, if you plan to use FRS to replicate the contents of shared folders, you must use NTFS as the file system.

To help users find data in DFS namespaces more easily, you can publish the UNC path for DFS links as shared folders in Active Directory. For example, if an administrator of the Reskit.com domain wants to publish the DFS link where users can install applications, the administrator can specify \\Reskit.com\Public\Apps as the path to the published folder. The administrator can also specify key words for that shared folder, such as "applications" or "Office." Domain users in a forest can locate the applications by using the Active Directory search tool in My Network Places to query for the application folder by name or key words.

For information about publishing shared folders in Active Directory, see "Publish a shared folder" in Help and Support Center for Windows Server 2003.

**Reviewing Rules for Creating Links**

When designing the namespace, review the following rules regarding link creation.

**Creating new links under existing links**
You cannot create a new link under an existing link. To create a hierarchy of links, specify additional folder names within the link name. For example, instead of creating a link called Groups, create links called Groups\Development, Groups\Management, Groups\Administrative, and so forth.

**Creating links to shared folders in other domains or forests**
If a client can access a link target in another trusted domain or trusted forest by using the target's UNC path, the client can also access the link target by using its DFS path, but only if the list of domains fits into the client's cache, which is 4 KB by default (roughly 2000 characters). If the list of domains is too large to fit into the 4-KB cache, the following actions occur:

- Clients running Windows 98 cannot access any domain-based DFS namespaces. To notify you of this issue, DFS writes an entry with the ID 14537 in the system log in Event Viewer on the domain controller that enumerates the domains.

- Computers running Windows NT 4.0, Windows 2000, Windows XP, and Windows Server 2003 automatically increase their cache size to accept the list of domains, up to a maximum of 56 KB.

If the list of domains exceeds 56 KB, DFS puts as many domains in the cache as it can until the cache reaches 56 KB. DFS then writes an entry with the ID 14536 in the system event log in Event Viewer to notify you of this issue. When populating the cache, DFS gives preference to local and explicitly trusted domains by filling the cache with their names first. Consequently, by creating explicit trust relationships with domains that host important DFS namespaces you can minimize the possibility that those domain names might be dropped from the list that is returned to the client.

**Important**

- To make sure that clients can access link targets in other trusted domains or trusted forests, you must use DNS names for all link targets and configure DFS to use fully qualified domain names in referrals. For more information, see article Q244380, "How to Configure Dfs to Use Fully Qualified Domain Names in Referrals." To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Creating links to mounted drives**
A mounted drive is a local volume attached to an empty folder on an NTFS volume. If C:\Root is a DFS root folder on Server1 (\\Server1\Root), and you create a folder C:\Root\Link1, where Link1 is a mounted drive (for example, Link1 points to drive D), you cannot create a link named Link1 in that DFS namespace.

**Creating links to different namespaces**
Windows Server 2003 supports creating links that point to other DFS namespaces. Linking to other namespaces is common in organizations that want to combine the availability benefits of domain-based DFS namespaces with the scalability of stand-alone DFS namespaces. For example, if an organization needs to create 10,000 links but does not want to divide these between two domain-based DFS namespaces, the organization can take the following steps:

1. Create a stand-alone DFS namespace with 10,000 links.

2. Create a domain-based DFS root.

3. Under the domain-based DFS root, create a link that points to the stand-alone DFS namespace.

When linking to other namespaces, you must follow these guidelines to make certain that clients can be redirected properly if a target is unavailable:

- If you plan to specify a domain-based DFS namespace as a link target (either the root or a link within that namespace), you cannot specify alternate link targets. (Windows Server 2003 enforces this restriction.)

- If you plan to specify a stand-alone DFS namespace as a link target (either the root or a link within that namespace), you can specify alternate link targets that are either stand-alone DFS roots or links within the stand-alone DFS namespace. Do not specify domain-based DFS roots or shared folders as alternate targets.

**Important**

- The DFS tools do not prohibit you from specifying domain-based DFS roots or shared folders as alternate targets. Therefore, follow these guidelines carefully.

When linking to other namespaces, review the following restrictions:

- A DFS path can consist of no more than eight hops through other DFS namespaces.
- Clients running Windows 98 might not correctly access links pointing to other DFS namespaces. Windows 98–based clients can only access the following types of links to other namespaces:
    - A link in a stand-alone DFS namespace that points to a stand-alone DFS root or link.
    - A link in a domain-based DFS namespace that points to a stand-alone DFS root. (This works only if the client has the latest Active Directory client installed, as described in article Q323466, "Directory Services Client Update for Windows 95 and Windows 98." To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

For additional rules for specifying multiple link targets, see "Choosing an Availability Method for Data in Link Targets" later in this chapter.

# Increasing the Availability of DFS Namespaces

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you create your initial namespace design, you need to review that design to determine whether part or all of the namespace needs to be available at all times. You can ensure DFS namespace availability at both the root and link target level. This helps prevent the situation in which the target servers are up and running but users cannot access them by using the namespace.

To increase the availability of DFS namespaces, take the following steps:

1. Choose an availability method for DFS roots.
2. Choose an availability method for data in link targets.
3. Determine where to place multiple targets.
4. Choose a replication method.

The following sections describe each of these steps.

# Choosing an Availability Method for DFS Roots

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you plan to create DFS namespaces that must be highly available, such as those that provide access to business-critical data, the availability method you choose depends on the root type.

**Stand-alone DFS roots**
You ensure the availability of a stand-alone DFS root by creating it on the cluster storage of a clustered file server by using the Cluster Administrator snap-in. For more information about making stand-alone DFS roots highly available, see "Increasing Data Availability by Using Clustering" later in this chapter.

**Domain-based DFS roots**
You ensure the availability of domain-based DFS roots by creating multiple root targets on nonclustered file servers or on the local storage of the nodes of server clusters. (Domain-based DFS roots cannot be created on cluster storage.) All root targets must belong to the same domain. To create root targets, use the Distributed File System snap-in or the Dfsutil.exe command-line tool. (For information about choosing servers to host root targets, see "Designing a DFS Namespace" earlier in this chapter.)

To ensure the availability of domain-based DFS roots, you must have at least two domain controllers and two root targets within the domain that is hosting the root. If you have only one domain controller, and it becomes unavailable, the namespace is inaccessible. Similarly, if you have only a single root target, and the server hosting the root target is unavailable, the namespace is also unavailable.

### Note

- If you plan to use more than 16 root targets, or if you have root servers in remote sites that connect to the PDC emulator master across slow links, consider enabling root scalability mode. For more information about root scalability mode, see "Reviewing DFS Size Recommendations" earlier in this chapter.

After you determine which roots need to be highly available, document your decisions. For an Excel spreadsheet to assist you in documenting the high-availability requirements of DFS roots, see "DFS Configuration Worksheet" (Sdcfsv_1.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "DFS Configuration Worksheet" on the Web at http://www.microsoft.com/reskit).

# Choosing an Availability Method for Data in Link Targets

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As you design your namespace, you need to identify link targets whose data must be highly available. There are two ways to increase the availability of data in link targets:

- Create a single link that points to a link target on a clustered file server.
- Create multiple link targets and replicate content among them.

You can create link targets that point to clustered file servers in both types of namespaces. However, if you want to replicate content among multiple link targets, the type of namespace determines your replication options.

**Using replication in stand-alone DFS namespaces**
In a stand-alone DFS namespace, you must replicate the files by copying them manually, using scripts, using Robocopy.exe, which is available in the *Windows Server 2003 Deployment Kit,* or by using other replication tools. The Distributed File System snap-in does not provide a user interface for configuring FRS replication in stand-alone DFS namespaces. To configure replication manually, consult the documentation supplied with your replication tools.

**Using replication in domain-based DFS namespaces**
The Distributed File System snap-in in Windows Server 2003 provides a user interface for creating the FRS topology and schedule on servers running Windows Server 2003. If you do not want to use FRS in a domain-based DFS namespace, you can replicate files by copying them manually or by using third-party replication tools.

For more information about replication, see "Choosing a Replication Method" later in this chapter.

**Note**

- The Distributed File System snap-in is also part of the Windows Server 2003 Administration Tools Pack; you can install this pack on computers running Windows XP with Service Pack 1 (SP1) or later and create FRS schedules and topologies on remote servers running Windows 2000. For more information, see article Q304718, "Administering Windows 2000-Based and Windows Server 2003-Based Computers Using Windows XP Professional-Based Clients." To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

If you plan to use multiple link targets to ensure data availability, you need to configure link targets correctly. Each link can have targets that correspond to only one of the following options:

- One or more shared folders.
- One or more stand-alone DFS paths anywhere in the stand-alone DFS namespace, including the root.
- A single domain-based DFS path anywhere in the domain-based DFS namespace, including the root.

**Important**

- The DFS tools do not prohibit you from creating links that conflict with these guidelines. Therefore, follow these guidelines carefully.

After you determine which link targets need to be highly available, document your decisions. For an Excel spreadsheet to assist you in documenting which links require multiple link targets, see "DFS Configuration Worksheet" (Sdcfsv_1.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "DFS Configuration Worksheet" on the Web at http://www.microsoft.com/reskit).

# Placing Multiple Targets

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you evaluate where to place multiple targets, you should plan to place at least one target in the same Active Directory site where users access the data. Doing so enables clients to use fast, inexpensive bandwidth to access the target. Use multiple same-site targets to ensure namespace availability in each site and to avoid the need to use expensive bandwidth if one of the same-site targets fails or is taken offline. Using multiple same-site targets also provides load sharing among the targets in the site.

After you determine where to place multiple targets, you also need to consider where clients will be redirected if the primary target is unavailable. DFS supports three methods of target selection, which are described in the following sections. These methods apply to both stand-alone and domain-based DFS namespaces. After you determine the method of target selection for each link or root, document your decisions. For an Excel spreadsheet to assist you in documenting the target selection methods, see "DFS Configuration Worksheet" (Sdcfsv_1.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "DFS Configuration Worksheet" on the Web at http://www.microsoft.com/reskit).

**Important**

- If you have a mix of root servers running Windows 2000 Server and Windows Server 2003, target selection is random if a root server running Windows 2000 Server provides a referral for a link target created in Windows Server 2003, regardless of which target method you configure. For more information about target selection, see "Designing a DFS Namespace" earlier in this chapter.

**Default target selection**

If the last (or only) target in an Active Directory site fails or is taken offline, DFS directs clients to another target in the same site, if a target is available. Clients are directed to a random target if no same-site targets are available. DFS does not consider bandwidth cost, connection speed, or the target server's processing load when choosing the random target.

**Restricted same-site target selection**

By using Dfsutil.exe /InSite parameter, you can limit client access to only those targets that are in the same site as the client. You enable this feature on a DFS root or on individual links in the namespace. If you enable this feature on the root, referrals for any link in the namespace return only targets that are in the same site as the client. If this functionality is disabled on the root, the individual settings on each link are used. When using this feature, plan to have at least one target (or two targets, for fault tolerance) in every site, and plan to monitor servers to make sure they are online and accessible. If no same-site targets exist, clients in that site are denied access to the data in the namespace.

**Note**

- The /InSite parameter takes effect after you stop and restart the Distributed File System service on each root server or when the service reads the DFS metadata, which happens every hour by default.

**Least expensive target selection**

If you create a stand-alone or domain-based DFS root on a server running Windows Server 2003, and the domain controller acting as the Intersite Topology Generator (ISTG) is also running Windows Server 2003, you can use the /SiteCosting parameter in Dfsutil.exe to enable DFS to choose an alternate target based on connection cost if no same-site targets are available. Windows Server 2003 uses the site and costing information in Active Directory to determine whether sites are linked by inexpensive, high-speed links or by expensive WAN links.

Site costing is not available in the following situations:

- When a stand-alone DFS namespace is hosted on a server that is not part of any domain.

- When the closest domain controller acting as the ISTG is running Windows 2000 Server.

  (This situation occurs when there are only domain controllers running Windows 2000 Server in the site of the DFS root server, or when there are no domain controllers in the site of the DFS root server and the closest site with at least one domain controller has only Windows 2000 Server domain controllers in that site. The closest site is defined in Active Directory.)

If you plan to enable site costing, review the following:

- You can enable site costing on a per-namespace basis.

- When the domain controller acting as the ISTG is running Windows 2000 Server, DFS uses the default target selection, described earlier in this section. If domain controllers running Windows 2000 Server and Windows Server 2003 exist in a site, the ISTG role is automatically given to the domain controller running Windows Server 2003.

For more information about defining sites in Active Directory, see "Designing the Site Topology" in *Designing and Deploying Directory and Security Services* of this kit.

# Choosing a Replication Method

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you plan to use multiple targets and you want to synchronize data in those targets, you need to choose a replication method. You have several methods for replicating data:

- A manual replication method (such as using the command-line tool Robocopy.exe, which is available in the *Windows Server 2003 Deployment Kit*)
- FRS
- A third-party replication tool

It is not mandatory to use FRS to keep targets synchronized. In fact, by default, FRS is not enabled for DFS targets in domain-based DFS namespaces. However, in general you do want to make sure that the underlying shared folders that correspond to DFS links and targets are synchronized to present the same data to users, regardless of the folder that they want to access.

The following sections describe when to use manual replication or FRS. For an Excel spreadsheet to assist you in documenting the replication method for each target, see "DFS Configuration Worksheet" (Sdcfsv_1.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "DFS Configuration Worksheet" on the Web at http://www.microsoft.com/reskit). For information about using third-party replication tools, consult the documentation provided by your software vendor.

**When to Use Manual Replication**

If the data in the shared folder is static, you can replicate the data by doing a one-time copy of the data to a target in the replica set. Even if the data in the shared folder is dynamic but changes infrequently, you might want to keep the targets synchronized by downloading the initial copies over the network and then manually updating them with changes. You must use manual replication if you plan to use a stand-alone DFS namespace or if one or more link targets for a particular link do not run Windows 2000 Server or Windows Server 2003.

**When to Use FRS**

FRS works by detecting changes to file and folders in a replica set and replicating those changes to other file servers in the replica set. When a change occurs, FRS replicates the entire file, not just the changed bytes. You can use FRS only if you are using a domain-based DFS namespace, and only servers running a Windows 2000 Server or Windows Server 2003 operating system can be part of a replica set. In addition, all replica sets must be created on NTFS volumes.

FRS offers a number of advantages over manually copying files, including:

**Continuous replication** FRS can provide continuous replication, subject to server and network loads. When a file or folder change occurs, and the file or folder is closed, FRS can begin replicating the changed file or folder to outbound partners (that is, the replica members that will receive the changed file or folder) within five seconds.

**Replication scheduling** You can schedule replication to occur at specified times and durations as needed by your organization. Scheduling replication to occur during evening hours, for example, can reduce the cost of transmitting data over expensive WAN links. Replicating data during off-hours also frees up network bandwidth for other uses.

**Compression** To save disk space, FRS compresses files in the staging directory by using NTFS compression. Files sent between replica members remain compressed when transmitted over the network.

**Authenticated RPC with encryption** To provide secure communications, FRS uses Kerberos authentication protocol for authenticated remote procedure call (RPC) to encrypt the data sent between members of a replica set.

**Fault-tolerant replication path** FRS does not rely on broadcast technology, and it can provide fault-tolerant distribution via multiple connection paths between members. If a given replica member is unavailable, the data will flow via a different route. FRS uses logic that prevents a file from being sent more than once to any given member.

**Conflict resolution** FRS can resolve file and folder conflicts to make data consistent among the replica members. If two identically named files on different servers are added to the replica set, FRS uses a "last writer wins" algorithm, which means that the most recent update to a file in a replica set becomes the version of the file or folder that replicates to the other members of the replica set. If two identically named folders on different servers are added to the replica tree, FRS identifies the conflict during replication and renames the folder that was most recently created. Both folders are replicated to all servers in

the replica set, and administrators can later merge the contents of two folders or take some other measure to reestablish the single folder.

**Replication integrity** FRS relies on the update sequence number (USN) journal to log records of files that have changed on a replica member. Files are replicated only after they have been modified and closed. As a result, FRS does not lose track of a changed file even if a replica member shuts down abruptly. After the replica member comes back online, FRS replicates changes that originated from other replica members, as well as replicating local changes that occurred before the shutdown. This replication takes place according to the replication schedule.

When you use FRS, the link targets might not always be completely synchronized. As a result, one client's view of a link in a DFS namespace can be different from another client's view of the same link. This inconsistency can happen when clients have been referred to different link targets in the namespace. Link targets do become consistent with time, but you might experience temporary inconsistencies due to replication latency when updates are occurring. For more information about using FRS, see "Choosing an Availability Strategy for Business-Critical Data" later in this chapter.

FRS is typically used to keep link targets synchronized. It is also possible to put files and folders directly in a domain-based DFS root target and then enable replication on the root so that the files and folders are replicated to all root targets. However, avoid enabling replication on domain-based DFS roots for the following reasons:

- Morphed folders can occur under the DFS root folder. Morphed folders occur when two or more identically named folders on different servers are added to the replica tree. FRS identifies the conflict during replication, and the receiving member protects the original copy of the folder and renames (*morphs*) the later inbound copy of the folder. The morphed folder names have a suffix of "_NTFRS_xxxxxxxx," where "xxxxxxxx" represents eight random hexadecimal digits.

  Morphed folders occur in replicated roots for the following reason: When you create a link in the namespace, DFS creates a link folder under each root folder on every root server. For example, if you add 1,000 links to a namespace, DFS creates a link folder under the DFS root folder for each of those 1,000 links on every root server. When you enable FRS replication on the root, FRS attempts to replicate its local copy of the folder structure to every root server. Because each root server has a local copy of the same folder structure as the incoming changes, FRS identifies the duplicate folder names and renames the folders that were most recently created. FRS then replicates all morphed folders to all root targets in the replica set.

  **Note**

  - If morphed folders do occur, you must use the /RemoveReparse:<DirectoryName> parameter in Dfsutil.exe to delete each morphed folder. For more information about morphed folders, see "Choosing an Availability Strategy for Business-Critical Data" later in this chapter.

- When adding a new root target to an FRS replicated root, you cannot replicate the contents of individual folders in the root based on business priority. Instead, the entire contents of the root are replicated to the new root target. On the other hand, if you enable replication only on individual links, you are creating multiple replica sets, which allows you to enable replication on the most important links first and then enable replication on the links in the namespace as desired.

- You cannot take individual root targets offline. For example, if you are adding a new root target, users who are referred to the new member might see incomplete data until replication is complete. On the other hand, if you enable replication on individual links, you can take a new link target offline while the initial replication takes place or whenever you want to restrict access to a particular link target.

# Example: An Organization Designs a DFS Namespace

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An organization with 35,000 users in one site designs a stand-alone DFS namespace to provide unified access to 1.4 terabytes (TB) of both business-critical and nonessential software. The team responsible for designing and deploying the namespace chooses a stand-alone DFS namespace for the following reasons:

- The team is not a member of the Domain Admins group, and corporate security policy prevents them from becoming members of this group.
- Corporate security policy also prohibits the team from creating a domain to host a domain-based DFS namespace.

When designing the namespace, the team needs to provide access to the following types of software:

- Business-critical software and operating systems
- Previous (archived) versions of software and operating systems
- Multimedia software that runs from the network
- Training courseware

To ensure the availability of the namespace, the team creates the stand-alone DFS root, \\software\public, on a two-node clustered file server. Each node has two Pentium III 1.26-gigahertz (GHz) CPUs and 256 MB of RAM. The root server does not provide any other services.

When evaluating users' availability requirements for the different types of software, the team determines that the business-critical software and operating systems must be available at all times. In addition, because this is the most frequently accessed software, the team wants good response times. To provide the desired availability and performance, the team uses four servers as link targets. These servers each have two Pentium III 733-MHz CPUs and 256 MB of RAM.

Although the multimedia software is not business critical, the team uses two servers as link targets for this software to improve server response times, because the client portion of the multimedia software accesses files from the server. The team does not use redundant servers for the remaining software, because it is not business critical, and users can tolerate temporary downtime of those servers.

Figure 2.8 describes the DFS namespace for this example.

**Figure 2.8 A Stand-Alone DFS Namespace Used for Software Installation**

When updating software on the \\archsvr, \\mmsoft, and \\trainsvr servers, the team adds new files directly to the servers. To update software on the business-critical \\software servers, the team copies the new files to a staging server, \\stagesvr. The team uses Robocopy scripts on \\stagesvr to copy the data to the \\software servers. By making changes only at the staging server, the team makes sure that no accidental changes are made on the \\software servers. The team also uses the staging server as the backup source, because it contains source files for a number of servers in addition to the \\software servers. The backup team backs up the other servers individually.

To prevent the staging server from becoming overloaded, the team does not make the staging server part of the namespace, so users do not directly access the server. The team also increases the hardware specifications of this server to meet the increased disk and CPU utilization required for copying files to the \\software servers and to support backups. The hardware configuration has four Pentium III Xeon 700-MHz processors and 1 gigabyte (GB) of RAM.

While deploying the namespace in the production environment, the team learned a number of valuable lessons that can help other organizations as they test and deploy their namespaces:

- When setting permissions on the clustered root server, follow the guidelines in "Planning Cluster Security" later in this chapter. Test the clustered root server to verify that permissions work correctly after a failover occurs.

- Be sure to change the Cluster service password as specified by your organization's password policy. Windows Server 2003 does not send notification that the password is about to expire. If the password expires, problems can occur at failover. For more information about Cluster service passwords, see "Change the Cluster service account password" in Help and Support Center for Windows Server 2003.

- Stagger new software announcements so that users do not overload the servers while trying to install new software. For example, send e-mail notification to a percentage of users each day.

# Planning File Server Availability

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you plan for file server availability, begin by ensuring the uptime of the physical file server. Next, determine whether the file server contains business-critical data. If it does, you need to decide whether to use an availability strategy, such as replication or clustering, to ensure the availability of the data. If data on the file server is temporary or not business critical, continue to "Planning File Server Security" later in this chapter.

Figure 2.9 describes the planning process for file server availability.

**Figure 2.9 Planning File Server Availability**

# Planning for File Server Uptime

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The following guidelines provide basic steps to increase the uptime of file servers. For comprehensive coverage of these topics, see "Planning for High Availability and Scalability" in this book.

**Choosing Hardware for Reliability and Availability**
Implement a well-planned hardware strategy to increase file server availability while reducing support costs and failure recovery times. You can choose hardware for reliability and availability by following these guidelines:

- Choose hardware from the Windows Server Catalog for products in the Windows Server 2003 family.
- Establish hardware standards.
- Keep spares or stand-by systems for redundancy.
- Use fault-tolerant network components, server cooling, and power supplies.
- Use error checking and correcting (ECC) memory. ECC memory uses a checking scheme to guarantee that the failure of any one bit out of a byte of information is corrected.
- Use fault-tolerant storage components, such as redundant disk controllers, hot-swappable disks and hot spares, and disks configured as redundant arrays of independent disks (RAID). For more information about RAID, see "Planning the Layout and RAID Level of Volumes" later in this chapter.
- Use disk resource management tools, such as disk quotas, to ensure that users always have available disk space.
- Keep a log or database of changes made to the file server. The log should contain dated entries for hardware failures and replacements, service pack and software installations, and other significant changes.
- Deploy FRS-compliant antivirus software on link target computers prior to adding files to FRS replicated links or adding new members to the replica set.

**Maintaining the Physical Environment**
Maintain high standards for the environment in which the file servers must run. Neglecting the environment can negate all other efforts to maintain the availability of file servers. Take the following measures to maintain the physical environment:

- Maintain proper temperature and humidity.
- Protect servers from dust or contaminates.
- For power outages, provide a steady supply of power for the servers by using uninterruptible power supply (UPS) units or standby generators.
- Maintain server cables.
- Secure the server room.

**Planning for Backup and Preparing for Recovery**
Backups are essential for high-availability file servers, because the ultimate recovery method is to restore from backup. To plan for backup and recovery:

- Create a plan for backup.

- Monitor backups.
- Decide between local and network backups.
- Check the condition of backup media.
- Perform trial restorations on a regular basis. A trial restoration confirms that your files are properly backed up and can uncover hardware problems that do not show up with software verifications. Be sure to note the time it takes to either restore or re-replicate the data so that you will know how long it takes to bring a server back online after a failure.
- Perform regular backups of clustered file servers and test cluster failures and failover policies. For more information about backing up server clusters and testing policies, see "Backing up and restoring server clusters" and "Test Cluster Failures and Failover Policies" in Help and Support Center for Windows Server 2003.
- If you are using DFS and FRS, put a procedure in place for recovering failed members of an FRS replica set. For more information about troubleshooting FRS, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

**Choosing Software for Reliability**

Installing incompatible or unreliable software reduces the overall availability of file servers. To choose software for reliability, follow these guidelines:

- Select software that is compatible with Windows Server 2003.
- Select signed drivers. Microsoft promotes driver signing for designated device classes as a mechanism to advance the quality of drivers, to provide a better user experience, and to reduce support costs for vendors and total cost of ownership for customers. For more information about driver signing, see the Driver Signing and File Protection link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.
- Select software that supports the high-availability features you require, such as server clusters and online backup.

# Identifying Business-Critical File Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you plan for file server uptime, identify file servers that must be highly available. These file servers typically contain business-critical data that is required for an organization's central purpose, such as software distribution points, e-mail or business databases, and internal or external Web sites. File servers need to be highly available for the following reasons as well:

- **The file server contains one or more stand-alone DFS roots.** If you create a stand-alone DFS root on a file server, and the server fails or is taken offline for maintenance, the entire DFS namespace is unavailable. Users can access the shared folders only if they know the name of the file servers where the shared folders are located. To make stand-alone DFS namespaces fault tolerant, you can create the roots on clustered file servers.

- **Your organization is consolidating file servers.** Consolidation leads to a greater dependency on fewer file servers, so you must ensure the availability of the remaining file servers.

- **Your organization has existing SLAs.** Service Level Agreements (SLAs) and Organization Level Agreements (OLAs) specify the required uptime for file servers, usually defined as the percentage of time that the file server is available for use. For example, your organization might require that file servers have 99.7-percent uptime regardless of the type of data they contain. To meet these agreements, some organizations deploy clustered file servers and assign experienced administrators to manage those file servers. In addition to deploying hardware, these administrators use defined and tested processes to fulfill these agreements.

You do not need to implement additional availability strategies on file servers that store temporary or non-business-critical files. For example, if the file server fails in some way, but users can tolerate the loss of the file server for the time it takes to repair the file server or restore the data from backup, you do not need to use an availability strategy such as replication or clustering. Instead, you can work to decrease the amount of time it takes to restore the file server.

# Choosing an Availability Strategy for Business-Critical Data

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If a file server contains business-critical data, you need to make certain that the data is highly available. Windows Server 2003 provides two primary strategies for increasing data availability: FRS and clustering.

**FRS** This strategy involves creating one or more domain-based DFS namespaces, using link targets that point to multiple file servers and using File Replication service (FRS) to synchronize the data in the link targets. This chapter describes the design and deployment process for FRS, although you can also synchronize data manually by using tools such as Robocopy or by using third-party replication tools.

**Clustering** A server cluster is a group of individual computer systems working together cooperatively to provide increased computing power and to provide continuous availability of business-critical applications or resources. This group of computers appears to network clients as if it were a single system, by virtue of a common cluster name. A cluster can be configured so that the workload is distributed among the group, and if one of the cluster members fails, another cluster member automatically assumes its duties.

Both of these strategies involve using multiple file servers to ensure data availability. If for some reason you cannot use multiple file servers, follow the guidelines in "Planning for File Server Uptime" earlier in this chapter to increase the availability of the physical server.

When evaluating these two strategies, you must keep in mind your organization's tolerance for inconsistent data. FRS can cause temporary data inconsistency as data is replicated across multiple servers. Clustered file servers maintain only one copy of the data; therefore, data inconsistency does not occur.

**Note**

- If your organization plans to implement geographically dispersed clusters for disaster tolerance, you need to understand your data consistency needs in different failure and recovery scenarios and work with the solution vendors to match your requirements. Different geographically dispersed cluster solutions provide different replication and redundancy strategies, ranging from synchronous mirroring across sites to asynchronous replication. For more information about geographically dispersed clusters, see "Designing and Deploying Server Clusters" in this book.

**Using FRS as an Availability Strategy**

You can use FRS to replicate data in domain-based DFS namespaces on file servers running a Windows 2000 Server or Windows Server 2003 operating system. When evaluating FRS, you must determine whether your organization can tolerate periods of inconsistent data that can occur within a replica set. Data inconsistency can occur at the file and folder level as follows:

- 07FRS uses a "last writer wins" algorithm for files. This algorithm is applied in two situations: when the same file is changed on two or more servers, and when two or more different files with the same name are added to the replica tree on different servers. The most recent update to a file in a replica set becomes the version of the file that replicates to the other members of the replica set, which might result in data loss if multiple masters have updated the file. In addition, FRS cannot enforce file-sharing restrictions or file locking between two users who are working on the same file on two different replica set members.

- FRS uses a "last writer wins" algorithm when a folder on two or more servers is changed, such as by changing folder attributes. However, FRS uses a "first writer wins" algorithm when two or more identically named folders on different servers are added to the replica tree. When this occurs, FRS identifies the conflict during replication, and the receiving member protects the original copy of the folder and renames (*morphs*) the later inbound copy of the folder. The morphed folder names have a suffix of "_NTFRS_xxxxxxxx," where "xxxxxxxx" represents eight random hexadecimal digits. The folders are replicated to all servers in the replica set, and administrators can later merge the contents of the folders or take some other measure to reestablish the single folder.

Temporary data inconsistency due to replication latency is more likely to occur in geographically diverse sites with infrequent replication across slow WAN links. If you want to use replication among servers in the same site, consistency is probably not an issue, because the replication can occur quickly after the file changes — assuming that only one user makes changes to the data. If two users make changes to the data, replication conflicts occur and one user loses those changes.

Replication works well in the following scenarios.

**When the data is read-only or changes infrequently**
Because changes occur infrequently, the data is usually consistent. In addition, FRS has less data to replicate, so network bandwidth is not heavily affected.

**When the sites are geographically dispersed and consistency is not an issue**
Geographically dispersed sites might have slower bandwidth connections, but if your organization does not require the data in those sites to always be consistent with each other, you can configure replication in those sites on a schedule that make sense for your organization. For example, if your organization has sites in Los Angeles and Zimbabwe, you can place one or more replicas of the data in servers in those sites and schedule replication to occur at night or during periods of low bandwidth use. Because in this scenario replication could take hours or days to update every member, the delay must be acceptable to your organization.

**When each file is changed by only one person from one location**
Replication conflicts rarely occur if only a single user changes a given file from a single location. Some common scenarios for single authorship are redirected My Documents folders and other home directories. Conversely, if users roam between sites, replication latency could cause the file to be temporarily inconsistent between sites.

**When replication takes place among a small number of servers in the same site**
Replication latency is reduced by frequently replicating data using high-speed connections. As a result, data tends to be more consistent.

Replication should not be used in the following scenarios.

**In organizations with no operations group or dedicated administrators**
Organizations that do not have the staff or the time to monitor FRS event logs on each replica member should not implement FRS. Organizations must also have well-defined procedures in place to prevent the accidental or unintentional deletion of data in the replica set, because deleting a file or folder from one replica member causes the file or folder (and its contents) to be deleted from all replica members. In addition, if a folder is moved out of the replica tree, FRS deletes the folder and its contents on the remaining replica members. To avoid having to restore the files or folders from backup, you can enable shadow copies on some of the replica members so that you can easily restore a file or folder that was accidentally deleted. For more information about shadow copies, see "Designing a Shadow Copy Strategy" later in this chapter. For more information about FRS logs, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

**In organizations that do not update virus signatures or closely manage folder permissions**
A virus in FRS-replicated content can spread rapidly to replica members and to clients that access the replicated data. Viruses are especially damaging in environments where the Everyone group has share permissions or NTFS permissions to modify content. To prevent the spread of viruses, it is essential that replica members have FRS-compatible, up-to-date virus scanners installed on the servers and on clients that access replicated data. For more information about preventing the spread of viruses, see "Planning Virus Protection for File Servers" and "Planning DFS and FRS Security" later in this chapter.

**When the rate of change exceeds what FRS can replicate**
If you plan to schedule replication to occur during a specified replication window, verify that FRS can replicate all the changed files within the window. Replication throughput is determined by a number of factors:

- The number and size of changed files
- The speed of the disk subsystem
- The speed of the network
- Whether you have optimized the servers by placing the replica tree, the staging directory, and the FRS data on separate disks.

Each organization will have different FRS throughput rates, depending on these factors. In addition, if your data compresses extremely well, your file throughput will be higher. To determine the replication rate, perform testing in a lab environment that resembles your production environment.

If the amount of data changes exceeds what FRS can replicate in a given period of time, you need to change one of these factors, such as increasing the speed of the disk subsystem (number of disks, mechanical speed, or disk cache) or network. If no change is possible, FRS is not recommended for your organization.

**In organizations that always use clustered file servers**
Some organizations use clustered file servers regardless of whether the server contains business-critical data. Although storing FRS-replicated content on the cluster storage of a clustered file server might imply increased availability of the data, combining clustering and FRS is not recommended. Data might become inconsistent among the members of the replica set, thus defeating the purpose of clustering, which is to have highly available data that remains consistent because only one copy of the data exists. In addition, Windows Server 2003 does not support configuring FRS to replicate data on cluster storage.

**In organizations that use Remote Storage**
Remote Storage is a feature in Windows Server 2003 that automatically copies infrequently used files on local volumes to a library of magnetic tapes or magneto-optical disks. Organizations that use Remote Storage must not use FRS on the same volume. Specifically, do not perform any of the following tasks:

- Do not create a replica set on a volume that is managed by Remote Storage.
- Do not add a volume that contains folders that are part of an FRS replica set to Remote Storage.
- If you use Remote Storage for volumes that contain FRS replica sets, backup tapes might be damaged or destroyed if FRS recalls a large number of files from Remote Storage. The damage occurs because FRS does not recall files in media order. As a result, files are extracted randomly, and the process can take days to complete and might damage or destroy the tape in the process. Random extraction from magneto-optical disks can also be extremely time consuming.

### Caution

- Windows Server 2003 does not prevent you from using Remote Storage and FRS replica sets on the same volumes, so take extra precautions to avoid using these two features on the same volume.

**When locks by users or processes prevent updates to files and folders**
FRS does not replicate locked files or folders to other replica members, nor does FRS update a file on a replica member if the local file is open. If users or processes frequently leave files open for extended periods, consider using clustering instead of FRS.

**When the data to be replicated is on mounted drives**
If a mounted drive exists in a replica tree, FRS does not replicate the data in the mounted drive.

**When the data to be replicated is encrypted by using EFS**
FRS does not replicate files encrypted by using EFS, nor does FRS warn you that EFS-encrypted files are present in the replica set.

**When the FRS jet database, FRS logs, and staging directory are stored on volumes where NTFS disk quotas are enabled**
If you plan to store a replica set on a volume where disk quotas are enabled, you must move the staging directory, FRS jet database, and FRS logs to a volume where disk quotas are disabled. For more information, see "Planning the Staging Directory" later in this chapter.

**Using Clustering as an Availability Strategy**
If the data changes frequently and your organization requires consistent data that is highly available, use clustered file servers. Clustered file servers allow client access to file services during unplanned and planned outages. When one of the servers in the cluster is unavailable, cluster resources and applications move to other available cluster nodes. Server clusters do not guarantee nonstop operation, but they do provide sufficient availability for most business-critical applications, including file services. A cluster service can monitor applications and resources and automatically recognize and recover from many failure conditions. This ability provides flexibility in managing the workload within a cluster and improves overall system availability.

Server cluster benefits include the following:

**High availability** Ownership of resources, such as disks and IP addresses, is automatically transferred from a failed server to a surviving server. When a system or application in the cluster fails, the cluster software restarts the failed application on a surviving server, or it disperses the work from the failed node to the remaining nodes. As a result, users experience only a momentary pause in service.

**Manageability** You can use the Cluster Administrator snap-in to manage a cluster as a single system and to manage applications as if they were running on a single server. You can move applications to different servers within the cluster, and you can manually balance server workloads and free servers for planned maintenance. You can also monitor the status of the cluster, all nodes, and resources from anywhere on the network.

**Scalability** Server clusters can grow to meet increased demand. When the overall client load for a clustered file server exceeds the cluster's capabilities, you can add additional nodes.

Clustered file servers work well in the following scenarios.

**When multiple users access and change the files**
Because only one copy of the file exists, Windows Server 2003 can enforce file locking so that only one user can make changes at a time. As a result, data is always consistent.

**When large numbers of users access data in the same site**
Clustered file servers are useful for providing access to users in a single physical site. In this case, you do not need a replication method to provide data consistency among sites.

**When files change frequently and data consistency is a must**
Even with a large number of changes, data is always consistent and there is no need to replicate the changes to multiple servers.

**When you want to reduce the administrative overhead associated with creating many shared folders**
On clustered file servers, you can use the Share Subdirectories feature to automatically share any folders that are created within a folder that is configured as a File Share resource. This feature is useful if you need to create a large number of shared folders.

**When you want to ensure the availability of a stand-alone DFS root**
Creating stand-alone DFS roots on clustered file servers allows the namespaces to remain available, even if one of the nodes of the cluster fails.

**When you want to make encrypted files highly available**
Windows Server 2003 supports using the EFS clustered file servers. Using EFS in FRS replica sets is not supported. For more information about using EFS on clustered file servers, see "Planning Encrypted File Storage" later in this chapter.

Some issues to consider when using clustered file servers include the following.

**Dynamic disks are not available**
If you want to use dynamic disks, you must use them on nonclustered file servers or on the local storage devices of the cluster. If the node hosting the local storage devices fails, the data becomes unavailable until the node is repaired and brought back online.

If you need to extend the size of basic volumes used for shared cluster storage, you can do so by using DiskPart. For more information about extending basic volumes, see "Extend a basic volume" in Help and Support Center for Windows Server 2003.

**Clustered file servers must use complete cluster systems**
For your server clusters to be supported by Microsoft, you must choose complete cluster systems from the Windows Server Catalog for the Windows Server 2003 family. For more information about support for server clusters, see article Q309395, "The Microsoft Support Policy for Server Clusters and the Hardware." To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Increasing Data Availability by Using FRS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To design an FRS replication strategy, you need to take the following steps:

1. Identify data to replicate.
2. Choose the replication topology.
3. Design the replication schedule.
4. Plan the staging directory.
5. Determine connection priorities.

The following sections describe each of these steps.

**Important**

- If you configure FRS to replicate files on file servers running Windows 2000, it is highly recommended that you install the Windows 2000 Service Pack 3 (SP3) and the post-SP3 release of Ntfrs.exe, or install later service packs that include this release. For more information about updating FRS, see article 811370, "Issues That Are Fixed in the Post-Service Pack 3 Release of Ntfrs.exe." To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

For more information about FRS security, see "Planning DFS and FRS Security" later in this chapter.

# Identifying Data to Replicate

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you identify which DFS roots and links require multiple replicated targets, as described in "Increasing the Availability of DFS Namespaces" earlier in this chapter, you also need to consider the following issues.

**Size of the USN journal**
The default USN journal size in Windows Server 2003 is 512 MB. If your volume contains 400,000 files or fewer, no additional configuration is required. For every 100,000 additional files on a volume containing FRS-replicated content, increase the update sequence number (USN) journal by 128 MB. If files on the volume are changed or renamed frequently (regardless of whether they are part of the replica set), consider sizing the USN journal larger than these recommendations to prevent USN journal wraps, which can occur when large numbers of files change so quickly that the USN journal must discard the oldest changes (before FRS has a chance to detect the changes) to stay within the specified size limit. To recover from a journal wrap, you must perform a nonauthoritative restore on the server to synchronize its files with the files on the other replica members. For more information about USN journal wraps, see article Q292438, "Troubleshooting Journal_Wrap Errors on Sysvol and DFS Replica Sets." To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Where to store the replica tree**
To provide the best consistency and minimize administrative intervention, carefully plan where to store the replica tree. Your choice will depend on the amount of storage on the server, the volume layout, the number of files on the volume that do not participate in a replica set, and the number of replica sets on the server.

- If you have a single replica tree, store it on its own volume if possible, or store it on a volume that also stores other user data. Adjust the USN journal size based on the total number of files on the volume.
- If you have more replica trees than volumes, store multiple replica trees on each volume and adjust the USN journal size based on the total number of files on the volume.
- If you can create a volume for each replica tree, store each replica tree on its own volume and adjust the USN journal accordingly.

The staging directory also requires careful placement. For more information, see "Planning the Staging Directory" later in this chapter.

**Replicated link targets to omit from the DFS namespace**
When you omit a replicated link target from the namespace, you disable referrals so that DFS does not direct clients to the link target. However, the link target still replicates with other members. Disabling DFS referrals for replica members is useful for a number of scenarios. For example, you can use such a member for any of the following purposes:

- As a backup server. For example, assume you have five servers in a replica set. You might make four of the servers part of the DFS namespace and use the fifth server as a backup source. In this scenario, DFS never refers clients to the fifth server.
- As a reference server. For example, you omit (from the namespace) the server where all changes originate, thus ensuring that you can always introduce new content without being blocked because of open files. The reference server becomes the "known good" server; all other servers should contain identical content.
- As a way to update application data. For example, you have two replica members, ServerA and ServerB, which contain application data that is frequently updated. You can disable referrals for ServerA, update the application data, and enable referrals to ServerA. You can then repeat the procedure on ServerB. In this scenario, one of the replica members is always available while the other is being updated.

To omit a replicated link target from the namespace, configure the link target within the DFS namespace and configure replication as desired by using the Distributed File System snap-in. Then use the **Enable or Disable Referral** command in the Distributed File System snap-in to disable referrals to the link targets that you want to omit from the namespace.

**Files or folders to exclude from replication**
You can use the Distributed File System snap-in to set filters that exclude subfolders (and their contents) or files from replication. You exclude subfolders by specifying their name, and you exclude files by using wild cards to specify file names and extensions. By default, no subfolders are excluded. The default file filters exclude the following files from replication:

- File names starting with a tilde (~) character
- Files with .bak or .tmp extensions

Filters act as exclusion filters only for new files and folders added to a replica set. They have no effect on existing files in the replica set. For example, if you change the existing file filter from "*.tmp, *.bak" to "*.old, *.bak," FRS does not go through the replica set and exclude all files that match *.old, nor does it go through the replica set and begin to replicate all files that match *.tmp. After the filter change, new files matching *.old that are added to the replica set are not replicated. New files matching *.tmp that are added to the replica set are replicated.

Any file in the replica set that was excluded from replication under the old file filter (such as Test.tmp, created when the old filter was in force) is automatically replicated under the new file filter only after the file is modified. Likewise, changes to any file that was not excluded from replication under the old filter (such as Test.old, created when the old filter was in force) continue to replicate under the new filter, until you explicitly delete the file.

These rules apply in the same manner to the directory exclusion filter. If a directory is excluded, all subdirectories and files under that directory are also excluded.

Regardless of the filters you set, FRS always excludes the following from replication:

- NTFS mounted drives
- Files encrypted by using EFS
- Any reparse points except those associated with DFS namespaces. If a file has a reparse point used for Hierarchical Storage Management (HSM) or Single Instance Store (SIS), FRS replicates the underlying file but not the reparse point.
- Files on which the temporary attribute has been set

For more information about configuring filters, see the *Windows Security Collection* of the *Windows Server 2003 Technical Reference* (or see the Windows Security Collection on the Web at http://www.microsoft.com/reskit).

**Number of servers in the replica set**
Will you replicate data among three servers or three hundred servers? As the number of servers increases, configuring the topology and schedule becomes more complex, and it takes longer to replicate data to all members of the replica set. If many members exist in the replica set, and if any member can originate new data, the amount of aggregate bandwidth consumed can be very high. Also note that any server with outbound connections is a server that can potentially originate content and thus requires careful monitoring.

**Number of replica sets per server**
Although there is no limit to the number of replica sets that can be hosted on a single server, it is recommended that you host no more than 150 replica sets on a single server to provide optimal replication performance. The optimal number of replica sets for servers in your organization depends on the CPU, memory, disk input/output (I/O) throughput, and the amount of data changed.

**Network bandwidth between sites**
Replicating data between sites that are connected with slow WAN links requires careful planning of the topology and schedule, because FRS does not provide bandwidth throttling. If the sites have a high-bandwidth connection, but business-critical databases and other applications use that connection as well, schedule replication so that it does not consume bandwidth that is needed for other uses.

**Amount of data in the replica tree**
If the replica tree includes a large amount of data, and a new member is served by a low-bandwidth link, prestage the replica tree on the new member. Prestaging a replica tree preserves security descriptors and object IDs and involves restoring the data to the new member without using the low-bandwidth link. For example, you can restore a backup of the replica tree on the new member, or you can place the new member in the same site as an existing member and prestage the replica tree by using a high-bandwidth local area network (LAN) connection. For more information about adding new replica members, see "Adding

a New Member to an Existing Replica Set" later in this chapter.

**How frequently the data changes**
If the data that is to be replicated changes frequently, estimate the total amount of data that will be generated by each replica member over a period of time. Data that changes frequently is more difficult to keep synchronized across multiple servers, especially if those servers are located across WAN links. If replication latency is a concern, consider clustering instead of replication.

**Whether you want to use single master replication**
FRS is a multimaster replication engine, which means that new content and changes to existing content can originate from any member. If you want to limit the servers that can originate data, you can set up single master replication in one of the following ways:

- Set NTFS permissions on targets to control who can update data in the replica tree.
- Configure the replication topology so that a target does not have any outbound connections.

### Important

- If you use this method, do not directly make changes on replica members that have no outbound connections. Changes made directly on a server that has no outbound connections will not replicate, and the server replica tree will be inconsistent and potentially unpredictable.

**Speed of recovery from hardware failures**
If a server contains a large amount of replicated, business-critical data, be sure to use redundant server components, such as hardware RAID, redundant disk controllers, and redundant network cards to reduce the likelihood that a hardware failure could cause the server to become unavailable. To further increase availability, use multiple servers in each site so that if a server in the site is unavailable due to hardware problems, clients in that site can access the remaining servers as you repair and restore the data on the failed server. Using multiple servers is also useful for remote sites where repair time is lengthy and in cases where the amount of replicated data is so large that it cannot be restored from a central site within the required restoration window.

**Expected growth of replicated data**
You need to know whether you plan to replicate larger and larger amounts of data over time so that you can make sure that your topology, schedule, and bandwidth can handle the additional data.

**Expected increase in the number of replica members**
If you plan to deploy a small number of servers at first and then deploy additional servers over time, you need to make sure that your topology and bandwidth can handle the new servers. For example, if you plan to add 100 more servers, and each of those servers can originate data, you must make sure that your network has the bandwidth to replicate this data. On the other hand, if you are deploying 100 new servers, but only one of those servers can originate data, bandwidth might not be a limiting factor, although you do need to make sure that your bandwidth can handle the initial synchronization of data among servers.

# Choosing a Replication Topology

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The replication topology describes the logical connections that FRS uses to replicate files among servers. To minimize the network bandwidth required for replication, identify where your bandwidth is highest and lowest on your network, and model your FRS replication topology after the physical topology of your network.

You use the Distributed File System snap-in to select a replication topology. After you add a second link target to a link, you are prompted to configure replication by using the Configure Replication Wizard, which allows you to perform the following tasks:

- Choose the initial master whose contents are replicated to the other targets. The initial master is only relevant during the creation of the replica set. After that, the server that acted as the initial master is treated no differently from any other server.
- Choose the location of the staging directory. By default, the staging directory is placed on a different volume than the content to be replicated.
- Choose the replication topology: ring, hub and spoke, full mesh, or custom. If you choose custom, you can add or delete connections to or from the replica set. For the other three standard topologies, you can only enable or disable connections between target servers.

The following describes the four topology types available in the Distributed File System snap-in. For an Excel spreadsheet to assist you in documenting your decision after you choose the topology, see "FRS Configuration Worksheet" (Sdcfsv_2.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "FRS Configuration Worksheet" on the Web at http://www.microsoft.com/reskit).

**Ring topology**

Figure 2.10 illustrates a ring topology. In a ring topology, files replicate from one server to another in a circular configuration, with each server connected to the servers on either side of it in the ring. Choose a ring topology if your physical network topology resembles a ring topology. For example, if each server is located in a different site and has existing connectivity with neighboring servers, you can choose the ring topology so that each server connects only to neighboring servers. Because the ring topology is bidirectional, each connection is fault tolerant. If a single connection or server fails, data can still replicate to all members in the opposite direction.

**Figure 2.10 Ring Topology**

If you plan to create a ring topology with more than seven members, consider adding shortcut connections between some of the members to reduce the number of hops required for data to replicate to all members.

**Hub and spoke topology**

Figure 2.11 illustrates hub and spoke topology. In a hub and spoke topology, you designate one server as the *hub*. Other servers, called *spokes*, connect to the hub. This topology is typically used for WANs that consist of faster network connections between major computing hubs and slower links connecting branch offices. In this topology, files replicate from the hub server to the spoke servers and vice versa, but files do not replicate directly between two spoke servers. When you choose this topology, you must choose which server will act as the hub. If you want to set up multiple hubs, use a custom topology. Using multiple hubs is recommended, because using only one hub means that the hub is a single point of failure.

**Figure 2.11 Hub and Spoke Topology**

**Full mesh topology**

Figure 2.12 illustrates a full mesh topology. In a full mesh topology, every server connects to every other server. A file created on one server replicates directly to all other servers. Because each member connects to every other member, the propagation of change orders for replicating files can impose a heavy burden on the network. To reduce unnecessary traffic, use a different topology or delete connections you do not actually need. A full mesh topology is not recommended for replica sets with five or more members.

**Figure 2.12 Full Mesh Topology**

**Custom topology**

With a custom topology, you create the connections between the servers yourself. One example of a custom topology is a redundant hub and spoke topology. In this configuration, a hub site might contain two file servers that are connected by a high-speed link. Each of these two hub servers might connect with four branch file servers in a hub and spoke arrangement. An example of this topology is shown in "Example: An Organization Designs a Replication Strategy" later in this chapter.

Figure 2.13 illustrates another type of hub and spoke topology known as a *multitier redundant hub and spoke* with an optional staging server used for introducing changes into the replica set.

**Figure 2.13 Multitier Redundant Hub and Spoke Topology**

# Designing a Replication Schedule

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you use the Distributed File System snap-in to configure replication, FRS schedules replication to take place 24 hours a day, seven days a week. Whenever you copy a file to a target that participates in replication, or when an existing file in the replica set is changed, FRS replicates the entire file to the other targets using the connections specified in the replication topology. Continuous replication is advised only for environments that meet the following criteria:

- The replica members are all connected by high-bandwidth connections, such as hub servers in a redundant hub and spoke topology.
- The amount of data to be replicated is not so large that it interferes with the bandwidth required for other purposes during peak or off-peak hours.
- The application whose data is being replicated needs rapid distribution of file changes, such as antivirus signature files or login scripts.

If your environment does not meet these criteria, plan to create a replication schedule so that data is replicated at night or during other times as appropriate. A replication schedule involves enabling and disabling replication so that it occurs at specified times on specified days. For example, you might schedule replication to occur beginning at 12:00 midnight and ending at 2:00 A.M. every day.

When determining the replication schedule, consider the following issues:

**Amount of data to be replicated and the length of the replication window** Estimate the amount of data to be replicated so that you can choose a duration that is long enough to replicate all the data. In DFS namespaces, replication stops when the schedule window closes, and any remaining files are delayed until the next replication window opens. If you occasionally put a large amount of data into the replica set, FRS might take several replication periods to replicate all the data.

**Amount of latency your organization can tolerate** If you plan to replicate data that changes frequently, consider the amount of latency that you can tolerate in keeping your targets synchronized and the amount of bandwidth that is consumed during replication.

**Whether you want to stagger schedules** If you are using a redundant hub and spoke topology with several hubs, you can split the replication load among the hubs by staggering the schedule. An example of this schedule is described in "Example: An Organization Designs a Replication Strategy" later in this chapter.

For an Excel spreadsheet to assist you in documenting the replication schedule, see "FRS Configuration Worksheet" (Sdcfsv_2.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "FRS Configuration Worksheet" on the Web at http://www.microsoft.com/reskit).

# Planning the Staging Directory

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The staging directory acts as a buffer by retaining copies of updated files until replication partners successfully receive them and move them into the target directory. The following sections describe the benefits and design considerations for staging directories. For an Excel spreadsheet to assist you in documenting the staging directory settings and location, see "FRS Configuration Worksheet" (Sdcfsv_2.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "FRS Configuration Worksheet" on the Web at http://www.microsoft.com/reskit).

**Why FRS Uses a Staging Directory**

The staging directory acts as a queue for changes to be replicated to downstream partners. After the changes are made to a file and the file is closed, the file content is compressed, written to the staging directory, and replicated according to schedule. Any further use of that file does not prevent FRS from replicating the staging file to other members. In addition, if the file is replicated to multiple downstream partners or to members with slow data links, using a staging file ensures that the underlying file in the replica tree can still be accessed.

### Note

- A new or updated file remains in the staging directory of a replica member with downstream partners even after the file has replicated to all members. The file is retained for seven days in order to optimize future synchronizations with new downstream partners. After seven days, FRS deletes the file. Do not attempt to delete any files in the staging directory yourself.

**Staging Directory Size**

The size of the staging directory governs the maximum amount of disk space that FRS can use to hold those staging files and the maximum file size that FRS can replicate. The default size of the staging directory is approximately 660 MB, the minimum size is 10 MB, and the maximum size is 2 TB. The largest file that FRS can replicate is determined by the staging directory size on both the upstream partner (the replica member that sends out the changed file) and downstream partners (the replica member that receives the changed file) and whether the replicated file, to the extent that it can be compressed, can be accommodated by the current staging directory size. Therefore, the largest file that FRS can replicate is 2 TB, assuming that the staging directory size is set to the maximum on upstream and downstream partners.

**Managing Staging Directory Capacity**

When FRS tries to allocate space for a staging file and is not successful, either because there is not enough physical disk space or because the size of the files in the staging directory has reached 90 percent of the staging directory size, FRS starts to remove files from the staging directory. Staged files are removed (in the order of the longest time since the last access) until the size of the staging directory has dropped below 60 percent of the staging directory limit. Additionally, staging files for downstream partners that have been inaccessible for more than seven days are deleted. As a result, FRS does not stop replicating if the staging directory runs out of free space. This means that if a downstream partner goes offline for an extended period of time, the offline member does not cause the upstream partner's staging directory to fill with accumulated staging files.

### Note

- In Windows Server 2003, FRS detects and suppresses excessive replication that could be caused when you use Group Policy to overwrite file permissions or when you use antivirus software that overwrites security descriptors. In these examples, writes to files cause no net content changes. When FRS detects a significant increase in the number of changes made to a file, FRS logs an event with ID 13567 in the File Replication service event log. Despite the FRS response to excessive replication caused by applications, services, or security policies, you should investigate the source of the excessive replication and eliminate it.

The fact that FRS removes files from the staging directory does not mean that the underlying file is deleted or will not be replicated. The change order in the outbound log still exists, and the file will eventually be sent to downstream partners when they process the change order. However, before replication can take place, the upstream partner must recreate the file in the staging directory, which can affect performance. Recreating the staging file can also cause a replication delay if the file on the upstream partner is in use, preventing FRS from creating the staging file.

A staging directory can reach 90 percent of its capacity in the following situations:

- **More data is being replicated than the staging directory can hold.** If you plan to replicate more than 660 MB of data, or if you expect that the largest file to replicate will be 660 MB or larger, you must increase the size of the staging directory. Use Table 2.7 for sizing guidelines.

- **A slow outbound partner.** Construct replica connections that have comparable bandwidth for all outbound partners. It is also a good idea to balance that bandwidth for inbound and outbound connections. If you cannot balance the bandwidth, increase the size of the staging directory.

- **Replication is disabled.** If a file is changed or added to the replica set while replication is disabled, the staging directory must be large enough to hold data awaiting replication during the off-time or else older staged files are removed. Replication still occurs, but less optimally.

Table 2.7 describes a range of sizing guidelines for staging directories. Use the numbers in Table 1.7 as a baseline for testing and then adjust the numbers as necessary for your environment. Also, note that the numbers in Table 1.7 apply to each replica set on a server. If a server contains multiple replica sets, you must follow these guidelines for each staging directory.

**Table 2.7 Staging Directory Size Guidelines per Replica Set**

| Scenario | Minimum | Acceptable | Best Performance |
|---|---|---|---|
| Adding a new replica member | Whichever is larger:<br>• 660 MB<br>• Take the size of the 128 largest files in the replica tree, multiplied by the number of downstream partners, and then multiply that number by 1.2. | Whichever is larger:<br>• 660 MB<br>• Take the size of the 128 largest files in the replica tree, multiplied by the number of downstream partners, and then multiply that number by 1.2. | Whichever is larger:<br>• 660 MB<br>• Take the size of the 128 largest files in the replica tree, multiplied by the number of downstream partners, and then multiply that number by 1.2. |
| Increasing the staging directory space to account for backlog caused by replication schedules | No additional requirement | Add space equal to the maximum quantity of expected file changes in a seven-day period multiplied by 1.2. | Add space equal to the expected size of the replica tree, multiplied by 1.2. |
| Additional recommendations | No additional recommendations | Use dedicated disks for the staging directory. | Use dedicated, high-performance disks for the staging directory. |
| Suitability for large replica sets | Not recommended | Recommended | Recommended for organizations that require highest performance. |

**Note**

- The recommendations in Table 2.7 offer sufficient staging directory space for a worst-case scenario. In fact, the staging directory needs to be only as large as the largest 128 files, multiplied by the number of downstream partners that are concurrently performing a full synchronization against the replica member.

For more information about configuring the staging directory, see article Q329491, "Configuring Correct Staging Area Space for Replica Sets." To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

For information about changing the size of the staging directory, see "Deploying FRS" later in this chapter.

**Staging Directory Compression Considerations**

FRS replica members running Windows 2000 Server with Service Pack 3 (SP3) or Windows Server 2003 compress the files replicated among them. Compression reduces the size of files in the staging directory on the upstream partners, over the network between compression-enabled partners, and in the staging directory of downstream partners prior to files being moved into their final location.

To maintain backward compatibility, servers running Windows 2000 Server with SP3 or Windows Server 2003 generate uncompressed staging files when they send changed files to downstream partners running Windows 2000 Server with Service Pack 2 (SP2) or earlier (or to servers running Windows 2000 Server with SP3 or Windows Server 2003 that have compression explicitly disabled in the registry).

To accommodate environments that contain a combination of compression-enabled and compression-disabled partners, the server originating or forwarding changes must generate two sets of staging files for each modified file or folder: one compressed version for servers running Windows 2000 Server with SP3 or Windows Server 2003, and one uncompressed version for partners that have compression explicitly disabled or that are running Windows 2000 Server with SP2 or earlier. To mitigate the generation of two sets of staging files, you can take one of the following steps:

- Confirm that you have sufficient disk space and an appropriately sized staging directory on all replica members.
- Explicitly disable compression in the registry until all members of the replica set are running Windows 2000 Server with SP3 or Windows Server 2003. For information about disabling replication, see article Q288160, "Error Message: Error Compressing Data," in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.
- Rapidly deploy Windows 2000 Server with SP3 or Windows Server 2003 on all members of the replica set, especially if you are replicating a large amount of content.

**Choosing the Staging Directory Location**

You can choose the location of the staging directory when you use the Distributed File System snap-in to configure a replica set. By default, all replica sets on the server use the same staging directory, and the staging directory space limit applies to all staging directories on the local server. When the staging directory is shared among multiple replica sets, any one replica set can cause the staging directory to reach 90% capacity, at which point FRS begins to delete the oldest staging files for any of the replica sets.

To simplify staging directory management and any future recovery procedures, it is recommended that you configure replica sets in one of the following ways:

- Give each replica set its own staging directory, and place the staging directories on the same volume. This solution provides good recoverability while minimizing cost.
- Give each replica set its own staging directory, and put each staging directory on its own volume. This solution provides better recoverability, but at a higher cost.

Do not store the staging directory on a volume where NTFS disk quotas are enabled.

**Improving FRS Performance**

To distribute disk traffic, store the staging directory, FRS logs, the FRS jet database (Ntfrs.jdb), and replica trees on separate disks. Using separate disks for the log files is especially important when you configure FRS logging by using a high severity level. For the best replication performance, distribute disk I/O by placing the FRS logs and the staging directory on separate disks from that of the operating system and the disks containing the replica tree. In a hub and spoke topology, using separate disks is especially recommended for the hub servers.

### Important

- If you store the FRS jet database on a disk that has its write cache enabled, FRS might not recover if power to the drive is interrupted and critical updates are lost. Windows Server 2003 warns you about this by adding an entry with Event 13512 in the File Replication service event log. To leave write caching enabled for improved performance and to ensure the integrity of the FRS jet database, use an uninterrupted power supply (UPS) or a disk controller and cache with a battery backup. Otherwise, disable write caching until you can install a backup power supply.

When moving the FRS logs and FRS jet database, be sure that NTFS disk quotas are disabled on the target volume. For more information about moving the FRS logs and FRS jet database, see article Q221093, "HOW TO: Relocate the NTFRS Jet Database and Log Files," in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Determine Connection Priorities

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Connection priorities control the sequencing of the initial synchronization that occurs when you add a new member to a replica set or when you perform a nonauthoritative restore. By changing connection priorities, you can control which inbound partners go first based on resource considerations. (A server's inbound partners, also known as upstream partners, are those servers from which the new or recovered member can receive replicated content.) For example, you can specify that a new member first synchronize with a partner:

- Across a high-bandwidth network connection.
- That has low server activity.
- That has the most up-to-date files.

You configure connection priorities by using the three priority levels in the Distributed File System snap-in:

- **High.** All connections marked **High** must successfully synchronize before FRS attempts to synchronize medium-priority connections.
- **Medium.** At least one medium-priority connection must successfully complete an initial synchronization before FRS attempts to synchronize any low-priority connections. FRS attempts to synchronize all connections in the medium-priority level, but only one must be successful before FRS attempts to synchronize low-priority connections.
- **Low.** The default connection priority is low. For these connections, FRS attempts to synchronize one time, but any failure does not delay other synchronization attempts. If no medium- or high-priority connections exist, at least one low-priority connection must succeed before FRS considers the initial synchronization operation complete. If medium- or high-priority connections exist, none of the connections in the low-priority class needs to succeed for FRS to consider the initial synchronization operation complete.

**Important**

- Connection priorities are used for initial synchronizations only on custom topologies. If you use a ring, hub and spoke, or full mesh topology, connection priorities are used only on reinitialization during a nonauthoritative restore operation.

When evaluating your topology to determine connection priority, identify the following details for each replica member:

- All inbound connections
- The speed of those connections

Based on this data, determine which connection priority to assign to each inbound connection. The following guidelines will assist you in choosing the appropriate connection priority:

- Use medium priority or high priority only for high-bandwidth connections.
- If you plan to create a high-priority connection, note that if this connection fails, no other synchronization takes place for lower-priority partners until all high-priority connections have succeeded.
- Use low priority for low-bandwidth or unreliable connections.

**Note**

- Keep in mind that after the initial synchronization, connection priorities are ignored until you need to perform a nonauthoritative restore to recover a failed replica member.

For an Excel spreadsheet to assist you in documenting connection priorities, see "FRS Configuration Worksheet" (Sdcfsv_2.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "FRS Configuration Worksheet" on the Web at http://www.microsoft.com/reskit).

Figure 2.14 illustrates an organization's planned topology. The letters A through C represent inbound connections. The hub servers are connected by a high-bandwidth network connection, and two of the hub servers connect with branch servers by using low-bandwidth network connections.

**Figure 2.14 Sample FRS Topology**

In this topology, the administrator assigns connection priorities as follows:

- "A" connections use medium priority because the hubs are connected by high-bandwidth connections and the hub servers are expected to be up to date.

- "B" and "C" connections use low priority because the branch servers connect to the hubs across a low-bandwidth network.

When the hub servers in this example are deployed, Hub1 will be the initial master. Because the "A" connections are marked as medium priority, the two other hub servers will not attempt replication with the branch servers until initial replication completes with at least one other hub server.

The administrator specifies connections "B" and "C" as low priority because the branch servers have low-bandwidth network connections. In the event of a nonauthoritative restore for any of the hubs, using low priority causes the repaired hub server to replicate first from other hubs before replicating with the branch servers.

**Note**

- To increase the availability of data, the administrator can place multiple servers in each branch. If the servers in the branch use high-bandwidth connections to each other, the administrator can set medium priority for those inbound connections. That way, if one of the branch servers fails and is later restored, it will first attempt to replicate with a local branch server before replicating from the hub server across a slow network connection.

# Example: An Organization Designs a Replication Strategy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An organization uses Group Policy to distribute 10 GB of software to users in four sites. The software changes nightly, and it is important that clients have access to these updates the following day. To make the software files and updates highly available, the organization creates a domain-based DFS namespace for each branch and then uses the Distributed File System snap-in to configure replication. To make the updated software available even if a hub server is offline, the organization uses redundant hub servers that are connected by high-speed LAN links. The organization also uses staggered replication schedules to distribute the load between the hub servers. Figure 2.15 describes the FRS topology.

**Figure 2.15 Redundant Hub and Spoke Topology for Software Distribution to Branch Offices**

The organization uses a separate namespace for each branch so that if the local branch server is not available, the clients transparently access one of the hubs instead of another branch server. The organization enables the least-expensive target selection feature of DFS so that the clients always choose the local branch server when it is available.

In this scenario, the organization configures replication as follows:

- Each branch has its own replica set, and each replica set contains three members: the branch and the two hubs.
- Replication between the hubs is enabled at all times, so changes at one hub are immediately replicated to the other hub.
- Inbound connections between the hub servers are medium priority; all other inbound connections are low priority.
- Odd-numbered branches replicate with Hub1 from 6:00 P.M. until 7:30 P.M. and with Hub2 from 8:00 P.M. until 9:30 P.M.
- Even-numbered branches replicate with Hub2 from 6:00 P.M. until 7:30 P.M. and with Hub1 from 8:00 P.M. until 9:30 P.M.

As shown in Figure 2.15, all software updates originate at the hub servers and are replicated to the branch servers on a staggered schedule. If replication completes when the branch is connected to its primary hub, no replication takes place when the branch connects to its alternate hub, because the data will have already replicated between the hubs. Similarly, if one of the hub servers fails or is taken offline for maintenance, the branch servers replicate with the remaining hub, and when the offline hub is brought back online, the two hubs replicate immediately to synchronize their data.

Because of the large amount (10 GB) of software files, the organization prestages new branch servers by restoring the software files to the new branch servers while they are located at the staging site. The organization then transports the new branch servers to the branch sites for deployment. By prestaging the software files, the organization does not need to replicate the

initial 10 GB of files across the network. For more information about prestaging replica sets, see "Adding a New Member to an Existing Replica Set" later in this chapter.

# Increasing Data Availability by Using Clustering

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The information presented in this section assumes an understanding of basic cluster terminology. If you are not familiar with clustering, you can refer to a number of sources for further information:

- For general information about server clusters, including terminology, procedures, checklists, and best practices, see Help and Support Center for Windows Server 2003.
- For information about designing server clusters, see "Designing and Deploying Server Clusters" in this book.

You can use clustered file servers to make sure that users can access business-critical data, such as home directories and software distribution shares. You can also use clustered servers to consolidate multiple nonclustered file servers onto a clustered file server. Each server is then re-created on the cluster as a virtual server.

**Important**

- Because multiple network names might belong to the same server, File Share resources might appear under these names and might also be accessible through them. To avoid client connectivity interruptions, make sure that clients use the network name that is associated with the group in which the File Share resource belongs. For more information about using the proper network name, see article Q170762, "Cluster Shares Appear in Browse List Under Other Names" in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Choosing Virtual Server Names**

If you are migrating nonclustered file servers to clustered file servers, and you do not currently use (or plan to use) DFS, you should use the IP address and network name of each migrated server to create an identical virtual server on the clustered file server. Doing so allows users to continue to access data by using the server names that they are familiar with. You also ensure that links and shortcuts continue to work as they did before the migration.

**Choosing the File Share Resource Type**

A clustered file server uses the File Share resource type to make data available to users. You have three options when configuring this resource type:

**Normal share**

Normal shares function similarly to shared folders created on nonclustered file servers, except that you use the Cluster Administrator snap-in to create them. When you create a normal share, you publish a single folder to the network under a single name. Normal shares do not have required dependencies; however, if the normal share is located on cluster storage, the normal shares should, at a minimum, have dependencies on the cluster storage device (the Physical Disk or other storage-class resource), with the preferential addition of dependencies on the network name and IP address.

You can create a maximum of 1,674 resources, including File Share resources, on a cluster. To provide good failover performance, do not approach this limit in production environments. In addition, if you need to create a large number of normal shares, it is better to use the Share Subdirectories option.

**Share subdirectories (or hide subdirectories)**

A share subdirectories share publishes several network names: one each for a folder and all of its immediate subfolders. For example, if you create a share subdirectories share called Users, any folder you add to the Users folder is automatically shared.

**Important**

- When sharing subdirectories, do not use the same name for subfolders under different folders (for example, \folder1\name1 and \folder2\name1). The first shared subdirectory to come online will remain online, but the second shared subdirectory will not be initialized and will not come online.

Share subdirectories offer a number of advantages:

- They do not require you to create a File Share resource for every folder. As a result, you reduce the potential time and

CPU load needed to detect failures.

- They are an efficient way to create large numbers of related file shares on a single file server. For example, you can use this method to create a home directory for each user who has files on the server, and you can hide the subdirectory shares to prevent users from seeing the subdirectory shares when they browse the network.

- They allow administrators who are not experienced with server clusters or using the Cluster Administrator snap-in to easily create folders that are automatically shared.

When using the share subdirectories feature, determine the number of file shares you plan to host on the cluster, because the number of file shares affects server cluster capacity planning and failover policies. Specifically, you need to determine the following:

- The number of nodes you plan to have in the server cluster

- The number of node failures you want the server cluster to withstand while still providing acceptable performance

- Whether the remaining nodes can handle the load of the failed nodes

The number of nodes is important because a single node can support a limited number of file shares, which varies according to the amount of RAM in the server and which is described in "Reviewing File Server Limits" later in this chapter. If you want the cluster to be able to survive the loss of all but one node, make sure that the cluster hosts no more than the maximum number of file shares that can be hosted by a single node. This is especially important for two-node clusters, where the failure of one node leaves the single remaining node to pick up all the file shares.

In a four-node or eight-node cluster, you have other options that might be more appropriate, depending on the failure scenarios that you want to protect against. For example, if you want a four-node cluster to survive one node failing at any point, you can configure the file shares so that if one node fails, its file shares are spread across the remaining three nodes. In this scenario, each node can be loaded to 66 percent of the maximum number of file shares and still be within the maximum limit of a single node in the event of a single failure. In this case, the cluster can host three times the number of file shares that a single server can host. If you want to survive two nodes failing, a four-node cluster can hold twice as many files shares (because if two nodes fail, the remaining two nodes pick up the load from the two failed servers) and so on.

For more information about server cluster capacity planning and failover policies, see "Designing and Deploying Server Clusters" in this book.

**Note**

- For more information about using the Share Subdirectories option to create home directories, see article Q256926, "Implementing Home Folders on a Server Cluster," in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**DFS root**

You can use the File Share resource type to create a resource that manages a stand-alone DFS root on a cluster. The DFS root File Share resource has required dependencies on a network name, which can be either the cluster name or any other network name for a virtual server. However, it is recommended that you do not use the cluster name (in the Cluster group) for any resources.

The Cluster service manages a resource group as a single unit of failover. Therefore, if you want four DFS roots to fail over independently, create them in different groups. Each group has a network name or the virtual server name with which the root is associated.

When creating a DFS root in clustered file servers, review the following issues:

- The name that you specify for one DFS root cannot overlap with the names for the other DFS roots in the same cluster. For example, if you name one DFS share C:\Dfsroots\Root1, you cannot create other roots using names that are derived from the first DFS root, such as C:\Dfsroots or C:\Dfsroots\Root1\Root2, and so forth.

- On server clusters, do not create clustered DFS roots that have the same name as nonclustered DFS roots or shared folders.

- Clustered file servers running Windows Server 2003, Enterprise Edition and Windows Server 2003, Datacenter Edition support multiple stand-alone DFS roots. These DFS roots can exist in multiple resource groups, and each group can be hosted on a different node.

- Clustered file servers running Microsoft® Windows® 2000 Advanced Server or Windows® 2000 Datacenter Server support one DFS root per server. Mixed-version clusters running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition on some nodes and Windows 2000 on others only support one DFS root per cluster as well. For more information about mixed-version clusters and rolling upgrades, see "Deploying Clustered File Servers" later in this chapter.

  **Caution**

  - Do not make DFS configuration changes (for example, creating new roots, adding new links, new link targets, and so on) while operating a mixed-version cluster, because all DFS changes are lost upon failover.

For more information about creating DFS roots on a clustered file server, see article Q301588, "HOW TO: Use DFS on a Server Cluster to Maintain a Single Namespace," in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Using Shadow Copies on Server Clusters**

Windows Server 2003 supports creating shadow copies on cluster storage. Shadow copies are point-in-time copies of files that are stored on file servers running Windows Server 2003. By enabling shadow copies, you can reduce the administrative burden of restoring previously backed-up files for users who accidentally delete or overwrite important files.

If you plan to enable shadow copies on a server cluster, review the following issues:

- Cluster-managed shadow copies can be created only on cluster storage with a Physical Disk resource. In a cluster without cluster storage, shadow copies can be created and managed only locally.

- The recurring scheduled task that generates volume shadow copies must run on the same node that currently owns the storage volume (where the shadow copies are stored).

- The cluster resource that manages the scheduled task must be able to fail over with the Physical Disk resource that manages the storage volume.

- If you place the source volume (where the user files are stored) and the storage volume (where the shadow copies are stored) on separate disks, those disks must be in the same resource group.

- When you configure shadow copies using the procedure described in "Enable Shadow Copies for Shared Folders in a cluster" in Help and Support Center for Windows Server 2003, the resources and dependencies are set up automatically. Do not attempt to modify or delete these resources and dependencies directly.

To ensure availability, plan to enable shadow copies before you deploy the server cluster. Do not enable shadow copies in a deployed cluster. When you enable shadow copies, the shadow copy volumes (as well as all resources that directly or indirectly depend on the disk) go offline for a brief period while the resource dependencies are created. The shadow copy volumes are not accessible to applications and users while they are offline.

**Note**

- If you enable shadow copies before clustering your servers, you must disable, and then re-enable, shadow copies. If you cluster a disk containing a previously created shadow copy, the shadow copy might stop functioning after that disk's Physical Disk resource fails over.

For additional guidelines and information about shadow copies, see "Designing a Shadow Copy Strategy" later in this chapter. For in-depth information about using shadow copies on server clusters, see "Using Shadow Copies of Shared Folders in a server cluster" in Help and Support Center for Windows Server 2003.

# Example: An Organization Designs a Clustered File Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A large organization uses centralized file servers to store home directories for 3,000 users. The organization has an existing SLA that specifies its file servers must be 99.99 percent available, which means that the file servers can be offline no more than 53 minutes a year. To meet this level of availability, the organization implements clustered file servers in its data center, using a storage area network (SAN) for storage.

After evaluating storage and performance requirements, the organization determines that it needs one file server per 1,000 users, for a total of three file servers. The organization could implement a three-node cluster, but it decides to implement a four-node cluster instead. It will use three nodes to provide access to user directories and the fourth node to perform the following functions:

- Host a stand-alone DFS namespace to provide a unified view of the user directories on the remaining three nodes.
- Perform backups of the other three nodes in the evenings.
- Take over the resources of another node if the node fails or is taken offline for maintenance.

Figure 2.16 illustrates how the organization designs its four-node cluster.

**Figure 2.16 Four-Node Cluster**

To create the user directories, the administrator creates a File Share resource on three nodes and specifies the Share Subdirectories option. The administrator places each File Share resource in a virtual server (a resource group containing IP address and Network Name resources) and sets up dependencies between the File Share resource and the Network Name resource. The administrator then uses a script to quickly create the user directories, which are automatically shared after creation, and to set appropriate permissions for each user directory. The administrator creates another File Share resource on the fourth node and specifies the DFS root option and then uses the Distributed File System snap-in to create a link to each user directory. Users can access their shares by using the DFS path \\Home\Folders*Username*. Logon scripts also map user shares to each user's U: drive.

**Note**

- If the organization needs to provide access to user data when the complete site fails, due either to a total loss of power as a result of a natural disaster or another event, the organization can implement a geographically dispersed cluster.

For more information about designing server clusters, including capacity planning, failover policies, and geographically dispersed clusters, see "Designing and Deploying Server Clusters" in this book.

# Designing a Standard File Server Configuration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To maximize the reliability, availability, and performance of file servers, design one or more standard hardware and software configurations for file servers in your organization. Using a standard configuration for file servers provides a number of benefits:

- You experience less complexity managing and maintaining the hardware. Instead of learning to perform hardware tasks on multiple types of file servers, you need only to learn the task once.
- You reduce the amount of testing that must be done when updating drivers or applications on the file server. Instead of testing the fixes on multiple hardware configurations, you can test the updates on one file server and then deploy the updates to the other file servers.
- You can keep fewer spares on-site. For example, if you use the same type of hard disks in all file servers, you need fewer spare disks, reducing the cost and complexity of providing spares.
- You reduce the number of disk images or answer files you need to maintain, which is useful if you are using automated installation technologies, such as unattended installation or Remote Installation Services (RIS), to deploy your file servers.

**Important**

- If you have read "Planning File Server Availability" earlier in this chapter and you have decided to implement clustered file servers, review the chapter "Designing and Deploying Server Clusters" in this book for important guidelines on choosing and configuring cluster hardware and storage.

Figure 2.17 outlines the process for designing a standard file server configuration.

**Figure 2.17 Designing a Standard File Server Configuration**

# Evaluating Existing Hardware

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you evaluate your existing hardware, you must determine if the hardware meets the recommended hardware requirements for Windows Server 2003 and verify that the hardware is listed in the Windows Server Catalog for Windows Server 2003. If your hardware does not meet these requirements, you might need to acquire new hardware or upgrade your existing hardware.

Your organization might also have existing standards in place that specify the standard configuration for file servers. If so, make sure that your file servers meet those requirements as well.

**Reviewing the Recommended Hardware Requirements and the Windows Server Catalog**
Microsoft recommends that file servers running Windows Server 2003 should meet the hardware requirements listed in Table 2.8.

**Table 2.8 Recommended Hardware Requirements for Windows Server 2003**

| Operating System | CPU | RAM |
|---|---|---|
| Windows Server 2003, Standard Edition | 550 MHz | 256 MB |
| Windows Server 2003, Enterprise Edition | 550 MHz | 256 MB |
| Windows Server 2003, Datacenter Edition | 550 MHz* | 512 MB minimum |

*For servers on which you are upgrading from Windows 2000 Datacenter Server, the minimum processor speed is 400 MHz.

The section "Determining RAM and CPU Specifications" later in this chapter provides specific guidelines for how increasing CPU and RAM can improve file server performance. If the server provides additional services or acts as a domain controller, the server must meet higher requirements than those listed here. For more information about hardware requirements for domain controllers, see "Planning Domain Controller Capacity" in *Designing and Deploying Directory and Security Services* of this kit.

In addition to verifying that your hardware meets the recommended requirements for file servers, verify that all hardware devices on the file server are listed in the Windows Server Catalog. Only Designed for Windows Server 2003 hardware is included in the Windows Server Catalog, which means that the hardware is designed to take advantage of new features in Windows Server 2003.

For more information about hardware requirements for server clusters, see "Designing and Deploying Server Clusters" in this book.

Before you install Windows Server 2003, you can run a hardware and software compatibility check by running the Windows Upgrade Advisor from the Windows Server 2003 operating system CD. The compatibility check does not require you to actually begin an installation. To run the check, insert the Windows Server 2003 operating system CD in the CD-ROM drive and, when a display appears, follow the prompts for checking system compatibility. You will be offered the option to download the latest Setup files (by using Dynamic Update) when you run the check. If you have Internet connectivity, it is recommended that you allow the download.

Another way to run the Windows Upgrade Advisor is to insert the Windows Server 2003 operating system CD in the CD-ROM drive, open a command prompt, and type:

**d:\I386\winnt32 /checkupgradeonly**

In this example, **d** represents the CD-ROM drive.

For more information about hardware and software compatibility, see the following resources:

- To download the Windows Upgrade Advisor, see the Windows Upgrade Advisor link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

- For more information about hardware compatibility, see the Windows Server Catalog link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

- For more information about application compatibility, see "Planning and Testing for Application Deployment" in *Planning, Testing, and Piloting Deployment Projects* of this kit.

**Verifying That Mass Storage Controllers Are Supported**

If your file servers use a mass storage controller (such as a SCSI, RAID, or Fibre Channel adapter) for disks, confirm that it is compatible with products in the Windows Server 2003 family.

If your controller is compatible with products in the Windows Server 2003, but you are aware that the manufacturer has supplied a separate driver file for use with your operating system, obtain the file (on a floppy disk) before you begin Setup. During the early part of Setup, a line at the bottom of the screen prompts you to press F6. Further prompts guide you in supplying the driver file to Setup so that it can gain access to the mass storage controller.

If you are not sure whether you must obtain a separate driver file from the manufacturer of your mass storage controller, you can try running Setup. If the controller is not supported by the driver files on the Windows Server 2003 operating system CD, and it therefore requires a driver file supplied by the hardware manufacturer, Setup stops and displays a message saying that no disk devices can be found, or it displays an incomplete list of controllers. After you obtain the necessary driver file, restart Setup, and press F6 when prompted.

**Verifying That Your Hardware Meets Your Requirements**

If your organization has a standard configuration for file servers, verify that your existing file servers meet these requirements. If they do, proceed to "Planning File Server Security" later in this chapter. If your organization plans to update its standard file server configuration, continue to "Choosing the File Server Type."

**Identifying Servers to Use as Windows Server 2003 File Servers**

Identify the file servers on which you plan to run Windows Server 2003, as well as the servers that you plan to decommission as a result of consolidation or failure to meet hardware requirements.

# Choosing the File Server Type

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Two types of servers run Windows Server 2003: general-purpose servers and Windows Powered Network Attached Storage.

**General-purpose servers** A general-purpose server can function in a number of roles, including domain controller, print server, WINS server, DHCP server, application server, or an e-mail or database server. General-purpose servers provide administrators with the flexibility to configure server software and hardware as they choose. Administrators perform the necessary configuration and optimization that the server requires to perform its role.

**Windows Powered Network Attached Storage** Windows Powered Network Attached Storage solutions are dedicated file servers running Windows 2000 Server or Windows Server 2003. With built-in support for UNIX and Apple file protocols, Windows Powered Network Attached Storage solutions offer seamless integration in a heterogeneous environment.

Table 2.9 describes the features and capabilities of each file server type.

**Table 2.9 Features and Capabilities of File Server Types**

| Description | General-Purpose Server | Windows Powered Network Attached Storage |
|---|---|---|
| Comes preinstalled with Windows 2000 or Windows Server 2003. | ●* | ● |
| Offers the file system, security, reliability, and scalability features of Windows 2000 or Windows Server 2003. | ● | ● |
| Can provide services for purposes other than file sharing, such as domain controller or print, WINS, or DHCP server. | ● | |
| Can run applications, such as Microsoft® SQL Server 2000 or Exchange 2000 Server. | ● | |
| Comes preconfigured with NFS, File Transfer Protocol (FTP), AppleTalk, HTTP, WebDAV, and NetWare protocol support. | | ● |
| Can be deployed in as little as 15 minutes. | | ● |

* Some general-purpose servers come preinstalled with the appropriate operating system; however, other general-purpose servers require you to configure the volumes and install the operating system.

Some hardware vendors offer Windows Powered Network Attached Storage solutions in a cluster configuration. If your organization requires highly available servers, consult your hardware vendor for more information.

# Reviewing File Server Limits

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As you plan your file server configuration, keep in mind file system, storage, and other limits related to file servers. Table 2.10 describes these limits.

**Table 2.10 File System, Storage, and File Server Limits for Windows Server 2003**

| Description | Limit |
|---|---|
| Maximum size of a basic volume | 2 TB |
| Maximum size of a dynamic volume | 2 TB for simple and mirrored (RAID-1) volumes.<br>Up to 64 TB for spanned and striped (RAID-0) volumes. (2 TB per disk with a maximum of 32 disks per volume.)<br>Up to 62 TB for RAID-5 volumes. (2 TB per disk with a maximum of 32 disks per volume and 2 TB used for parity.) |
| Maximum number of dynamic volumes per disk group | 1,000<br>A disk group is collection of dynamic disks. Windows Server 2003 supports one disk group per server. |
| Maximum size of an NTFS volume | $2^{32}$ clusters minus 1 cluster<br>Using a 64-kilobyte (KB) cluster (the maximum NTFS cluster size), the maximum size of an NTFS volume is 256 TB minus 64 KB.<br>Using a 4-KB cluster (the default NTFS cluster size), the maximum size of an NTFS volume is 16 TB minus 4 KB. |
| Maximum file size on an NTFS volume | 16 TB ($2^{44}$ bytes) minus 64 KB |
| Maximum number of files on an NTFS volume | 4,294,967,295 ($2^{32}$ minus 1 file)<br>There is no limit to the number of files that can be stored in a folder. For recommendations on limiting the number of files stored on a volume, see "Determining Maximum Volume Size" later in this chapter. |
| Maximum number of clusters on an NTFS volume | 4,294,967,296 ($2^{32}$) |
| Maximum volumes per server | Approximately 2,000 volumes.<br>Up to 1,000 of these volumes can be dynamic volumes; the rest are basic volumes. Boot times increase as you increase the number of volumes. In addition, you must use mounted drives to access volumes when all drive letters on a server have been used. For more information about mounted drives, see "Using NTFS mounted drives" in Help and Support Center for Windows Server 2003. |

| | |
|---|---|
| Maximum number of shared folders on a server | Varies. The number of shares on a server affects server boot time. On a server with typical hardware and thousands of shares, boot time can be delayed by minutes. Exact delays depend on server hardware.<br><br>Shared folder information is stored in the system hive of the registry. For systems with less than 800 MB of RAM, the System hive can be as large as one-quarter of the physical memory. For systems with more than 800 MB of RAM, the maximum size of the System hive is 200 MB. If the system hive exceeds this limit, the server cannot mount the registry at startup and Windows Server 2003 cannot start. |

For information about optimizing NTFS performance, see the *Storage Technologies Collection* of the *Windows Server 2003 Technical Reference* (or see the Storage Technologies Collection on the Web at http://www.microsoft.com/reskit).

# Determining RAM and CPU Specifications

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

As hardware continues to improve, hardware vendors frequently change the RAM and CPU configurations in the servers they offer. Use the information about performance improvements and scaling factors in the sections that follow to choose the hardware that best meets your organization's needs.

When designing RAM and CPU specifications for server clusters, also consider the failover policy that you plan to use and the maximum number of File Share resources and share subdirectories that will be hosted on any one node after a failure. Each node must have the RAM and CPU resources required to host the resources of one or more failed nodes, depending on your failover policy. For more information about failover policies and server cluster capacity planning, see "Designing and Deploying Server Clusters" in this book.

**Note**

- Many of the figures presented in this section are derived from NetBench statistics for file server throughput. NetBench is a portable Ziff Davis Media benchmark program that measures how well a file server handles file I/O requests from 32-bit Windows clients. NetBench provides an overall I/O throughput score and average response time for servers, along with individual scores for clients. You can use these scores to measure, analyze, and predict how well your server can handle file requests from clients.

**Reviewing Windows Server 2003 CPU Specifications**

Table 2.11 describes the recommended CPU speed and number of processors supported by Windows Server 2003.

**Table 2.11 CPU Requirements for Windows Server 2003**

| Specification | Windows Server 2003, Standard Edition | Windows Server 2003, Enterprise Edition | Windows Server 2003, Datacenter Edition |
|---|---|---|---|
| Minimum recommended CPU speed | 550 MHz | 550 MHz | 550 MHz |
| Number of CPUs supported | 1–4 | 1–8 | 8–32 |

**Reviewing Operating System Performance Improvements**

Even if you plan to use existing hardware to run Windows Server 2003, you can benefit from performance enhancements available in Windows Server 2003, as well as client and server protocol improvements available when using clients running Windows XP Professional.

Table 2.12 describes performance improvements that can be gained by migrating to new operating systems on identical hardware.

**Table 2.12 Operating System Performance Improvements on the Same Hardware**

| Current Server and Client Operating Systems | New Server and Client Operating Systems | Improvement Factor |
|---|---|---|
| Windows NT Server 4.0 with Microsoft® Windows NT® Workstation 4.0 clients | Windows 2000 Server with Windows 2000 Professional clients | Up to 1.25X |
| Windows 2000 Server with Windows 2000 Professional clients | Windows Server 2003 with Windows XP Professional clients | Up to 2.2X |
| Windows NT Server 4.0 with Windows NT Workstation 4.0 clients | Windows Server 2003 with Windows XP Professional clients | Up to 2.75X |

These figures are based on the following assumptions:

- The server is uniprocessor (UP), 2P, 4P, or 8P.

- For each comparison, the server hardware is the same.
- No memory, disk, or network bottlenecks prevent the processor from performing at full capacity.

**Reviewing Performance Improvements Gained by Upgrading Processors**

Table 2.13 describes performance improvements that can be gained by upgrading server processors. Upgrading processors improves processing power, memory bandwidth, I/O bandwidth, and the system bus. These figures are based on actual processor improvements, not operating system improvements. If you plan to use processors that are faster than those listed here, performance will be greater than the following figures show.

**Table 2.13 Performance Improvements Gained by Upgrading Processors**

| Old Processor | New Processor (Server Class) | Improvement Factor |
|---|---|---|
| 200 MHz Intel Pentium Pro | 400 MHz Intel Pentium II Xeon | 2X |
| 400 MHz Intel Pentium II Xeon | 900 MHz Intel Pentium III Xeon | 2X |
| 200 MHz Intel Pentium Pro | 900 MHz Intel Pentium III Xeon | 4X |

**Reviewing Performance Improvements Gained by Adding Processors**

To increase performance, consider using more than one processor in your file servers. One advantage of using multiple processors is the ability to handle more concurrent clients, resulting in higher scaling factors at high client loads. Table 2.14 describes the NetBench throughput improvements gained by adding processors on file servers running Windows Server 2003.

**Table 2.14 Performance Improvements Gained by Adding Processors**

| Original Number of Processors | After Upgrade | Scaling Factor* |
|---|---|---|
| 1 | 2 | 1.4X to 1.6X |
| 2 | 4 | 1.3X to 1.4X |
| 1 | 4 | 1.8X to 2.3X |
| 4 | 8 | 1.3X to 1.4X |
| 1 | 8 | 2.4X to 3.2X |

* The scaling factors are based on a range of client loads.

**Determining the Client Load Based on Processor Utilization**

NetBench stresses the system by applying a heavy load on the file server. Microsoft used the most intensive CPU operations — file opens and file creates (subsequently described as *opens/creates*) — to translate a NetBench client load to a more realistic client load.

To determine the client load, Microsoft observed approximately 820 opens/creates per second at peak NetBench throughput (100-percent CPU utilization) on a Xeon 900-MHz server with a single processor (UP). Table 2.15 describes active client loads for light, medium, and heavy user loads at 70-percent CPU utilization. The client loads are defined as follows:

- Light: one open/create every 10 seconds
- Medium: two opens/creates every 10 seconds
- Heavy: three opens/creates every 10 seconds

Assuming that a light user load causes one open/create every 10 seconds, a UP Xeon 900-MHz server can handle 5,700 users at 70-percent CPU utilization and 8,200 users at 100-percent CPU utilization. (These figures are derived by dividing the opens/creates per second at peak NetBench throughput by the opens/creates per second for light users.)

The figures in Table 2.15 for the UP Xeon 900-MHz server are based on the following assumptions:

- No memory, disk, or network bottlenecks prevent the processor from performing at 100-percent capacity.
- The clients are running Windows XP.

The figures for 2P, 4P, and 8P Xeon 900-MHz servers were calculated by using the scaling factors described in Table 2.14. For example, on a 4P Xeon 900-MHz server, under a heavy client load of three opens/creates every 10 seconds, the server can handle 3,400 to 4,400 active users. This figure is derived by taking the 1,900 heavy-load users supported on a UP Xeon 900-MHz server and multiplying that figure by the UP-to-4P scaling factors of 1.8X to 2.3X provided in Table 2.14.

**Table 2.15 Number of Active Users Supported Based on a NetBench-Type Workload**

| Processor | Heavy Load | Medium Load | Light Load |
|---|---|---|---|
| UP Xeon, 900 MHz | 1,900 | 2,800 | 5,700 |
| 2P Xeon, 900 MHz | 2,600 to 3,000 | 3,900 to 4,500 | 8,000 to 9,100 |
| 4P Xeon, 900 MHz | 3,400 to 4,400 | 5,000 to 6,400 | 10,300 to 13,100 |
| 8P Xeon, 900 MHz | 4,600 to 6,100 | 6,700 to 9,000 | 13,700 to 18,200 |

**Determining RAM Specifications**

Using adequate RAM in file servers ensures that Windows Server 2003 can temporarily cache (store) files in memory, reducing the need to retrieve files from disk. Table 2.16 describes the minimum recommended RAM and maximum RAM for Windows Server 2003.

**Table 2.16 Minimum and Maximum RAM for Windows Server 2003**

| RAM Specification | Windows Server 2003, Standard Edition | Windows Server 2003, Enterprise Edition | Windows Server 2003, Datacenter Edition |
|---|---|---|---|
| Minimum recommended RAM | 256 MB | 256 MB | 512 MB minimum |
| Maximum RAM | 4 GB | 32 GB | 64 GB |

To determine the amount of RAM required to support the file server workload, review the number of remote file handles that can be efficiently supported by a file server running Windows Server 2003. Next, review how additional RAM affects the total size of files, or *file set size*, that can be held in memory at any time.

**Remote concurrent file handles**

A file server running Windows Server 2003 with 1 GB of RAM can efficiently support approximately 100,000 remote concurrent file handles, regardless of the size of the files. If your users are likely to have more than 100,000 files open at a time, plan to split this load across two or more servers.

**File set size**

On a file server with 1 GB of RAM, Windows Server 2003 can hold approximately 500 MB of file content and NTFS metadata in memory. (The amount of memory used for NTFS metadata depends on the depth of the directory hierarchy and query distribution, among other factors.) Windows Server 2003 uses the rest of the RAM for providing nonpaged pool and other operating system functions. For each additional gigabyte of RAM that you add, Windows Server 2003 can use the entire RAM capacity for storing file content in memory. For example, a file server with 3 GB of RAM can support approximately 2.5 GB of file content in memory. When the file set size exceeds the amount of memory, files are paged to disk. This paging can result in disk bottlenecks, though using a fast disk subsystem can alleviate this problem.

When determining how much RAM you plan to install in file servers, consider the following guidelines:

- When users typically access the same files, the file set is known as "hot," because the files are frequently stored in memory. For hot file sets, invest in more RAM to accommodate the entire hot file set. Typically, hot file sets are less than 1 percent of the file set, although this figure can vary.
- When users access random files, the file set is known as "cold." For cold file sets, invest in faster disks, because users

typically open files that are not already in memory, and the response time is limited by disk latency. For example, if you can cut disk latency in half by using a faster disk subsystem (including number of disks, mechanical speed, and disk cache), compare the cost of doing so to the amount of RAM it would take to achieve similar performance. Using a faster disk subsystem might be less expensive.

# Determining Storage Specifications

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is important to make sure that file servers have adequate, fault-tolerant storage. When determining storage specifications, perform the following tasks:

1. Estimate the amount of data to be stored.
2. Plan the amount of storage for each server configuration.
3. Determine the maximum volume size.
4. Plan the layout and RAID level of volumes.

The following sections describe each of these steps.

For more information about storage requirements for server clusters, see "Designing and Deploying Server Clusters" in this book.

# Estimating the Amount of Data to Be Stored

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you estimate the amount of data to be stored on a new file server, include the following information:

- The amount of data currently stored on any file servers that will be consolidated onto the new file server.
- If the file server will be a replica member, the amount of replicated data that will be stored on the new file server.
- The amount of data that you will need to store on the file server in the future.

A general guideline is to plan for faster growth than you experienced in the past. Investigate whether your organization plans to hire a large number of people and whether any groups in your organization are planning large projects that require extra storage.

You must also take into account the amount of space used by operating system files, applications, RAID redundancy, log files, and other factors. Table 2.17 describes some factors that affect file server capacity.

**Table 2.17 Factors That Affect File Server Capacity**

| Factor | Storage Capacity Required |
|---|---|
| Operating system files | At least 1.5 GB. To allow space for optional components, future service packs, and other items, allow an additional 3 GB to 5 GB for the operating system volume. |
| Paging file | 1.5 times the amount of RAM by default. |
| Memory dump | Depending on the memory dump file option that you choose, the amount of disk space required can be as large as the amount of physical memory plus 1 MB. |
| Applications | Varies according to the application, which can include antivirus, backup, and disk quota software; database applications; and optional components, such as Recovery Console, Windows Services for UNIX, and Windows Services for NetWare. |
| Log files | Varies according to the application that creates the log file. Some applications allow you to configure a maximum log file size. You must make sure that you have adequate free space to store the log files. |
| RAID solution | Varies. For more information about the RAID solutions, see "Planning the Layout and RAID Level of Volumes" later in this chapter. |
| Shadow copies | Ten percent of the volume by default, although increasing this size is recommended. For more information about shadow copies, see "Designing a Shadow Copy Strategy" later in this chapter. |
| Snapshots available on Windows Powered Network Attached Storage solutions | Some Windows Powered Network Attached Storage solutions support snapshots that are similar to the shadow copies feature available in Windows Server 2003. The amount of space that these snapshots consume varies according to the frequency of the snapshots and the amount of changed data. The default setting is 20 percent of the volume. |

# Planning Storage for Each Server Configuration

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The amount of disk space that is supported by a file server can be in the terabytes if the server is connected to high-capacity, direct-attached storage arrays or SAN-connected external storage arrays. However, your goal should not be to attach as much storage as possible to a file server. Instead, plan the amount of storage on a file server by examining your current backup solution and answering the following questions:

- How much data can your backup solution contain? Your backup solution should have the capacity to back up the entire file server.
- How much time do you have to complete your backup? You must be able to perform a full backup within a period of time that is acceptable to your organization and users. For organizations that use hardware-based snapshots and backup software that can back up open files, the backup window might not be an issue.
- How quickly do you need to restore data? In other words, do you need to be able to restore data and get the file server up and running within eight hours? Twenty-four hours? Verify that you can restore data within the required time.

If your organization provides file services to groups who have different storage requirements, you can design file server configurations with different amounts of storage. For example, a low-end file server might have 100 GB of storage, but a high-end file server might have 400 GB of storage. Because the high-end server will typically support more users, make sure that the RAM and CPU configuration is more robust than for the low-end server.

**Important**

- If you choose file server hardware that supports future storage expansion, answer the previous questions taking the additional storage into account. In other words, if you add more storage to an existing file server but cannot back up or restore the file server in the required time, you must deploy additional file servers or acquire a backup solution that can handle the extra storage.

Backup solutions are becoming faster and more sophisticated. If your current backup solution is not meeting your organization's needs, investigate new solutions, such as those that provide the following types of benefits:

- Many backup programs, including the Backup program that is available in Windows Server 2003, can back up files that are open, allowing administrators to back up a server without having to disconnect users or shut down processes that might have files open.
- Some backup programs offer software-based snapshots that take point-in-time images of a volume, creating virtual replicas without physically copying the data. Servers running Windows Server 2003 provide a similar feature, known as *shadow copies*. For more information about shadow copies, see "Designing a Shadow Copy Strategy" later in this chapter.
- Hardware vendors offer hardware-based snapshots (also called *split mirrors*, *snapshot mirrors*, or *clones*) that you can use to create mirror images of volumes to be used for online backup, application development, and testing purposes.
- Backup solutions designed for SAN-connected external storage arrays can perform backups without sending the data across the network. (These are known as *LAN-free backups*.) SAN backup solutions also offer serverless backups that move data directly from disk to tape.

# Determining Maximum Volume Size

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Volume sizes often vary, but it is important to set a maximum volume size. NTFS supports volumes up to 256 TB minus 64 KB ($2^{32}$ clusters minus 1 cluster), but it is recommended that you take the following factors into account when you determine the size of volumes in your file servers.

**Backup and restoration times**
Sizing your volumes to be the same size or smaller than your backup solution's capacity is a good guideline but not an absolute rule. For example, some organizations might back up files on a per-folder basis rather than on a per-volume basis. In this case, the organization would make sure that the size of each folder is smaller than the backup solution. This method, however, requires more backups — one for every folder. In the event that you must restore the data, this method also requires more restorations to restore all the folders on the volume, increasing the overall complexity and length of the process. Because emergency restorations are often done in a hurry and under pressure, let restoration time and simplicity be your guide for sizing volumes.

**Chkdsk times**
Although file system errors are rare on NTFS volumes, you need to consider the time required to run Chkdsk to repair any errors that occur. Chkdsk times are determined by the number of files on the volume and by the number of files in the largest folder. Chkdsk performance has improved significantly since Windows NT 4.0 and Windows 2000. As a result, downtime due to Chkdsk should be minimal. However, it is important to avoid having volumes that contain so many files that Chkdsk requires longer to complete than the amount of downtime your users can tolerate.

To determine how long Chkdsk takes to complete, run Chkdsk on a test server with a similar number of files as those stored on a typical file server volume. Based on these results, you can limit the number of files to be stored on a volume so that Chkdsk can complete within the acceptable time limit.

**Important**

- Windows Server 2003 provides some Chkdsk parameters that shorten the time required to run Chkdsk. However, if the volume contains file system errors, you must consider the volume at risk until you are able to run a full Chkdsk. For more information about running Chkdsk, see "Chkdsk" in Help and Support Center for Windows Server 2003.

If you need to store a large number of files on a file server and are concerned about Chkdsk times, you can distribute the files on separate volumes on the file server. If, however, you need those files to appear as though they are on a single volume, you can use mounted drives. When you create a mounted drive, you mount one local volume at any empty folder on another local NTFS volume. For example, you can create a folder called Data on volume E and then mount volume F to that folder. When you open the Data folder, the contents of volume F are displayed.

Mounted drives are also useful when you want to add more storage to an existing volume without having to extend the volume. For more information about mounted drives, including information on creating mounted drives on clustered file servers, see "Using NTFS mounted drives" in Help and Support Center for Windows Server 2003.

# Planning the Layout and RAID Level of Volumes

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you design a standard hardware configuration, determine what type of data you plan to store on the file server, the RAID type and level that is appropriate for each data type, and how you plan to divide the disk space into volumes.

**Evaluating Data Types**

Table 2.18 describes the types of data that are typically stored on file servers and the disk I/O characteristics of the data. Knowing the I/O characteristics can help you choose the RAID level that offers the best performance for that particular type of I/O. If you have other types of data stored on the file server, be sure to estimate their I/O characteristics as well.

**Table 2.18 Data Types and Their Characteristics**

| Data Type | Description | Disk I/O Characteristics |
|---|---|---|
| Operating system | The operating system, drivers, and any applications installed on the server, such as antivirus, backup, or disk quota software. | Server startup consists mostly of large reads, because the data required for startup is optimized on the disk. After startup completes, the disk I/O is mostly small reads. |
| Paging space | Space used by the paging file. | If the server memory is sized correctly, the disk I/O consists of small reads and writes. If the server experiences heavy reads and writes, the server needs more memory. |
| User and shared data | Documents, spreadsheets, graphics, and other data created by users and stored on the file server. | For user and shared data, disk I/O must be measured on a workload-by-workload basis. |
| Application files | Software that users install or run from the network. | For application files, disk I/O must be measured on a workload-by-workload basis. |
| Log files | Files used by database, communications, or transaction applications to store a history of operations (for example, the FRS log file). | Small or large writes, depending on the application. |

**Choosing Between Hardware and Software RAID**

Many computer manufacturers provide server-class computers that support hardware-based RAID. With hardware RAID, you use the configuration utility that is provided by the hardware manufacturer to group one or more physical disks into what appears to the operating system as a single disk, sometimes called a *virtual disk* or *logical unit (LUN)*. When you create the virtual disk, you also select a RAID level. Hardware RAID typically provides a choice of RAID-0 (striped), RAID-1 (mirrored), RAID-5 (striped with parity), and in some servers, RAID-0+1 (mirrored stripe). After creating these virtual disks, you use the Disk Management snap-in or the command-line tool DiskPart.exe in Windows Server 2003 to create one or more volumes on each virtual disk.

If your server hardware does not have built-in hardware RAID support, you can use the software RAID provided in Windows Server 2003 to create RAID-0 volumes, RAID-1 volumes, and RAID-5 volumes on dynamic disks. Although software RAID has lower performance than hardware RAID, software RAID is inexpensive and easy to configure because it has no special hardware requirements other than multiple disks. If cost is more important than performance, software RAID is appropriate. If you plan to use software RAID for write-heavy workloads, use RAID-1, not RAID-5.

**Note**

- Before you can use the software RAID in Windows Server 2003, you must convert basic disks to dynamic disks. In addition, dynamic disks are not supported on cluster storage. For more information about basic disks, dynamic disks, software RAID, and disk management, see the *Storage Technologies Collection* of the *Windows Server 2003 Technical Reference* (or see the Storage Technologies Collection on the Web at http://www.microsoft.com/reskit).

**Choosing the RAID Level**

Choosing the RAID level is a trade-off among the following factors:

- Cost
- Performance
- Availability
- Reliability

You can determine the best RAID level for your file servers by evaluating the read and write loads of the various data types and then deciding how much you are willing to spend to get the performance, reliability, and availability that your organization requires. Table 2.19 describes four common RAID levels; their relative costs, performance, and availability; and their recommended uses. The performance descriptions in Table 2.19 compare RAID performance to the performance of *just a bunch of disks (JBOD)* — a term used to describe an array of disks that is not configured using RAID.

**Table 2.19 Comparing RAID Levels**

| **Factors** | **RAID-0** | **RAID-1** | **RAID-5** | **RAID-0+1** |
|---|---|---|---|---|
| Minimum number of disks | 2 | 2 | 3 | 4 |
| Usable storage capacity | 100 percent | 50 percent | (N-1)/N disks, where N is the number of disks | 50 percent |
| Fault tolerance | None. Losing a single disk causes all data on the volume to be lost. | Can lose multiple disks as long as a mirrored pair is not lost. | Can tolerate the loss of one disk. | Can lose multiple disks as long as a mirrored pair is not lost. |
| Read performance | Generally improved by increasing concurrency. | Up to twice as good as JBOD (assuming twice the number of disks). | Generally improved by increasing concurrency. | Improved by increasing concurrency and by having multiple sources for each request. |
| Write performance | Generally improved by increasing concurrency. | Between 20 percent and 40 percent worse than JBOD for most workloads. | Worse unless using full-stripe writes (large requests). Can be as low as 25 percent of JBOD. | Can be worse or better depending on request size. |
| Best use | • Temporary data only | • Operating system<br>• Log files | • Operating system<br>• User and shared data[1]<br>• Application files[2] | • Operating system<br>• User and shared data<br>• Application files<br>• Log files |

[1] Place user and shared data on RAID-5 volumes only if cost is the overriding factor.

[2] Place application files on RAID-5 volumes only if cost is the overriding factor.

When determining the number of disks to compose a virtual disk, keep in mind the following factors:

- Performance increases as you add disks.
- Mean time between failure (MTBF) decreases as you add disks to RAID-5 or RAID-0 arrays.
- RAID-0+1 almost always offers better performance than RAID-1 when you use more than two disks.

- Usable storage capacity increases as you add disks, but so does cost.

**Using Dynamic Disks with Hardware RAID**

Using dynamic disks with hardware RAID can be useful in the following situations:

- You want to extend a volume, but the underlying hardware cannot dynamically increase the size of LUNs.
- You want to extend a volume, but the hardware has reached its maximum LUN size.

Before converting hardware RAID disks to dynamic disks, review the following restrictions:

- You cannot use dynamic disks on cluster storage. However, you can use the command-line tool DiskPart.exe to extend basic volumes on cluster storage. For more information about extending basic volumes, see "Extend a basic volume" in Help and Support Center for Windows Server 2003.
- If you plan to use hardware snapshots of dynamic disks, you cannot import the snapshot again on the same server, although you can move the snapshot to other servers.
- If you create a software RAID-0 volume across multiple hardware arrays, you cannot extend the RAID-0 later to increase its size. If you anticipate needing to extend the volume, create a spanned volume instead.

For more information about dynamic disks, see the *Storage Technologies Collection* of the *Windows Server 2003 Technical Reference* (or see the Storage Technologies Collection on the Web at http://www.microsoft.com/reskit). For best practices on using dynamic disks, see article Q329707, "Best Practices for Using Dynamic Disks on Windows 2000-Based Computers," in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Choosing the Cluster Size**

A *cluster* (or *allocation unit*) is the smallest amount of disk space that can be allocated to hold a file. NTFS uses 4-KB clusters for volumes over 2 GB. Using a 4-KB cluster size allows you to use NTFS compression on the volume. However, in some cases you might want to use a larger cluster size to optimize NTFS performance.

To determine the cluster size, evaluate the types of files to be stored on the volume so that you can determine whether to use the default 4-KB cluster size. Some important questions to answer include the following:

- Are the files typically the same size?
- Are the files smaller than the default cluster size?
- Do the files remain the same size or grow larger?

If the files are typically smaller than the default cluster size (for example, 4 KB) and do not increase, use the default cluster size to reduce wasted disk space. However, smaller clusters can increase fragmentation, especially when files grow to fill more than one cluster. Therefore, plan to adjust the cluster size accordingly when you format the volume. If the files you store tend to be large or increase in size, and you do not want to use NTFS compression, use 16-KB or 32-KB clusters to optimize performance.

**Important**

- If you plan to defragment volumes on which shadow copies are enabled, it is recommended that you use a cluster size of 16 KB or larger. If you do not, the number of changes caused by defragmentation can cause shadow copies to be deleted faster than expected. Note, however, that NTFS compression is supported only if the cluster size is 4 KB or smaller. For more information about shadow copies, see "Designing a Shadow Copy Strategy" later in this chapter.

**Determining the Volume Layout**

When you determine the volume layout, you evaluate the type of data to be stored and the number of volumes that you want to create. For better manageability, use separate volumes for each data type where possible, though the operating system and paging file are often placed on a single volume. For example, use one volume for the operating system and paging file and one or more volumes for shared user data, applications, and log files.

If performance is important, place different data types in separate volumes on different virtual disks. Using separate virtual disks is especially important for any data types that create heavy write loads, such as log files. For example, dedicate a single set of disks (composing a virtual disk) to handling the disk I/O created by the updates to the log file. Placing the paging file on a separate virtual disk can provide some minor improvements in performance, but not typically enough to make it worth the extra cost.

To gain some performance benefits while minimizing cost, it is often useful to combine different data types in one or more volumes on the same virtual disks. A common method is to store the operating system and paging file on one virtual disk and the user data, applications, and log files in one or more volumes on the remaining virtual disk.

**Note**

- On servers running Windows Server 2003, you can increase the size of basic volumes and dynamic volumes. If you plan to use basic volumes (primary partitions or logical drives), you can extend them on the same disk only, and the basic volume must be followed by contiguous unallocated space. If your hardware supports adding more physical disks to a virtual disk, make sure that the basic volume is the last volume on the disk. For more information about extending volumes and disk management, see the *Storage Technologies Collection* of the *Windows Server 2003 Technical Reference* (or see the Storage Technologies Collection on the Web at http://www.microsoft.com/reskit).

# Determining the Number of File Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The following section describes reasons why you might want to deploy additional file servers and how you can determine the number of file servers that you require.

**Consolidating Older File Servers**
Many organizations today are consolidating older file servers throughout the organization into fewer larger, more powerful file servers. Consolidation reduces the cost of managing multiple file servers and increases the efficiency of storage allocation and backup tasks.

If you plan to consolidate file servers running Windows NT 4.0 or Windows 2000 onto new file servers running Windows Server 2003, determine the number of file servers running Windows Server 2003 that is necessary to match or exceed the performance of your existing file servers. You can derive these figures by using the scaling factors provided in "Determining RAM and CPU Specifications" earlier in this chapter.

The following scenarios describe two consolidation situations based on the scaling factors presented in "Determining RAM and CPU Specifications" earlier in this chapter.

**Scenario 1: Consolidating file servers running Windows NT Server 4.0**
An organization plans to migrate its file services to file servers running Windows Server 2003. It currently has 100 Windows NT 4.0 file servers with the following hardware:

- UP Pentium Pro, 200 MHz
- 256 MB RAM
- Fast Ethernet network adapters

The organization plans to use the following hardware to consolidate file servers:

- 4P 900-MHz Intel® Pentium® III Xeon™
- 3 GB RAM
- Gigabit network adapters

To determine the number of file servers the organization needs when migrating to Windows Server 2003, use the scaling factors described in Table 2.20.

**Table 2.20 Consolidating File Servers Running Windows NT Server 4.0**

| Area of Improvement | Details | Scaling Factor |
|---|---|---|
| Operating system | As shown in Table 2.12, migrating from Windows NT 4.0 to Windows Server 2003 provides a 2.75X performance improvement. | 2.75X |
| Hardware upgrade | As shown in Table 2.13, migrating from a Pentium Pro, 200 MHz, to a Xeon, 900 MHz, provides a 4X performance improvement. | 4X |
| Processor scaling | As shown in Table 2.14, migrating from UP (one processor) servers to 4P servers provides a 1.8X performance improvement. | 1.8X |
| Total improvements | Multiply the scaling factors (2.75 x 4 x 1.8) | 19.8X |

Based on these figures, the organization can migrate 100 file servers running Windows NT 4.0 to five 4P Xeon 900-MHz

servers running Windows Server 2003. (To derive this number, divide 100 by 19.8.) The organization must also be sure that the five Xeon servers have adequate storage space to store the consolidated data, as well as future data, and that 3 GB of memory can handle the total workload of the 100 servers.

**Scenario 2: Consolidating file servers running Windows 2000 Server**
An organization plans to migrate its file services to file servers running Windows Server 2003. It currently has five Windows 2000 file servers with the following hardware:

- 4P 400-MHz Intel® Pentium® II Xeon™
- 1 GB RAM
- Gigabit network adapters

The organization plans to use the following hardware to consolidate file servers:

- 8P 900-MHz Intel® Pentium® III Xeon™
- 4 GB RAM
- Gigabit network adapters

To determine the number of file servers the organization needs when migrating to Windows Server 2003, use the scaling factors described in Table 2.21.

**Table 2.21 Consolidating File Servers Running Windows 2000 Server**

| Area of Improvement | Details | Scaling Factor |
|---|---|---|
| Operating system | As shown in Table 2.12, migrating from Windows 2000 Server to Windows Server 2003 provides a 2.2X performance improvement. | 2.2X |
| Hardware upgrade | As shown in Table 2.13, migrating from a Xeon, 400 MHz, to a Xeon, 900 MHz, provides a 2X performance improvement. | 2X |
| Processor scaling | As shown in Table 2.14, migrating from 4P servers to 8P servers provides a 1.3X performance improvement. | 1.3X |
| Total improvements | Multiply the scaling factors (2.2 x 2 x 1.3) | 5.7X |

Based on these figures, the organization can use a single 8P Xeon 900-MHz file server, assuming it has enough memory, disk, and network I/O available. To ensure the availability of the server, the organization should consider using a server cluster instead of a single stand-alone file server. For more information about increasing the availability of file servers, see "Planning File Server Availability" earlier in this chapter.

**Providing Additional Storage**
If your organization uses direct-attached storage for file servers, deploy as many file servers as it takes to meet your storage needs. If each of your file servers provides 500 GB of storage, and you need at least 2 TB of storage, you need a minimum of five file servers. You also need to provide the new file servers with enough processing power and memory to serve your clients. Use the factors described in "Determining RAM and CPU Specifications" earlier in this chapter.

**Providing More Processing Power**
If users experience delays when accessing file servers, there are a number of ways you can improve file server performance:

- Enable the Offline Files feature so that clients cache files locally instead of going to the file server whenever they need a file. You can also use this feature to enable automatic caching for programs. When you enable program caching on a shared folder, and a user runs a program from the shared folder, Windows Server 2003 copies the application .exe and .dll files as they are used and runs the files from the client's local cache, which reduces server load and network traffic. For simple programs that use a single .exe file, this feature enables the program to run correctly when the server is down or the client is not connected to the network. For programs that consist of multiple files (.exe and .dll), all files must be

cached on the local computer so that the program can run while offline. The user can ensure that all files are cached by choosing the **Make Available Offline** option from the **File** menu in Windows Explorer. For more information about the Offline Files feature, see "Offline settings for shared resources" and "Make a file or folder available offline" in Help and Support Center for Windows Server 2003.

- Place copies of heavily used shared folders with primarily read-only files on multiple file servers, and use DFS to provide load sharing. If you also plan to use the Offline Files feature, note that you can use this feature in conjunction with DFS only for clients running Windows XP Professional. For more information about Offline Files, see "Offline Files overview" in Help and Support Center for Windows Server 2003.

- Upgrade the processor, RAM, or disk subsystem in your existing file servers. Use the factors described in "Determining RAM and CPU Specifications" earlier in this chapter to determine the performance improvements you can gain by upgrading existing hardware.

**Providing Same-Site Data Access for Users**

If you have remote sites with expensive WAN links, you can deploy one or more file servers in those sites to provide users with fast, inexpensive LAN access to the file servers. For each site, take into account the storage and processing power needed by users in the site. You also need a backup and recovery procedure in place at each site in case one of the file servers fails.

# Determining the File Server Hardware Life Cycle

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The hardware life cycle is the amount of time that hardware is used before it is replaced with new hardware. Typical hardware life cycles are 12, 24, or 36 months. If your organization frequently adds new file servers to increase capacity or add new functionality, consider using a relatively short replacement cycle for file servers. This recommendation is based on the high rate of change in computers, disk subsystems, and other components. Maintaining a shorter cycle prevents the problem of servers that were purchased at the beginning of the cycle becoming obsolete before the end of the cycle. However, a shorter life cycle affects the manageability of file servers, because you must replace hardware, install the operating system and applications, and migrate data more frequently.

To transparently migrate files from decommissioned servers to new servers without affecting users, implement one or more DFS namespaces. For more information about DFS, see "Designing DFS Namespaces" earlier in this chapter.

For more information about deploying new servers and migrating data, see "Deploying File Servers" later in this chapter.

# Designing a Shadow Copy Strategy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can give users access to previous versions of files by enabling shadow copies, which provide point-in-time copies of files stored on file servers running Windows Server 2003. By enabling shadow copies, you can reduce the administrative burden of restoring previously backed up files for users who accidentally delete or overwrite important files. Shadow copies work for both open and closed files; therefore, shadow copies can be taken even when files are in use.

Shadow copies work by making a block-level copy of any changes that have occurred to files since the last shadow copy. Only the changes are copied, not the entire file. As a result, previous versions of files do not usually take up as much disk space as the current file, although the amount of disk space used for changes can vary depending on the application that changed the file. For example, some applications rewrite the entire file when a change is made, whereas other applications append changes to the existing file. If the entire file is rewritten to disk, the shadow copy contains the entire file. Therefore, consider the type of applications in your organization, as well as the frequency and number of updates, when you determine how much disk space to allocate for shadow copies.

**Important**

- Shadow copies do not eliminate the need to perform regular backups, nor do shadow copies protect you from media failure. In addition, shadow copies are not permanent. As new shadow copies are taken, old shadow copies are purged when the size of all shadow copies reaches a configurable maximum or when the number of shadow copies reaches 64, whichever is sooner. As a result, shadow copies might not be present for as long as users expect them to be. Be sure to consider user needs and expectations when you configure shadow copies.

Shadow copies are designed for volumes that store user data, such as home directories and My Documents folders that are redirected by using Group Policy, or other shared folders where users store data. Shadow copies work with compressed or encrypted files, and they retain whatever permissions were set on the files when the shadow copies were taken. For example, if a user is denied permission to read a file, that user would not be able to restore a previous version of the file, nor would the user be able to read the file after it has been restored.

Although shadow copies are taken for an entire volume, users must use shared folders to access shadow copies. Administrators on the local server must also specify the *servername**sharename* path to access shadow copies. If you or your users want to access a previous version of a file that does not reside in a shared folder, you must first share the folder.

**Collecting Information to Design a Shadow Copy Strategy**

When you design a shadow copy strategy, review the following topics. For an Excel spreadsheet to assist you in documenting your shadow copy design decisions, see "Shadow Copy and Disk Quota Configuration Worksheet" (Sdcfsv_7.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "DFS Configuration Worksheet" on the Web at http://www.microsoft.com/reskit).

**Shadow copy support in client operating systems**

Shadow copies can be accessed by computers running Windows Server 2003 and by computers running Windows XP Professional on which you have installed the Previous Versions Client pack (Twcli32.msi). This file is located in the Windows Server 2003 operating system in *windir*\system32\clients\twclient. You can install this file manually on clients or deploy the file by using the software distribution component of Group Policy. For more information about software distribution, see "Deploying a Managed Software Environment" in *Designing a Managed Environment* of this kit.

To access shadow copies from previous versions of Windows, including Windows 2000 and Windows XP Professional, you can download and install the Shadow Copy Client. For more information and to download the Shadow Copy Client, see the Shadow Copy Client Download link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Note**

- The Previous Versions Client and the Shadow Copy Client provide the same functionality, but the Shadow Copy Client can be installed on multiple operating systems, such as Windows 2000 and Windows XP Professional, whereas the Previous Versions Client can only be installed on Windows XP Professional.

If you have not yet deployed these operating systems or client packs on your clients, you can deploy a single computer (or as many as necessary) from which users can restore previous versions of files. You can also distribute the client pack on a case-

by-case basis to users who request that files be restored.

**Shadow copy support in server operating systems**
Shadow copies are available only on file servers running Windows Server 2003.

**Shadow copy support on server clusters**
There are a number of important considerations for managing shadow copies on cluster storage. For more information about managing shadow copies on server clusters, see "Using Shadow Copies of Shared Folders in a server cluster" in Help and Support Center for Windows Server 2003.

**File system requirements**
Shadow copies are available only on NTFS volumes.

**Recommended scenarios for using shadow copies**
Shadow copies work best when the server stores user files such as documents, spreadsheets, and graphics files. Do not use shadow copies to provide access to previous versions of application or e-mail databases.

**Amount of volume space to allocate to shadow copies**
When you enable shadow copies on a volume, you can specify the maximum amount of volume space to be used for the shadow copies. The default limit is 10 percent of the source volume (the volume being copied). Increase the limit for volumes where users frequently change files. Also, setting the limit too small causes the oldest shadow copies to be deleted frequently, which defeats the purpose of shadow copies and which will likely frustrate users. In fact, if the amount of changes is greater than the amount of space allocated to storing shadow copies, no shadow copy is created. Therefore, carefully consider the amount of disk space that you want to set aside for shadow copies, while keeping in mind user expectations for how many versions they want to be available. Your users might expect only a single shadow copy to be available, or they might expect three days' or three weeks' worth of shadow copies. The more shadow copies the users expect, the more storage you need to allocate for storing them.

Setting the limit too small can adversely affect other programs, such as the Backup program in Windows Server 2003 and other backup programs that support the Volume Shadow Copy service. During the backup process, these programs create temporary shadow copies for consistent backups. The temporary shadow copies count towards the volume space limit you specify for shadow copies. If the available volume space remaining in the limit is too small, the Volume Shadow Copy service can delete existing shadow copies to free up space for the temporary shadow copy. If there are no existing shadow copies, and the volume space limit cannot accommodate the temporary shadow copy, the backup might fail. For more information about the Volume Shadow Copy service, see the Storage Services link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

### Important

- Regardless of the volume space that you allocate for shadow copies, you can have a maximum of 64 shadow copies for any volume. When the 65th shadow copy is taken, the oldest shadow copy is purged.

**Frequency at which Windows Server 2003 creates shadow copies**
By default, Windows Server 2003 creates shadow copies at 7:00 A.M. and at 12:00 noon Monday through Friday. However, you can change the schedule to better accommodate users. Keep in mind that the more shadow copies you create, the more disk space the shadow copies can consume, especially if files change frequently. When you determine the schedule, avoid scheduling shadow copies to occur more than once per hour.

**Storing shadow copies on separate disks**
You can dedicate a volume on separate disks for storing the shadow copies of another volume on the same file server. For example, if user files are stored on H:\, you might use another volume, such as S:\, to store the shadow copies. Using a separate volume on separate disks provides better performance, and it is recommended for heavily used file servers. If you plan to use a separate volume for the storage area (where the shadow copies are stored), be sure to change the maximum size to **No Limit** to reflect the space available on the storage area volume instead of the source volume (where the user files are stored).

### Important

- If you plan to store the shadow copies on the same volume as the user files, note that a burst of disk I/O can cause all shadow copies to be deleted. If you cannot tolerate the sudden deletion of shadow copies, use a volume that will not be shadow copied, preferably on separate disks, for storing shadow copies.

**File servers containing mounted drives**
A mounted drive is a local volume attached to an empty folder (called a *mount point*) on an NTFS volume. If you enable shadow copies on a volume that contains mounted drives, the mounted drives are not included when shadow copies are taken.

In addition, if you share a mounted drive and enable shadow copies on it, users cannot access the shadow copies if they traverse from the host volume (where the mount point is stored) to the mounted drive.

For example, assume you have the folder E:\Data\Users, and the Users folder is a mount point for F:\. You enable shadow copies on both E:\ and F:\, you share E:\Data as \\Server1\Data, and you share E:\Data\Users as \\Server1\Users. In this example, users can access previous versions of \\Server1\Data and \\Server1\Users but not \\Server1\Data\Users.

**Defragmenting the volume where shadow copied files are stored**
If you plan to defragment volumes on which shadow copies are enabled, it is recommended that you use a cluster (or allocation unit) size of 16 KB or larger. If you do not, the number of changes caused by the defragmentation process can cause shadow copies to be deleted faster than expected. Note, however, that NTFS compression is supported only if the cluster size is 4 KB or smaller.

### Note

- To check the cluster size of a volume, use the **fsutil fsinfo ntfsinfo** command. If the volume contains data and you want to change the cluster size, you must back up the data on the volume, reformat it using the new cluster size, and then restore the data.

**Converting basic disks to dynamic disks**
If the volumes that contain the original files and the shadow copy storage area are on separate basic disks and you want to convert both of the disks to dynamic disks, you must follow these directions:

- **If the shadow copy storage area is not on the boot volume.** First dismount and take offline the volume that contains the original files. To do this, use Mountvol.exe with the /p parameter. Next, convert the disk that contains the storage area volume to a dynamic disk. After the conversion, you have 20 minutes to mount the volume that contains the original files and bring it online by using Mountvol.exe or the Disk Management snap-in; if you do not, you will lose the existing shadow copies. After you bring the volume that contains the original files back online, you can convert that disk to a dynamic disk.

- **If the shadow copy storage area is on the boot volume.** You can convert the disk that contains the storage area volume to a dynamic disk without having to dismount the volume that contains the original files. To complete the conversion, you must restart the computer twice. Next, convert the disk that contains the original files to a dynamic disk.

### Important

- If the disk that contains the original files is converted to a dynamic disk first, the shadow copies are deleted when you convert the disk that contains the storage area volume to a dynamic disk.

**Using DFS to provide access to volumes that contain shadow copies**
You can create DFS link targets on volumes that contain shadow copies, and users can retrieve previous versions of files from the DFS link target, just as they can from a regular shared folder. However, if you use multiple link targets for a DFS link, each of those link targets can reside on a different volume with its own shadow copies. As a result, the previous versions of files can vary, depending on which link target the user last accesses to change the file.

**Backing up shadow copies**
Windows Server 2003 does not support backing up shadow copies. When you back up a volume, shadow copies are not backed up.

**Using scripting to create shadow copies**
To create shadow copies by using scripts, use Vssadmin.exe to create the shadow copies and, optionally, use Schtasks.exe to schedule the creation of shadow copies. For more information about using these command-line tools, see "Vssadmin" and "Schtasks" in Help and Support Center for Windows Server 2003.

For more information about shadow copies, see "Shadow Copies for Shared Folders" in Help and Support Center for Windows Server 2003.

**Example: An Organization Designs a Shadow Copy Strategy**
A large organization allows users to redirect their My Documents folders to a central file server. When a user accidentally deletes or overwrites a file and requests that the file be restored, the process requires between 1 day and 3 days and up to three escalations before the backup/restore group can restore a file. The organization determines that it costs approximately $300 for support and escalation costs plus lost productivity while the restoration takes place.

To decrease the cost associated with restoring files and to increase user satisfaction, the organization enables shadow copies on its file servers. During the pilot program, the organization determines that the default settings for the schedule and storage volume allow two weeks of previous versions. When a user contacts the support group to have a file restored, the support group provides a copy of the Previous Versions Client pack to the user. It takes the user approximately five minutes to install the software and another five minutes to restore the file. As a result, a user can restore a file in 10 minutes instead of 1 day to 3 days, and user satisfaction is greatly increased.

# Designing a Disk Quota Strategy

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To prevent file servers from filling to capacity without warning, use disk quotas to track and control disk space usage on file servers. Windows Server 2003 provides disk quota functionality that tracks quotas on a per-user, per-volume basis. After you enable the warning level and limit, they apply to all users who own files stored on the volume. Any user who creates a new file is automatically assigned the current warning level and limit.

Windows Server 2003 quotas are well suited for volumes that store user data, such as redirected My Documents folders or other per-user folders. For example, an organization uses Group Policy to redirect its employees' My Documents and My Pictures folders to a file server volume that stores only user data, not group data. After evaluating the storage needs of users in the organization, the administrator chooses to set storage limits by enforcing a 300-MB disk quota for each user. The administrator also sets a 270-MB warning level. If a user needs additional storage, the user must get approval from his or her manager before the administrator can increase the quota for the individual user.

Windows Server 2003 disk quotas are not designed for project-oriented scenarios in which a shared folder is given a quota that is shared among a specified set of users. A wide range of Windows Server 2003–compatible, third-party products provide group quotas, per-folder quotas, and threshold event features that this scenario requires.

To design a quota strategy for volumes that store user data, review the following topics. For an Excel spreadsheet to assist you in documenting your disk quota design decisions, see "Shadow Copy and Disk Quota Configuration Worksheet" (Sdcfsv_7.xls) on the *Windows Server 2003 Deployment Kit* companion CD (or see "DFS Configuration Worksheet" on the Web at http://www.microsoft.com/reskit).

**File system requirements**
Disk quotas are available only on NTFS volumes.

**Tracking quotas vs. enforcing quotas**
Tracking quotas is useful if you want to track use of disk space without denying users access to a volume. Enforcing quotas denies disk space to users who exceed their limit. Users can determine how much disk space they have available on the volume by viewing the properties of a mapped shared folder in Windows Explorer.

**Determining how much disk space to provide to each user**
You can change quotas on a per-user basis if some users require additional disk space. For example, the current limit might be 200 MB, but you can specify which users have a 500-MB limit. You cannot assign quotas on a per-group basis.

When setting quotas, make sure that you have enough disk space to accommodate existing users and that you have enough extra free space to accommodate future growth. Each file that is stored on the volume can use up to 64 KB of NTFS metadata that is not charged to a user's quota. To avoid running out of disk space, you must leave sufficient disk space to accommodate this metadata.

**Using disk quotas on server clusters**
Use only domain-level accounts, because local accounts cannot be resolved when the disk fails over. For more information about configuring disk quotas on shared cluster disks, see article Q278365, "HOW TO: Configure Disk Quotas for a Shared Disk in a Cluster" in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Logging quota events**
Windows Server 2003 provides quota reporting by logging events in the event log when users exceed their warning level or quota limit. You can use Windows Management Instrumentation (WMI) for customized reporting by using the WMI classes Win32_DiskQuota, Win32_QuotaSetting, and Win32_VolumeQuotaSetting. For more information about WMI, see the Microsoft Windows Management Instrumentation (WMI) SDK link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

**Using disk quotas on DFS link targets**
DFS provides a simple way to create custom quotas on different volumes that appear to users as different folders on the same volume. If you are using DFS to provide multiple link targets, note that each of these link targets can reside on a volume with different quota settings. To keep the user experience consistent, use the same quota settings for each volume.

**Using disk quotas on shadow-copied volumes**
You can enable shadow copies and disk quotas on the same volume, and shadow copies do not count against a user's disk

quota.

**Note**

- For more information about file systems and Windows Server 2003 disk quotas, see the *Storage Technologies Collection* of the *Windows Server 2003 Technical Reference* (or see the Storage Technologies Collection on the Web at http://www.microsoft.com/reskit).

# Planning File Server Security

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Planning for file server security is vital for protecting your organization's sensitive or business-critical files. When planning for file server security, you need to protect not only the data but the physical server as well. In addition, if you plan to implement availability strategies, such as DFS or clustering, you need to take additional steps to secure the resources associated with these features.

Figure 2.18 describes the process for planning file server security.

**Figure 2.18 Planning File Server Security**

# Ensuring the Physical Security of Each File Server

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

For file servers that must maintain high availability, restrict physical access to only designated individuals. In addition, consider to what extent you need to restrict physical access to network hardware. The details of how you implement physical security depend on your physical facilities and your organization's structure and policies. You should also implement methods to restrict access to backup media and any instruction sheets that you create, such as the instructions that go in the recovery manual for a file server. Allowing unauthorized people to study documentation or configuration manuals means that they can quickly cause harm to the system if they are able to obtain access.

Even if the physical server is in a secure room, the file server might still be accessible through remote administration tools. Therefore, implement methods for restricting access to remote administration of file servers, and ensure that remote administration tools do not weaken your organization's security model. For example, remote administration tools do not always use strong authentication protocols, such as Kerberos V5, to authenticate users across the network. You might be able to implement weaker protocols, such as NTLM, depending on the remote management tool you use and the operating system that is running on the host you are administering. In addition, certain remote administration tools might transmit unencrypted data (plaintext) across the network. This makes your data vulnerable to network sniffers.

For more information about security and remote administration, see the *Storage Technologies Collection* of the *Windows Server 2003 Technical Reference* (or see the Storage Technologies Collection on the Web at http://www.microsoft.com/reskit).

# Planning Baseline Security

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The Windows 2000 Server Baseline Security Checklist provides instructions for configuring a baseline level of security on servers running Windows Server 2003. The checklist contains tasks such as using NTFS, using strong passwords, disabling unnecessary services, disabling unnecessary accounts, and more. For more information about the baseline security checklist, see the Windows 2000 Server Baseline Security Checklist link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

Run the Microsoft Baseline Security Analyzer (Mbsa.exe for the graphical user interface version; Mbsacli.exe for the command-line version). For more information about the Microsoft Baseline Security Analyzer, see the MBSA link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

To further enhance security, review the Microsoft Windows Update Web site regularly for patches that fix vulnerabilities and provide security enhancements. For more information about Windows Update, see the Windows Update link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Planning Virus Protection for File Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To protect file servers from viruses, plan to take the following precautions:

- Use Windows Server 2003–compatible antivirus software, and regularly update virus signature files.
- Back up files regularly so that damage is minimized if a virus attack does occur.
- With clustered file servers, you must use an antivirus program that is cluster aware. If it is not, failover might not occur correctly. If your organization does not have cluster-aware antivirus software, you can install antivirus software on a nonclustered server and use that server to periodically scan the drives that are mapped to the clustered file server. For more information about running antivirus software on server clusters, see article Q250355, "Antivirus Software May Cause Problems with Cluster Services," in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.
- For FRS-replicated content, you must use antivirus programs that are FRS compatible and that do not change the security descriptor of files. For more information about FRS compatible antivirus programs, see article Q815263, "Antivirus, Backup and Disk Optimization Programs That Are Compatible with the File Replication Service." To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Planning Access to Shared Folders

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When you plan access to shared folders, determine the type of permissions to use, who needs access to the folders, and the level of access that users require. You can also disable administrative shares and hide shared folders.

**Determining the Type of Permissions to Use**
Permissions define the type of access granted to a user or group for a file or folder. Windows Server 2003 offers two types of permissions:

- NTFS permissions restrict local and remote access to files and folders on NTFS volumes. When you create a new folder, it inherits permissions from its parent folder. When you create a file in a folder, the file inherits permissions from the parent folder.

- Share permissionsrestrict remote access to shared folders, but share permissions do not restrict access to users who log on to the server locally. Share permissions are available on both FAT and NTFS volumes.

To simplify administering and troubleshooting permissions, use NTFS permissions to control user and group access to file system resources.

Although NTFS is recommended as the primary method for securing folders, you must keep in mind that default share permissions are assigned when you share a folder, and the default share permissions have changed for Windows Server 2003. Windows 2000 and Windows XP grant the Everyone group the Full Control share permission, but Windows Server 2003 grants the Everyone group the Read share permission. This change increases the security of shared folders and helps prevent the spread of viruses.

Because the more restrictive permissions always apply when you use a combination of share and NTFS permissions, you might need to change the default share permissions if you want users to be able to add or change files in the folder. If you do not change the default share permissions, users will have the Read share permission even if you grant users NTFS permissions such as Write or Modify.

If you use a clustered file server, you must create share permissions by using the Cluster Administrator snap-in, not Windows Explorer. In addition, if you plan to use the Share Subdirectories option, you must use NTFS permissions to secure the subdirectories. For more information about these options, see "Planning Cluster Security" later in this chapter.

**Determining Who Needs Access to the Folders**
To increase security and prevent users from browsing through shared folders that are not relevant to their jobs, assign permissions only to groups that require access to the shared folders.

To reduce administrative overhead when assigning permissions, do the following:

- Assign permissions to groups rather than to users.

- Place users in global groups or universal groups, nest these groups within domain local groups, and then assign the domain local groups permissions to the folder.

You do not need to deny permissions for specific groups. When permission to perform an operation is not explicitly granted, it is implicitly denied. For example, if you allow the Marketing group, and only the Marketing group, permission to access a shared folder, users who are not members of the Marketing group are implicitly denied access. The operating system does not allow users who are not members of the Marketing group to access the folder.

Deny access to folders only in the following scenarios:

- You want to exclude a subset of a group (for example, an individual user) that has permissions.

- You want to exclude one or more special permissions when you have already granted Full Control to a user or group.

**Note**

- If you plan to redirect your users' My Documents folders, note that each user is granted exclusive access to his or her My Documents folder on the file server. If you need to access a user's My Documents folder, you have two choices: take ownership of the folder or follow the instructions provided in article Q288991, "Enabling the Administrator to Have Access to Redirected Folders" in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

#### Determining the Level of Access That Users Require

Assign the most restrictive permissions that still allow users to perform required tasks. The following descriptions explain the permissions that are associated with folders on NTFS volumes.

**Write** Users can copy or paste new files and subfolders in the folder and change folder attributes. However, users cannot open or browse the folder unless you grant the Read permission. Assigning Write permission is useful for folders where users can file confidential reports, such as timesheets, that only the manager or shared folder administrator can read.

**Read** Users can see the names of files and subfolders in a folder and view folder attributes, ownership, and permissions. Users can open and view files, but they cannot change files or add new files. Assign the Read permission if users need only to read information in a folder and they do not need to delete, create, or change files.

**List Folder Contents** Users can see the names of files and subfolders in the folder. However, users cannot open files to view their contents.

**Read & Execute** Users have the same rights as those assigned through the Read permission, as well as the ability to traverse folders. Traverse folders rights allow a user to reach files and folders located in subdirectories, even if the user does not have permission to access portions of the directory path.

**Modify** Users can delete the folder and perform the actions permitted by the Write and Read & Execute permissions. Because Modify gives users the ability to delete the folder, use Modify permission only for administrators or for the group or department owner of the folder.

**Full Control** Users can change permissions, take ownership, delete subfolders and files, and perform the actions granted by all other permissions. Because Full Control gives users the ability to delete the folder, use Full Control permission only for administrators or for the group or department owner of the folder.

For more information about permissions and file servers, see "Permissions on a file server" in Help and Support Center for Windows Server 2003.

#### Determining Whether to Disable Administrative Shares

Windows Server 2003 creates shared folders, known as *administrative shares*, by default when you start a server or when you stop and then start the Server service. These folders are shared for administrative purposes, and they allow users and applications with the appropriate administrative rights to gain access to the system remotely. For example, some backup software applications use these shares to remotely connect to systems to back up data.

Administrative shares have default share permissions that restrict access to members of only a few security groups. Each share name is appended with a dollar sign ($), which hides the share from users who browse the server. One type of administrative share is the root folder of every volume (C$, D$, and so on).

You can disable these administrative shares temporarily or permanently. For more information about disabling administrative shares and an overview of remote administration, see the *Storage Technologies Collection* of the *Windows Server 2003 Technical Reference* (or see the Storage Technologies Collection on the Web at http://www.microsoft.com/reskit).

#### Determining Whether to Hide Shared Folders

You can hide a shared folder by appending a dollar sign ($) to the shared folder name. Hiding shared folders is useful when you want to make a shared folder available over the network while keeping it hidden from people browsing on the network.

Hiding shared folders does not necessarily make them more secure, because anyone who knows the name of the server and the shared folder can connect to it. Therefore, you must set the necessary NTFS permissions on the shared folder so that access is granted only to the appropriate groups.

# Planning Encrypted File Storage

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows 2000, Windows XP, and Windows Server 2003 support storing files that are encrypted using EFS. However, remote decryption is a potential security risk, because files are decrypted before transmission on the local server, and they are transmitted unencrypted over the network in plaintext. Therefore, before you allow encrypted files to be stored on file servers, decide whether the risk associated with transmitting unencrypted files over the network is acceptable.

You can greatly reduce or eliminate this risk by enabling Internet Protocol security (IPSec) policies, which encrypts data that is transmitted between servers, or by using Web Distributed Authoring and Versioning (WebDAV) folders. WebDAV folders have many advantages compared to shared folders, so you should use them whenever possible for remote storage of encrypted files. WebDAV folders require less administrative effort and provide greater security than shared folders. WebDAV folders can also securely store and deliver files that are encrypted with EFS over the Internet by means of Hypertext Transfer Protocol (HTTP).

Before users can encrypt files that reside on a remote file server, you must designate the file server as trusted for delegation. Doing so allows all users with files on that server to encrypt their files. For more information about enabling encryption on a file server, see "Enable a remote server for file encryption" in Help and Support Center for Windows Server 2003. Note that when encrypting files on a WebDAV server, the server does not need to be trusted for delegation.

**Important**

- To enable EFS on a clustered file server, you must perform a number of steps to configure the environment correctly. For more information about enabling EFS on server clusters, see "Create a cluster-managed encrypted file share" in Help and Support Center for Windows Server 2003.

If you allow users to store encrypted files on file servers, review the following issues:

- Users can encrypt files on remote NTFS volumes only when both the user's computer and the file server are members of the same Windows Server 2003 forest. (This restriction does not apply to WebDAV folders.)
- Users must have Write or Modify permissions to encrypt or decrypt a file.
- Users cannot encrypt files that are compressed. If users encrypt a compressed file or folder, the file or folder is uncompressed.

For more information about EFS and using WebDAV folders to store encrypted files, see "Encrypting and decrypting data" and "Internet Information Services (IIS) 6.0 overview" in Help and Support Center for Windows Server 2003. For more information about configuring IPSec, see the *Networking Guide* of the *Windows Server 2003 Resource Kit* (or see the Networking Guide on the Web at http://www.microsoft.com/reskit).

# Planning DFS and FRS Security

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When planning to secure DFS namespaces and content replicated by FRS, follow these guidelines:

- Use NTFS permissions to secure DFS targets. If you are using FRS to replicate DFS link target information, any permission changes you make on one member of the replica set replicate to other members. If you are not using FRS for automatic replication, you must set the permissions on targets and manually propagate any changes that occur.

- When setting NTFS permissions, always use the path of the physical folder (*servername**sharename*) instead of navigating through the DFS namespace to set permissions. This is especially important when you have multiple link targets for a given link. Setting permissions on a folder by using its DFS path can cause the folder to inherit permissions from its parent folder in the namespace. In addition, if there are multiple link targets, only one of them gets its permissions updated when you use the DFS path.

- If you plan to use share permissions, note that FRS does not replicate share permissions; therefore, you must plan to implement identical share permissions for each shared folder in a replica set. If you do not, users might have inconsistent access to shared folders across the network.

- To prevent the spread of viruses in read-only FRS-replicated content, give the appropriate groups the NTFS Read & Execute permission, create a group for administrators who update content, and assign that group the NTFS Modify permission. Do not grant permissions to the Everyone group. For additional recommendations, see "Permissions on a file server" in Help and Support Center for Windows Server 2003.

- For FRS-replicated content, you must use antivirus programs that are FRS compatible and that do not change the security descriptor of files. For more information about FRS compatible antivirus programs, see article Q815263, "Antivirus, Backup and Disk Optimization Programs That Are Compatible with the File Replication Service." To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

- You must have permissions on the DFS configuration object in Active Directory to add and delete roots to a domain-based DFS namespace.

- You can create DFS link targets that point to shared folders containing data that is encrypted by using EFS. However, you cannot use FRS to replicate those files among multiple link targets.

- Do not enable the RestrictAnonymous registry value on DFS root servers. Doing so restricts anonymous access and causes DFS referral failures. This registry value is also part of the HiSecWeb security template, which is designed to help secure Internet Information Services (IIS) at the operating system level. For more information about the RestrictAnonymous registry value, see article Q246261, "How to Use the RestrictAnonymous Registry Value in Windows 2000." For more information about the HiSecWeb template, see article Q316347, "IIS 5: HiSecWeb Potential Risks and the IIS Lockdown Tool," in the Microsoft Knowledge Base. To find these articles, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Planning Cluster Security

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When planning to secure clustered file servers, follow these guidelines:

- After you create a folder by using Windows Explorer, verify that the Cluster service account has the Read permission on the folder so that you can share the folder properly by using Cluster Administrator. (Do not share the folder by using Windows Explorer.)

- Use Cluster Administrator to set share permissions. If you change file share permissions using Windows Explorer or My Computer, instead of using **Permissions** on the **Parameters** tab in Cluster Administrator, the permissions are lost when the resource is taken offline.

**Note**

- When you set file share permissions by using Cluster Administrator, the default permissions give the Everyone group the Read permission. When you set file share permissions by using Cluster.exe, the Everyone group has the Full Control permission.

    - To secure File Share resources on the local server, use Windows Explorer to assign NTFS permissions on the physical folder, because share permissions apply only when users connect to the clustered file server across the network.

    - Do not assign NTFS permissions to local groups on clustered file servers. These permissions will have no meaning when the clustered disk resource is moved to another server. Therefore, always assign permissions to a domain local group.

    - By default, access to cluster file shares is disabled to anonymous users. To allow anonymous access to specific file shares, you can either enable Kerberos V5 authentication on the Network Name resource that is associated with the file share or you can change the local security policy setting. For more information about configuring these Kerberos properties, see "Enable Kerberos authentication for virtual servers" in Help and Support Center for Windows Server 2003.

    - When you create File Share resources by using the Share Subdirectories option, the subdirectories inherit the permissions of the parent. If you are using the subdirectories as user folders, and you want to allow only the user and administrator to access the folder, set NTFS permissions on each subfolder.

    - To enable EFS on a clustered file server, you must perform some steps to configure the environment correctly. These steps are described in "Create a cluster-managed encrypted file share" in Help and Support Center for Windows Server 2003.

For more information about server cluster security, see "Best practices for securing server clusters" in Help and Support Center for Windows Server 2003.

# Deploying File Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Deploying file servers involves installing Windows Server 2003 on the physical servers, adding the servers to the network, and then implementing the design decisions you made throughout this chapter. Organizations that plan to deploy clustered file servers must take the additional step of configuring the clusters; all other organizations can begin by choosing the installation method. Figure 2.19 describes the file server deployment process.

**Figure 2.19 File Server Deployment Process**

# Installing Windows Server 2003

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you install Windows Server 2003, you need to decide whether to perform clean installations or upgrades. You also need to decide if you want to perform an automated installation.

**Choosing Between Clean Installations and Upgrades**
If your servers are new and do not contain operating systems, you must perform clean installations. If you have existing servers, you can perform clean installations or upgrades. Consider the following points when choosing between a clean installation and an upgrade.

Choosing a new installation:

- If you reformat your hard disk and then perform a new installation, the efficiency of your disk might improve (compared to not reformatting it). Reformatting also gives you the opportunity to modify the size or number of disk partitions to make them match your requirements more closely.

- If you want to practice careful configuration management (for example, for a server where high availability is important), you might want to perform a new installation on that server instead of an upgrade. This is especially true on servers on which you have upgraded the operating system several times in the past.

Choosing an upgrade:

- With an upgrade, configuration is simpler, and you retain your existing users, settings, groups, rights, and permissions.

- With an upgrade, you do not need to reinstall files and applications. As with any major changes to the hard disk, however, it is recommended that you back up the disk before beginning an upgrade.

**Preparing for a Clean Installation on Existing File Servers**
Review the following issues before performing a clean installation on existing file servers:

- If you are performing a clean installation on a file server that contains a domain-based DFS root, remove the server as a DFS root before you begin the installation.

- If you are performing a clean installation on a member of an FRS replica set, use the Distributed File System snap-in (available in Windows Server 2003 or in the Windows Server 2003 Administration Tools Pack) to remove all inbound and outbound FRS connections to the server before beginning the clean installation.

**Upgrading Existing File Servers**
If you plan to upgrade file servers to Windows Server 2003, review the following issues:

- **Service pack requirements for servers running Windows NT 4.0.** Before you can upgrade a server that is running Windows NT 4.0 to Windows Server 2003, you must first install Windows NT 4.0 Service Pack 5 or a later version.

- **Upgrading servers that contain multidisk volumes.** If a server contains multidisk volumes, review the following issues:

    - If you are upgrading from Windows NT Server 4.0 to Windows Server 2003, verify that your backup software and hardware are compatible with both Windows NT Server 4.0 and Windows Server 2003. Next, back up and then delete all multidisk volumes (volume sets, mirror sets, stripe sets, and stripe sets with parity) before you upgrade, because Windows Server 2003 cannot access these volumes. Be sure to verify that your backup was successful before deleting the volumes. After you finish upgrading to Windows Server 2003, create new dynamic volumes, and then restore the data.

    - If you are upgrading from Windows NT Server 4.0 to Windows Server 2003, and the paging file resides on a

multidisk volume, you must use System in Control Panel to move the paging file to a primary partition or logical drive before beginning Setup.

- If you are upgrading from Windows 2000 Server to Windows Server 2003, you must use Disk Management to convert all basic disks that contain multidisk volumes to dynamic disks before beginning Setup. If you do not do this, Setup does not continue.

- **Upgrading servers that contain multiple DFS roots.** If you are running a prerelease version of Windows Server 2003, Standard Edition, and the server hosts multiple DFS roots, only one of those roots will be available after the upgrade. For more information about this and other DFS issues during upgrades, see "Deploying DFS" later in this chapter.

- **Upgrading servers that are part of FRS replica sets.** To keep the data in a replica set available during the upgrade, stagger the upgrades of replica members.

**Choosing Automated Installations**

Many large organizations use automated installations to install Windows Server 2003. Bulk installations are faster, easier, less expensive, more consistent, and more efficient than having users or IT professionals sit at servers and enter data manually. Windows Server 2003 provides the following tools and methods that you can use to design and deploy very simple or very sophisticated automated installations:

- Remote Installation Services (RIS)

- System Preparation Tool (Sysprep)

- Unattended Installation

These automated installation methods address a variety of specific issues, and each method has inherent advantages and disadvantages, depending on the environment in which you use these methods. To determine the best methods to use in the context of your specific environment, see "Choosing an Automated Installation Method" in *Automating and Customizing Installations* of this kit.

# Deploying Clustered File Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The cluster installation method you choose depends on whether you have existing clustered file servers. If you do have existing clustered file servers, you have several options when upgrading server clusters:

- Perform a new installation of Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition, and configure the cluster at the same time.
- Upgrade a cluster that is running Windows NT Server 4.0, Enterprise Edition.
- Upgrade a cluster that is running Windows 2000, possibly through a rolling upgrade.

There are two major advantages to a rolling upgrade. First, there is minimal interruption of service to clients. (However, server response time might decrease during the phases in which fewer nodes handle the work of the entire cluster.) Second, you do not have to recreate your cluster configuration. The configuration remains intact during the upgrade process.

**Caution**

- Do not make DFS configuration changes (for example, adding new links, new link targets, and so on) while operating a mixed-version cluster, because all DFS changes are lost upon failover.

You cannot perform a rolling upgrade directly from Windows NT Server 4.0, Enterprise Edition to Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition. Instead you have two options:

- You can maintain cluster availability by performing an upgrade to Windows 2000 first (as specified in the Windows 2000 documentation), and then upgrade to Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition.
- You can perform a nonrolling upgrade directly from Windows NT 4.0 to Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition. Note that a nonrolling upgrade does not allow you to maintain cluster availability.

For comprehensive information about choosing the cluster installation method and performing the actual installation, see "Designing and Deploying Server Clusters" in this book and see "Installing and upgrading on cluster nodes" in Help and Support Center for Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition.

Regardless of the installation type, evaluate your cluster hardware for compatibility with Windows Server 2003. For more information about choosing cluster hardware, see "Designing and Deploying Server Clusters" in this book.

After you have installed Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition and configured the server cluster, use the following sections for information about creating mounted drives and File Share resources on server clusters.

**Creating Mounted Drives on Server Clusters**

If you assign drive letters to the cluster storage devices, Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition, limit the total number of such devices to 23. Mounted drives are not subject to this limit; you can use mounted drives to access more than 23 cluster storage devices in your server cluster.

When using NTFS mounted drives with server clusters, follow these recommendations:

- Make sure that you create unique mounted drives so that they do not conflict with existing local drives on any node in the cluster.
- Do not create mounted drives between disks on the cluster storage device (cluster disks) and local disks.
- Do not create mounted drives from the cluster disk that contains the quorum resource (the quorum disk). You can,

however, create a mounted drive from the quorum disk to a clustered disk.

- Mounted drives from one cluster disk to another must be in the same cluster resource group, and they must be dependent on the root disk.

- Use Event Viewer to check the system log for any Cluster service errors or warnings indicating mount point failures. These errors are listed as ClusSvc in the **Source** column and as Physical Disk Resource in the **Category** column.

For more information about creating mounted drives, see "Create a mounted drive" in Help and Support Center for Windows Server 2003.

**Creating File Share Resources**

After you choose the cluster installation method and create the server cluster, migrate existing data on existing file servers, if necessary, and then create one or more File Share resources by using the Cluster Administrator snap-in or by creating scripts. For more information about creating a cluster-managed file share, see "Create a cluster-managed file share" in Help and Support Center for Windows Server 2003.

If you prefer to use scripts to create File Share resources, see article Q284838, "How to Create a Server Cluster File Share with Cluster.exe" in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources. For more information, see "Managing a Server Cluster from the Command Line" in Help and Support Center for Windows Server 2003.

After you create the File Share resources, you can enable shadow copies on cluster storage. For more information about enabling shadow copies on server clusters, see "Enable Shadow Copies for Shared Folders in a cluster" in Help and Support Center for Windows Server 2003.

# Migrating File Server Data

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you plan to consolidate file servers or replace outdated servers with new servers, migrate existing applications and data to the new servers. To ensure the success of the migration, create a detailed and well-tested migration plan that does the following:

- Minimizes the amount of time that data is unavailable to users
- Minimizes the impact on network bandwidth
- Minimizes the cost of the migration
- Ensures that no data loss occurs during the migration

The following sections describe the tasks for creating a migration plan

# Identifying Data to Migrate

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Large organizations rarely have time to take all production data offline before migrating it. Instead, they typically move data gradually, migrating different classes of data in stages. A migration plan should identify which data to move, where to move it, and the order in which it should be moved. File server data can usually be classified in the following classes:

- Business-critical data
- Application data
- Personal data (such as home directories)
- Profiles or other configuration data
- Departmental or group data
- Other data types, such as special projects or temporary data

**Important**

- Be sure to review any legal or copyright issues that might arise when you migrate data. For example, if users are storing MP3 files on the file server, you might violate copyrights by copying those files. If you are copying applications, make sure that doing so does not violate any licensing agreements.

When creating your migration plan, determine whether you want to consolidate different classes of data at different rates, onto different hardware, onto servers with different SLAs, or to different locations. Also, consider the importance of the data when planning your migration. For example, to minimize the impact of any problems during the migration, you might choose to move nonessential data first, followed by business-critical data.

In addition to identifying which data to move, you can also identify data that you do not need to move, such as duplicate, obsolete, or non-business-related files. Eliminating these files from your migration plan decreases the number of files that you need to migrate and increases the amount of available storage on the target server after the migration.

# Identifying Migration Risks

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The next step is to assess the risks associated with data migration. The best way to identify these risks is to set up a test lab with clients and servers, similar to those in your production environment, and conduct trial migrations. In addition to testing your actual migration method, test any applications that are installed on client computers to determine if the applications are affected by the migration. For example, applications that depend on components stored on a particular file server might not work correctly if the file server or share is renamed after the migration is complete. If you identify problems, update your migration plan so that you prevent or mitigate those problems.

There are a number of solutions you can implement either before or during the migration to prevent problems from occurring. For example, you can ensure that shortcuts and links on client computers work correctly after the migration by doing one of the following:

- **Implementing DFS.** If you have implemented DFS before the migration, the migration is transparent to users; you just need to update the link target location.

- **Migrating to clustered file servers.** In this case, the migration is transparent if you create virtual servers that use the same name as the previously used file servers. You can also transparently migrate any stand-alone DFS namespaces to clustered file servers. Using the previous server names, create your virtual servers, and then migrate the namespaces by using Dfsutil.exe.

- **Using a third-party migration tool.** Use a tool that can identify and fix broken links, such as OLE links or application-related links in the registry.

No migration plan is complete until you develop and test "back-out" procedures to follow if the migration fails at any stage in the process. Verify that you can restore data to its previous state and location in the event that you need to roll back the migration.

The following sections describe additional risks to consider during the migration.

**NTFS permissions**

When evaluating migration methods, determine whether the methods support migrating NTFS permissions. If you use domain local groups to assign permissions to files and folders, members of those groups will have the same access to the files and folders after they are moved to the new server. However, if you assign permissions to computer local groups, members of those groups cannot access the files after the migration. Either reconfigure permissions to use domain local groups before the migration, or plan to create new computer local groups on the target server and give those groups the appropriate permissions to the files after the migration is complete.

**NTFS compression**

If you use compression on the source servers, determine if you still require compression on the target server. Hardware on the target server is typically more powerful, with greater storage capacity. Therefore, compression might not be necessary, although you do need to account for the additional space required by the uncompressed data. Also, when you copy compressed files from one server to another, the compression attribute is lost unless you enable compression on the target volume.

**Files encrypted by using EFS**

Migrating encrypted files has a number of risks. Only administrators who are EFS recovery agents can copy or move files that are encrypted by other users. When these administrators copy or move encrypted files to a remote shared folder, the files are decrypted locally, transmitted in plaintext, and then re-encrypted on the target server only if the remote computer is trusted for delegation and the target volume uses NTFS. When the files are encrypted again on the target server, they have new file encryption keys that are encrypted by using the administrator's public key, if it is available, or by using a new public key, which EFS generates if the profile is unavailable. As a result, the users who originally encrypt the files are no longer able to access them. Therefore, do not copy or move encrypted files from one server to another; use a backup and restore method instead.

**Important**

- When EFS recovery agents copy encrypted files to a target server that is not trusted for delegation, or to a target volume that uses FAT, the files become plaintext on the target server.

For more information about EFS recovery agents, see "Designing a Public Key Infrastructure" in *Designing and Deploying Directory and Security Services* of this kit.

**Choosing a Migration Method**
Because many migration methods require downtime to move data, migrating data can be challenging in the following situations:

- The data has high uptime requirements as specified by SLAs in your organization, and the migration method might require more downtime than the SLA allows.
- Users expect to be able to access that data throughout their workday or at all times.

When planning your migration, consider the advantages and disadvantages of each migration method that is available to you, such as those described in the following sections. Your organization might use other methods not described here.

**Backup and restore data**
This method involves making a backup of the source server and restoring the data on a target server. Depending on your backup method and hardware, this method might involve moving tapes from one backup device to another (for direct-attached backup hardware) or restoring data from a tape library.

Advantages:

- Large organizations routinely back up and restore data, so you can use existing backups to begin the migration.
- Backing up and restoring data does not impact network bandwidth when it is performed on the local servers.
- You can use this method to migrate encrypted files.
- Disadvantages:
- Both the source server and the target server must support the backup device and its related software.
- If users are accessing files during the backup, you must make arrangements to migrate files that change while the backup occurs.
- Backup programs do not migrate shared folder information to the destination server. As a result, folders that are shared on the source server are not shared when you restore them on the destination server. You must share the destination folders manually or by using scripts, and then use Permcopy.exe, which is available on the *Windows Server 2003 Deployment Kit* companion CD, to migrate any share permissions. For more information about Permcopy.exe, click **Tools** in Help and Support Center for Windows Server 2003, and then click "Windows Resource Kit Tools Help"

**Use third-party migration tools, hardware, or services provided by hardware vendors**
A number of third-party migration tools can automate the entire migration process. These migration tools typically offer features such as bandwidth throttling, scheduling, incremental file migration, and monitoring. Many hardware vendors also provide hardware solutions and services that can assist you in migrating data.

**Copy the data**
This method involves using Robocopy.exe to copy data from one server to another and then using Permcopy.exe to migrate share permissions. Use the **/SEC** parameter in Robocopy.exe to copy NTFS permissions from the source folder to the destination folder. After you finish moving the data, share the folders on the target server (either manually or by using scripts), and then use Permcopy.exe to copy share permissions from the source server to the target server.

Permcopy.exe and Robocopy.exe are available on the *Windows Server 2003 Deployment Kit* companion CD. For more information about Permcopy.exe and Robocopy.exe, click **Tools** in Help and Support Center for Windows Server 2003, and then click "Windows Resource Kit Tools Help."

Advantages:

- These tools are available as part of the *Windows Server 2003 Deployment Kit*.

- This method is simple if you are migrating a small amount of data.
- Robocopy.exe gives you a number of options for migrating data, including the following:
    - Using file names, wildcard characters, paths, or file attributes to include or exclude source files as candidates for migrating.
    - Controlling the number of times that Robocopy.exe retries an operation after encountering a recoverable network error.
    - Scheduling copy jobs to run automatically.
- Disadvantages:
- Files are copied across the network, which can impact network bandwidth.
- This method should not be used to migrate encrypted files.
- If users are accessing files as the files are copied, you must make arrangements to migrate files that change while the copy occurs.
- This method might take a long time to complete if you are migrating large amounts of data.
- This method does not migrate shared folder information to the destination server. As a result, folders that are shared on the source server are not shared when you copy or restore them on the destination server. You must share the destination folders manually or by using scripts, and then use Permcopy.exe to migrate any share permissions.

**Completing the Migration**

After you migrate data, verify that users can access the data on the new servers by completing the following tasks:

- Verify that NTFS and share permissions are migrated correctly.
- If a logon script maps drives to the old file servers, update the scripts so that they point to the new file servers.
- If the migrated folders are DFS link targets, update the link information so that it points to the new file server.
- If the migrated folders are redirected My Documents folders, use Group Policy to specify the new file server.
- If you migrate data to a clustered file server, create the necessary File Share resources.

# Deploying DFS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you upgrade a server containing a DFS root, ensure that the namespace will be available after the upgrade. After Windows Server 2003 is installed, either through a clean installation or upgrade, you can create new DFS namespaces or migrate existing DFS namespaces to servers running Windows Server 2003. If you create a new namespace, you can use the information provided by the design team in the "DFS Configuration Worksheet" (Sdcfsv_1.xls).

**Upgrading Servers That Contain DFS Namespaces**
If a file server contains existing DFS roots, they are converted as follows:

- When you upgrade a server running Windows NT 4.0 to Windows Server 2003, any DFS roots are converted to Windows Server 2003 stand-alone DFS roots.

- When you upgrade a server running Windows 2000 to Windows Server 2003, stand-alone DFS roots and domain-based DFS roots are converted to Windows Server 2003 stand-alone DFS roots and domain-based DFS roots, respectively.

In the following scenarios, DFS roots are not available after upgrade:

- If you upgrade a server that hosts a root on a FAT volume, the namespace is unavailable until you convert the volume to NTFS.

**Upgrading Prerelease Versions of Windows Server 2003, Standard Edition**
If you are running a prerelease version of Windows Server 2003, Standard Edition, and that server hosts multiple DFS roots, only one of those roots will be available after the upgrade. This is because Windows Server 2003, Standard Edition cannot host multiple namespace roots until you apply a hotfix (as described below).

To work around this issue, upgrade to Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition, or use the following procedure:

1. Before upgrading to Windows Server 2003, Standard Edition, open a command prompt window and use the **Dfsutil.exe** command with the **/Export** parameter to export all but one of the namespaces to text files.

2. Use the **Dfsutil.exe** command with the **/RemFtRoot** parameter to remove any extra domain-based roots from the server, or the **/RemStdRoot** parameter to remove a standalone namespace root.

| **Note** |
| --- |
| If you cannot remove a namespace root using the **/RemFtRoot** or **/RemStdRoot** parameters, use the **Dfsutil.exe/UnmapFtRoot** or **/Clean** parameters to force the removal of the roots. |

1. At the command prompt, type **netstop dfs & net start dfs**

   The DFS service will be briefly unavailable when the service is stopped and restarted, so perform this procedure during a period of low namespace usage.

2. Upgrade the server to Windows Server 2003, Standard Edition, and then install the hotfix described in Microsoft Knowledge Base article 903651 on the Microsoft Web site at http://support.microsoft.com/default.aspx?scid=kb;en-us;903651. This hotfix enables a server running Windows Server 2003, Standard Edition to host multiple domain-based roots.

3. Use **Dfsutil.exe** with the **/Import** parameter to import each namespace you deleted.

**Delegating the Administration of DFS Namespaces**
Use the procedures below to allow members of the local Administrators group on each root server to create and manage domain-based DFS namespaces. For more information about delegating permission to manage a DFS namespace, see "Designing a DFS Namespace" earlier in this chapter.

The following procedure grants the selected user the ability to create new DFS namespaces as well as administer existing ones.

**To delegate a user to administer DFS**

1. In the Active Directory Users and Computers snap-in, on the **View** menu, click **Advanced Features**.
2. In the console tree, double-click the **System** folder to expand it.
3. Click the **DFS-Configuration** folder.

   Any existing root objects appear in the details pane.
4. Right-click **DFS-Configuration**, and then click **Properties**.
5. On the **Security** tab, click **Add**.
6. Type the name of the user to whom you want to delegate administrative rights, and then click **OK**.
7. Select the user Full Control permission, and then click **OK**.

Use the following procedure to allow a user to have DFS administrative permissions only within a single DFS namespace.

**To grant a user permission to administer only a single DFS namespace**

1. In the Active Directory Users and Computers snap-in, on the **View** menu, click **Advanced Features**.
2. In the console tree, double-click the **System** folder to expand it.
3. Click the **DFS-Configuration** folder.

   Any existing root objects appear in the details pane.
4. Right-click the root object that you want to allow the user to administer, and then click **Properties**.
5. On the **Security** tab, click **Add**.
6. Type the name of the user, and then click **OK**.
7. Verify that the user is granted the Full Control permission, and then click **OK**.

**Creating New DFS Namespaces on Stand-Alone Servers**
Use the Distributed File System snap-in or the command-line tools Dfscmd.exe and Dfsutil.exe to create the root and link targets on stand-alone (nonclustered) file servers. The following topics in Help and Support Center for Windows Server 2003 provide information about using these tools:

- "Checklist: Creating a distributed file system"
- "Dfscmd"

For more information about installing Dfsutil.exe, see Windows Support Tools.

If you plan to enable FRS on link targets in the DFS namespace, see "Deploying FRS" later in this chapter.

**Creating New DFS Namespaces on Clustered Servers**
Use the Cluster Administrator snap-in to create a stand-alone DFS namespace on a clustered file server. For more information about creating a DFS root on server clusters, see "Create a cluster-managed file share" in Help and Support for Windows Server 2003.

**Migrating or Consolidating Existing Namespaces on New Servers**
If you have namespaces on existing file servers that you want to consolidate onto a file server that is running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition, or if you want to move a namespace from one server to another, you can use the Dfsutil.exe support tool to export the namespace from the source server to the destination server.

In the following example, an administrator wants to migrate the following namespaces on different servers to a single server running Windows Server 2003, Enterprise Edition.

- \\NT4SVR\Marketing (a stand-alone DFS root on a server running Windows NT Server 4.0)
- \\W2KSVR\Public (a stand-alone DFS root on a server running Windows 2000 Server)

First, the administrator creates the following stand-alone DFS roots on the server running Windows Server 2003, Enterprise Edition:

- \\NETSVR\Marketing
- \\NETSVR\Public

Next, the administrator installs Windows Support Tools from the Windows Server 2003 operating system CD and then uses the Dfsutil.exe tool to run the following commands:

```
          Dfsutil /Root:\\NT4SVR\Marketing /export:Nt4.txt
Dfsutil /Root:\\W2KSVR\Public /export:w2k.txt
```

Finally, the administrator runs the following commands to import the namespaces onto the server running Windows Server 2003, Enterprise Edition:

```
          Dfsutil /Root:\\NETSVR\Marketing /import:Nt4.txt /set
Dfsutil /Root:\\NETSVR\Public /import:w2k.txt /set
```

**Using Dfsutil.exe to Customize the Namespace**
Use the Dfsutil.exe parameters listed in Table 2.22 to customize the namespace. For more information about using Dfsutil.exe, see Windows Support Tools.

**Table 2.22 Dfsutil.exe Parameters Used to Customize the Namespace**

| Customization | Dfsutil.exe Parameter |
|---|---|
| Enable root scalability mode | /RootScalability |
| Add site information to root servers running Windows 2000 Server | /UpdateWin2kStaticSiteTable |
| Remove site information from root servers running Windows 2000 Server | /PurgeWin2kStaticSiteTable |
| Enable restricted same-site target selection | /InSite |
| Enable closest or least expensive target selection | /SiteCosting |

# Deploying FRS

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After you have deployed a domain-based DFS namespace, you are ready to deploy FRS. This section describes the following FRS deployment scenarios:

- Deploying a new replica set
- Adding a new replica member to an existing replica set

This section also provides an overview of the tasks required to deploy each scenario. For detailed procedures for each scenario, see the worksheets specified in the relevant sections. The worksheets also provide information about using Sonar.exe to monitor the status of your FRS deployment. Sonar.exe is available on *Windows Server 2003 Deployment Kit* companion CD. For more information about Sonar.exe, click **Tools** in Help and Support Center for Windows Server 2003, and then click Windows Resource Kit Tools Help.

# Deploying a New Replica Set

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

If you are deploying a new replica set, use the "FRS Configuration Worksheet" (Sdcfsv_2.xls) that was completed by the file services design team to begin the deployment. If the design team did not use this job aid, you will need the following information:

- The names of the link targets to be replicated. These link targets form the replica set.
- The FRS topology (ring, full mesh, hub and spoke, or custom) to use for each replica set. If the topology is custom, you also need the inbound and outbound connections for each replica member.
- The FRS replication schedule for each connection.
- The location and size of the staging directory.
- The connection priorities for each inbound connection.

Use the following information to choose the appropriate FRS deployment scenario:

- See "Deploying an Empty Replica Set" later in this section if you have two or more existing link targets on which you want to enable replication and the link targets do not contain data.
- See "Deploying a Replica Set with Existing Content" later in this section if you have two or more existing link targets that contain data and the link targets are currently in use in your organization.
- See "Adding a New Member to an Existing Replica Set" later in this chapter if you have an existing replica set and you want to add a new member.

**Deploying an Empty Replica Set**

This scenario requires that you have deployed your domain-based DFS namespace but you do not have any files and folders in the link targets that you plan to replicate. This scenario is the most efficient way to deploy FRS, because replica members perform their join operation on an empty tree. When you add files to the tree, FRS builds a single staging file for each file in the tree and uses those files to source all direct outbound partners.

**Important**

- When you deploy a new replica set using these scenarios, it is recommended that you deploy two replica members connected by high-bandwidth links and then prestage additional members, especially if they are located in remote sites with slow-bandwidth connections. For more information about adding members to a replica set, see "Adding a New Member to an Existing Replica Set" later in this chapter.

Before you begin, choose a procedure for either a standard topology (ring, hub and spoke, or full mesh) or a custom topology.

**Deploying a standard FRS topology**

To deploy a ring, hub and spoke, or full mesh topology, perform the following tasks:

1. Disable referrals to the link targets to be replicated.
2. Configure the USN journal.
3. Configure replication for a standard topology, and choose the staging directory location.
4. Adjust the size of the staging directory.

5. Verify that replication is working.
6. Set the initial replication schedule.
7. Configure filters to exclude files or folders from replication (optional).
8. Copy the data into the replica tree, and verify that the data is consistent.
9. Optimize the replication schedule (optional).
10. Enable referrals to the replicated link targets.
11. Configure connection priorities (optional).

For a Word document that provides detailed instructions on completing each of these tasks, "Deploying a Standard FRS Topology for an Empty Replica Set" (Sdcfsv_3.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Deploying a Standard FRS Topology for an Empty Replica Set" on the Web at http://www.microsoft.com/reskit). After you complete these tasks, you can notify users that the DFS namespace is available.

**Deploying a custom FRS topology**
To deploy a custom FRS topology, perform the following tasks:

1. Disable referrals to the link targets to be replicated.
2. Configure the USN journal.
3. Configure replication for a custom topology, choose the staging directory location, and configure connection priorities.
4. Adjust the size of the staging directory.
5. Verify that replication is working.
6. Set the initial replication schedule (optional).
7. Configure filters to exclude files or folders from replication (optional).
8. Copy the data into the replica tree, and verify that the data is consistent.
9. Enable referrals to the replicated link targets.
10. Optimize the replication schedule (optional).

For a Word document that provides detailed instructions on completing each of these tasks, see "Deploying a Custom FRS Topology for an Empty Replica Set" (Sdcfsv_4.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Deploying a Custom FRS Topology for an Empty Replica Set" on the Web at http://www.microsoft.com/reskit). After you complete these tasks, you can notify users that the DFS namespace is available.

**Deploying a Replica Set with Existing Content**
In this scenario, you have deployed a DFS namespace with existing content in one or more link targets, but you are not using FRS to keep those link targets synchronized. Users know about and use the namespace, and they might be accessing files from the link targets. This scenario is more complex than deploying FRS in an empty directory tree for a number of reasons:

- Users or applications might have locks on files or folders, which can prevent FRS from originating outgoing changes and receiving incoming changes.
- If files exist on the initial master, FRS builds a unique staging file for each file in the tree for each direct outbound partner. In other words, each partner gets its own set of files, which is more disk I/O and disk space intensive.

- The files in the replica tree of the initial master become authoritative, which means that after replication completes, the replica tree on each member is identical to the replica tree on the initial master. For servers that are not the initial master, FRS moves any files that existed in the replica tree to a folder named "NtFrs_PreExisting___See EventLog."

For these reasons, it is recommended that you create a new link and link targets (essentially setting up an empty replica set), configure replication as desired, and copy the existing data into the new replica tree. After replication is complete, change the name of the link that is associated with the replica set so that users can access the new replica set by using the existing link name.

**Important**

- This procedure requires enough disk space on each replica member to store two copies of the files — one copy is the existing data, and the second copy is the data in the newly created replica tree.

In the following procedures, "existing link" refers to the link that already contains data in its link targets, and "new link" is the link that you create with replicated link targets.

**To create a new link and link targets**

1. If users can modify files in the link targets, disable referrals to the link targets for the existing link, and then close all open files.

2. Create a new link, and then follow the procedure in one of the following documents to set up an empty replica set:

   - "Deploying a Standard FRS Topology for an Empty Replica Set" (Sdcfsv_3.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Deploying a Standard FRS Topology for an Empty Replica Set" on the Web at http://www.microsoft.com/reskit).

   - "Deploying a Custom FRS Topology for an Empty Replica Set" (Sdcfsv_4.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Deploying a Custom FRS Topology for an Empty Replica Set" on the Web at http://www.microsoft.com/reskit).

   Be sure to disable referrals to the new link targets so that users do not access them.

3. Copy the data to be replicated into the replica tree.

   This step is complete when the files are replicated successfully to all replica members.

4. In the Distributed File System snap-in, under the existing link, add the same link targets that you added under the new link. Be sure to clear the **Add this target to the replication set** check box.

5. If you have not done so already, disable referrals, and then close all open files so that users are no longer accessing any files in the existing link targets.

6. Under the existing link, remove the link targets that are not replicated. After you complete this step, the existing link and the new link have identical link targets.

Figure 2.20 shows how two example links, Existing Link and New Link, appear in the Distributed File System snap-in at the end of this procedure.

**Figure 2.20 Two Links in the Distributed File System Snap-in**

Next, use the following procedure to change the link name that is associated with the new replica set to match the existing link name.

**To match the new link name with the existing link name**

1. In the Active Directory Users and Computers snap-in, click the **View** menu, and then click **Advanced Features**.

2. In the console tree, under the domain where the DFS root is located, navigate to **System**, **File Replication Service**, **DFS Volumes**.

   When you expand **DFS Volumes**, you should see existing DFS replica sets, including the one that you created in the previous procedure. The replica set is identified as **rootname|newlinkname**. Identify the correct replica set before you continue.

3. To change the name of the link that is associated with the replica set, right-click the replica set, and then click **Rename**.

4. After **rootname|**, type the name of the existing link over the name of the new link.

Figure 2.21 shows how the **rootname|newlink** name appears at Step 2 and after Step 4.

**Figure 2.21 Changing the Link Name**

To complete the deployment, delete the new link.

**To delete the new link**

1. In the Distributed File System snap-in, locate the new link.

   The new link should no longer have replication enabled. It might be necessary to close and reopen the snap-in for the updates to appear.

2. Right-click the new link, and then click **Delete Link**.

3. Enable referrals to the link targets for the existing link.

# Adding a New Member to an Existing Replica Set

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you add a new member to an existing replica set, determine how to source the new member. You have two choices:

- **Replicate the files to the new member across the network.** When you replicate files across the network to the new member, you add the server as a link target within an existing replica set. When you add the new member to the topology, you can create a single inbound connection so that you source from a specific server, such as a server with fast connectivity, or you can add a computer with redundant inbound connections where it sources according to connection priority and schedule.

- **Prestage the files on the new member.** When you prestage files, you use a backup program to back up the replica tree and restore it on the new member. Using a backup program is required to preserve the file object IDs and security descriptors. (Command-line tools such as Copy.exe, Xcopy.exe, and Robocopy.exe do not preserve these items, and they cannot be used to prestage files.) After you restore the files, FRS replicates to the new member any files that changed since the backup was created, thus minimizing the number of files that are replicated across the network.

The method you choose typically depends on the size of the replica set and the available network bandwidth. You should replicate files over the network only if one of the following conditions exists:

- You have a high-bandwidth network, and you can afford to use part of that bandwidth for the initial replication.

- You have a low-bandwidth network, and you can afford to use that bandwidth for initial replication, and you also have the time to wait for the initial replication to complete.

If neither of these conditions exists, you should prestage the new member.

The following sections describe three possible scenarios for adding a new replica member:

- Prestaging a new replica member to avoid replicating files across the network.

- Adding a new replica member that contains no content. In this scenario, files are replicated across the network.

- Adding a new replica member that contains a copy of the content. In this scenario, the new member has an existing copy of the files, but these files are not prestaged. The files from the initial master are replicated across the network.

**Prestaging a New Replica Member**

In this scenario, you have an existing replica set, and you want to add a new replica member by prestaging it. After you prestage the new member and enable replication, FRS moves the prestaged files in the replica tree on the new member to the NtFrs_PreExisting____See_EventLog folder, but FRS then moves back to the replica tree any files that have the same object ID and content as the files in the master replica set. FRS replicates across the network only the files that were added or changed since you prestaged the files.

Before you can prestage a new replica member, one of the following events must occur:

- At least seven days have passed since you enabled replication between the first two members.

- You clear the outbound change log by modifying the registry on all direct upstream partners.

To prestage a new replica member, perform the following tasks:

1. Configure the USN journal.

2. Prestage the new replica member.

3. Create a new link target, add it to the replica set, and then specify the staging directory location.
4. Disable referrals to the new link target.
5. Configure connection objects, the initial schedule, and connection priorities (custom topologies only).
6. Adjust the size of the staging directory.
7. Verify that replication is working on the new member.
8. Enable referrals to the link target.
9. Optimize the replication schedule.
10. Configure connection priorities (standard topologies only).

For a Word document to assist you in completing each of these tasks, see "Prestaging a New Replica Member" (Sdcfsv_5.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Pre-staging a New Replica Member" on the Web at http://www.microsoft.com/reskit). After you complete these tasks, you can notify users that the DFS namespace is available.

**Adding a New Replica Member That Contains No Content**
In this scenario, the new replica member does not contain a copy of the replica tree. Data will replicate across the network according to the replication schedule.

To add a new replica member that contains no content, perform the following tasks:

1. Configure the USN journal.
2. Create a new link target, add it to the replica set, and then specify the staging directory location.
3. Disable referrals to the new link target.
4. Configure connection objects, the initial schedule, and connection priorities (custom topologies only).
5. Adjust the size of the staging directory.
6. Verify that replication is working on the new member.
7. Enable referrals to the link target.
8. Optimize the replication schedule (optional).
9. Configure connection priorities (standard topologies only).

For a Word document to assist you in completing each of these tasks, see "Adding a New Replica Member that Contains No Content" (Sdcfsv_6.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Adding a New Replica Member that Contains No Content" on the Web at http://www.microsoft.com/reskit). After you complete these tasks, you can notify users that the DFS namespace is available.

**Adding a New Replica Member That Contains a Copy of the Content**
In this scenario, the new replica member already contains a copy of the replica tree. You might have copied the data to the server manually (using Robocopy, for example), but you have not prestaged the new member. (Remember that prestaging preserves the file object IDs and security descriptors.) Because the data is not prestaged, the initial master replicates the entire replica tree to the new member, even if the new member already contains identical files. On the new replica member, FRS moves any files that existed in the replica tree to a folder named "NtFrs_PreExisting____See_EventLog." After replication completes, you can either delete this folder or move any unique files back into the replica tree.

To add a new replica member that contains a copy of the content, perform the following tasks:

1. Follow the procedures in "Adding a New Replica Member that Contains No Content" (Sdcfsv_6.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Adding a New Replica Member that Contains No Content" on the Web at http://www.microsoft.com/reskit).

2. After replication completes, locate the folder "NtFrs_PreExisting____See_EventLog" on the new replica member.

3. Do one of the following:

   - If the folder contains unique files that are not part of the replica set, copy those files back into the replica tree.

   - If you do not want to save any of the files, delete the folder.

# Configuring File Server Settings

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Many procedures for configuring file server settings are provided in Help and Support Center for Windows Server 2003. Table 2.23 lists subjects and file server topics that can be useful for configuring file server settings. For best results in identifying Help topics by title, in Help and Support Center, under the **Search** box, click **Set search options**. Under **Help Topics**, select the **Search in title only** checkbox.

**Table 2.23 Help and Support Center Topics Related to File Server Settings**

| Subject | Topic Title |
|---|---|
| Sharing folders | "Share a folder or drive" |
| Enabling disk quotas | "Checklist: Setting up disk quotas" |
| Enabling shadow copies | "Checklist: Deploying Shadow Copies for Shared Folders" |
| Setting NTFS permissions | "Set, view, change, or remove permissions on files and folders" |
| Enabling encryption on file servers | "Enable a remote server for file encryption" |
| Remotely managing file servers | "Using Web Interface for Remote Administration" |
| Managing disks and volumes | "Disk Management overview" and "DiskPart" |
| Enabling encryption on clustered file servers | "Create a cluster-managed encrypted file share" |
| Enabling client-side caching on clustered file servers | "Set client-side caching for a File Share resource" |
| Enabling shadow copies on cluster storage | "Enable Shadow Copies for Shared Folders in a cluster" |

# Additional Resources for Designing and Deploying File Servers

  Use Dfscmd.exe to create links and add link targets. For more information about Dfscmd.exe, see Command-line reference A-Z.

- Dfsutil.exe

  Use Dfsutil.exe to configure and troubleshoot DFS namespaces. For more information about Dfsutil.exe, see Windows Support Tools.

- DiskPart.exe

  Use DiskPart.exe to manage disks and volumes from the command line. For more information about DiskPart.exe, see Command-line reference A-Z.

- Permcopy.exe

  Use Permcopy.exe to copy shared folder permissions from one shared folder to another. For more information about

Permcopy.exe, see Windows Resource Kit Tools Help.

- Robocopy.exe

  Use Robocopy.exe to maintain identical copies of a folder tree in multiple locations. For more information about Robocopy.exe, see Windows Resource Kit Tools Help.

- Sonar.exe

  Use Sonar.exe to monitor key statistics about FRS members in a replica set. For more information about Sonar.exe, see Windows Resource Kit Tools Help.

- Windows Server 2003 Administration Tools Pack

  Use the Windows Server 2003 Administration Tools Pack to remotely manage servers running Windows Server 2003 from computers running Windows XP. For more information about installing this tools pack, see article Q304718, "Administer Windows 2000–Based Computers Using Windows XP Professional Clients," in the Microsoft Knowledge Base. To find this article, see the Microsoft Knowledge Base link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources.

# Designing and Deploying Print Servers

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Adding or upgrading print servers, consolidating servers, or creating print server clusters can increase the reliability, availability, and manageability of your printing environment. Network and print administrators in medium-to-large organizations can deploy and manage print servers more efficiently by properly planning and deploying a network printing solution.

**In This Chapter**

Overview of the Print Server Deployment Process

Inventorying the Current Printing Environment

Designing the New Printing Environment

Deploying Print Servers

Additional Resources for Designing and Deploying Print Servers

**Related Information**

- For conceptual information about network printing and Windows clustering, see the *Storage Technologies Collection* of the *Windows Server 2003 Technical Reference* (or see the Storage Technologies Collection on the Web at http://www.microsoft.com/reskit).

# Overview of the Print Server Deployment Process

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Deploying print servers running the Microsoft® Windows® Server 2003, Standard Edition or Windows® Server 2003, Enterprise Edition operating systems lets your organization share printing resources across the network, allowing client computers to send print jobs to printers attached locally to a print server and to printers accessible across the Internet. Windows Server 2003 provides a number of solutions that can benefit your organization.

**Cross-platform printing support** Windows Server 2003 supports printing from Microsoft® Windows® 95, Windows® 98, Windows® Millennium Edition, Windows NT® version 4.0, Windows® 2000, Windows® XP Professional, or UNIX or Linux operating systems.

**Increased availability** If your business relies on high availability of network printers, you can cluster print servers or install a standby server to increase print server availability.

**Driver versioning** To improve stability, Windows Server 2003 restricts the installation of older printer drivers, which can cause the system to become unresponsive. You can override these restrictions if your network has clients that require older printer drivers.

**Consolidation tools** If you have too many print servers to manage efficiently in your current printing environment, you can use the Print Migrator tool to help automate printer consolidation on Windows Server 2003. Instead of recreating all of the printer objects manually, you can back up existing printers and restore them to your new print servers.

**Rich printer status reporting** If you use the standard port monitor, you can receive status reports when the printer runs out of paper, runs low on toner, or is stopped by a paper jam.

**Easy location of nearby printers** If you implement the Active Directory® directory service, your users can easily find printers that are published in Active Directory based on attributes that you designate.

**Improved security** New local Group Policy settings can control which individuals have access to the print queue over the network.

**Centralized printer management** Windows Server 2003 lets you remotely manage and configure printers from any computer running Windows Server 2003.

If your current network environment has a mix of clients and print servers running different operating systems, you can improve the interoperability, availability, and efficiency of your print servers by properly designing your new printing environment. After the design team creates a design, and the deployment team implements that design in a test lab, you are ready to deploy your new Windows Server 2003 print servers in a production environment.

Effectively deploying print servers that run Windows Server 2003 is a three-phase process, as illustrated in Figure 3.1.

**Figure 3.1 Designing and Deploying Print Servers**

A print server design team completes the first two phases: examining your current environment and designing a new printing environment. During these phases, the design team collects information that is vital to the deployment process, determines your immediate and long-term printing needs, recommends improvements to the printing environment, and creates an appropriate printing strategy.

A print server deployment team completes the final phase of the deployment process by implementing the design team's

decisions. The deployment team's responsibilities include adding printing capabilities to existing or newly created clustered servers, installing Windows Server 2003 on the print servers, creating the printers, and ensuring that clients receive the required printer connections.

**Note**

- For a list of the job aids that are available to assist you in deploying print servers, see "Additional Resources for Designing and Deploying Print Servers" later in this chapter.

# Inventorying the Current Printing Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The first phase in moving to a Windows Server 2003–based printing environment is gathering information about your current printing environment. Document the port types, printer names, share names, IP address, driver models and driver versions of each printer that you plan to replace or migrate. This information helps you plan details of the deployment process and gives you a way to rebuild printers if a server fails.

Figure 3.2 illustrates the place of this phase in the design and deployment process.

**Figure 3.2 Inventorying the Current Printing Environment**

A number of tools can help you inventory your current printing environment. These tools can also be useful if you decide to migrate your existing print servers to new print servers that are running Windows Server 2003. The tools you can use depend on your current operating system:

- Windows Server 2003 includes scripts written in the Microsoft® Visual Basic® Scripting Language that you can use to inventory your current printing environment.
- If you are in a Windows NT 4.0 domain, you must use PrnAdmin to inventory your current printing environment.

**Note**

- For a worksheet to assist you in inventorying your printing environment, see "Print Server Inventory Worksheet" (Sdcpsv_1.doc) on the *Microsoft® Windows® Server 2003 Deployment Kit* companion CD (or see "Print Server Inventory Worksheet" on the Web at http://www.microsoft.com/reskit).

#### Visual Basic Scripts

Table 3.1 lists information that you might require while inventorying your printing environment and the scripts you can use to obtain that information. These scripts are located in the Windows\System32 directory.

**Table 3.1 Scripts That Provide Print Server Information**

| Information Needed | Script |
|---|---|
| Print server name | Prnmngr.vbs |
| Print queue name | Prnmngr.vbs |
| Printer driver name | Prnmngr.vbs |
| Print port type | Prnport.vbs |
| Print port configuration | Prnport.vbs |
| Print device IP address | Prnport.vbs |

For a list of parameters for each script listed in Table 6.1, perform the following procedure.

**To list the parameters for the Visual Basic scripts listed in Table 6.1**

1. Open a **Command Prompt**, and then move to the Windows/System32 directory.

2. At the command prompt, type:

   **cscript *scriptname*.vbs**

**PrnAdmin**
If you are migrating from Windows NT 4.0 to Windows Server 2003, you can use Prnadmin.dll to inventory your current environment. PrnAdmin enumerates ports, drivers, printers, or forms on local or remote printers. The Visual Basic script for the PrnAdmin utility is named Prnmgr.vbs.

You can find the PrnAdmin utility on the *Windows Server 2003 Deployment Kit* companion CD. To install PrnAdmin, type the following command:

```
regsvr32 "C:\Program Files\Resource Kit\PrnAdmin.dll"
```

### Important

- The preceding command syntax assumes that you installed the contents of the *Windows Server 2003 Resource Kit* companion CD in the default location, C:\Program Files\Resource Kit. If you install the contents in a different location, you must use that path in the syntax.

**PrnAdmin syntax**
The command-line syntax for PrnAdmin is:

```
cscript prnmgr.vbs [-adx[c]] [l] [-cserver] [-bprinter] [-mdriver model]
[-pdriver path] [-r port] [-f file]
```

**PrnAdmin example**
The following command lists all printers on the print server \\adminserver:

```
cscript prnmgr.vbs -l -c \\adminserver
```

# Designing the New Printing Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

After inventorying your current printing environment, your design team can start designing your new printing environment. Figure 3.3 illustrates the component tasks in this phase and its position in the design and deployment process.

**Figure 3.3 Designing the New Printing Environment**

**Note**

- For a worksheet to assist you in designing your printing environment, see "Print Server Design Worksheet" (Sdcpsv_2.doc) on the *Windows Server 2003 Deployment Kit* companion CD (or see "Print Server Design Worksheet" on the Web at http://www.microsoft.com/reskit).

# Increasing the Efficiency of the Printing Environment

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When designing your new printing environment, examine your existing environment to determine if you need to make more efficient use of your resources. Examine the efficiency of both printing performance and printing management.

**Printing Performance**

You might need to make adjustments to servers that are not responding at the levels that you require. If users are waiting an unacceptable amount of time for jobs to print, you can improve the performance of your print servers by replacing older print devices with newer, faster devices.

Another option is to create a printer pool in which two or more of the same model printers connect to one print server and behave as a single printer. You can make the printer pool appear to users as a single printer by using multiple ports on the print server to connect the printers to one logical printer (the printer's software interface on the print server). When a user prints a document to the printer pool, the document prints to the first available printer in the pool. Users do not have to know which printer is available. The logical printer checks for an available port and then sends documents to ports in the order in which the documents are added to the print queue. A printer pool also eases administration, because you can manage multiple printers from the same logical printer on the print server.

If you have remote offices that experience bandwidth limitations while connected to a central print server, consider placing print servers in those offices. However, increasing performance in this manner has a drawback: If the print server fails, someone on-site must troubleshoot or restart the server. In addition, if your print server also hosts other services, restarting the server causes those other services to go offline as well.

**Printing Management**

You might also have more print servers than you need. If you have more print servers than you can manage efficiently, consider consolidating some of your print servers. For more information about consolidating print servers, see "Designing for Efficient Use of Hardware in Printing" later in this chapter.

# Optimizing Print Server Availability

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

By evaluating your availability requirements, you can determine if you need to increase print server availability and minimize downtime if a server stops responding. Certain users or groups in your organization might need highly available network printing. An accounting group, for example, might print time-sensitive documents such as payroll checks. In such a case, you need to examine high-availability solutions for that group.

If you determine that you have users who need highly available printing, you should consider either creating a print server cluster or putting a standby system in place in the event that your print server becomes unavailable. Both of these methods have trade-offs in cost and manageability. The following sections describe these trade-offs and can help you decide which method is more appropriate for your organization.

**Creating Clustered Print Servers to Increase Availability**

A *cluster* is a group of individual computer systems working together to provide increased computing power and to ensure continuous availability of mission-critical applications or services. The computers in this group use a common cluster name, appear to network clients as a single system, and distribute the cluster's workload among the group.

Clustered print servers provide failover and failback capabilities, which enhance the availability of print servers by allowing individual print servers, known as *nodes*, to fill in for each other if one of them fails (although there might be a short period when the printers are unavailable while the resources fail over to the other nodes). With clustered print servers, you also can perform maintenance on one node, without interrupting printing operations, by moving the cluster resources to another node.

You can create clusters only on servers that run Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition. However, after you set up a cluster on these computers, you can administer the cluster, including installing and configuring printers, from any computer on the network that is running Windows 2000, Windows XP Professional with Service Pack 1 and the Administration Tools Pack, or Windows Server 2003. For information about installing the Administration Tools Pack, see "Windows Server 2003 Administration Tools Pack Overview" in Help and Support Center for Windows Server 2003.

Before deciding whether to use clustered print servers to increase printer availability, consider the following requirements:

- Clustered print servers have additional costs and hardware requirements. A clustered print server requires two or more physical servers running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition. Because of the specialized hardware and the software requirements, the overall cost of implementing clustered print servers can be greater than the cost of providing a standby print server.

- Clustered print servers require administrator expertise. Implementing and maintaining clustered print servers requires experience or specialized training. Less experienced administrators might cause significant problems and delays, and mistakes can lower the availability of the print servers.

- For more information about deploying Windows server clusters, see "Designing and Deploying Server Clusters" in this book.

**Creating Standby Servers to Increase Availability**

Using a standby server to increase print server availability is a simple, low-cost alternative to clustering. The best method for setting up a standby server is to make sure that the hardware and software, including drivers, are exactly the same as the standard print server configuration that the design team has created. If you have a standby print server based on the standard print server configuration, you can replace any print server on your network that is based on the same configuration. In the event that a print server stops responding, rename the standby server to the same name as the server that you are replacing, and then connect the standby server to your network. For more information about standard print server configurations, see "Designing for Efficient Use of Hardware in Printing" later in this chapter.

Consider the following issues before creating standby print servers:

- Standby print servers carry additional costs. Providing a standby server requires two servers for each of the print servers that you want to be highly available. Ideally, these two servers have identical hardware and software configurations, including patches and printer drivers. The minimum requirements for a standby server are the same as the requirements for any server running Windows Server 2003.

- Standby print servers require additional maintenance. If you use standby servers, any changes that you make to the primary print server need to be made to the standby server also. If a server stops responding, you can rename the standby server and remove the primary print server from the network by using a Remote Desktop Connection.

- This method of increasing availability can result in some downtime, which is limited to the time that it takes to rename the standby print server, attach it to the network, and remove the primary print server.

- Users must resubmit any print jobs that failed to print. Print jobs that have been spooled but have not yet printed when the server stops responding must be resubmitted to the standby server after it replaces the primary print server.

# Determining Hardware and Driver Requirements

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before deploying a new Windows Server 2003 print environment, examine your existing print server hardware. If any of your hardware does not meet the recommended hardware requirements for Windows Server 2003 and does not appear in Windows Server Catalog, you must acquire new hardware or upgrade your existing hardware. For more information about hardware requirements, see the Windows Server Catalog link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources

You must also consider which printer driver versions you will need. Depending on the mix of client operating systems in your environment, you might need to install different printer driver versions on different client computers in order to print to the same printer.

# Designing for Efficient Use of Hardware in Printing

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

When determining your print server hardware requirements, consider both the sizing and placement of servers to maximize availability of printing resources, and determine whether you want to consolidate any existing print servers. After you make these design choices, consider creating a standard print server configuration to simplify the management and maintenance of your hardware.

**Determining Print Server Sizing**

When planning the printing strategy for your organization, consider the following factors as you estimate the number and types of printers that you need, both now and in the future:

- Determine how to divide and allocate printing resources. High-volume printers generally have more features, but a breakdown affects more users.
- Consider the printer features that you need, such as color printing, duplex printing, multibin mailboxes, envelope feeders, and stapling. Determine which users need these features and the physical locations of these users.
- Estimate any additional hardware requirements. Managing a large number of printers or many large documents requires a large amount of memory and disk space, and, potentially, a more powerful computer. If you need to store a copy of everything you print, you must provide additional disk space.
- Consider dedicating a server exclusively to printing. If you are considering using a server for both file and print sharing, remember that printing operations require a large amount of data input/output (I/O), and that the operating system gives priority to file operations over printing operations.
- Match printing volume as closely as possible to a printer's duty cycle (the number of pages the printer was designed to print per month). Maintenance problems are generally reduced if printing volume is less than or equal to the printer's duty cycle.
- Consider printing-speed requirements. In addition to the processing speed of the printer itself, network considerations also affect printing speed. Typically, printers that are attached directly to the network with network adapters offer faster throughput than printers attached with parallel buses. However, print throughput rates also depend on network traffic, the type of network adapter, and the protocol used.
- To increase the throughput of a print server, relocate the print spool folder. For best results, move the spool folder to a dedicated disk drive that does not share any files, including paging files, with the operating system.

The appropriate hardware for an organization varies widely depending on business requirements. Many businesses have relatively simple printing needs, while others have more complex printing needs. For example, when the graphics department of an advertising agency determines that it needs a high-speed color printer, the administrator locates the printer in the same area of the building as the graphics department. To avoid conflicts with other I/O operations on the server, the administrator also designates the D: drive on the print server as the print spool folder. For more information about print server sizing, see the Print Services link on the Web Resources page at http://www.microsoft.com/windows/reskits/webresources

**Determining Print Server Placement**

The placement of printers and print servers can affect both the efficiency of users and the congestion on your network. To minimize printing traffic in your network environment, locate printers close to the people who use them. Also, if some users print sensitive documents, consider locating their printers in an area of the building that only authorized personnel can access.

**Determining Whether to Consolidate Printers**
