- Summary – this is analogous to the information shown for the corresponding tab on a Group Policy Modeling node. In particular, this page shows the component status for the various Group Policy extensions. This information tells you whether there were any issues with a particular extension and is a good place to begin troubleshooting.

- Settings – this is analogous to the information shown for the corresponding tab on a Group Policy Modeling node.

- Events – this tab shows all policy-related events from the target computer (see Figure 29). Note that to gather this data, the user performing the query must have access to remotely view the event log. By default, this access is granted to all users on Windows XP, but not on Windows Server 2003. This data is useful for troubleshooting Group Policy issues. For example if the summary report indicates that a particular Group Policy component failed to process, you may be able to determine why by looking for errors and warnings in the event log.

**Figure 29**

# Platform Dependencies

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

GPMC exposes features that are available in the underlying operating system. Because new features have been added to Group Policy since Windows 2000, certain features will only be available in GPMC depending on the operating system that has been deployed on the domain controllers and clients. This section describes these dependencies. In general, there are four key issues that determine whether a feature is available in GPMC:

- Windows Server 2003 Active Directory schema must be available to delegate Group Policy Modeling or Group Policy Results
- Windows Server 2003 domain controller must be available to run Group Policy Modeling
- Windows Server 2003 domain configuration (ADPrep /DomainPrep) must be available to use WMI Filters
- Clients must be running Windows XP or Windows Server 2003 in order to generate Group Policy Results data.

Windows and Active Directory platform dependencies are summarized below in Table 4.

**Table 4 - Group Policy Version Dependencies**

| Dependency | Feature | Reason |
|---|---|---|
| Windows Server 2003 Active Directory Schema | Delegation of Group Policy Modeling and Group Policy Results | The Generate Resultant Set of Policy (Logging) and Generate Resultant Set of Policy (Planning) permissions needed for this operation are only available with the Windows Server 2003 Active Directory schema |
| Windows Server 2003 Domain Controller in the forest | Group Policy Modeling | The simulation is performed by the Resultant Set of Policy Service which is only available on domain controllers running Windows Server 2003 |
| Windows Server 2003 domain configuration (DomainPrep) | WMI Filters | ADPREP /DomainPrep configures the domain for Windows 2003 Active Directory including configuration for WMI Filters |
| Clients must be running Windows XP or Windows Server 2003 | Group Policy Results | Clients must be instrumented to log Group Policy Results data when policy is processed. This capability is only available on the listed systems |

There is no dependency from the Group Policy perspective on whether a domain is in native mode or mixed mode.

# GPMC Options

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The options dialog box allows the user to customize how certain features work in GPMC. The options dialog box is available from the **View** menu in GPMC. The options menu includes tabs for Columns, Reporting, and General options which allow the user to control GPMC as described below:

- Columns

  This tab allows you to control the columns displayed and their order for the following list views in GPMC: **Group Policy Inheritance**, **Group Policy Objects**, **Linked Group Policy Objects** and **WMI Filters**. The columns to display can be selected by checking the appropriate column names in the **Columns** tab of the GPMC options. The order can be set by moving column names up or down in the list.

- Reporting

  This tab allows you to customize the location where GPMC searches for .adm files used by reporting functions in GPMC. The reporting functions in GPMC require the .adm file for the GPO to display properly. The search location option allows the user to specify a custom search folder for the .adm files, which takes precedence over the default option of first searching the Windows folder then the SYSVOL folder of the GPO. This option is discussed further in the "Reporting on GPO Settings" section earlier in this white paper.

- General

  This tab allows you to:

  - Enable or disable trust detection. By default you can only add a forest to GPMC for which there is a 2-way trust with the forest of the user running GPMC. You can optionally enable GPMC to work with only 1-way trust. By using the **Stored User Names and Passwords** in Windows XP and Windows Server 2003, you can also enable access to un-trusted forests, as described earlier in the “Managing Multiple Forests” section,

  - Enable or disable confirmation dialog boxes to distinguish between GPOs and GPO Links. As mentioned previously, GPMC distinguishes between GPOs and GPO-links in several ways. One method is a confirmation dialog box which appears by default when a user clicks on a GPO-link. This option controls whether that confirmation is displayed.

  - Display the domain controller name beside the domain name. By default, GPMC displays the domain controller that GPMC is using for each domain in the result pane when you go to the **Domains** node in the console. Using this option you can specify that GPMC should always display the domain controller in parentheses as part of the name of the domain in the console tree.

# Internet Explorer Enhanced Security Configuration Considerations

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Windows Server 2003 includes a new default security configuration for Internet Explorer, called Internet Explorer Enhanced Security Configuration (ESC). ESC impacts the Security Zones and Privacy settings within the Internet Explorer Maintenance settings of a GPO. The Security Zones and Privacy settings can either be ESC enabled or not.

- When you edit settings for Security Zones and Privacy settings in a GPO from a computer where ESC is enabled, that GPO will contain ESC-enabled settings. When you look at the HTML report for that GPO, the Security Zones and Privacy header will be appended with the text **(Enhanced Security Configuration enabled)**.

- When you edit settings for Security Zones and Privacy settings in a GPO from a computer where ESC is not enabled, that GPO will contain ESC-disabled settings. ESC is not enabled on any computer running Windows 2000 or Windows XP, nor on computers running Windows Server 2003 where ESC has been explicitly disabled.

ESC settings deployed through Group Policy will only be processed on and applied by computers where ESC is enabled. ESC settings will be ignored on computers where ESC is not enabled (all computers running Windows 2000 and Windows XP, and Windows Server 2003 computers where ESC has been explicitly disabled). The converse is also true: A GPO that contains non-ESC settings will only be processed on and applied by computers where ESC is not enabled.

Furthermore, ESC impacts the functionality contained in the HTML reports produced by GPMC as follows.

- On computers with ESC enabled a prompt appears when you attempt to view reports in GPMC. This happens because the reports contain a script that allows you to expand and collapse sections of the reports using **Show** and **Hide**. To use the **Show** and **Hide** functionality in these reports, you must add the *About:security_MMC.exe* site to the Trusted Sites zone in Internet Explorer. This site represents all Web pages that are hosted inside MMC. You can do this by clicking **Add** on the **Internet Explorer** prompt. This opens the **Trusted sites** dialog box with the correct entry (*About:security_mmc.exe*) for the page being called by GPMC. Click **Add,** and then click **Close** in the **Trusted sites** dialog box to add this site to the Trusted sites zone. If the *About:security_mmc.exe site* is not added to the Trusted sites zone, the reports appear fully expanded and cannot be collapsed.

- In addition, the Explain text for a given setting in the HTML report is available by clicking on any setting in the Administrative Templates section of the GPO, assuming you have already added *About:security_MMC.exe* to the list of trusted sites. A prompt appears when you attempt to view the Explain text for a given administrative template setting in the HTML report. This prompt will ask if you want to add the *about:blank* site to the list of trusted sites. This is not recommended because it could significantly compromise the security of Internet Explorer on that computer. If you do not add the *about:blank* site to the list of trusted sites, you will not lose significant functionality in GPMC. You will still be able to view the Explain text, however, the Print and Close buttons in the Explain text dialog box will not be functional. To close the dialog, use the close box in the upper right corner.

# Scripting Group Policy-related Tasks

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The GPMC user interface is based on a set of COM interfaces that accomplish most of the operations performed by GPMC. These interfaces are available to Windows scripting technologies like JScript and VBScript as well as programming languages such as Visual Basic and VC++. For example, the following capabilities are scriptable using these interfaces:

- Creating/deleting/renaming GPOs.
- Linking/unlinking GPOs and WMI filters.
- Delegation:
    - Security on GPOs and WMI filters.
    - Group Policy-related security on sites, domains, OUs.
    - Creation rights for GPOs and WMI filters.
- Generating reports of GPO settings.
- Generating reports of RSOP data.
- Backup/Restore of GPOs.
- Import/Export, Copy/Paste of GPOs.
- Search for GPOs, WMI filters, SOMs, and backups.

These interfaces are discussed in detail in the GPMC software development kit (SDK) located in the %programfiles%\gpmc\scripts\gpmc.chm help file on systems where GPMC has been installed. The contents of the GPMC SDK are also available in the Platform SDK.

GPMC comes with a number of sample scripts (written mostly in VBScript but some JScript) that form a toolkit of scripts that administrators can use to directly administer a Group Policy environment or as examples to build more elaborate management tools. The scripts are installed in the %programfiles%\gpmc\scripts directory. Table 5 shows a list of scripts that are provided to do the associated types of Group Policy administrative tasks:

**Table 5**

| Administrative task | Script name | Description |
|---|---|---|
| Back up a GPO | BackupGPO.wsf | Backs up all GPOs in a domain to the specified backup directory. |
| Back up all GPOs in a domain | BackupAllGPOs.wsf | Given a GPO name or a GUID, backs up the GPO to a specified backup directory. |
| Create a GPO with default options | CreateGPO.wsf | Creates a GPO with the specified name, in the current domain, using the default options. |
| Create a migration table | CreateMigrationTable.wsf | Populates the entries of a migration table with security principals and UNC paths that are referenced in a GPO or backup. |

| | | |
|---|---|---|
| Copy a GPO | CopyGPO.wsf | Creates a new GPO and copies the settings from the source GPO into the new destination GPO, given a source GPO name or GUID and a new destination GPO name. |
| Create a policy environment using an XML representation | CreateEnvironmentFromXML.wsf | Reads an XML file that specifies a policy environment; for example, OUs, GPOs, links, and security groups. The script can either create the environment in a domain by creating the objects, or delete the environment by deleting objects specified in the XML file. |
| Create an XML representation of a policy environment | CreateXMLFromEnvironment.wsf | Reads an existing policy environment and creates an XML file representing that environment. The XML file captures information about OUs, GPOs, and GPO links, and security on GPOs. You can use this script in conjunction with the CreateEnvironmentFromXML.wsf script to create a replica of domain for staging purposes. |
| Delete a GPO | DeleteGPO.wsf | Deletes the specified GPO when given a GPO name or GUID. By default the script deletes links to that GPO within the same domain. |
| Grant Permissions for all GPOs in a Domain | GrantPermissionOnAllGPOs.wsf | Grants a user or group the specified level of permission for all GPOs in the specified domain. |
| Generate a report for a GPO | GetReportsForGPO.wsf | Creates an HTML and XML report for a given GPO at a given location in the file system. |
| Generate a report for all GPOs in the domain | GetReportsForAllGPOs.wsf | Creates HTML and XML reports for all GPOs in the domain, at a given location in the file system. |
| Import settings into a GPO | ImportGPO.wsf | Imports the settings from the specified backup to the existing destination GPO in the domain |
| Import multiple GPOs into a domain | ImportAllGPOs.wsf | Creates a new GPO and imports settings into that GPO for each backed-up GPO stored at a specific file system location. |
| Restore a GPO | RestoreGPO.wsf | Restores a backed-up GPO. |
| Restore all GPOs | RestoreAllGPOs.wsf | Restores all GPOs that are stored at a given file system location |
| Grant permissions for GPOs linked to a domain, OU, or site | SetGPOSecurityBySOM.wsf | Grants a user or group the specified permission type for all GPOs that are linked to a specified domain, OU, or site. You can specify **Read, Apply, Edit, FullEdit,** or **None** for the permission type. |
| Set GPO permissions | SetGPOPermissions.wsf | Sets the permission level for a security principal on a given GPO. You can specify **Read, Apply, Edit, FullEdit,** or **None** for the permission type. |
| Set permissions to create GPOs | SetGPOCreationPermissions.wsf | Grants or removes the ability to create GPOs in a domain for a given security principal. |

| | | |
|---|---|---|
| Set policy-related permissions on a given site, domain, or OU | SetSOMPermissions.wsf | Sets policy-related permissions on a given scope of management (SOM). A SOM is any site, domain, or OU. |
| List all GPOs in a domain | ListAllGPOs.wsf | Prints all GPOs in the specified domain. |
| List disabled GPOs | FindDisabledGPOs.wsf | Prints all GPOs in the specified domain that are disabled or partially disabled. |
| List GPO information | DumpGPOInfo.wsf | Prints the information for a specific GPO, including creation time, modification time, owner, status, version number, links, security groups that filter the GPO, and security groups that have full control, edit, read, or custom permissions. |
| List scope of management information | DumpSOMInfo.wsf | Prints all information for a specific Scope of Management (SOM), including GPO links and policy related permissions on the SOM. A SOM is any site, domain, or OU. |
| List GPO by policy extension | FindGPOsByPolicyExtension.wsf | Prints all GPOs in the specified domain for which a specific policy extension is configured; for example, find all GPOs that contain the Software Installation or Folder Redirection policy settings. |
| List GPOs by security group | FindGPOsBySecurityGroup.wsf | Prints all GPOs that for which a given security principal has the specified permission on that GPO. You can specify **Read, Apply, Edit,** or **Fulledit** for the permission type. |
| List GPOs with duplicate names | FindDuplicateNamedGPOs.wsf | Prints all GPOs in the specified domain that have duplicate names. |
| List GPOs without Apply permission | GPOsWithNoSecurityFiltering.wsf | Prints all GPOs in the specified domain that do not apply to anyone because **Apply** permission is not set on the GPO. |
| List GPOs Orphaned in SYSVOL | FindOrphanedGPOsInSYSVOL.wsf | Finds and prints all GPOs in SYSVOL with no corresponding component in Active Directory. |
| List domains and OUs with external GPO links | FindSOMsWithExternalGPOLinks.wsf | Prints all domains and OUs in the specified domain that link to a GPO in a different domain. |
| List unlinked GPOs in a domain | FindUnlinkedGPOs.wsf | Prints all GPOs in the specified domain that have no links. Links outside the domain, including site links, are not checked. |
| Print the scope of management policy tree | ListSOMPolicyTree.wsf | Prints all SOMs in the specified domain with the list of GPOs that are linked to the domain and each OU. |
| List GPO backups in a given file system location | QueryBackupLocation.wsf | Prints information about all backed up GPOs at the file system location specified by the user. |

All of the scripts are intended for command line operation. The user can execute a script using the following command (using the CreateGPO script as an example) from a command shell:

*Cscript CreateGPO.wsf*

Alternatively, you can set Cscript to be the default scripting engine by using this command:

*cscript //H:cscript*

The user will need to run the scripts from the %programfiles%\gpmc\scripts directory or by specifying the path to the scripts directory. To see usage details for any script, use the "/?" command line option.

# Related Links (Administering Group Policy with Group Policy Management Console)

Updated: April 7, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

# Maintaining the MIIS 2003 Database

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This topic provides basic guidelines for monitoring and backing up your Microsoft® Identity Integration Server 2003 database. Because MIIS 2003 uses Microsoft® SQL Server™ 2000 for database services and storage, this topic contains information about SQL Server 2000 in addition to information about MIIS 2003.

**In This White Paper**

Overview of Maintaining MIIS 2003

Overview of the SQL Server 2000 Implementation for MIIS 2003

Configuring SQL Server 2000 to Support MIIS 2003

SQL Server 2000 Databases Used by MIIS 2003

SQL Server 2000 Backup Types and Recovery Models

Backup Strategies for Your MIIS Database

Creating a New Backup Device

Scheduling Full Database Backups by Using the Database Maintenance Plan Wizard

Scheduling Differential Database Backups by Using SQL Server Enterprise Manager

Scheduling Backups of the System Databases

Ensuring Failover and High Availability

Monitoring the MIIS Database

Establishing a Performance Baseline

Setting Alerts to Monitor System Events

Additional Ways to Monitor the MIIS Database

Optimizing the MIIS Database

Additional Resources (Maintaining the MIIS 2003 Database)

# Overview of Maintaining MIIS 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

MIIS 2003 uses SQL Server 2000 as its data store. Because your MIIS 2003 data is a critical asset to your organization, it is important to back up your MIIS database regularly. It is also important to monitor your installation of SQL Server 2000 on a regular basis to assure optimum performance and reliability.

This topic assumes that you already have a thorough working knowledge of MIIS 2003 and some familiarity with SQL Server 2000. For more information about SQL Server 2000, see Microsoft SQL Server 2000 Books Online, which you can install during SQL Server 2000 installation and then access from the Start menu through All Programs. Optionally, see "Getting Started with SQL Server Books Online" on the Microsoft MSDN Web site at http://go.microsoft.com/fwlink/?LinkID=7107.

# Overview of the SQL Server 2000 Implementation for MIIS 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is important to understand the relationship between SQL Server 2000 editions and the editions of MIIS 2003. It is also important to understand some general recommendations for running SQL Server 2000 and the MIIS database. For example, backup types and recovery models, which are a part of SQL Server database maintenance, are critical to the safety concerns of your MIIS 2003 data.

**SQL Server 2000 and Windows Server 2003 Supported Editions**
Each edition of MIIS 2003 is supported by specific editions of Microsoft® Windows Server™ 2003 and SQL Server 2000. Table 1 lists the Windows Server 2003 and SQL Server 2000 editions that support each edition of MIIS 2003.

**Table 1 Windows Server 2003 and SQL Server 2000 Editions**

| This MIIS 2003 Edition | Is Supported by These Windows Server 2003 Editions | And by These SQL Server 2000 Editions |
|---|---|---|
| Standard Edition | Standard Edition<br><br>Enterprise Edition | Enterprise Edition (with SP3*)<br><br>Standard Edition (with SP3) |
| Enterprise Edition | Enterprise Edition | Enterprise Edition (with SP3) |

* Service Pack 3.

**MIIS 2003 Requirements for SQL Server 2000**
The following are MIIS 2003 requirements for SQL Server 2000:

- SQL Server 2000 and MIIS 2003 can be installed on the same server or different servers, but they must be located in the same domain.
- If you configure SQL Server 2000 to use a communications port other than the default SQL Server port 1433, you must use the SQL Server Client Network Utility on the computer on which you run MIIS 2003 to set the communications port to be used by SQL Server clients on that computer.

For more information about setting the communications port, see “Configuring SQL Server 2000 to Support MIIS 2003” later in this topic.

**Recommendations for Running SQL Server 2000 to Support MIIS 2003**
The following recommendations for running SQL Server 2000 will help you to improve the performance and efficiency of your MIIS 2003 installation:

- Do not attempt to manually modify data that is stored in the MIIS database. Modify the database only by using Identity Manager, which can determine if and what changes are necessary.
- Maintain your transaction log files for the MIIS database on a separate drive from the drive that contains the MIIS database.
- To ensure availability and provide redundancy in large-scale environments, use SQL Server clustering with MIIS 2003, Enterprise Edition.
- In addition to using the performance improvement methods described elsewhere in this document, use performance tuning to optimize SQL Server 2000 performance.

For information about SQL Server 2000 performance tuning, see “Chapter 20 - RDBMS Performance Tuning Guide for Data Warehousing” on the Microsoft Web site at http://go.microsoft.com/fwlink/?LinkID=17516.

# Configuring SQL Server 2000 to Support MIIS 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

To meet the requirements and recommendations for MIIS 2003, be sure that your SQL Server 2000 implementation is configured correctly. First, verify that the correct version of SQL Server 2000 is running in your environment. Then, check whether SQL Server 2000 is configured to use the correct communications port, and reconfigure it, if necessary.

**To verify that the correct version of SQL Server 2000 is running**

1. In Microsoft SQL Server, click **Query Analyzer**.
2. In the **Connect to SQL Server** dialog box, type your server name, click a connection option, and then click **OK**.
3. In the **Query** box, type or select the appropriate version.
4. On the **Query** menu, click **Execute**.

The query returns the version of SQL Server 2000 that is running. Ensure that you are running version number **8.00.760**, which indicates SQL Server 2000 SP3 or later.

By default, SQL Server 2000 uses communications port 1433. If SQL Server 2000 is configured to use a port other than 1433, you must use the SQL Server Client Network Utility on the computer running MIIS 2003 in order to change the communications port. You must do this even if MIIS 2003 is running on the same computer that SQL Server 2000 is running on.

**To determine which communications port that SQL Server 2000 is using**

1. In **Microsoft SQL Server**, click **Server Network Utility**.
2. On the **General** tab, under **Enabled Properties**, click **TCP/IP**, and then click **Properties**. The configured port is listed in **Default port**.

**To change the communications port that SQL Server 2000 is using**

1. On the computer that is running MIIS 2003, open **Microsoft SQL Server**, and then click **Client Network Utility**. (If this item does not appear, you must first install the SQL Server client tools from the SQL Server 2000 installation media.)
2. On the **General** tab, under **Enabled protocols by order**, click **TCP/IP**, and then click **Properties**.
3. In the **Default port** box, type the communications port in use by SQL Server 2000, and then click **OK**.
4. Click **OK** to close the Client Network Utility.

| **Important** |
| --- |
| The server and client port numbers must match. |

# SQL Server 2000 Databases Used by MIIS 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The implementation of SQL Server 2000 that is used by MIIS 2003 contains both an MIIS database for use by MIIS 2003 and several SQL Server system databases for use by SQL Server 2000. In addition, a SQL Server 2000 implementation can include several sample databases.

**To view the SQL Server system databases and the MIIS database**

1. In **Microsoft SQL Server**, click **Enterprise Manager**.

2. Expand **Microsoft SQL Servers**, expand **SQL Server Group**, expand *servername* (where servername represents the computer on which SQL Server 2000 is running), and then expand **Databases**.

3. Click a database to view.

   To view more information about a database, right-click the database, and then click **Properties**.

**MicrosoftIdentityIntegrationServer Database in SQL Server 2000**

When MIIS 2003 is installed, a SQL Server 2000 database that is named **MicrosoftIdentityIntegrationServer** is created within SQL Server 2000. The **MicrosoftIdentityIntegrationServer** database contains all the metadirectory data used by MIIS 2003, including the following:

- Metaverse data
- Management agent data
- Connector space data
- Rules extension data
- Object link data
- Management agent run profiles
- Management agent run history
- Joiner log

The **MicrosoftIdentityIntegrationServer** database does not contain any of the following:

- Event log files
- Contents of the directory at C:\ProgramFiles\Microsoft Identity Integration Server\MaData
- Administrative scripts

**SQL Server 2000 System Databases**

In addition to the MIIS database, SQL Server 2000 contains several system databases, which are created when you install SQL Server 2000.

**Master** The database that controls the operation of each instance of SQL Server. It is installed automatically with each instance of SQL Server and keeps track of user accounts, remote user accounts, and remote servers with which each instance can interact. It also tracks ongoing processes, configurable environment variables, system error messages, tapes and disks available on the system, and active locks.

**Msdb** The database used to store scheduling information, and backup and restore history information.

**Distribution** A database on the Distributor that stores data for replication, including transactions, snapshot jobs, synchronization status, and replication history information.

**Model** A database installed with SQL Server that provides the template for new user databases. SQL Server 2000 creates a new database by copying the contents of the model database and then expanding it to the size requested.

| ⚠**Caution** |
| --- |
| Do not delete the SQL Server 2000 system databases. These databases are critical to the core functionality of SQL Server 2000. |

**Sample Databases**

In addition to the MIIS database and SQL Server system databases, your implementation of SQL Server 2000 might include two sample databases: **Northwind** and **pubs**. To save disk space in your production environment, you can delete these two databases from SQL Server 2000.

**To delete the Northwind and pubs sample databases**

1. In **Microsoft SQL Server**, click **Enterprise Manager**.

2. Expand **Microsoft SQL Servers**, expand **SQL Server Group**, expand *servername* (where *servername* represents the computer on which SQL Server 2000 is running), and then expand **Databases**.

3. Right-click the sample database that you want to delete, click **Delete**, and then click **Yes** to confirm the deletion.

# SQL Server 2000 Backup Types and Recovery Models

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

SQL Server 2000 provides three different backup types and three different recovery models. You can combine these backup types and recovery models in different ways, depending on your data recovery requirements.

**SQL Server 2000 Backup Types**

You can perform three different types of backups on the MIIS database: database (or full), differential, and transaction log.

**Database (or Full)** Full database backups are the default and the starting point for all other types of backups. A full database backup captures the entire database, including all entries in the transaction log—excluding any unallocated extents in the files. Pages are read directly from disk to increase the speed of the operation.

**Differential** Differential backups capture *all* the data that has changed since the *last* full database backup. Differential backups will increase the speed of the backup operation as well as the restore. Because only the changed or newly allocated extents (bitmap tracking) are captured, differential backups are faster and smaller than full database backups. During a recovery, the last differential backup can be restored without applying a series of the individual transaction log backups or differential backups. All changed data is captured in the last differential backup.

**Transaction log** Transaction log backups serially capture modifications to the database. Backups of the transaction log provide a history of the transactions that have taken place within the database. The backups of the log are then used in the recovery process to restore the database fully, to a point in time. Transaction log backups are applied to recover a database by rolling forward (redoing) any committed changes not reflected in the database and rolling back (undoing) uncommitted transactions. Log backups are smaller and are taken more frequently than full or differential backups.

For more information about these backup types, see "Chapter 3 - Backing Up and Restoring Databases" on the Microsoft TechNet Web site at http://go.microsoft.com/fwlink/?LinkID=15117.

**SQL Server 2000 Recovery Models**

SQL Server 2000 provides three different recovery models: Full Recovery, Bulk-Logged Recovery, and Simple Recovery. The recovery model determines whether and how transaction logs can be backed up. The recovery model that you choose has a significant impact on system performance (especially during heavy data loads) and also on your ability to recover data.

By default, the MIIS database is configured to use the Simple Recovery model. Administrators can choose to enhance their data recoverability options by using the Full Recovery or Bulk-Logged Recovery model. These enhanced methods can dramatically improve disk performance by reducing the amount of disk space used by the log. However, using the Full Recovery or Bulk-Logged Recovery model also makes backup and restoration procedures more complex.

Be sure that you thoroughly understand the differences between the recovery models before you apply the Full Recovery or Bulk-Logged Recovery model. Table 2 lists and describes the SQL Server 2000 recovery models.

**Table 2 SQL Server 2000 Recovery Models**

| Model | Benefits | Work-Loss Exposure | Recovery Point |
|---|---|---|---|
| Full Recovery | No work is lost due to a lost or damaged data file.<br><br>Can recover to a specified point in time (for example, prior to an application or user error). | None. However, if the log is damaged, changes made since the most recent log backup are lost and must be redone. | Can recover to any point in time. |
| Bulk-Logged Recovery | Permits high-performance bulk copy operations.<br><br>Minimal log space is used by bulk operations. | If the log is damaged, or bulk operations occurred after the most recent log backup, changes made since the last backup must be redone. | Can recover to the end of any backup. |

| | | | |
|---|---|---|---|
| Simple Recovery | Permits high-performance bulk copy operations.<br><br>Reclaims log space to keep space requirements small. | Changes made after the most recent database or differential backup are lost and must be redone. | Can recover to the end of any backup. |

| **Note** |
|---|
| For more information about recovery models, see "Backing Up and Restoring Databases" on the Microsoft MSDN Web site at http://go.microsoft.com/fwlink/?LinkID=10575. |

You can change your recovery model to accommodate changes in your recovery requirements.

**To change SQL Server 2000 recovery models**

1. In **Microsoft SQL Server**, click **Enterprise Manager**.

2. Expand **Microsoft SQL Servers**, expand **SQL Server Group**, expand *servername* (where *servername* represents the computer on which SQL Server 2000 is running), and then expand **Databases**.

3. Right-click the MIIS database, and then click **Properties**.

4. On the **Options** tab, in the **Model** list, click a recovery model.

After you change the recovery model, it is recommended that you perform a full database backup.

# Backup Strategies for Your MIIS Database

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You need to establish and document a backup and restore plan for your MIIS 2003 database, being sure to thoroughly test your plan in a simulation of your production environment.

| **Note** |
| --- |
| For more information about developing backup and restore plans for SQL Server databases, see "Chapter 3 – Backing Up and Restoring Databases" on the Microsoft TechNet Web site at http://go.microsoft.com/fwlink/?LinkID=15117. |

Unless specified otherwise, this section provides instructions for using the Simple Recovery model, which is the default recovery model for MIIS 2003.

For information about backing up the SQL Server 2000 databases when you are using the Full Recovery or Bulk-Logged Recovery models, see "Backing Up and Restoring Databases" on the Microsoft MSDN Web site at http://go.microsoft.com/fwlink/?LinkID=10575.

Table 3 lists the recommended backup activities that are necessary to ensure the recoverability of your MIIS database, including the back up frequency for each.

**Table 3 Recommended Backup Activities**

| Backup Activity | When You Install | Intraday | Daily | Monthly | Quarterly |
| --- | --- | --- | --- | --- | --- |
| Create a backup device. | X | | | | |
| Determine an offsite storage location for your backups. | X | | | | |
| Determine and document your backup procedures. | X | | | | |
| Perform differential backups. | | X | | | |
| Perform transaction log backups. | | X | | | |
| Automatically shrink unused database file space. | | | X | | |
| Perform full database backups. | | | X | | |
| Back up the MIIS 2003 encryption keys. | | | | X | |
| Back up the **master** and **msdb** system databases in SQL Server. | | | | X | |
| Back up the entire MIIS 2003 installation. | | | | X | |
| Back up the entire SQL Server 2000 installation. | | | | X | |
| Perform a test recovery of your data in a test environment by using your production backups. | | | | | X |
| Review your backup procedures and amend as necessary | | | | | X |

**Note**

If your SQL Server implementation also contains other databases that are used by MIIS 2003 or other applications, be certain to develop a backup and restore plan that includes those databases. For a more detailed administrative schedule for SQL Server 2000, see the SQL Server 2000 Operations Guide on the Microsoft TechNet Web site at http://www.microsoft.com/technet/prodtechnol/sql/2000/maintain/sqlops0.mspx.

Backing up your MIIS database involves first creating a backup device within SQL Server 2000 and then implementing your database backup plan. Finally, you must back up the MIIS 2003 encryption keys. You can back up SQL Server 2000 databases by using the Database Maintenance Plan Wizard or SQL Server Enterprise Manager.

# Creating a New Backup Device

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Before you can create backups of your MIIS database, you must create a new backup device in SQL Server 2000 by using SQL Server Enterprise Manager. The physical backup device (a tape drive, for example) must already be installed and configured before you perform this procedure.

**To create a new backup device by using SQL Server Enterprise Manager**

1. In **Microsoft SQL Server**, click **Enterprise Manager**.
2. Expand **SQL Server**, and then expand **Management**.
3. Right-click **Backup**, and then click **New Backup Device**.
4. In the **Name** box, enter the name of the device, and then click **OK**.

| **Note** |
| --- |
| For more information about SQL Server 2000 backup devices, see "Backing Up and Restoring Databases" on the Microsoft MSDN Web site at http://go.microsoft.com/fwlink/?LinkID=10575. |

# Scheduling Full Database Backups by Using the Database Maintenance Plan Wizard

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The easiest way to back up your MIIS database is to use the Database Maintenance Plan Wizard, which is available in SQL Server Enterprise Manager. By using the Database Maintenance Plan Wizard, you can create a job that runs full database backups and transaction log backups on a scheduled basis.

The procedures for backing up the MIIS database are the same as those for backing up SQL Server databases.

| **Important** |
| --- |
| It is recommended that you schedule transaction log backups to occur more frequently than the database backups (for example, every four hours). Backing up the transaction log truncates (removes) logged transactions and can improve performance. |

**To schedule backups by using the Database Maintenance Plan Wizard**

1. In **Microsoft SQL Server**, click **Enterprise Manager**.
2. Expand the server group where the **MicrosoftIdentityIntegrationServer** database is located, and then expand the server.
3. On the **Tools** menu, click **Database Maintenance Planner**.
4. On the **Start** page, click **Next**.
5. On the **Select databases** page, click **These databases**, click **MicrosoftIdentityIntegrationServer**, and then click **Next**.
6. On the **Update Data Optimization** page, if you want the database to be shrunk automatically, freeing up unused space, do the following:

   | **Note** |
   | --- |
   | For an optional method of shrinking the database, see "Using the Auto Shrink Option to Maintain a Minimum of 25% Unused Space" later in this section.<br><br>It is recommended that you choose one of these methods to automatically (and regularly) shrink database size. |

   - Select **Remove unused space from database files**, and then in the **When it grows beyond box**, keep the default value of 50 megabytes and in the **Amount of free space to remain after shrink** box, keep the default value of 10%,
   - Click **Change**, and then specify a schedule that shrinks the database, setting a time that is at least one hour before your scheduled full backups.

     Allowing one hour usually gives sufficient time for the database shrink to complete before the scheduled backup begins.
7. Click **Next** until you reach the **Specify the Database Backup Plan** page.
8. On the **Specify the Database Backup Plan** page, do the following:

   - Select the **Back up the database as part of the maintenance plan** and **Verify the integrity of the backup**

**when complete** check boxes.

- Under **Location to store the backup file**, click the tape or disk on which you want to store the backup, and then click **Change**.
- In the **Edit Recurring Job Schedule** dialog box, specify the frequency, time, and duration of your backup job.
- Make sure that the **Enable schedule** check box is selected, and then click **OK**.

9. (Optional) If using the Full Recovery or Bulk-Logged Recovery model, do the following:

   - On the **Specify the Transaction Log Backup Plan** page, select **Back up the transaction log as part of the maintenance plan**, and **Verify the integrity of the backup when complete**.
   - Under **Location to store the backup file**, click the tape or disk on which you would like to store the backup, and then click **Change**.
   - In the **Edit Recurring Job Schedule** dialog box, specify the frequency, time, and duration of your backup job.
   - Make sure that the **Enable schedule** check box is selected, and then click **OK**.

10. On the **Specify Transaction Log Backup Disk Directory** page, select a location for the transaction log backup, and then specify if you want older backup files automatically removed.

11. Accept the default selections on the remaining wizard pages until you reach the **Completing the Database Maintenance Plan Wizard** page, and then in the **Plan Name** textbox, type a name for your backup plan.

**Using the Auto Shrink Option to Maintain a Minimum of 25% Unused Space**

In addition to shrinking the database automatically (see step 6 of the preceding procedure), you can also use the Auto Shrink option to automatically shrink the database each time the database file contains more than 25% unused space. It is recommended that you choose one of these methods to automatically shrink database size on a regular basis.

For more information about shrinking the database, see Microsoft SQL Server Books Online.

**To enable Auto Shrink**

- In **Databases**, right click the **MicrosoftIdentityIntegrationServer** database, click **Properties**, click **Options**, and then in **Settings**, select **Auto Shrink**.

# Scheduling Differential Database Backups by Using SQL Server Enterprise Manager

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can use SQL Server Enterprise Manager to schedule differential database backups of the MIIS database.

**To back up the database by using SQL Server Enterprise Manager**

1. In **Microsoft SQL Server**, click **Enterprise Manager**.
2. Expand the server group where the **MicrosoftIdentityIntegrationServer** database is located, and then expand the server.
3. On the **Tools** menu, click **Backup Database**.
4. In the **Database** list, click **MicrosoftIdentityIntegrationServer**.
5. Under **Backup**, click **Database - differential**.
6. Under **Destination**, select the backup device on which you want the backup to be performed.
7. Select the **Schedule** check box, and then click the ellipsis (...) next to the **Schedule** check box.
8. In the **Edit Schedule** dialog box, click **Change**, and then set the frequency of the backup schedule in the **Edit Recurring Schedule** dialog box.
9. Click **OK** three times to return to Enterprise Manager.

| **Note** |
| --- |
| For more information about differential database backups, see "Chapter 3 - Backing Up and Restoring Databases" on the Microsoft TechNet Web site at http://go.microsoft.com/fwlink/?LinkID=15117. |

# Scheduling Backups of the System Databases

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

It is important to back up the **master** and **msdb** databases any time they change. At a minimum, it is recommended that you perform monthly backups of the system databases.

**Master** database changes occur as a result of:

- Adding logins or other login security-related operations in SQL Server 2000.
- Changing any server-wide or database configurations.
- Creating or removing logical backup devices.
- Configuring the server for distributed queries and remote procedure calls, such as adding linked servers or SQL Server 2000 remote logins.

**Msdb** database changes occur as a result of:

- Scheduling tasks.
- Storing Data Transformation Services (DTS) packages created by using the DTS Import/Export Wizard to an instance of SQL Server.
- Maintaining online backup and restore history.
- Replicating.

You can schedule backups of the **master** and **msdb** databases by using the Database Maintenance Plan Wizard procedure for scheduling full database backups and substituting the appropriate database on the **Select databases** page. For more information about this procedure, see “Scheduling Full Database Backups by Using the Database Maintenance Plan Wizard” earlier in this topic.

# Backing Up the MIIS 2003 Encryption Key

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You need to regularly back up the encryption key that MIIS 2003 uses to encrypt data and credentials. Failure to back up encryption keys can lead to loss of encrypted data and credentials. To back up the encryption key, use the MIIS Key Management Utility.

The MIIS Key Management Utility has two different user interfaces: command line and a Windows wizard. For most backup and restore operations of the encryption key, the command line interface is sufficient. For more advanced backup operations of the encryption key, for example, to add a new encryption key to the key set or to abandon an existing key set and create a new set, you need to use the MIIS Key Management wizard.

To back up the encryption key, you must be logged on as a member of an MIIS security group and have administrative credentials on the local computer.

**To back up the MIIS 2003 encryption key by using the command line**

1. On the server where MIIS 2003 is running, change the directory by typing the following at the command line:

   **cd %Programfiles%\Microsoft Identity Integration Server\bin**

2. Type the following at the command line to save the encryption key to a floppy disk:

   **miiskmu /e a:keyback.bin /u miisadmin ***

   **Table 4 Parameters for the Miiskmu Command**

| Parameter | Description |
|---|---|
| /e | Exports the key set to a file. |
| **a:***keyback.bin* | For the a: drive, specifies the file name in which you are saving the encryption key. |
| /u | Specifies the MIIS 2003 service account credentials. |
| *miisadmin* | Specifies the MIIS service account. |

**To back up the MIIS 2003 encryption key by using the MIISkmu wizard**

1. Click **Start**, point to **All Programs** and **Microsoft Identity Integration Server**, and then click **Key Management Utility**.

2. Follow the instructions in the wizard.

| **Note** |
|---|
| When using the MIISkmu wizard, you might need to stop the Microsoft Identity Integration Server service in Windows Services in order to enable advanced options. |

# Restoring the MIIS Database

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The steps required to recover from an MIIS database failure vary according to the severity of the failure. Based on the severity of the failure, you might need to complete one or several steps, including recovering your MIIS 2003 server, recovering your SQL Server 2000 server, and restoring the MIIS database and the SQL Server 2000 system databases.

If you need to recover your server before you restore the MIIS database (for example, because of a server hardware failure), you will need to complete some or all of the following steps:

- **Reinstall the operating system on the server.** Ensure that the server role is configured in the way that it was previously, either as a standalone server or as a member of an Active Directory® directory service domain. If the server is a standalone server, use the Windows Server 2003 Backup tool to restore the local Security Accounts Manager (SAM) database. Note that you can use the same server name or a different name.

- **Install SQL Server 2000.** Use the same installation options that you used for the previous installation.

- **Restore the MIIS database and the SQL Server 2000 system databases.** If you are not using the simple recovery model or if there are differential backups since the last full backup was created, you must also restore those differential backups to recover incomplete transactions.

- **Install MIIS 2003 on your server.** Use the same configuration for the options that you used for the previous installation. When you are prompted for the encryption key during Setup, insert the disk that includes the MIIS 2003 encryption key.

The procedures for restoring the MIIS database are the same as those for restoring other SQL Server databases. For general information about restoring SQL Server databases, see "Chapter 3 – Backing Up and Restoring Databases" on the Microsoft TechNet Web site at http://go.microsoft.com/fwlink/?LinkID=15117.

# Recommendations for Backing Up and Restoring the MIIS Database

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The following recommendations will help you to optimize your process for maintaining the MIIS database:

- In addition to making regular SQL Server database backups, use the Windows Server 2003 Backup tool to create an Automated System Recovery (ASR) of the servers running MIIS 2003 and SQL Server 2000 on a regular (at least monthly) basis. You can use an ASR set to restore your servers if a disaster occurs.

  For more information about creating an ASR set, see "Safeguarding your system" in Help and Support Center for Windows Server 2003.

- Test backup and restore procedures on a regular basis and before a disaster occurs. As a guide, test your backup and restore procedures at least once every three months.

- Always keep your backups offsite in a secure location, to lessen any losses that could occur from fire, disaster, or accident.

- Make a full backup of your MIIS database everyday.

- On SQL Server 2000, back up the **master** and **msdb** system databases at least monthly.

- After you complete a backup, verify all your backup media.

# Ensuring Failover and High Availability

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

You can create a standby server that is running MIIS 2003 before you set up your primary server running MIIS 2003. If the SQL Server 2000 installation that contains your MIIS database resides on a separate server from the primary and standby MIIS 2003 installations, you can activate the standby server to ensure that MIIS 2003 is available even if your primary system fails. To activate a standby server running MIIS 2003, you need to run MIISactivate on the standby server by using the Microsoft Identity Integration Server service account credentials and the most recent backup copy of the MIIS 2003 encryption key.

For more information about MIISactivate, see “MIISactivate: Server activation tool” in MIIS 2003 Help. For more information about the MIIS 2003 encryption keys, see “MIISkmu: Encryption key management tool” in MIIS 2003 Help. For more information about backing up your encryption key, see “Backing Up the MIIS 2003 Encryption Key” earlier in this topic.

# Monitoring the MIIS Database

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Monitoring the MIIS database requires that you first establish a performance baseline for your implementation. The goal of baseline monitoring is to document how the SQL Server 2000 installation that hosts the MIIS database operates under normal conditions. Establishing a baseline helps you identify problems more quickly.

After you document your performance baseline, you need to continue monitoring on an ongoing basis the performance of the SQL Server 2000 installation that hosts the MIIS database. A number of tools are available to assist you with ongoing performance monitoring.

# Establishing a Performance Baseline

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Baseline performance monitoring involves establishing a performance baseline for your system. A performance baseline includes a single performance chart accompanied by an interpretation of the results, based on your environment. Many elements of the chart, such as the timeframe, vary according to the environment. You can use System Monitor in Windows Server 2003 to establish your performance baseline. The System Monitor chart can be created in real time or based on a performance log file. It is recommended that you base your chart on a log file, because this allows you to record statistics for an extended period.

When establishing your performance baseline, you must select the sampling interval and the server from which to monitor. The sampling interval determines the amount of disk space that your baseline requires. (Using performance counters on the server does not add much overhead to the server running SQL Server.) If you find that your baseline data is taking up too much disk space, you can use a larger interval between data samples. The larger the sampling interval you use, however, the less accurate your graph will be.

You can monitor remotely; however, use of the counters across a network connection for an extended period of time can congest traffic on your network. If you have disk space on your server for the performance log files, it is recommended that you record performance log information locally.

Because of performance impacts related to the number of counters being sampled and the frequency with which sampling occurs, it is important to test the number of counters and the frequency of data collection so you can determine the balance that meets the needs of your environment while still providing useful performance information. For the initial performance baseline, however, it is recommended that you use the highest number of counters possible and the highest frequency available.

Table 5 lists the recommended performance counters to include in your performance baseline.

**Table 5 Performance Counters for Baseline Performance Monitoring**

| Object\Counter | Definition | Recommendations |
|---|---|---|
| Memory\Pages/sec | The number of pages read from or written to disk to resolve hard page faults. This counter serves as a primary indicator of the types of faults that cause system-wide delays. | Although it is normal to have some spikes, this counter generally remains at or close to zero. |
| Network Interface\Bytes total/sec | Number of bytes traveling over the network interface per second. This counter only reflects the local network connection. | If this value stays below 50 percent of your available network bandwidth, the network adapter on the server running SQL Server 2000 is not likely to cause any performance bottlenecks. |
| PhysicalDisk\Disk Transfers/sec | The rates of read and write operations on the disk. Define a counter for each physical disk on the server. | |
| PhysicalDisk\Avg. Disk Queue Length | The average numbers of both read and write requests that were queued for the selected disk during the sample interval. | The number of requests should not exceed two times the number of spindles constituting the physical disk. If the number of requests is too high, you can add additional disks or replace the existing disks with faster disks. |
| SQLServer:Memory Manager\Total Server Memory | The total memory in use by SQL Server 2000. | Add memory to the server if this value is generally higher than the amount of physical memory in the server. |

| | | |
|---|---|---|
| SQLServer:Access Methods\Full Scans/sec | The number of unrestricted full scans. These can either be base table or full index scans. | |
| SQLServer:Buffer Manager\Buffer Cache Hit Ratio | The percentage of pages that were found in the buffer pool without having to incur a read from disk. | When this percentage is high, your server is operating at optimal disk I/O efficiency. If this value decreases over time, you might consider adding physical memory to your server. |
| SQLServer:Databases\Log Growths | The total number of log growths for the selected database. | Run against your application database instance. |
| SQLServer:Databases Application Database\Percent Log Used | The percent of space in the log that is in use. | Run against your application database instance. |
| SQLServer:Databases Application Database\Transactions/sec | The number of transactions started for the database. | Run against your application database instance. |
| SQLServer:General Statistics\User Connections | The number of users connected to the system. | Research any dramatic shifts in this value. |
| SQLServer:Latches\Average Latch Wait Time | The average latch wait time, in milliseconds, for latch requests that had to wait. | If this number is high, your server might have resource limitations. |
| SQLServer:Locks\Average Wait Time | The average amount of wait time, in milliseconds, for each lock request that resulted in a wait. | |
| SQLServer:Locks\Lock Waits/sec | The number of lock requests that could not be satisfied immediately and required the caller to wait before the lock was granted. | |
| SQLServer:Locks\Number of Deadlocks/sec | The number of lock requests that resulted in a deadlock. | |
| SQLServer:Memory Manager\Memory Grants Pending | The current number of processes waiting for a workspace memory grant. | |

For information about how to use System Monitor to create performance charts and logs, see “Monitoring performance” in Help and Support Center for Windows Server 2003.

# Setting Alerts to Monitor System Events

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

An alert is a notification that is generated as a result of an event. You can use alerts for ongoing system monitoring; for example, you can set an alert to notify you if CPU usage reaches 100 percent.

To monitor your MIIS 2003 implementation, it is recommended that you use alerts for the following events:

- **Errors affecting service.** Whenever possible, ensure that each known critical error has an alert associated with it. If you cannot associate the error with an alert, consider writing a query to test for the error state, and then run the query on an ongoing basis, configuring an alert to be generated when the query finds the error.

- **Deadlocks.** Ensure that when the value of any SQLServer:Locks\Number of Deadlocks counter exceeds a given threshold, it generates an alert. If an application does not typically cause deadlocks, set this threshold to 1 or 2. If you run concurrent management agents, set this threshold from 10 to 20.

- **CPU usage.** If your application typically freezes or degrades at a certain level of CPU usage, set an alert to be generated when the CPU usage exceeds that level.

- **Disk usage.** If your application freezes or degrades at a certain disk usage level (or queue level), set an alert to be generated when the disk usage exceeds that level.

- **Table scans.** Ensure that your application database generates an alert if excessive table scans occur. First, establish the baseline value for excessive table scans in your environment. To determine your baseline, monitor the SQLServer:Access Methods\Full Scans/sec counter for a period of time; then set an alert. If you have many small tables that do not require indexes, a large number of acceptable table scans can occur before the number becomes excessive.

For information about setting and managing alerts, see “Performance Logs and Alerts” in Help and Support Center for Windows Server 2003.

# Additional Ways to Monitor the MIIS Database

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

In addition to using performance counters and alerts, MIIS 2003 and SQL Server 2000 provide the following ways to monitor the MIIS database and SQL Server 2000 system databases:

- Use the error log in SQL Server Enterprise Manager.
- Use Event Viewer to monitor SQL Server events recorded in the Windows application log.
- Use Current Activity in SQL Server Enterprise Manager for ongoing monitoring.
- Use SQLDiag.exe to collect detailed information.
- Use a Query Analyzer session if SQL Server Enterprise Manager is unavailable.

**Use the Error Log in SQL Server Enterprise Manager**

You can use the error log in SQL Server Enterprise Manager for ongoing performance monitoring. The SQL Server error log enables you to determine how well the SQL Server 2000 installation that hosts the **MicrosoftIdentityIntegrationServer** database is functioning.

**To view the SQL Server error log**

1. In **SQL Server Enterprise Manager**, expand a server group, and then expand a server.
2. Expand **Management**, and then expand **SQL Server Logs**.
3. Click the SQL Server log that you want to view.

Error log details appear in the details pane.

**Use Event Viewer to Monitor SQL Server Events**

Event Viewer allows you to monitor SQL Server events recorded in the Windows application log. This log is separate from the SQL Server error log. SQL Server 2000 messages can be identified by their source, **MSSQLSERVER** or **SQLSERVERAGENT**.

**To view messages in the Windows application log**

1. Open **Event Viewer**.
2. In the console tree, click **Application Log**.
3. In the details pane, right-click an event, and then click **Properties**.

**Use Current Activity for Ongoing Monitoring**

You can use Current Activity in SQL Server Enterprise Manager for ongoing monitoring. Current Activity displays a snapshot of information regarding processes, user activity, and locks held by processes and on objects. Because using this tool requires no overhead, it can be helpful to view Current Activity when you encounter a problem state. Note that the information in Current Activityis only a snapshot; for ongoing performance monitoring, you must refresh this snapshot regularly.

You can use Current Activity to do the following:

- Monitor blocked and blocking transactions.
- Monitor users that are currently connected and their last executed statement.
- View all locks by database object.

- Terminate a selected process or send a message to the user who is executing a problematic transaction to terminate the transaction.

| **Important** |
| --- |
| Keep in mind that if you decide to terminate a process, the command might require a lengthy rollback. Hence, use this feature sparingly. |

**To view the Current Activity window**

1. In **SQL Server Enterprise Manager**, expand a server group, and then expand a server.
2. Expand Management, and then expand Current Activity.
3. Click **Process Info**.

The current server activity is displayed in the details pane.

**Use SQLDiag.exe to Collect Detailed Information**

You can gather detailed information about the current state of SQL Server 2000 — including current user information, DLL versions, configuration information, and database size information — by using the Sqldiag.exe tool, which is located in *drive*:\ProgramFiles\Microsoft SQL Server\Mssql\Binn\.

To run this tool, type the following at the command line:

**sqldiag -O filename -X**

**Table 6 Parameters for the Sqldiag Command**

| Parameter | Description |
| --- | --- |
| -O | Directs all Sqldiag.exe output to a single file. |
| *filename* | Specifies the name of the file where you want to direct the command output. |
| -X | Excludes error logs. |

For more information about Sqldiag.exe parameters, type **sqldiag /?** at the command line.

Sqldiag.exe can take up to a few minutes to complete. When Sqldiag.exe completes successfully, it writes a file named *filename*, which lists detailed SQL Server 2000 information, to the server.

**Use a Query Analyzer Session if SQL Server Enterprise Manager Is Unavailable**

There might be times when SQL Server Enterprise Manager cannot access SQL Server 2000 but a Query Analyzer session can. In these cases, you can use the **SP_WHO** SQL Server stored procedure to discover information about current connection count and connection details.

For more information, see "SP_WHO" in the Microsoft SQL Server 2000 Books Online, which you can install during SQL Server 2000 installation and then access from the Start menu through All Programs. Optionally, see "Getting Started with SQL Server Books Online" on the Microsoft MSDN Web site at http://go.microsoft.com/fwlink/?LinkID=7107.

# Optimizing the MIIS Database

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The performance of a server running MIIS 2003 is significantly affected by the performance of the MIIS database. To maintain optimum performance, you might need to modify the default settings for SQL Server 2000 and the MIIS database.

**Configuring the Transaction Log to Optimize Performance**

The transaction log significantly affects performance. A transaction can be small or large depending on the type of data processing that is required. For example, renaming a forest can require the renaming of each object in the forest. Collectively, renaming all objects in the forest constitutes a single large transaction. A transaction can also be small, such as when a single user object is changed and that change must be synchronized among other data sources. In either case, whether the transaction is small or large, the performance of the transaction log can be significantly affected by disk performance, growth, and truncation (clearing).

To optimize your transaction log, you might need to do any of the following:

- Create the transaction log on a separate disk or redundant array of independent disks (RAID) device. The transaction log file is written serially; therefore, using a separate dedicated disk allows the disk heads to stay in place for the next write operation.

- When using a Full Recovery or Bulk-Logged Recovery model, be sure to clear the log periodically to prevent the log from filling up and diminishing performance. For more information about backing up and truncating the transaction log, see "Scheduling Full Database Backups by Using the Database Maintenance Plan Wizard" earlier in this topic.

- Never delete the transaction log file. Deleting the transaction log file can lead to corruption of the database.

- When running one or more large transactions, set the log file growth percentage to a number greater than 10%, which is the default setting. A single large transaction can generate a large amount of transaction log data. If the log file growth percentage is not set high enough to handle that growth, the number of transaction log growth requests can significantly slow or stall performance.

**To change the transaction log file growth**

1. In **Enterprise Manager**, right-click the **MicrosoftIdentityIntegrationServer** database, then click **Properties**, and then click the **Transaction Log** tab.

2. In **File Growth**, select **In megabytes**, and then enter a number equal to 1/50th (or up to four gigabytes, whichever is less) of space available on the drive where the transaction log resides.

**Clearing Management Agent Run History**

Another way to optimize the performance of a server running MIIS 2003 is to regularly clear the management agent run history. You can clear run histories from the MIIS 2003 Server up to a specified date by using MIISClearRunHistory in the Resource Tool Kit for Microsoft Identity Integration Server 2003, an unsupported set of tools that is available on the Microsoft Download Center at http://go.microsoft.com/fwlink/?LinkID=22788. Clearing run histories helps minimize the amount of space required for the MIIS database.

# Additional Resources (Maintaining the MIIS 2003 Database)

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

These resources contain additional information related to this topic.

# Network Load Balancing Event Messages

Updated: July 1, 2003

Applies To: Windows Server 2003 with SP1

Published: July 1, 2003

**In This White Paper**

- Microsoft Windows 2000 Server and Windows Server 2003 Common NLB Events
- Microsoft Windows Server 2003-only NLB Events

This document contains a complete list of all Network Load Balancing (NLB) event messages, their causes, and detailed instructions for remedial actions, if any. The event severity and the format of each event are specified to aid the development of custom scripts.

The first section contains the events that are common for both Microsoft Windows Server 2000 and Microsoft Windows Server 2003 releases. The difference in the event formats and user actions between the two server versions is explained. The second section contains only those events that are new in Microsoft Windows Server 2003.

| **Note** |
| --- |
| The event source reported for all of the messages described in this document will be WLBS. |

**About Alert Severity**

Three levels of alert severity are indicated in Network Load Balancing event messages. Some events do not have an alert severity associated with them, and they are noted in this white paper.

- **E- Error.** A significant problem, such as loss of data or loss of functionality. Administrator action will likely be required to correct the error.
- **W - Warning.** An event that is not necessarily significant, but might indicate a possible future problem. Administrator action may or may not be required to correct the error.
- **I - For information only.** An event that typically describes the successful operation of an application, driver, or service. Typically no administrator action is required.

# Microsoft Windows 2000 Server and Windows Server 2003 Common NLB Events

Updated: July 1, 2003

Applies To: Windows Server 2003 with SP1

**Event ID: 1**

**Alert Severity:** Unused

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: %3. %4*

**Windows 2000 Server Event Text:** *%4 %1: %2. %3*

**Event ID: 2**

**Alert Severity:** Unused

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: %3. %4*

**Windows 2000 Server Event Text:** *%4 %1: %2. %3*

**Event ID: 3**

**Alert Severity:** Unused

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: %3. %4*

**Windows 2000 Server Event Text:** *%4 %1: %2. %3*

**Event ID: 4**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: %3 started. %4*

**Windows 2000 Server Event Text:** *%4 %1: %2 started. %3*

**Error Message Explanation:** This event is logged to inform you that cluster operations have started in response to a user-initiated action.

**User Action (Windows Server 2003):** No user action is required.

**User Action (Windows 2000 Server):** No user action is required.

**Event ID: 5**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Cluster mode started with host ID %2. %3*

**Windows 2000 Server Event Text:** *%4 %1 :cluster mode started with host ID %2. %3*

**Error Message Explanation:** This event is logged to inform you that cluster operations have started in response to a user-initiated action.

**User Action (Windows Server 2003):** No user action is required.

**User Action (Windows 2000 Server):** No user action is required.

**Event ID: 6**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Cluster mode stopped. %3. %4*

**Windows 2000 Server Event Text:** *%4 %1: cluster mode stopped. %2. %3*

**Error Message Explanation:** This event is logged to inform you that cluster operations have stopped in response to a user-initiated action.

**User Action (Windows Server 2003):** No user action is required.

**User Action (Windows 2000 Server):** No user action is required.

**Event ID: 7**

**Alert Severity:** E

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Internal error. Please contact technical support. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: Internal error. Please contact technical support. %2. %3*

**Error Message Explanation:** Network Load Balancing Clustering cannot complete the task because an error occurred.

**User Action (Windows Server 2003):** Contact your product support person. For more information about product support, see Help and Support. Alternatively, see Product Support Services at http://www.microsoft.com/homepage/ms.htm.Under the **Resources** area in the navigation pane, point to **Support**, and then click **Support Home**.

**User Action (Windows 2000 Server):** Contact Microsoft Product Support Services. For more information about product support, see Help. Alternatively, see Product Support Services at http://www.microsoft.com/homepage/ms.htm. Under the **Resources** area in the navigation pane, point to **Support**, and then click **Support Home**.

**Event ID: 8**

**Alert Severity:** E

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Error registering driver with NDIS. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: Error registering driver with NDIS. %2. %3*

**Error Message Explanation:** The Network Load Balancing driver cannot register with the Network Driver Interface Specification (NDIS). Therefore, the host will not respond to the TCP/IP traffic on this adapter.

**User Action (Windows Server 2003):** Restart your computer. If the problem continues, use Network Connections in Control Panel to disable and then re-enable the network adapter. If this does not resolve the problem, contact your product support person. For more information about product support, see Help and Support. Alternatively, see Product Support Services at http://www.microsoft.com/homepage/ms.htm. Under the **Resources** area in the navigation pane, point to **Support**, and then click **Support Home**.

**User Action (Windows 2000 Server):** Restart your computer. If the problem continues, use Network Connections in Control Panel to disable and then re-enable the network adapter. If this does not resolve the problem, contact Microsoft Product Support Services. For more information about product support, see Help. Alternatively, see Product Support Services at http://www.microsoft.com/homepage/ms.htm. Under the **Resources** area in the navigation pane, point to **Support**, and then click **Support Home**.

**Event ID: 9**

**Alert Severity:** E

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Driver does not support the media type that was requested by TCP/IP. NLB will not bind to this adapter. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: driver does not support media type that was requested by TCP/IP. %2. %3*

**Error Message Explanation:** In order for Network Load Balancing (NLB) to work, it must bind to an Ethernet network adapter. This event is logged when the NLB driver cannot bind to an Ethernet network adapter because it is not supported.

**User Action (Windows Server 2003):** Verify that a supported Ethernet network adapter is installed in this computer, and then bind NLB to it.

**User Action (Windows 2000 Server):** Verify that a supported Ethernet network or Fiber Distributed Data Interface (FDDI) network adapter is installed in this computer, and then bind NLB to it.

**Event ID: 10**

**Alert Severity:** E

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Driver could not allocate a required memory pool. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: driver could not allocate required memory pool. %2. %3*

**Error Message Explanation:** The Network Load Balancing (NLB) driver could not allocate memory.

**User Action (Windows Server 2003):** To increase the amount of available memory, try one of more of the following:

1. Add additional random access memory (RAM) to the host.

2. Close programs on the host that might be consuming memory.

3. Force the NLB driver to reload. Reloading will occur if you restart the host or disable all network adapters that are bound to NLB and then re-enable those adapters.

**User Action (Windows 2000 Server):** To increase the amount of available memory, try one or more of the following:

1. Add additional random access memory (RAM) to the host.

2. Close programs on the host that might be consuming memory.

3. Using **Network Connections** in Control Panel disable and then re-enable the network adapter that is bound to NLB.

**Event ID: 11**

**Alert Severity:** E

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Driver could not open device \DEVICE\ %3. %4*

**Windows 2000 Server Event Text:** *%4 %1: driver could not open device. %2. %3*

**Error Message Explanation:** Network Load Balancing (NLB) cannot bind to the network adapter. A possible reason is that the medium is not supported.

**User Action (Windows Server 2003):** Bind NLB to an Ethernet network adapter. If you are already using an Ethernet network adapter, examine the status code of the event message. The returned status code is included in the Data area at the bottom of the Event Properties dialog box.

The status code will correspond to a specific error condition as follows:

- 0xC0010019 = The adapter specified is not supported. In this case, you need to use a different adapter.

- 0xC000009A = The requested operation failed because NDIS could not allocate sufficient memory or initialize the state it uses to track an open binding. For this status, try adding additional memory.

- If the status code is not listed here or you cannot resolve the problem based on the information provided, contact your product support person. For more information about product support, see Help and Support. Alternatively, see Product Support Services at http://www.microsoft.com/homepage/ms.htm. Under the **Resources** area in the navigation pane, point to **Support**, and then click **Support Home**.

**User Action (Windows 2000 Server):** Bind NLB to an Ethernet network adapter. If you are already using an Ethernet network adapter, examine the status code of the event message. The returned status code is included in the **Data** area at the bottom of the **Event Properties** dialog box.

The status code will correspond to a specific error condition as follows:

- 0xC0010019 = The adapter specified is not supported. In this case, you need to use a different adapter.

- 0xC000009A = The requested operation failed because NDIS could not allocate sufficient memory or initialize the state it uses to track an open binding. For this status, try adding additional memory.

- If the status code in the message is not listed here or you cannot resolve the problem based on the information provided, contact your product support person. For more information about product support, see Help. Alternatively, see Product Support Services at http://www.microsoft.com/homepage/ms.htm. Under the **Resources** area in the navigation pane, point to **Support**, and then click **Support Home**.

**Event ID: 12**

**Alert Severity:** E

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Driver could not announce virtual NIC \DEVICE\ %3 to TCP/IP. %4*

**Windows 2000 Server Event Text:** *%4 %1: driver could not announce virtual NIC %2 to TCP/IP. %3*

**Error Message Explanation:** This event is logged to inform you that a call to Network Driver Interface Specification (NDIS) in order to bind the TCP/IP protocol to Network Load Balancing failed.

**User Action (Windows Server 2003):** No user action is required.

**User Action (Windows 2000 Server):** No user action is required.

**Event ID: 13**

**Alert Severity:** W

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Driver temporarily ran out of resources. Increase the %3 value under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\WLBS\Parameters\{GUID} key in the registry. %4*

**Windows 2000 Server Event Text:** *%4 %1: driver temporarily ran out of resources. Increase the %2 value under \SYSTEM\CurrentControlSet\Services\%4\Parameters key in the registry. %3*

**Error Message Explanation:** *When the Network Load Balancing (NLB) driver loads, NLB allocates blocks of memory for internal use. While this driver was loading, more memory was required than was initially allocated. Usually this is an indication that the load-balanced program is very heavily utilized.*

**User Action (Windows Server 2003):** *NLB does not automatically increase the amount of memory used for its internal processes. Instead, advanced users can manually increase the value in the registry. The path to the registry key specified in the logged event is incorrect. The correct path is: HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\WLBS\Parameters\Interface\{GUID}. The registry key to change is specified in the message. The GUID is the globally unique identifier of the network adapter that is experiencing the problem. This is the network adapter that is bound to NLB. If NLB is, or has been, bound to multiple network adapters, you can find the correct adapter by looking at the value for the ClusterIPAddress key for each GUID entry in the registry.*

*It is recommended that you double the existing value of this registry key. After increasing the value, you must re-bind NLB to the adapter that was experiencing the problem. To do this, do one of the following:*

- *Restart the host,*
- Disable and then re-enable the appropriate network adapter, or
- Remove and then re-add NLB to the appropriate network adapter

If increasing the value does not correct the problem, contact your product support person. For more information about product support, see Help and Support. Alternatively, see Product Support Services at http://www.microsoft.com/homepage/ms.htm.

Under the **Resources** area in the navigation pane, point to **Support**, and then click **Support Home**.

For more information about Windows Registry best practices, see Help and Support.

**User Action (Windows 2000 Server):** NLB does not automatically increase the amount of memory used for its internal processes. Instead, advanced users can manually increase the value of the specified registry key. It is recommended that you double the existing value. After increasing the value, reload NLB. To do this, do one of the following:

- *Restart the host,*
- Remove and then re-add NLB to the network adapter that is bound to NLB, or
- Disable and then re-enable the appropriate network adapter.

*If increasing the value does not correct the problem, contact Microsoft Product Support Services. For more information about product support, see Help. Alternatively, see Product Support Services at* http://www.microsoft.com/homepage/ms.htm.

Under the **Resources** area in the navigation pane, point to **Support**, and then click **Support Home**.

For more information about Windows Registry best practices, see Help.

**Event ID: 14**

**Alert Severity:** E

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Cluster network address %3 is invalid. Please check the NLB configuration and make sure that the cluster network address consists of six hexadecimal byte values separated by dashes. %4*

**Windows 2000 Server Event Text:** *%4 %1: cluster network address %2 is invalid. Please check %4 Setup page and make sure that it consists of six hexadecimal byte values separated by dashes. %3*

**Error Message Explanation:** *The cluster network MAC address is not in the following form xx-xx-xx-xx-xx-xx, where x is a hexadecimal value. Leading zeroes are optional.*

**User Action (Windows Server 2003):** *To change the MAC address to a valid form, open the***Properties** dialog box for this Network Load Balancing (NLB) cluster. If the **Network address** text box is available, NLB is set up for manual configuration of the network address and you should change the address to a correct MAC address.

*If the Network address text box is unavailable (it is dimmed), then NLB is configured to calculate the MAC address automatically and there is a problem doing so. Contact Microsoft Product Support Services for assistance. For more information about product support, see Help. Alternatively, see Product Support Services at* http://www.microsoft.com/homepage/ms.htm.

Under the **Resources** area in the navigation pane, point to **Support**, and then click **Support Home**.

**User Action (Windows 2000 Server):** To change the MAC address to a valid form, open the Properties dialog box for this Network Load Balancing (NLB) cluster. If the **Network address** text box is available, NLB is set up for manual configuration of the network address and you should change the address to a correct MAC address.

*If the Network address text box is unavailable (it is dimmed), then NLB is configured to calculate the MAC address automatically and there is a problem doing so. Contact Microsoft Product Support Services for assistance. For more information about product support, see Help. Alternatively, see Product Support Services at* http://www.microsoft.com/homepage/ms.htm.

Under the **Resources** area in the navigation pane, point to **Support**, and then click **Support Home**.

**Event ID: 15**

**Alert Severity:** W

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Dedicated IP address %3 is invalid. The driver will proceed assuming that there is no dedicated IP address. Please check the NLB configuration and make sure that the dedicated IP address consists of four decimal byte values separated by dots. %4*

**Windows 2000 Server Event Text:** *%4 %1: dedicated IP address %2 is invalid. Will proceed assuming that there is no dedicated IP address. Please check %4 Setup page and make sure that it consists of four decimal byte values separated by dots. %3*

**Error Message Explanation:** *The specified dedicated IP address is not valid. The cluster will continue to converge. However, you will not be able to use the dedicated IP address for such tasks as managing the host or for other non-cluster related communication.*

**User Action (Windows Server 2003):** *No user action is required. However, if you want to use a dedicated IP address, you must enter a valid address.*

**User Action (Windows 2000 Server):** *No user action is required. However, if you want to use a dedicated IP address, you must enter a valid address.*

**Event ID: 16**

**Alert Severity:** E

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Cluster IP address %3 is invalid. Please check the NLB configuration and make sure that the cluster IP address consists of four decimal byte values separated by dots. %4*

**Windows 2000 Server Event Text:** *%4 %1: cluster IP address %2 is invalid. Please check %4 Setup page and make sure that it consists of four decimal byte values separated by dots. %3*

**Error Message Explanation:** *This event is logged when the cluster IP address in the registry is not valid because it was manually changed to an incorrect address .*

**User Action (Windows Server 2003):** *Use Network Load Balancing Manager to change the cluster IP address to a valid IP address. For more information, see Help and Support.*

**User Action (Windows 2000 Server):** *Use Network Load Balancing to change the cluster IP address to a valid IP address. For*

*more information, see Help.*

**Event ID: 18**

**Alert Severity:** W

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Duplicate cluster subnets detected. The network may have been inadvertently partitioned. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: duplicate cluster subnets detected. The network may have been inadvertently partitioned. %2 %3*

**Error Message Explanation:** *The hosts in this cluster formed two or more separate clusters. This is usually caused by network partitioning that prevents the Network Load Balancing (NLB) heartbeats of one or more hosts from reaching all of the other hosts in the cluster. This event is logged when the network problem is corrected and the hosts converge back into a single cluster.*

**User Action (Windows Server 2003):** Investigate *the cause of the network partitioning. No investigation of NLB is necessary.*

**User Action (Windows 2000 Server):** *Investigate the cause of the network partitioning. No investigation of NLB is necessary.*

**Event ID: 19**

**Alert Severity:** W

**Windows Server 2003 Event Text:** NLB Cluster %2 %1: Could not allocate additional connection descriptors. Increase the %3 value under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\WLBS\Parameters\{GUID} key in the registry. %4

**Windows 2000 Server Event Text:** *%4 %1: could not allocate additional connection descriptors. Increase the %2 value under \SYSTEM\CurrentControlSet\Services\%4\Parameters key in the registry. %3*

**Error Message Explanation:** *Descriptors are used to track connections that are being load-balanced by Network Load Balancing (NLB). A fixed number of descriptors (controlled by a registry key value) are allocated when the NLB driver is loaded. This event is logged to warn you that the pool of descriptors has been exhausted. It might be necessary for NLB to reuse descriptors that are currently tracking existing active connections in order to track the state of new connections. This might have unexpected consequences and could result in legitimate connections being reset.*

**User Action (Windows Server 2003):** *Advanced users can increase the maximum number of descriptors that are allocated by changing the appropriate key in the registry. The registry key specified in the message is incorrect. Instead, you should increase the value of the following registry key:*
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\WLBS\Parameters

\Interface\{GUID}\MaxDescriptorAllocs.

*The GUID is the globally unique identifier of the network adapter that is experiencing the problem. This is the network adapter that is bound to NLB. If NLB is, or has been, bound to multiple network adapters, you can find the correct adapter by looking at the value for the ClusterIPAddress key for each GUID entry in the registry.*

*It is recommended that you double the existing value of this registry key. After increasing the value, you must re-bind NLB to the adapter that was experiencing the problem (as identified by the GUID in the message). To do this, do one of the following:*

- *Restart the host,*
- Disable and then re-enable the appropriate network adapter, or
- Remove and then re-add NLB to the appropriate network adapter.

*If increasing the value does not correct the problem, contact your product support person. For more information about product support, see Help and Support. Alternatively, see Product Support Services at* http://www.microsoft.com/homepage/ms.htm.

Under the **Resources** area in the navigation pane, point to **Support**, and then click **Support Home**.

For more information about Windows Registry best practices, see Help and Support.

**User Action (Windows 2000 Server):** Advanced users can double the number of descriptors that are allocated by changing the specified key in the registry. After increasing the value, reload NLB. To do this, do one of the following:

- *Restart the host,*

- Disable and then re-enable the appropriate network adapter, or
- Remove and then re-add NLB to the appropriate network adapter.

*If increasing the value does not correct the problem, contact Microsoft Product Support Services. For more information about product support, see Help. Alternatively, see Product Support Services at* http://www.microsoft.com/homepage/ms.htm.

Under the **Resources** area in the navigation pane, point to **Support**, and then click **Support Home**.

For more information about Windows Registry best practices, see Help.

**Event ID: 20**

**Alert Severity:** E

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Port rules with duplicate single host priority %3 detected on the network. Please check the NLB configuration on all hosts that belong to the cluster and make sure that they do not contain single host rules with duplicate priorities for the same port range. %4*

**Windows 2000 Server Event Text:** *%4 %1: port rules with duplicate single host priority %2 detected on the network. Please check %4 Setup dialog on all hosts that belong to the cluster and make sure that they do not contain single host rules with duplicate priorities for the same port range. %3*

**Error Message Explanation:** *When you configure a port rule as a single host, traffic to the port or ports governed by that port rule is handled exclusively by the host whose priority has the lowest numeric value. This event is logged when the local host's single host priority is identical to the single host priority of another host. The cluster will not converge until the problem is corrected.*

User Action (Windows Server 2003): *Using Network Load Balancing (NLB) Manager, edit the single host port rule on one of the hosts to give it a unique priority within the cluster. For more information about using NLB Manager to assign a unique priority to a host, see Help and Support.*

**User Action (Windows 2000 Server):** *Edit the single host port rule on one of the hosts to give it a unique priority within the cluster. For more information about using Network Load Balancing to assign a unique priority to a host, see Help.*

**Event ID: 21**

**Alert Severity:** E

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Host %3 does not have the same number or type of port rules as this host. Please check the NLB configuration on all hosts that belong to the cluster and make sure that they all contain the same number and type of port rules. %4*

**Windows 2000 Server Event Text:** *%4 %1: host %2 does not have the same number or type of port rules as this host. Please check %4 Setup dialog on all machines that belong to the cluster and make sure that they all contain the same number and the same type of port rules. %3*

**Error Message Explanation:** *This event is logged when another host in the cluster either contains a different number of port rules from the local host, or its configured port rules conflict with the port rules of the local host. The cluster will not converge until the problem is corrected.*

**User Action (Windows Server 2003):** *Using Network Load Balancing (NLB) Manager, edit the port rules as appropriate on each host so that the port rules are consistent on all hosts in the cluster. For more information about editing port rules in NLB, see Help and Support.*

**User Action (Windows 2000 Server):** *Edit the port rules as appropriate on each host so that the port rules are consistent on all hosts in the cluster. For more information about editing port rules in Network Load Balancing, see Help.*

**Event ID: 23**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Enabled traffic handling for rule containing port %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: enabled traffic handling for rule containing port %2. %3*

**Error Message Explanation:** *This event is logged to inform you that, in response to a user-initiated action, this host will handle new load balanced traffic for the specified port rule.*

**User Action (Windows Server 2003):** *No user action is required.*

**User Action (Windows 2000 Server):** *No user action is required.*

**Event ID: 24**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Disabled ALL traffic handling for rule containing port %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: disabled ALL traffic handling for rule containing port %2. %3*

**Error Message Explanation:** *This event is logged to inform you that, in response to a user-initiated action, network traffic arriving over ports governed by the specified port rule will no longer be handled by this host.*

**User Action (Windows Server 2003):** *No user action is required.*

**User Action (Windows 2000 Server):** *No user action is required.*

**Event ID: 25**

**Alert Severity:** W

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Port %3 not found in any of the valid port rules. %4*

**Windows 2000 Server Event Text:** *%4 %1: port %2 not found in any of the valid port rules. %3*

**Error Message Explanation:** *This event is logged when a user issues a command to control or query the state of a load-balanced port, but not applicable port rule is found. The command was ignored.*

**User Action (Windows Server 2003):** *No user action is required unless you expected this port to be governed by a port rule. In that case, you must configure a port rule to govern this port. For more information about configuring a port rule in Network Load Balancing, see Help and Support.*

**User Action (Windows 2000 Server):** *No user action is required unless you expected this port to be governed by a port rule. In that case, you must configure a port rule to govern this port. For more information about configuring a port rule in Network Load Balancing, see Help.*

**Event ID: 26**

**Alert Severity:** W

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Port rules cannot be enabled/disabled while cluster operations are stopped. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: port rules cannot be enabled/disabled while cluster operations are stopped. %2 %3*

**Error Message Explanation:** *This event is logged when a disable or enable command is issued to a host which has been either stopped or suspended. The command was ignored.*

**User Action (Windows Server 2003):** *Before issuing a disable or enable command, you must start (or resume and start) Network Load Balancing on the host.*

**User Action (Windows 2000 Server):** *Before issuing a disable or enable command, you must start (or resume and start) Network Load Balancing on the host.*

**Event ID: 28**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Host %3 converged with host(s) %4 as part of the cluster.*

**Windows 2000 Server Event Text:** *%4 %1: host %2 converged with host(s) %3 as part of the cluster.*

**Error Message Explanation:** *This event is logged to inform you that the specified host has joined the cluster.*

**User Action (Windows Server 2003):** *No user action is required.*

**User Action (Windows 2000 Server):** *No user action is required.*

**Event ID: 29**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Host %3 converged as DEFAULT host with host(s) %4 as part of the*

*cluster.*

**Windows 2000 Server Event Text:** *%4 %1: host %2 converged as DEFAULT host with host(s) %3 as part of the cluster.*

**Error Message Explanation:** *This event is logged to inform you that the specified host has joined the cluster. This host is now the default host and will handle all traffic that is not governed by any port rules.*

**User Action (Windows Server 2003):** *No user action is required. If you do not want this host to be the default host, reconfigure the host priority settings. For more information about reconfiguring host priorities in Network Load Balancing, see Help and Support.*

**User Action (Windows 2000 Server):** *No user action is required. If you do not want this host to be the default host, reconfigure the host priority settings. For more information about reconfiguring host priorities in Network Load Balancing, see Help.*

**Event ID: 30**

**Alert Severity:** W

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Dedicated network mask %3 is invalid. The driver will ignore the dedicated IP address and network mask. Please check the NLB configuration and make sure that the dedicated network mask consists of four decimal byte values separated by dots. %4*

**Windows 2000 Server Event Text:** *%4 %1: dedicated network mask %2 is invalid. Will ignore dedicated IP address and network mask. Please check %4 Setup page and make sure that it consists of four decimal byte values separated by dots. %3*

**Error Message Explanation:** *This event is logged when the subnet mask entered for the dedicated IP address is not valid. The cluster will continue to operate. However, you cannot use the dedicated IP address, so you cannot use it to manage the host or for other non-cluster-related communication.*

**User Action (Windows Server 2003):** *No user action is required. The cluster will continue to operate. However, if you want to use the dedicated IP address, enter a valid subnet mask. For more information about entering a subnet mask in Network Load Balancing, see Help and Support.*

**User Action (Windows 2000 Server):** *No user action is required. The cluster will continue to operate. However, if you want to use the dedicated IP address, enter a valid subnet mask. For more information about entering a subnet mask in Network Load Balancing, see Help.*

**Event ID: 31**

**Alert Severity:** E

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Cluster network mask %3 is invalid. Please check the NLB configuration and make sure that the cluster network mask consists of four decimal byte values separated by dots. %4*

**Windows 2000 Server Event Text:** *%4 %1: cluster network mask %2 is invalid. Please check %4 Setup page and make sure that it consists of four decimal byte values separated by dots. %3*

**Error Message Explanation:** *This event is logged when the subnet mask entered for the cluster IP address is not valid.*

**User Action (Windows Server 2003):** *Correct the subnet mask for the cluster IP address. For more information about correcting the subnet mask in Network Load Balancing, see Help and Support.*

**User Action (Windows 2000 Server):** *Correct the subnet mask for the cluster IP address. For more information about correcting the subnet mask in Network Load Balancing, see Help.*

**Event ID: 32**

**Alert Severity:** W

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Both the dedicated IP address and network mask must be specified. The driver will ignore the dedicated IP address and network mask. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: both dedicated IP address and network mask have to be entered. Will ignore dedicated IP address and network mask. %2 %3*

**Error Message Explanation:** *This event is logged when either the dedicated IP address or its subnet mask was not entered. The cluster will continue to operate. However, you cannot use the dedicated IP address, so you cannot use it to manage the host or for other non-cluster-related communication.*

**User Action (Windows Server 2003):** No user action is required. The cluster will continue to operate. However, if you want to use the dedicated IP address, enter a valid dedicated IP address and subnet mask. *For more information about entering a*

*dedicated IP address and subnet mask in Network Load Balancing, see Help and Support.*

**User Action (Windows 2000 Server):** No user action is required. The cluster will continue to operate. However, if you want to use the dedicated IP address, enter a valid dedicated IP address and subnet mask. *For more information about entering a dedicated IP address and subnet mask in Network Load Balancing, see Help.*

**Event ID: 33**

**Alert Severity:** W

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Remote control request rejected from %3 due to an incorrect password. %4*

**Windows 2000 Server Event Text:** *%4 %1: remote control request rejected from host %2 due to incorrect password. %3*

**Error Message Explanation:** *This event is logged when remote control is enabled on this server and a remote control request was received for the cluster. However, the remote control password received is not correct. A legitimate user might have accidentally entered the wrong password, or someone else might have tried to guess the password.*

**User Action (Windows Server 2003):** The source IP address of the remote control request is provided in the message. Use this information to determine the computer from which the remote control command was issued. This might help identify who issued the remote control command.

**Warning:** The Network Load Balancing remote control option presents many security risks, including the possibility of data tampering, denial of service, and information disclosure. We strongly recommend that you do not enable remote control, and that instead you use NLB Manager or other remote management tools such as Windows Management Instrumentation (WMI).

**User Action (Windows 2000 Server):** The source IP address of the remote control request is provided in the message. Use this information to determine the computer from which the remote control command was issued. This might help identify who issued the remote control command.

**Warning:** The Network Load Balancing remote control option presents many security risks, including the possibility of data tampering, denial of service, and information disclosure. We strongly recommend that you do not enable remote control, and that instead you use NLB Manager or other remote management tools such as Windows Management Instrumentation (WMI).

**Event ID: 34**

**Alert Severity:** E

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Error querying parameters from the registry key \HLKM\SYSTEM\CurrentControlSet\Services\WLBS\Parameters\%3. Please fix the NLB configuration and run wlbs reload followed by wlbs start. %4*

**Windows 2000 Server Event Text:** *%4 %1: error querying parameters from the registry key %2. Please run %4 setup dialog to fix the problem and run %4 reload followed by %4 start. %3*

**Error Message Explanation:** *This event is logged when there is an error processing the Network Load Balancing settings from the registry. For example, the registry key could not be opened, or a value that is not valid was read from one or more registry parameters. The most likely cause of this error is manual configuration of the registry instead of making configuration changes through the NLB properties dialog box.*

**User Action (Windows Server 2003):** *The registry hive specified in the message is incorrect. The correct hive is: HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\WLBS\Parameters\Interface\{GUID}. The GUID identified in the message is the correct GUID. The GUID reference is the globally unique identifier of the network adapter that is experiencing the problem.*

*Advanced users should examine the registry keys in this hive to determine which registry parameter caused the event. To do this, consider comparing the registry entries of a host in the cluster that is working correctly to the registry entries of the host that is reporting the error. Also examine the event log for related events that might indicate more specific problems with the registry.*

*For more information about Windows Registry best practices, see Help and Support.*

**User Action (Windows 2000 Server):** *Refer to the message to determine the registry hive in which the error occurred. Advanced users should examine the registry keys in that hive to determine which registry parameter caused the event. To do this, consider comparing the registry entries of a host in the cluster that is working correctly to the registry entries of the host that is reporting the error. Also examine the event log for related events that might indicate more specific problems with the registry.*

*For more information about NLB registry settings, see the Windows 2000 Server Resource Kit . For more information about*

*Windows Registry best practices, see Help.*

**Event ID: 35**

**Alert Severity:** E

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Cluster mode cannot be enabled due to parameter errors. All traffic will be passed through to TCP/IP. Restart cluster operations after fixing the problem by running wlbs reload followed by wlbs start. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: cluster mode cannot be enabled due to parameter errors. All traffic will be passed to TCP/IP. Restart cluster operations after fixing the problem by running %4 reload followed by %4 start. %2 %3*

**Error Message Explanation:** *This event is probably logged because of incorrectly configured settings that are being read from the registry; in particular, IP addresses, IP subnet masks, or MAC addresses. Until this problem is corrected, this host will remain stopped and will not join the cluster.*

**User Action (Windows Server 2003):** *Look for additional Network Load Balancing (NLB) events that indicate errors reading from the registry or other configuration problems. You can also use NLB Manager to diagnose configuration problems. After you determine the specific error, correct the problem, and then run nlb reload' followed by 'nlb start'. If you cannot determine the specific error, contact your product support person.*

*For more information about product support, see Help and Support. Alternatively, see Product Support Services at* http://www.microsoft.com/homepage/ms.htm. *Under the* **Resources** area in the navigation pane, point to **Support**, and then click **Support Home**.

**User Action (Windows 2000 Server):** *Look for additional Network Load Balancing events that indicate errors reading from the registry or other configuration problems. After you determine the specific error, correct the problem, and then run wlbs reload' followed by wlbs start'. If you cannot determine the specific error, contact Microsoft Product Support Services. For more information about product support, see Help. **Event ID: 36**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Registry parameters successfully reloaded. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: registry parameters successfully reloaded. %2 %3*

**Error Message Explanation:** *This event is logged to inform you that the registry parameters have been reloaded successfully.*

**User Action (Windows Server 2003):** *No user action is required.*

**User Action (Windows 2000 Server):** *No user action is required.*

**Event ID: 37**

**Alert Severity:** W

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Version mismatch between the driver and control programs. Please make sure that you are running the same version of all NLB components. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: version mismatch between the driver and control programs. Please make sure that you are running the same version. %2 %3*

**Error Message Explanation:** *This event is logged when incompatible Network Load Balancing binaries are installed, for example, if a Windows 2000 version of wlbs.exe is installed with a version of wlbs.sys created for a member of the Windows Server 2003 family of operating systems.*

**User Action (Windows Server 2003):** *Replace the conflicting binary.*

**User Action (Windows 2000 Server):** *Replace the conflicting binary.*

**Event ID: 38**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Adjusted traffic handling for rule containing port %3. %4*

**Windows 2000 Server Event Text:** *%4 %1: adjusted traffic handling for rule containing port %2. %3*

**Error Message Explanation:** *This event is logged to inform you that, in response to a user-initiated action, the load weight of a port rule has changed.*

**User Action (Windows Server 2003):** *No user action is required.*

**User Action (Windows 2000 Server):** *No user action is required.*

**Event ID: 39**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Disabled NEW traffic handling for rule containing port %3. %4*

**Windows 2000 Server Event Text:** *%4 %1: disabled NEW traffic handling for rule containing port %2. %3*

**Error Message Explanation:** *This event is logged to inform you that, in response to a user-initiated action, new network traffic is disabled for this specific port rule.*

**User Action (Windows Server 2003):** *No user action is required.*

**User Action (Windows 2000 Server):** *No user action is required.*

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Disabled NEW traffic handling for all port rules. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: disabled NEW traffic handling for all port rules. %2 %3*

**Error Message Explanation:** *This event is logged to inform you that, in response to a user-initiated action, new network traffic is disabled for all port rules.*

**User Action (Windows Server 2003):** *No user action is required.*

**User Action (Windows 2000 Server):** *No user action is required.*

**Event ID: 42**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Enabled traffic handling for all port rules. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: enabled traffic handling for all port rules. %2 %3*

**Error Message Explanation:** *This event is logged to inform you that, in response to a user-initiated action, this host will handle new load-balanced traffic for all port rules.*

**User Action (Windows Server 2003):** *No user action is required.*

**User Action (Windows 2000 Server):** *No user action is required.*

**Event ID: 43**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Disabled ALL traffic handling for all port rules. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: disabled ALL traffic handling for all port rules. %2 %3*

**Error Message Explanation:** *This event is logged to inform you that, in response to a user-initiated action, network traffic arriving over ports governed by any port rule will no longer be handled by this host.*

**User Action (Windows Server 2003):** *No user action is required.*

**User Action (Windows 2000 Server):** *No user action is required.*

**Event ID: 43**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Disabled ALL traffic handling for all port rules. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: disabled ALL traffic handling for all port rules. %2 %3*

**Error Message Explanation:** *This event is logged to inform you that, in response to a user-initiated action, network traffic arriving over ports governed by any port rule will no longer be handled by this host.*

**User Action (Windows Server 2003):** *No user action is required.*

**User Action (Windows 2000 Server):** *No user action is required.*

**Event ID: 44**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Connection draining started. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: connection draining started. %2 %3*

**Error Message Explanation:** *This event is logged to inform you that, in response to a user-initiated action, this host will stop accepting new network traffic. When there are no more active connections, this host will stop its cluster operations.*

**User Action (Windows Server 2003):** *No user action is required. For more information about the drain command, see Network Load Balancing in Help and Support.*

**User Action (Windows 2000 Server):** *No user action is required. For more information about the drain command, see Network Load Balancing in Help.*

**Event ID: 45**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Connection draining interrupted. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: connection draining interrupted. %2 %3*

**Error Message Explanation:** *This event is logged to inform you that the host was draining when a stop or suspend command was issued by a user.*

**User Action (Windows Server 2003):** *No user action is required. For more information about the drain command, see Network Load Balancing in Help and Support.*

**User Action (Windows 2000 Server):** *No user action is required. For more information about the drain command, see Network Load Balancing in Help.*

**Event ID: 46**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: %3 remote control request received from %4.*

**Windows 2000 Server Event Text:** *%4 %1: %2 remote control request received from host %3.*

**Error Message Explanation:** *This event is logged when the cluster has received and is processing a remote control command.*

**User Action (Windows Server 2003):** *Verify that you know who is issuing the remote control commands and that this person is authorized to do so. The source IP address of the remote control request is provided in the message. Use this to determine the computer from which the remote control command was issued. This might help identify the person who issued the remote control command.*

**Warning:** The Network Load Balancing (NLB) remote control option presents many security risks, including the possibility of data tampering, denial of service, and information disclosure. It is strongly recommended that you do not enable remote control, and that you instead use NLB Manager or other remote management tools such as Windows Management Instrumentation (WMI).

**User Action (Windows 2000 Server):** *Verify that you know who is issuing the remote control commands and that this person is authorized to do so. The source IP address of the remote control request is provided in the message. Use this to determine the computer from which the remote control command was issued. This might help identify the person who issued the remote control command.*

**Warning:** The Network Load Balancing (NLB) remote control option presents many security risks, including the possibility of data tampering, denial of service, and information disclosure. It is strongly recommended that you do not enable remote control, and that you instead use NLB Manager or other remote management tools such as Windows Management Instrumentation (WMI).

**Event ID: 47**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Cluster mode control resumed. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: cluster mode control resumed. %2 %3*

**Error Message Explanation:** *This event is logged to inform you that, in response to a user-initiated action, cluster operations have resumed.*

**User Action (Windows Server 2003):** *No user action is required. For more information about the resume command, see Network Load Balancing in Help and Support.*

**User Action (Windows 2000 Server):** *No user action is required. For more information about the resume command, see Network Load Balancing in Help.*

**Event ID: 48**

**Alert Severity:** I

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Cluster mode control suspended. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: cluster mode control suspended. %2 %3*

**Error Message Explanation:** *This event is logged to inform you that, in response to a user-initiated action, cluster operations have been suspended.*

**User Action (Windows Server 2003):** *No user action is required. For more information about the suspend command, see Network Load Balancing in Help and Support.*

**User Action (Windows 2000 Server):** *No user action is required. For more information about the suspend command, see Network Load Balancing in Help.*

**Event ID: 49**

**Alert Severity:** E

**Windows Server 2003 Event Text:** *This error cannot occur on Windows Server 2003 systems.*

**Windows 2000 Server Event Text:** *%4 %1: Network Load Balancing can only be installed on systems running Windows 2000 Advanced Server or Datacenter Server. %2 %3*

**Error Message Explanation:** *To use Network Load Balancing, you must install Windows 2000 Advanced Server or Windows 2000 Datacenter Server on this computer. NLB is also available on all members of the Windows Server 2003 family.*

**User Action (Windows Server 2003):** *This error cannot occur on Windows Server 2003 systems.*

**User Action (Windows 2000 Server):** *To use NLB, install Windows 2000 Advanced Server or Datacenter Server. NLB is also available on all members of the Windows Server 2003 family.*

**Event ID: 50**

**Alert Severity:** E

**Windows Server 2003 Event Text:** *NLB Cluster %2 %1: Cannot add cluster MAC address. The maximum number of multicast MAC addresses are already assigned to the NIC. %3 %4*

**Windows 2000 Server Event Text:** *%4 %1: cannot add cluster MAC address. The maximum number of multicast MAC addresses are already assigned to the NIC. %2 %3*

**Error Message Explanation:** *The network adapter has the maximum number of multicast MAC addresses assigned to it already. Other programs might have added multicast addresses with the result that Network Load Balancing cannot add the MAC addresses needed to operate an NLB cluster in multicast mode.*

**User Action (Windows Server 2003):** *Perform one or more of the following to correct the problem.*

1. Use a network adapter that allows an increased number of multicast MAC addresses to be configured.

2. Operate the cluster in unicast mode.

*For more information about unicast and multicast mode, see Network Load Balancing in Help and Support.*

**User Action (Windows 2000 Server):** Perform one or more of the following to correct the problem.

1. Use a network adapter that allows an increased number of multicast MAC addresses to be configured.

2. Operate the cluster in unicast mode.

*For more information about unicast and multicast mode, see Network Load Balancing in Help.*

# Microsoft Windows Server 2003-only NLB Events

Updated: July 1, 2003

Applies To: Windows Server 2003 with SP1

*These events are new in Windows Server 2003 and are therefore only logged on computers running Windows Server 2003.*

**Event ID: 51**

**Alert Severity:** E

**Event Text:** *NLB Cluster %2 %1: Cannot bind NLB to this adapter due to memory allocation failure. %3 %4*

**Error Message Explanation:** *This event is logged when there is not enough memory to bind Network Load Balancing to this network adapter.*

**User Action:** To increase the amount of available memory, try one or more of the following:

1. Add additional random access memory (RAM) to the host.
2. Close programs on the host that might be consuming memory.
3. Force the NLB driver to reload. Reloading will occur if you restart the host or disable all network adapters that are bound to NLB and then re-enable those adapters.

**Event ID: 52**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1: Registry parameters successfully reloaded without resetting the driver. %3 %4*

**Error Message Explanation:** Certain changes, such as adding a new port rule, require Network Load Balancing to be stopped and restarted. Other changes do not require NLB to be stopped and restarted. This event is logged to inform you that changes were made to the NLB configuration which did not require NLB to be stopped and restarted.

**User Action:** No user action is required.

**Event ID: 53**

**Alert Severity:** E

**Event Text:** *NLB Cluster %2 %1: The adapter to which NLB is bound does not support dynamically changing the MAC address. NLB will not bind to this driver. %3 %4*

**Error Message Explanation:** To be operated in unicast mode, Network Load Balancing must alter the unicast MAC address on the network adapter that it will be using. This event is logged when the network adapter to which NLB is trying to bind does not support dynamic changing of its unicast MAC address.

User Action: Replace the network adapter with one that supports changing the unicast MAC address dynamically. Alternatively, operate the cluster in multicast mode.

**Event ID: 54**

**Alert Severity:** W

**Event Text:** *NLB Cluster %2 %1: Host %3* MAY be a Windows 2000 or NT 4.0 host participating in a cluster utilizing virtual cluster support. Virtual Clusters are only supported in a homogeneous Windows Server 2003 cluster. %4

**Error Message Explanation:** Virtual clusters, which are Network Load Balancing clusters where specific port rules are assigned to specific virtual IP addresses, are configured on this host, but at least one host in this cluster has one or more port rules that are not valid and appear to be missing the virtual IP address specification. Therefore, either:

- A Windows 2000 or Windows NT 4.0 host exists in the cluster. Virtual clusters require a cluster containing only hosts running products in the Windows Server 2003 family, or
- A Windows Server 2003 host with an incorrectly configured port rule exists in the cluster.

The cluster will not converge until the problem is corrected.

**User Action:** If there is a Windows 2000 or Windows NT 4.0 host in the cluster, either remove it or stop using virtual clusters on the Windows Server 2003 hosts.

If the cluster contains only Windows Server 2003 hosts, then use NLB Manager to check the port rule configuration of all hosts to ensure that all hosts have compatible port rule configurations.

For more information about virtual clusters and port rules, see Network Load Balancing in Help and Support.

**Event ID: 55**

**Alert Severity:** E

**Event Text:** *NLB Cluster %2 %1:* Inconsistent bi-directional affinity (BDA) teaming configuration detected on host %3. The team in which this cluster participates will be marked inactive and this cluster will remain in the converging state until consistent teaming configuration is detected. %4

**Error Message Explanation:** A bidirectional affinity (BDA) team is a set of adapters on a single host that act in concert. This event is logged when the local host and the remote host specified in the message have inconsistent BDA configurations. The BDA configuration must be identical on all hosts in a cluster. This is enforced through the Network Load Balancing heartbeat mechanism. The cluster will not converge until the problem is corrected.

**User Action:** If this event is followed by an NLB 58 event in Event Viewer, no user action is needed. If this event is not followed by an NLB 58 event, then you need to change your BDA configuration. BDA configuration is specified by the Microsoft Internet Security and Acceleration Server (ISA Server) configuration. For more information about configuring BDA, see the relevant ISA Server documentation.

**Event ID: 56**

**Alert Severity:** E

**Event Text:** *NLB Cluster %2 %1:* Invalid bi-directional affinity (BDA) teaming port rules detected. Each member of a BDA team may have no more than one port rule whose affinity must be single or class C if multiple host filtering is specified. To add this cluster to a team, correct the port rules and run 'wlbs reload' followed by 'wlbs start'. %3 %4

**Error Message Explanation:** A bidirectional affinity (BDA) team is a set of adapters on a single host that act in concert. A team ID identifies the different network adapters that belong to the same BDA team. The team ID is a {GUID} that uniquely identifies the team to which an adapter belongs. This event is logged when this adapter has been configured as a member of a BDA team, but the specified team ID is either missing or not valid.

**User Action:** Correct the BDA team ID, and then run nlb reload' followed by 'nlb start'. BDA configuration is specified by the Microsoft Internet Security and Acceleration Server (ISA Server) configuration. For more information about configuring BDA, see the relevant ISA Server documentation.

**Event ID: 57**

**Alert Severity:** E

**Event Text:** *NLB Cluster %2 %1:* Invalid bi-directional affinity (BDA) team ID detected. Team IDs must be a GUID of the form {xxxxxxxx-xxxx-xxxx-xxxx-xxxxxxxxxxxx}. To add this cluster to a team, correct the team ID and run 'wlbs reload' followed by 'wlbs start'. %3 %4

**Error Message Explanation:** A bidirectional affinity (BDA) team is a set of adapters on a single host that act in concert. This event is logged when this adapter has been configured as a member of a BDA team, but the configured port rules do not comply with the requirements for using BDA. The use of BDA requires a single port rule that covers all ports (0 65535), configured as either Single or Class C affinity.

**User Action:** Correct the BDA teaming port rules, and then run nlb reload' followed by 'nlb start'. BDA configuration is specified by the Microsoft Internet Security and Acceleration Server (ISA Server) configuration. For more information about configuring BDA, see the relevant ISA Server documentation.

**Event ID: 58**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* Consistent bi-directional affinity (BDA) teaming configuration detected again. The team in which this cluster participates has been re-activated. %3 %4

**Error Message Explanation:** A bidirectional affinity (BDA) team is a set of adapters on a single host that act in concert. This event is logged to inform you that a valid and consistent BDA configuration has been detected and therefore the team has

been activated.

**User Action:** No user action is required.

**Event ID: 59**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* The bi-directional affinity (BDA) team which this cluster has attempted to join already has a designated master. This cluster will not join the team and will remain in the stopped state until the parameter errors are corrected and the cluster is restarted by running 'wlbs reload' followed by 'wlbs start'. %3 %4

**Error Message Explanation:** A bidirectional affinity (BDA) team is a set of adapters on a single host that act in concert. A single adapter from each team must be assigned the role of master for that team. This event is logged when this adapter attempts to join a BDA team as the master but the team already has an active master.

**User Action:** Correct the BDA team parameters, and then run nlb reload' followed by 'nlb start'. BDA configuration is specified by the Microsoft Internet Security and Acceleration Server (ISA Server) configuration. For more information about configuring BDA, see the relevant ISA Server documentation.

**Event ID: 60**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* The bi-directional affinity (BDA) team in which this cluster participates has no designated master. The team is inactive and will remain inactive until a master for the team is designated and consistent BDA teaming configuration is detected. %3 %4

**Error Message Explanation:** A bidirectional affinity (BDA) team is a set of adapters on a single host that act in concert. One adapter on each cluster host must be the master for that team. This event is logged when the team that this adapter has just joined does not have an active master yet. This might be a transient condition due to the binding order of adapters in the system.

**User Action:** If this event is followed by an NLB 61 event in Event Viewer, no user action is required.

If this event is not followed by an NLB 61 event, then you need to change your BDA configuration to make it consistent across all hosts. BDA configuration is specified by the Microsoft Internet Security and Acceleration Server (ISA Server) setup. For more information about configuring BDA, see the relevant ISA Server documentation.

**Event ID: 61**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* This cluster has joined a bi-directional affinity (BDA) team as the designated master. If the rest of the team has been consistently configured, the team will be activated. %3 %4

**Error Message Explanation:** A bidirectional affinity (BDA) team is a set of adapters on a single host that act in concert. A single adapter from each team must be assigned the role of master for that team. This event is logged to inform you that this adapter has joined a BDA team as the master.

**User Action:** No user action is required.

**Event ID: 62**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* This cluster has left a bi-directional affinity (BDA) team in which it was the designated master. If other adapters are still participating in the team, the team will be marked inactive and will remain inactive until a master for the team is designated and consistent BDA teaming configuration is detected. %3 %4

**Error Message Explanation:** A bidirectional affinity (BDA) team is a set of adapters on a single host that act in concert. One adapter on each cluster host must be the master for that team. This event is logged when the master has just left the BDA team and a new master must be configured for the team to operate. Note that this can be a transient condition caused by a re-configuration of BDA teaming.

**User Action:** If this event is followed by an NLB 61 event in Event Viewer, no user action is required.

If this event is not followed by an NLB 61 event, then you need to change your BDA configuration. BDA configuration is specified by the Microsoft Internet Security and Acceleration Server (ISA Server) setup. For more information about configuring BDA, see the relevant ISA Server documentation.

**Event ID: 63**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* Initiating convergence on host %3. Reason: Host %4 is joining the cluster.

**Error Message Explanation:** This event is logged for informational purposes only.

**User Action:** If this event is followed by an NLB 28 event, NLB 29 event, NLB 71 event, or NLB 72 event in Event Viewer, no user action is required.

If this event is not soon followed by one of these other events, use Network Load Balancing (NLB) Manager to determine the specific configuration problem and then correct as appropriate. For more information about Network Load Balancing, see Help and Support.

**Event ID: 64**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* Initiating convergence on host %3. Reason: Host %4 has conflicting configuration.

**Error Message Explanation:** This event is logged for informational purposes only.

**User Action:** If this event is followed by an NLB 28 event, NLB 29 event, NLB 71 event, or NLB 72 event in Event Viewer, no user action is required.

If this event is not soon followed by one of these other events, use Network Load Balancing (NLB) Manager to determine the specific configuration problem and then correct as appropriate. For more information about Network Load Balancing, see Help and Support.

**Event ID: 65**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* Initiating convergence on host %3. Reason: Host %4 is converging for an unknown reason.

**Error Message Explanation:** This event is logged for informational purposes only.

**User Action:** If this event is followed by an NLB 28 event, NLB 29 event, NLB 71 event, or NLB 72 event in Event Viewer, no user action is required.

If this event is not soon followed by one of these other events, use Network Load Balancing (NLB) Manager to determine the specific configuration problem and then correct as appropriate. For more information about Network Load Balancing, see Help and Support.

**Event ID: 66**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* Initiating convergence on host %3. Reason: Host %4 is configured with the same host ID.

**Error Message Explanation:** This event is logged for informational purposes only.

**User Action:** If this event is followed by an NLB 28 event, NLB 29 event, NLB 71 event, or NLB 72 event in Event Viewer, no user action is required.

If this event is not soon followed by one of these other events, use Network Load Balancing (NLB) Manager to determine the specific configuration problem and then correct as appropriate. For more information about Network Load Balancing, see Help and Support.

**Event ID: 67**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* Initiating convergence on host %3. Reason: Host %4 is configured with a conflicting number of port rules.

**Error Message Explanation:** This event is logged for informational purposes only.

**User Action:** If this event is followed by an NLB 28 event, NLB 29 event, NLB 71 event, or NLB 72 event in Event Viewer, no user action is required.

If this event is not soon followed by one of these other events, use Network Load Balancing (NLB) Manager to determine the specific configuration problem and then correct as appropriate. For more information about Network Load Balancing, see Help and Support.

**Event ID: 68**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* Initiating convergence on host %3. Reason: Host %4 has changed its port rule configuration.

**Error Message Explanation:** This event is logged for informational purposes only.

**User Action:** If this event is followed by an NLB 28 event, NLB 29 event, NLB 71 event, or NLB 72 event in Event Viewer, no user action is required.

If this event is not soon followed by one of these other events, use Network Load Balancing (NLB) Manager to determine the specific configuration problem and then correct as appropriate. For more information about Network Load Balancing, see Help and Support.

**Event ID: 69**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* Initiating convergence on host %3. Reason: Host %4 is leaving the cluster.

**Error Message Explanation:** This event is logged for informational purposes only.

**User Action:** If this event is followed by an NLB 28 event, NLB 29 event, NLB 71 event, or NLB 72 event in Event Viewer, no user action is required.

If this event is not soon followed by one of these other events, use Network Load Balancing (NLB) Manager to determine the specific configuration problem and then correct as appropriate. For more information about Network Load Balancing, see Help and Support.

**Event ID: 71**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* Host %3 converged with %4 host(s) as part of the cluster. Note: The list of cluster members was too large to fit in this event log - see the first data dump entry for a binary map of the cluster membership or run 'wlbs query' to see a list of cluster members.

**Error Message Explanation:** This event is logged to inform you that the specified host has joined the cluster.

**User Action:** No user action is required. If you do not want this host to be the default host, reconfigure the host priority settings. For more information about Network Load Balancing, see Help and Support.

**Event ID: 72**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* Host %3 converged as DEFAULT host with %4 host(s) as part of the cluster. Note: The list of cluster members was too large to fit in this event log - see the first data dump entry for a binary map of the cluster membership or run 'wlbs query' to see a list of cluster members.

**Error Message Explanation:** This event is logged to inform you that the specified host has joined the cluster. This host will be the default host and will handle all traffic that is not governed by any port rules.

**User Action:** No user action is required. If you do not want this host to be the default host, reconfigure the host priority settings. For more information about Network Load Balancing, see Help and Support.

**Event ID: 73**

**Alert Severity:** E

**Event Text:** *NLB Cluster %2 %1:* Cluster IGMP multicast IP address %3 is invalid. Please check the NLB configuration and make sure that the cluster IGMP multicast IP address consists of four decimal byte values separated by dots. %4.

**Error Message Explanation:** The Internet Group Management Protocol (IGMP) multicast IP address in the registry is not valid.

**User Action:**

1. Open the following registry key: HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\WLBS\Parameters\Interface\{GUID}, where the GUID is the globally unique identifier of the network adapter that is experiencing the problem. This is the network adapter that is bound to Network Load Balancing. If NLB is, or has been, bound to multiple network adapters, you can find the correct adapter by looking at the value for the ClusterIPAddress key for each GUID.

2. Examine the IPtoMcastIP key and verify that it is a non-zero value. If it is a value of zero, change it to a value of one.

3. In Network Connections, open NLB Properties (do not use NLB Manager).

4. Click OK. This action forces NLB to recalculate the IGMP multicast address automatically and subsequently reload the NLB driver.

*If these actions do not resolve the problem, contact Microsoft Product Support Services. For more information about product support, see Help and Support. Alternatively, see Product Support Services at* http://www.microsoft.com/homepage/ms.htm. Under the **Resources** area in the navigation pane, point to **Support**, and then click **Support Home**.

For more information about Windows Registry best practices, see Help and Support.

**Event ID: 74**

**Alert Severity:** W

**Event Text:** *NLB Cluster %2 %1:* Unable to update the NLB host state in the registry. This will affect the ability of NLB to persist the current state across a reboot if NLB has been configured to do so. To predict the state of NLB at the next reboot, please delete the HKLM\SYSTEM\CurrentControlSet\Services\WLBS\Parameters\{GUID}\%3 registry value, which will cause the state at the next reboot to revert to the user-specified preferred initial host state. %4.

**Error Message Explanation:** A Network Load Balancing (NLB) host can be in one of three states: started, stopped or suspended. The preferred state of NLB on startup can be configured to be any one of the three available states. Each time the server restarts, the host assumes that initial state. However, NLB can be configured to remember a suspended state. This can be used to override the preferred initial state if a host is restarted while suspended and this option has been selected. The host will remain suspended upon completion of the restart, regardless of the specified initial state. NLB therefore must track the last known state of the host to correctly configure the host during a restart. If NLB cannot save that information to the registry, the startup state of the cluster at this restart and subsequent restarts might not be what is expected.

**User Action:** The registry key specified in the message is incorrect. To be able to predict the state of the NLB host at the next restart, advanced users should delete the following registry key, if it exists:

HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\WLBS\Parameters\Interface\{GUID}\HostState. The GUID is the globally unique identifier of the network adapter that is experiencing the problem. This will be the network adapter that is bound to NLB. If NLB is, or has been, bound to multiple network adapters, you can find the correct adapter by looking at the value for the ClusterIPAddress key for each GUID entry in the registry.

Deleting this key ensures that on the next restart, NLB will use the preferred initial host state.

For more information about Windows Registry best practices, see Help and Support.

**Event ID: 75**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* Current NLB host state successfully updated in the registry.

**Error Message Explanation:** This event is logged for informational purposes only.

**User Action:** No user action required.

**Event ID: 76**

**Alert Severity:** W

**Event Text:** *NLB Cluster %2 %1:* Last known NLB host state not found in the registry. The state of this host will revert to the user-specified preferred initial host state. %3 %4

**Error Message Explanation:** A Network Load Balancing (NLB) host can be in one of three states: started, stopped or suspended. The preferred state of NLB on startup can be configured to be any one of the three available states. Each time the server restarts, the host assumes that initial state. However, NLB can be configured to remember a suspended state. This can be used to override the preferred initial state if a host is restarted while suspended and this option has been selected. The host will remain suspended upon completion of the restart, regardless of the specified initial state. NLB therefore must track the last known state of the host to correctly configure the host during a restart. If NLB cannot read that information from the registry, the startup state of the cluster at this restart might not be what is expected.

**User Action:** No user action is required. NLB will attempt to correct this condition over time.

**Event ID: 77**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* This host is configured to persist 'Started' states across reboots. Because the last known state of this host was started, the host will be re-started regardless of the user-specified preferred initial host state. To stop the host, use 'wlbs stop' or 'wlbs suspend'. %3 %4

**Error Message Explanation:** This event is logged for informational purposes only.

**User Action:** No user action is required. If you want to change the default state, use Network Load Balancing (NLB) Manager to make the change. For more information about Network Load Balancing, see Help and Support.

**Event ID: 78**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* This host is configured to persist 'Stopped' states across reboots. Because the last known state of this host was stopped, the host will remain stopped regardless of the user-specified preferred initial host state. To start the host, use 'wlbs start'. %3 %4

**Error Message Explanation:** This event is logged for informational purposes only.

User Action: No user action is required. If you want to change the default state, use Network Load Balancing (NLB) Manager to make the change. For more information about Network Load Balancing, see Help and Support.

**Event ID: 79**

**Alert Severity:** I

**Event Text:** *NLB Cluster %2 %1:* This host is configured to persist 'Suspended' states across reboots. Because the last known state of this host was suspended, the host will remain suspended regardless of the user-specified preferred initial host state. To start the host, use 'wlbs resume' followed by 'wlbs start'. %3 %4

**Error Message Explanation:** This event is logged for informational purposes only.

**User Action:** No user action is required. If you want to change the default state, use Network Load Balancing (NLB) Manager to make the change. For more information about Network Load Balancing, see Help and Support.

**Event ID: 80**

**Alert Severity:** W

**Event Text:** *NLB Cluster %2 %1:* Windows 2000 or NT 4.0 host(s) are participating in this cluster. Consult the relevant NLB documentation concerning the potential limitations of operating a mixed cluster. %3 %4

**Error Message Explanation:** Certain features of Network Load Balancing are not designed to work in a mixed cluster, that is, in a cluster with hosts running a product in the Windows Server 2003 family along with hosts running Windows 2000 or Windows NT 4.0. These features include virtual clusters, bidirectional affinity, and IPSec load balancing (such as VPN).

**User Action:** These features can be used if the cluster contains only hosts running a product in the Windows Server 2003 family. If you require any of these features, remove all hosts running Windows 2000 and Windows NT 4.0 from the cluster. For more information about Network Load Balancing, see Help and Support.

**Event ID: 81**

**Alert Severity:** W

**Event Text:** *NLB Cluster %2 %1:* NLB was unable to open the TCP connection callback object and will therefore be unable to track TCP connections. %3 %4

**Error Message Explanation:** Network Load Balancing tracks TCP connections to ensure affinity to the host servicing the connection. If NLB cannot open a communication channel with the TCP/IP stack, it cannot guarantee, under certain conditions, that a given TCP connection is serviced by the same host for its duration.

**User Action:** Try restarting the host. If restarting fails to establish communication with the TCP/IP stack, advanced users can force NLB to track TCP connections itself by setting the following REG_DWORD value to 0 (zero):
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\WLBS\Parameters\Global\EnableTCPNotification

**Note**

The key will not exist by default. You must create it.

You must restart the computer after making this change. This latter method of tracking TCP connections is less robust than using the TCP/IP stack, but it ensures TCP connection affinity in most cases. This method is not recommended if you are using multiple network adapters with asymmetric traffic flow (that is, using different network adapters to handle outbound vs. inbound NLB traffic).

For more information about Windows Registry best practices, see Help and Support.

**Event ID: 82**

**Alert Severity:** E

**Event Text:** *NLB Cluster %2 %1:* The network adapter to which NLB is bound does not support NDIS packet indications, which is commonly caused by outdated network adapter hardware and/or drivers. In order to properly load-balance incoming load, NLB requires that adapters support NDIS packet indications. %3 %4

**Error Message Explanation:** Your computer is using a network adapter that is either older or non-server-class. Network Load Balancing (NLB) requires that network adapters support Network Driver Interface Specification (NDIS) packet indications. NLB no longer accepts the older NDIS Packet Receive indications from network adapters. Incoming packets that arrive via this older mechanism will be dropped by NLB.

**User Action:** Verify that the drivers for the network adapter are up-to-date and that your network adapter is listed in the Windows Catalog as a supported adapter for the Windows Server 2003 family of products. If necessary, install a different (newer) network adapter that supports NDIS packet receives. For more information, see the Windows Catalog at http://go.microsoft.com/fwlink/?LinkID=37604.

**Event ID: 83**

**Alert Severity:** E

**Event Text:** *NLB Cluster %2 %1:* Duplicate dedicated IP address %3 was discovered on the network. Please check the NLB configuration on all hosts that belong to the cluster and make sure that they all contain unique dedicated IP addresses. %4

**Error Message Explanation:** Another host in the cluster has an identical dedicated IP address.

**User Action:** Check the Network Load Balancing configuration on all hosts that are members of the cluster, and verify that they are all configured with unique dedicated IP addresses. For more information about Network Load Balancing, see Help and Support.

**Event ID: 84**

**Alert Severity:** W

**Event Text:** *NLB Cluster %2 %1:* NLB was unable to open the NLB public connection callback object and will therefore be unable to track connections. %3 %4

**Error Message Explanation:** Network Load Balancing (NLB) tracks TCP connections to ensure affinity to the host servicing the connection. In a Microsoft Internet Security and Acceleration Server (ISA Server)/NLB deployment, if NLB cannot open a communication channel with the firewall engine, it cannot guarantee, under certain conditions, that a given TCP connection is serviced by the same host for its duration.

**User Action:** This communication medium with the firewall engine is required for ISA Server/NLB deployments. Check the ISA Server installation to verify that it is correctly configured, and then try restarting the host.

**Event ID: 4096**

**Alert Severity:** W

**Event Text:** Configuration completed. Microsoft Cluster service is also installed on this machine, and this may prevent the proper operation of both.

**Error Message Explanation:** This computer is a member of a server cluster. Network Load Balancing can interfere with a server cluster's use of network adapters: therefore, Microsoft does not support this configuration.

**User Action:** Either do not install NLB on this computer, or remove this computer from the server cluster.

**Event ID: 12288**

**Alert Severity:** I

**Event Text:** Configuration update %2 started by %1 on adapter %3

**Error Message Explanation:** This event is logged to inform you that a user action was initiated using Network Load Balancing Manager.

**User Action:** No user action is required.

**Event ID: 12289**

**Alert Severity:** I

**Event Text:** Configuration update %2 completed with status %1 on adapter %3. Information log contains: %n%4

**Error Message Explanation:** This event is logged to inform you that a user action was initiated using Network Load Balancing Manager.

**User Action:** No user action is required.

# Implementing Common Desktop Management Scenarios with the Group Policy Management Console

Updated: May 3, 2004

Applies To: Windows Server 2003 with SP1

This white paper describes six scenarios for using Group Policy to manage users' desktop environments. This document is a companion to a set of preconfigured Group Policy object (GPO) scenarios, available for download from this page. These GPO scenarios are intended to be starting points from which you can develop settings tailored to your environment. These scenarios illustrate of the range of features manageable by using Group Policy. This white paper includes coverage of Windows Server 2003 and the Group Policy Management Console (GPMC).

**In This White Paper**

Introduction (Implementing Common Desktop Management Scenarios with the Group Policy Management Console)

Understanding and Using the Scenarios

Deploying the Scenarios

Configuring Specific Features

Switching Between Scenarios

Extending the Scenarios

Appendix A: GPO Scenario Policy Settings

Appendix B: Running CommonScenarios.msi

# Introduction (Implementing Common Desktop Management Scenarios with the Group Policy Management Console)

Updated: March 2, 2005

Applies To: Windows Server 2003 with SP1

**Group Policy Overview**

The IntelliMirror® management technologies provide Active Directory-based change and configuration management of user and computer settings on computers running a member of the Microsoft® Windows® Server 2003 or Microsoft Windows® 2000 families of operating systems, or the Microsoft® Windows® XP Professional operating system. Group Policy provides the infrastructure for IntelliMirror by allowing you to specify settings for registry-based policy, security, software installation, scripts, folder redirection, Remote Installation Services, and Internet Explorer maintenance.

The Group Policy settings that you create are contained in a Group Policy object (GPO). By linking a GPO to selected Active Directory Service containers – sites, domains, and organizational units (OUs) – you can apply these settings to the users and computers in those Active Directory containers. Group Policy inheritance and precedence determine where and how you link GPOs. By default, options set in GPOs linked to higher levels of Active Directory containers – sites, domains and OUs – are inherited by all containers at lower levels, though inheritance does not occur across domains. Because lower-level GPOs apply last, they override higher-level GPOs and can provide lower-level OUs with a different set of Group Policy settings.

To manage GPOs, you use the Group Policy Management Console (GPMC) or its scripting interfaces. GPMC is a new tool, released at the launch of Windows Server 2003. It is important to note, however, that GPMC is a very effective tool for managing Group Policy in Windows 2000 domains and, with the exception of a few new features, does not require Windows Server 2003 to be running in your environment.

It is assumed that the reader of this white paper has an understanding of basic Group Policy principles.

**About the Common Desktop Scenarios**

Group Policy is a rich and flexible technology providing the capability to efficiently manage a large number of computer and user accounts through a centralized, "one-to-many" model. With this flexibility comes the potential for complexity. For example, Group Policy in Windows Server 2003 exposes almost 1,000 configurable settings. This can initially appear a daunting task – how does the administrator assess the relative importance of these settings, and what features enabled by Group Policy might be considered when deploying a solution?

This Common Desktop Scenarios white paper provides a structured, tested, and consistent set of pre-packaged GPOs and associated documentation, with the goal of lowering the "barrier of entry" for those assessing Group Policy.

The scenarios described in this white paper provide a good starting point from which you can begin evaluating and understanding Group Policy. By implementing these scenarios in a test environment, you should be able to:

- Quickly understand the scope of Group Policy and consider how to use a wide number of settings.
- List some of the important solutions enabled by Group Policy.
- Gain familiarity with some of the new functionality introduced with GPMC, particularly the backup/import of GPOs and Group Policy reports.
- Reach conclusions about how to implement Group Policy in your production environment.

| **Note** |
| --- |
| The approach taken in this white paper has significant differences to previously released versions. These differences primarily reflect the new features available in GPMC and are described fully later in this document. |

**How to Use the Common Desktop Scenarios**

The GPOs provided with this white paper were created using the Backup capability of GPMC. This new tool provides a single entry point for management of Group Policy in your environment and can manage both Windows 2000 and Windows Server 2003 domains. You can download the Group Policy Management Console (GPMC) from the Microsoft Web site

(http://go.microsoft.com/fwlink/?linkid=12946). You can import these GPOs into your environment as a first step toward implementing the common scenarios. The details of each scenario are described in this document and further documented in a spreadsheet, as well as in HTML-based reports generated using the Group Policy Reports capability of GPMC for each of the GPOs.

In many cases, a scenario might deliver a specific computer/user configuration that is close to the required environment for your production environment and might not need significant changes. In other cases, it might be necessary to substantially modify the GPOs provided to ensure alignment with your business goals.

The GPOs can be implemented and validated in a test environment, modified (where necessary) to map to your specific needs, and – after appropriate testing – copied or imported into a production environment.

The mere act of importing the scenario GPOs into your domain has no immediate impact on computers or users. To affect target accounts, the GPOs must be linked to an appropriate Scope of Management (SOM) – a site, domain, or OU which you want to manage using these GPOs. This means that the reader with limited test resources might choose to import the GPOs into a production environment and – before applying to a set of computer or user accounts – link to a SOM that has a more limited number of accounts, effectively forming a controlled pilot program. After completing the pilot program and testing any required changes, the GPOs can be linked to broader SOMs. This approach is most effective when computers and users are targeted through OUs, and the majority of this white paper assumes that this is the targeting mechanism used (unless noted otherwise).

| **Note** |
| --- |
| You can download the CommonScenarios.msi installation package, which includes this document and supporting files, from the Microsoft Download Center. |

**Overview of the Scenarios**
The following is a list of the scenarios along with typical examples.

**Lightly Managed**
Use this scenario for power users or developers who require considerable control over their computer. You can also use this scenario in an organization where tightly managed desktops are not acceptable to users or where desktop management is highly delegated. Along with the other scenarios, the Lightly Managed scenario supports increased security and promotes consistency of user experience, both of which can be beneficial even where a tightly managed desktop is not appropriate.

The Lightly Managed scenario has the following characteristics:

- Is the least managed of all of the scenarios.
- Allows users to customize most settings that affect them but prevents them from making harmful system changes.
- Includes settings that reduce help desk costs and user downtime.
- Supports *free-seating*, which means users can sit down at any computer and access all their resources, applications, and data as if they were sitting at their own computer. This also simplifies your file-backup scenarios, because users' files are all stored on designated file servers.
- Typically has a core set of applications assigned to either the user or the computer, which are always available. Users can also install applications that have been published for them, which they can choose to install.

**Mobile**
The Mobile scenario is relevant to mobile/laptop computers and their users. This scenario pays particular attention to the disconnected user who frequently needs to work offline and occasionally resynchronize with the corporate network.

The Mobile scenario has the following characteristics:

- Can be used by users who are away from the office most of the time, who log on using low-speed, dial-up links, but who also occasionally log on using high-speed network links.
- Can also be used by users who are away from the office only occasionally and who log on by using remote access or remote network links.

- Allows users continuous access to their data and configuration settings whether the computer is connected to or disconnected from the network.

- Partially supports free-seating (can optionally support full free-seating) to facilitate centralized data backup and to enable users to access important data and settings from additional computers.

- Allows users to disconnect from the network without logging off or shutting down.

**Multi-User**
Use this scenario in a university computer laboratory or library where users can save some customizations, such as desktop wallpaper and color scheme preferences, but are not allowed to change hardware or connection settings.

The Multi-User scenario has the following characteristics:

- Allows basic customization of the desktop environment. Users can save desktop configurations, but they cannot customize network, hardware, and system settings.

- Supports free-seating; users can log onto any computer and get their data and settings. No cached state is maintained on the computer when they leave.

- Users have restricted write access to the local computer and can only write data to their user profile and to redirected folders.

- Has a set of applications that are always available (assigned), as well as applications that can be installed and removed as necessary (published).

- Is highly secure.

**AppStation**
The AppStation scenario is used when you require highly restricted configurations with only a few applications. Use this scenario in vertical applications such as marketing, claims and loan processing, and customer-service scenarios.

The AppStation scenario has the following characteristics:

- Allows minimal customization by the user.

- Allows users to access a small number of applications appropriate to their job role.

- Does not allow users to add or remove applications.

- Supports free-seating.

- Provides a simplified desktop and Start menu.

- Users have restricted write access to the local computer and can only write data to their user profile and to redirected folders.

- Is highly secure.

**TaskStation**
Use the TaskStation scenario when you need the computer dedicated to running a single application, such as on a manufacturing floor, as an entry terminal for orders, or in a call center.

The TaskStation scenario is similar to the AppStation scenario, with the following changes:

- It has only one application installed, which automatically starts when the user logs on.

- No desktop or Start menu is present.

**Kiosk**
Use this scenario in a public area, such as in an airport where passengers check in and view their flight information. Because the computer is normally unattended, it needs to be highly secure.

The Kiosk scenario has the following characteristics:

- Is a public workstation.
- Runs only one application.
- Uses only one user account and automatically logs on. The system automatically resets to a default state at the start of each session.
- Runs unattended.
- Is highly secure.
- Is simple to operate, with no logon procedure.
- Does not allow users to make changes to the default user or system settings.
- Does not save data to the disk.
- Is always on (the user cannot log off or shut down the computer).

A workstation that uses the Kiosk scenario is similar to a TaskStation, but users are anonymous in that they all share a single user account that automatically logs on at computer startup. This is achieved by modifying the Kiosk machine in a manner described later in this document. Users cannot customize their environment and user states are not preserved.

Although user sessions are usually anonymous, a user can log on to an application-specific account, such as to a Web-based application through Internet Explorer (assuming Internet Explorer is the "kiosk application" launched at startup).

The dedicated application could be a Line of Business (LOB) application, an application hosted in Internet Explorer, or another application, such as one available in Microsoft Office. The default application should not be Windows Explorer or any other shell-like application. Windows Explorer allows more access to the computer than is appropriate for a Kiosk computer. Be sure the command prompt is disabled and Windows Explorer cannot be accessed from any application you use for this purpose.

Applications used for kiosk scenarios should be carefully checked to ensure they do not contain "back doors" that allow users to circumvent system policies. For example, they should not allow users access to applications that access the file system. Ideally, you should only use applications that comply with The Application Specification for Windows 2000, are Certified for Windows, and that check for Group Policy settings before giving users access to prohibited features. For more information, see the "The Application Specification for Windows 2000" at the Microsoft Web site (http://go.microsoft.com/fwlink/?linkid=1636). Older applications will not normally be Group Policy-aware, so try to disable any features that allow users to bypass administrative policy.

The registry entries **Run** and **RunOnce** are disabled in the Kiosk scenario through associated policy settings.

| **Important** |
| --- |
| Applications that use the **RunOnce** entry to finish an installation or upgrade will fail when the **Do not process the Run Once list** Group Policy setting is enabled. |

Please see the "Scenario Comparison" table in Appendix A for a comparison of features across scenarios.

# Understanding and Using the Scenarios

Updated: May 3, 2004

Applies To: Windows Server 2003 with SP1

The scenarios are implemented through the use of GPOs provided in the .MSI package with this white paper. By linking appropriate combinations of GPOs to OUs for computer and user settings, you can be implement each of the scenarios in your environment. This section describes the general characteristics of the GPOs and how they can be linked to OUs.

#### How the Scenarios Are Designed

### Separate GPOs for Computer and User Policy Settings

Most scenarios are directly associated with two GPOs – one for computer configuration and another for user configuration. For example, the **Lightly Managed** scenario is directly associated with the **Lightly Managed (Machine)** GPO for computer configuration and the **Lightly Managed (User)** GPO for user configuration. This approach simplifies troubleshooting, makes the application of GPOs somewhat more intuitive, and is a Group Policy best practice.

### "Base GPOs" for Common Settings

Many of the scenarios share a considerable number of policy settings and associated values. This version of the Common Scenarios white paper introduces the concept of the "base GPO," which is more relevant in a real-world, production environment than the monolithic GPOs packaged with previous versions.

The base GPOs (two each for **Lightly Managed** and **Highly Managed**) contain Group Policy settings common to other "child" scenarios (see the next section). The GPOs for these child scenarios extend these base GPOs by enabling, disabling, or changing the values of a relatively small number of settings tailored to their specific requirements.

### Scenario/GPO Relationships

To implement any of the scenarios, the GPOs must be linked to Scope of Management (SOM) containers - a site, domain or OU. Most of the GPOs packaged with the white paper are designed to be linked to OUs, rather than sites or domains.

| **Note** |
| --- |
| The GPOs provided are intended to assemble common policy settings and their relationships are technically independent of any OU hierarchy you might implement. For scenarios that require more than one GPO you might either link separate GPOs in a chain of OUs (Group Policy inheritance) or link multiple GPOs to a single OU (Group Policy precedence) – these options are covered in more detail later in this white paper. |

The following list illustrates the relationships between GPOs.

#### Machine Policy GPOs

### Lightly Managed

Mobile – No differences from Lightly Managed GPO, so no machine GPO exists for Mobile

### Highly Managed

AppStation - No differences from Highly Managed GPO, so no machine GPO exists for AppStation

Multi-User – GPO provided

TaskStation – GPO provided

Kiosk – GPO provided

#### User Policy GPOs

### Lightly Managed

Mobile – GPO provided

### Highly Managed

AppStation - GPO provided

Multi-User – GPO provided

TaskStation – GPO provided

Kiosk – GPO provided

For example, the AppStation scenario shares many of its Group Policy settings with the Highly Managed GPOs, as follows:

- On the machine side of policy for the AppStation scenario, the settings are identical in all regards to that of the Highly Managed scenario and, as such, there is no AppStation-specific GPO for machine policy settings. To implement machine settings appropriate to the AppStation scenario, it is only necessary to ensure that the Highly Managed (Machine) GPO is linked to a SOM containing the target machines.

- By comparison, some differences exist for user policy settings between Highly Managed and AppStation. For this reason, a GPO is provided for the user policy settings in the AppStation scenario, which contains differences from the Highly Managed user GPO. To implement user settings for the AppStation scenario, it is necessary that both the Highly Managed (User) and AppStation (User) GPOs are linked – directly or otherwise - to a SOM containing the target users. This can be achieved through either Group Policy inheritance or precedence when GPOs are linked to the same container.

The AppStation scenario is an exception - most scenarios are implemented through two GPOs – one for computer configuration and another for user configuration (the AppStation scenario uses only user configuration). In addition, most are associated with the base scenarios, **Lightly Managed** and **Highly Managed**, through Group Policy inheritance and/or precedence. With these issues in mind, the GPOs listed in Table 1 are effective for each scenario.

**Table 1. Scenario GPOs**

| Scenario Name | Base GPO Name | Scenario-Specific GPO Name |
|---|---|---|
| **Lightly Managed** | | |
| **Computer** | Lightly Managed (Machine) | N/A (no changes from base) |
| **User** | Lightly Managed (User) | N/A (no changes from base) |
| **Mobile** | | |
| **Computer** | Lightly Managed (Machine) | N/A (no changes from base) |
| **User** | Lightly Managed (User) | Mobile (User) |
| **AppStation** | | |
| **Computer** | Highly Managed (Machine) | N/A (no changes from base) |
| **User** | Highly Managed (User) | AppStation (User) |
| **Multi-User** | | |
| **Computer** | Highly Managed (Machine) | Multi-User (Machine) |
| **User** | Highly Managed (User) | Multi-User (User) |
| **TaskStation** | | |
| **Computer** | Highly Managed (Machine) | TaskStation (Machine) |
| **User** | Highly Managed (User) | TaskStation (User) |
| **Kiosk** | | |
| **Computer** | Highly Managed (Machine) | Kiosk (Machine) |
| **User** | Highly Managed (User) | Kiosk (User) |

**Purpose of the Highly Managed GPOs**

The Highly Managed scenario is a virtual scenario – its purpose is to provide a set of settings common to other scenarios

(specifically, the Multi-User, AppStation, TaskStation, and Kiosk scenarios). As such, the Highly Managed GPOs are not intended (or tested) to operate in their own context. Instead, the other scenarios are enabled by ensuring that the Highly Managed GPOs affect accounts through Group Policy inheritance or precedence. In short, no computer or user account should exist in OUs designed specifically for a Highly Managed scenario.

**Creating a Test Environment**

In previous versions of this white paper, a considerable number of scripts were necessary to create and configure the GPOs provided with the white paper. With the advent of GPMC – and specifically its Import functionality – these scripts are no longer necessary. The GPOs have been backed up and provided with this white paper, which allows you to import them directly into your environment.

To assist in creation of this environment, a script included with GPMC, CreateEnvirommentFromXML.wsf, is used to create a hierarchy of OUs, create GPOs, and link the GPOs to the OUs appropriately. A script called CreateCommonScenarios.cmd is provided with this white paper to call this script with the appropriate parameters.

After successfully running the script, you will have OUs and linked GPOs configured similar to those shown in Figure 1.

**Figure 1. GPMC Screenshot of Scenario GPOs**

**Linking GPOs to OUs to Create Scenarios**

There are two broad approaches available for using the GPOs to create scenarios in your environment. To illustrate these options, the AppStation scenario is used, which is an extension of the Highly Managed scenario (many of the AppStation settings are defined by the Highly Managed GPOs).

**Linking GPOs to a Hierarchy of OUs (Group Policy Inheritance)**

With this option, create an OU hierarchy where the AppStation OUs (one each for Computer and User accounts) are children to the Highly Managed OUs. Figure 2 illustrates how the GPOs would be linked.

**Figure 2. Linking Scenario GPOs Using Inheritance**

Note that because the machine policy for the AppStation scenario does not differ from that of the Highly Managed scenario, no AppStation (Machine) GPO exists. Technically, it is not necessary to place AppStation affected computers in the AppStation OU

because they might reside in the Highly Managed OU and be affected by the same settings. However, for clarity and to easily accommodate the potential for future differences between Highly Managed and AppStation GPOs (on the machine side), there might be value in retaining the AppStation OU. After the appropriate GPOs are linked to these OUs, the computer and user accounts would be moved into the appropriate AppStation OUs.

**Linking GPOs Directly to OUs (Group Policy Precedence)**
In this approach, you only create two OUs (one each for Computer and User accounts). For each, both the Highly Managed and AppStation GPOs are linked directly to the OU. This is illustrated by Figure 3.

**Figure 3. Linking Scenario GPOs Using Precedence**

After linking the GPOs, it is important to ensure that the precedence of the GPOs is such that the AppStation GPOs take priority over Highly Managed GPOs. GPMC provides a simple and intuitive interface for enforcing this precedence. This is achieved by selecting a container, such as an OU, in the GPMC tree view and using the **Linked Group Policy Objects** tab in the right pane to adjust ordering of GPOs linked to that container.

After creating the OUs and GPO links, move the computer and user accounts into the appropriate AppStation OUs.

**Differences with Earlier Versions of the Common Scenarios**
An earlier version of this white paper focused on Windows 2000 domains. Since that time, a number of Group Policy enhancements have become available, most notably GPMC. The following areas differ between the Windows 2000 and Windows Server 2003 common scenarios.

**Base GPOs**
As described earlier, the base GPOs (Lightly Managed and Highly Managed) are a new concept in this version of the white paper.

**GPMC-Based GPO Deployment**
GPMC provides a significant number of features – Backup, Import, Copy and so on – that significantly simplify managing GPOs. This white paper takes full advantage of these new capabilities by providing backed-up copies of GPOs which can easily be imported into your test environment.

**Environment Creation Script (CreateCommonScenarios.cmd)**
GPMC includes a series of example scripts which illustrate the automation of common Group Policy operations. One such script is CreateEnvironmentFromXML.wsf which uses an XML file to recreate an environment (typically OUs, GPOs, and GPO links) in your domain. An XML file (CommonScenarios.xml) is included with this white paper to facilitate the use of the script to largely automate the creation of your environment.

A command file – CreateCommonScenarios.cmd – is packaged with this white paper to streamline the installation of a sample environment.

It is important to note that while the script must be run from either a Windows XP or Windows Server 2003 computer, the domain in which it creates the sample environment can be either a Windows 2000 or Windows Server 2003 domain.

**Group Policy Reports Documentation**
GPMC provides a new way to report the contents of GPOs – Group Policy Reports. These are HTML reports that document all aspects of each GPO. Reports for each of the GPOs are provided with this CommonScenarios.msi as a documentation tool. When you make changes to the GPOs, GPMC can help you document the changes by using Group Policy Reports.

**New Group Policy Settings**
Windows Server 2003 delivers a number of new settings not just for that operating system but also for Windows XP Professional. Many of these settings are used in the updated scenario GPOs.

**Consolidated Spreadsheet of Group Policy Settings**

The Windows 2000 and Windows XP versions of the scenarios installed one spreadsheet for each scenario. This revised version includes a consolidated spreadsheet – CommonScenarios.xls - and each scenario is listed in a separate column. Using Microsoft Excel column filtering, this can be a helpful way to quickly compare GPO settings.

# Deploying the Scenarios

Updated: March 2, 2005

Applies To: Windows Server 2003 with SP1

This section describes the steps necessary to implement the scenarios. As a prerequisite, it is assumed that you have created a fully operational Active Directory domain and have validated the integrity and operation of the underlying DNS infrastructure. Group Policy is dependent on a well-configured, reliable Active Directory environment.

| **Note** |
| --- |
| You can download the CommonScenarios.msi installation package, which includes this document and supporting files, from the Microsoft Download Center. |

The following steps are necessary to implement the scenarios:

1. Run the CommonScenarios.msi package to copy the GPOs, scripts, and associated documentation (such as this white paper) to your administrative workstation.

2. Create an appropriate OU environment.

3. Use GPMC to import the scenario GPOs into your environment.

4. Link the GPOs to OUs.

   Two options are available to cover steps 2 - 4:

   a. Automatically create an OU hierarchy, GPOs, and GPO links using a script provided with this white paper (CreateCommonScenarios.cmd).

   b. Manually implement each step (create OUs, import GPOs, and so on). This is a more flexible approach but will take a little longer to implement.

On completion of these steps – and regardless of the approach taken (scripted or manual) - you will perform the following steps to complete configuration and testing of the scenarios:

- Configure specific scenario features (see the "Configuring Specific Features" section)

- Create Computer and User accounts for use within the scenarios.

- Test scenarios.

**Test and Production Environment Considerations**

Before installing the scenarios into your environment (described in the next section), you should understand the options available for testing. There are two primary ways in which you can incorporate the GPOs into your environment for testing; by linking the GPOs to test OUs in your production domain or by using a separate test domain (either in the same or a different forest).

**Using Test OUs in Your Production Environment**

Where a separate test domain (the preferred approach) is not feasible, the scenario GPOs can be imported to a production environment and linked to OUs created in that domain specifically for test purposes. These OUs should be well-segmented from those used for regular production purposes. The benefit of this approach is that you need not create infrastructure to support a separate domain (domain controllers, networking, and so on). The disadvantage is that misconfiguration of accounts, GPOs, or GPO links can directly affect the production environment.

**Using a Separate Test Domain**

With this approach, you use a domain that is separate from that of your production environment (trusts may or may not exist

between the test and production environments). This can allow you to run a more realistic test by modeling the test domain on your existing domain, so you can test domain-wide settings and other interactions as needed. A significant benefit of using this approach is that the impact of errors through inappropriately linked or filtered GPOs is significantly less than is evident in a production environment. The primary drawback of this approach is that you need to set up domain controllers and other supporting infrastructure (networking, DNS, and so on) that implements the test domain. If possible, use this approach.

**Considerations Across Forests and Domains**
The two domains used for test and production purposes might or might not be in the same forest. Further, if they are in separate forests, a forest trust might or might not exist, because a forest trust can only be established between Windows Server 2003 forests.

Where a trust exists between the domains (for example, where the test and production domains are in the same forest and the default transitive trusts exist), an administrator with the appropriate rights in each domain can use GPMC to copy GPOs between domains. This can be as simple as dragging and dropping GPOs between domains using the GPMC graphical user interface. Note that if the GPOs in your test environment include security principals (for example, group names) or UNC paths (for example, when specifying your Folder Redirection parameters), migration tables will help you handle any changes you might need to make across domain boundaries. The Migration Table Editor – part of GPMC – provides a simple interface for editing migration tables. For more information, see the "Migrating GPOs Across Domains with GPMC" white paper at the Microsoft Web site (http://go.microsoft.com/fwlink/?linkid=14321).

Where a trust does not exist, the follow options are available:

- Create your OU structure and use the GPMC **Import** function to create new GPOs in the production environment. The backup from which you import GPOs might be that provided with this white paper or – if you have already tailored the GPOs to your needs – from a backup set that you created.

- Use the CreateEnvironmentFromXML.wsf script (a sample script installed with GPMC – see GPMC Help for more information) to create the default OU environment in your production domain and, if necessary, rename OUs and GPOs to better reflect naming/structural conventions in your production environment.

- Use the Stored User Names and Password feature of Windows XP to store credentials for a user in a non-trusted domain.

**Test Environment Recommendation**
Where adequate resources are available (domain controllers, networking infrastructure, and so on), it is strongly recommended that the GPOs are imported into a test domain. Using a separate domain provides you with a relatively safe environment in which to assess the GPOs and also allows more flexibility in regards to testing domain-wide Group Policy settings.

**Installing the Common Scenario Scripts and GPOs**
Packaged with this white paper is a series of scripts and GPO backups that form the basis of your deployment of the common scenarios. The CommonScenarios.msi file installs these components – including the white paper itself – into the "%programfiles%\Microsoft\Group Policy Common Scenarios" folder and creates menu options on the Start Menu for some of these components (for example, a link to the white paper and its associated spreadsheet). After running this package, the following directory structure is created:

**%programfiles%\Microsoft\Group Policy Common Scenarios**

**\Documentation (Common Scenarios white paper and spreadsheet)**

**\GPO-Backups (GPMC-originated backups of the scenario GPOs)**

**\GPO-Reports (GPMC-originated reports for each GPO in HTML format)**

**\Environment (XML representation of example OU structure for scenarios)**

**\Scripts (scripts used to create example environment)**

It is assumed that the computer on which this directory is created already has GPMC installed (the supplied scripts include calls to GPMC scripting interfaces). GPMC requires either Windows XP Professional or Windows Server 2003 (see GPMC documentation for further details about requirements). The directory in which the common scenarios files are installed is hereafter referred to as the <**installdir**>, (typically %programfiles%\Microsoft\Group Policy Common Scenarios).

In addition to installing the files, a **Group Policy Common Scenarios** menu on the user's **Start/Programs** menu is created. This menu provides access to the white paper, the spreadsheet, a shortcut to the Group Policy Reports directory, and a

command line configured to start in the %programfiles%\Microsoft\Group Policy Common Scenarios\Scripts directory.

After you run the installer, you must import the GPOs associated with the scenarios into your domain. There are two options to achieve this: a quick method to create an overall common scenarios test environment (a sample OU structure, GPOs, and GPO links), and a more manual process where creation of OUs, GPOs and GPO links are separate steps.

**Deployment Option 1: Quick Setup Using CreateCommonScenarios.cmd**
A script is included to assist with installing a representative OU structure, GPOs, and GPO links into your environment. This script is named **CreateCommonScenarios.cmd** and is installed into the <**installdir**>**\Scripts** directory. The script calls a sample script installed by GPMC –(CreateEnvironmentFromXML.wsf) which is installed in the **%programfiles%\GPMC\Scripts** directory.

CreateCommonScenarios.cmd initiates the following tasks:

- Creates an example OU hierarchy, representing locations for computer and user accounts
- Creates the scenario GPOs, including default permissions
- Links the scenario GPOs to the appropriate OUs

**Running CreateCommonScenarios.cmd**
To run the script, do the following:

1. Click **Start**, click **Programs**, click **Group Policy Common Scenarios**, and then click **Common Scenarios Scripts Command Prompt**.
2. From the command prompt, type **CreateCommonScenarios**, and then press **Enter**.

**Results of Running the Script**
By running the script against your domain, you create a self-contained test environment with the appropriate OUs and GPOs linked to those OUs. Note that might still need to create or edit GPOs linked at the domain level, especially where account policy settings are modified but this is specific to your domain and outside the scope of the scenario GPOs. To avoid potential conflict with your existing environment, no domain-level policy settings are implemented through the scenarios.

**Modifying the Behavior of CreateCommonScenarios.cmd**
The CreateCommonScenarios.cmd script is a wrapper for the CreateEnvironmentFromXML.wsf script, which is installed with GPMC. In some cases you might need to change the default behavior of this script. For example, if you want to modify the domain controller against which the script is run. Any parameters passed directly to the CreateCommonScenarios.cmd script are passed on to the CreateEnvironmentFromXML.wsf script. For more information about the parameters supported by the CreateEnvironmentFromXML.wsf script, see GPMC Help.

**Deployment Option 2: Manual Deployment Steps Using the GPMC GUI**
This method is more time-consuming but allows you greater control over your OU design and GPO links.

**Create an Appropriate OU Test Environment**
You need to create OUs for the users and computers you want to manage within your domain. If your environment requires a more complex OU structure than that described in this document, refer to the "Designing the Active Directory Logical Structure" chapter of the *Designing and Deploying Directory and Security Services* book in the *Windows Server 2003 Deployment Kit*. For more information, see the Microsoft Web site (http://go.microsoft.com/fwlink/?linkid=18341).

**Use GPMC to Import GPOs**
The GPOs provided with this white paper can also be imported into your environment manually, using a GPMC sample script, as follows:

```
cscript %programfiles%\gpmc\scripts\ImportAllGPOs.wsf <installdir>\GPO-Backups
```

**Note**

"Cscript" can be omitted if you have previously configured cscript as the default scripting environment for your machine. More specifically, if you have previously run:

**cscript //hh:cscript**

this will set cscript as the default environment, in which case the following command would work:

**%programfiles%\gpmc\scripts\ImportAllGPOs.wsf <installdir>\GPO-Backups**

The ImportAllGPOs.wsf script will result in all the GPOs provided in the <installdir>GPO-Backups directory being created in your environment and their settings imported. On completion of this step you will then need to link the GPOs to the OUs you have created.

The same result can be achieved through the GPMC MMC-snap-in, do the following:

1. Create empty GPOs (no policy settings) in your environment by right-clicking the Group Policy object node and selecting **New** from the context menu. Create one GPO for each of the Common Scenario GPOs, using the names documented in the "How the Scenarios Are Designed" section of this white paper.

2. In GPMC, right-click each GPO and then click **Import**. Go to the <installdir>\GPO-Backups directory and import policy settings from the appropriate backed-up GPO.

**Link GPOs to OUs**

To apply the settings of a GPO to the users and computers of a domain, site, or OU, you need to add a link to that GPO. You can add one or more GPO links to each domain, site, or OU by using GPMC. Keep in mind that creating and linking GPOs is a sensitive privilege that should be delegated only to administrators who are trusted and understand Group Policy.

To link an existing GPO

1. In GPMC, right-click a domain or OU, and then click **Link an Existing GPO here**.

2. In the **Select GPO** dialog box, click the GPO which you want to link, and then click **OK**. In the left pane, the GPO is displayed beneath the domain or OU to which it is linked.

You can simultaneously link multiple GPOs to an Active Directory object by holding down the **CTRL** key while selecting GPOs.

**Post-Installation Configuration**

After you have created an environment in which you wish to host your scenario GPOs – either automatically by using the CreateCommonScenarios.cmd script or manually – you must carry out a number of additional steps to finalize the configuration of certain aspects of your environment. This section describes each of these steps.

**Configure Scenario Features**

Configuration for Roaming User Profiles and Redirected Folders require you to enter UNC paths specific to your environment (into the user objects within the Active Directory and to the appropriate GPOs, respectively). See the "Configuring Specific Features" section for more details.

**Create Computer and User Accounts**

Using the Active Directory Users and Computers snap-in, create a sufficient number of user accounts to allow you to test each of the scenarios.

It is important to note that any one scenario is implemented through the combination of user and computer accounts, each of which should be affected by GPOs associated with the same scenario. For example, to achieve the TaskStation scenario, a user in the CommonScenarios/Users/TaskStation OU might log on to a computer in the CommonScenarios/Computer/TaskStation OU. Any "cross matching" of user and computer scenarios is untested and might cause unforeseen results.

**Migrating the Scenarios to a Production Environment**

After testing and potentially customizing the Common Scenario environment, you might wish to move into a production environment. The following approaches can be used:

- **Manual creation in production environment.** With this approach, you create each of the OUs from either GPMC or Active Directory Users and Computers. The GPOs are either copied (if a trust exists between the source and target environments) or created/imported (where file-based GPO backups are used). Then link the GPOs to the OUs and move

the users/computers into the OUs as appropriate.

- **Use the CreateXMLFromEnvironment and CreateEnvironmentFromXML scripts.** The CreateXMLFromEnvironment script – included with GPMC as a sample script – allows the administrator to create an XML file representing all the policy-related objects (OUs, GPOs, and GPO links). Optionally, you can specify a starting OU rather than the entire domain. The script creates a representation of the OU and its linked GPOs in the specified XML file. This file can then be used by the CreateEnvironmentFromXML script to create a mirrored OU structure and associated GPOs and links in the target environment. When planned carefully, these two scripts can help create an initial framework in your production environment.

For more information about managing GPOs across domains, see the "Migrating GPOs Across Domains with GPMC" white paper at the Microsoft Web site (http://go.microsoft.com/fwlink/?linkid=14321).

**Removing the Scenarios from Your Environment**

Removing the scenarios from your environment is a relatively simple task. Use the following steps to remove them:

- Move computer and user accounts that you need to retain into alternative OUs, as necessary. Reconfigure user objects, as appropriate, to modify Roaming User Profile paths.

- Validate that each scenario GPO is linked to the expected SOMs (using the **Scope** tab within GPMC). This step is important to ensure that no unexpected cross-domain or other links exist.

- Delete each scenario GPO.

- Validate that the scenario OUs are empty, and then use Active Directory Users and Computers to remove those OUs.

- If you added the domain GPO, validate, unlink, and delete that GPO as appropriate.

If you have used the CreateCommonScenarios.cmd script to create your sample environment, then the CreateEnvironmentFromXML.wft sample script was called implicitly. This script has an **/undo** switch that removes the environment described by the XML file passed as an argument. See GPMC online Help for further details on this script.

In addition to these issues, please refer to the section "Switching Between Scenarios" for more factors that might also be relevant when removing scenarios (for example, "tattooing" the registry with security settings).

# Configuring Specific Features

Updated: May 3, 2004

Applies To: Windows Server 2003 with SP1

This section describes the various features configured in the common scenarios GPOs.

**Roaming User Profiles**
A user profile is a group of settings and files that define the user's environment. A profile includes program items, screen colors, network connections, window sizes and positions, and so on. Roaming User Profiles (RUP) enable the server-based storage of user profiles, which means that users can move between computers and see an identical environment. The RUP is downloaded to the user when s/he logs on and, by default, is stored back on the server when the user logs off. This feature is one component of the concept of "free-seating" – the capability for users to roam between computers yet maintain an identical environment.

**Scenarios in Which Roaming User Profiles are Used**
Due to the order in which logon, profile creation/loading, and the application of GPOs occurs, it is not possible to specify the location of a user profile using Group Policy. For this reason, specifying the user profile location is a distinct and separate step from the application of GPOs. Therefore, to ensure that a user is configured correctly, it is important to move that user into the appropriate OU and, additionally, configure the user object as described below.

The common scenarios leverage Roaming User Profiles as follows:

- **Used:** Lightly Managed, Highly Managed, Multi-User, AppStation, and TaskStation
- **Optionally Used:** Mobile User
- **Not Used:** Kiosk

**Roaming User Profiles Configuration Steps**
For the purposes of illustration, this document assumes a server named **CommonServer** is available to store user profiles. The following steps are necessary to create a share for user profiles and configure user accounts appropriately.

1. On the CommonServer computer, create a folder called **profiles**.
2. Share this folder as **profiles$**.
3. Set share permissions to **Full Control** for the **Everybody** group (security will be enforced by NTFS permissions when the user profile folders are created).
4. Ensure that caching for this folder is disabled (only use caching for folders where you do not store profiles).
5. For each account for which Roaming User Profiles is required, set the profile path in the user object to \\CommonServer\profiles$\%user name% (the Active Directory Users and Computers MMC snap-in is the most common way to edit this parameter). At the time the user profile is created, the %user name% environment variable will be resolved to the name of the user.

**Roaming User Profile Notes**
It is a best practice to allow the user-specific accounts (in the **Profiles** folder) to be automatically created at the time the user profile is first established. This ensures that the appropriate set of NTFS permissions and ownership are set on the folder.

| **Important** |
| --- |
| Roaming User Profiles have their own caching mechanism, which can interfere with Offline Files synchronization and can lead to unexpected behavior and loss of data. Therefore, make sure that caching is disabled for the shares where you store profiles. |

**Redirected Folders**

Folder Redirection allows the contents of a folder in the user's profile to be redirected to a location on the network. For example, you can move My Documents, which is typically part of the user's profile and cached on the local drive, to a folder in the user's home directory on the network. Enabling this feature is useful because the My Documents and Application Data folders often contain large amounts of data. Enabling Folder Redirection helps speed up logon and logoff time because the contents of the redirected folders are not copied along with the rest of the user profile.

In most cases when you use Folder Redirection, you will combine it with Offline Files so that users can access cached copies of the redirected folders when disconnected from the network. In fact, with Windows XP, all redirected folders are also cached locally by default (this is not the case with Windows 2000).

If you have a high volume of users that use a single computer, consider enabling the **At logoff, delete local copy of user's offline files** Group Policy setting to prevent the local hard drive from filling up with cached files from multiple users. This setting is located under Computer Configuration\Administrative Templates\Network\Offline Files.

| **Caution** |
| --- |
| You should use this policy setting with caution. If a user has been working offline and has not synchronized their changes, their changes will be lost at logoff when their offline files are deleted. |

When you implement Folder Redirection, the destination folders are automatically created, and security is configured on these folders automatically. You can change the security of redirected folders by checking or clearing **Grant the user exclusive rights to foldername**,which is located in this path: User Configuration\Windows Settings\Folder Redirection*foldername* - **Settings** tab.

For example, if you redirect the My Documents folder to \\CommonServer\Docs*%User name%*, do not create a **User Name** folder in advance. If the folder exists in advance and the current user is not the owner of the folder and its contents, the redirection process fails. If the folder does not exist prior to folder redirection, however, it is created and the user is made the owner of that folder. If you use the **Create a folder for each user under the root path** option in the **Target Folder Location** dropdown box, Folder Redirection automatically appends %user name% to the root path you specify.

| **Important** |
| --- |
| If you must create the folder in advance, ensure that the user is the owner of the folder and its contents. To change the ownership of a file or folder, use Windows Explorer or the Subinacl.exe utility. For more information, see the Microsoft Web site (http://go.microsoft.com/fwlink/?linkid=18341). |

| **Note** |
| --- |
| When Group Policy Folder Redirection settings go out of scope, by default, they leave the redirection in place. The **Settings** tab has an option that allows you to redirect the folders to the local computer; however, avoid using this option. The default setting is the safest because no data is moved when a Folder Redirection policy falls out of scope. Any new Folder Redirection policy then redirects as appropriate. |

#### Scenarios in Which Folder Redirection is Used

The common scenarios leverage Folder Redirection as follows:

- **My Documents and Application Data Redirection:** Lightly Managed, Highly Managed, Mobile, Multi-User, AppStation and TaskStation

- **None:** Kiosk

#### Redirected Folders Configuration Steps

Because a server name is specified when configuring redirected folders, the GPOs provided with this CommonScenarios.msi do not specify Folder Redirection properties. To fully implement the scenarios in your environment, you must carry out the following steps.

1. On the CommonServer computer, create a folder called **redirected**.

2. Share this folder as **redirected$** (the full share name would therefore be *CommonServer**redirected$*).

3. Set share permissions for the *redirected*$ share to **Full Control** for the **Everyone** group (security will be enforced by

NTFS permissions when the user profile folders are created).

4. For both the **Lightly Managed (User)** and **Highly Managed (User)** GPOs, do the following:

    a. In GPMC, right-click the GPO, and then click **Edit**.

    b. Within the Group Policy Object Editor, go to *User Configuration/Windows Settings/Folder Redirection*.

    c. Right-click the **My Documents** node and click **Properties**.

    d. In the **Properties** dialog box, change the **Setting** list to **Basic – Redirect everyone's folder to the same location**.

    e. Leave the **Target Folder Location** list set to **Create a folder for each user under the root path**.

    f. Set the **Root Path** field to \\CommonServer\redirected$, and then click **OK**. Folder Redirection automatically appends %user name% to the path specified.

    g. Right-click the **Desktop** node and click **Properties**.

    h. In the **Properties** dialog box, change the **Setting** dropdown box to **Basic – Redirect everyone's folder to the same location**.

    i. Leave the **Target Folder Location** list set to **Create a folder for each user under the root path**.

    j. Set the **Root Path** field to \\CommonServer\redirected$\, and then click **OK**. Folder Redirection automatically appends %user name% to the path specified.

    k. Close the GPO.

**Redirected Folders Notes**

The steps above ensure that all scenarios – except the Kiosk scenario – implement redirected folders. Because the Kiosk scenario is a child of the Highly Managed scenario, it is necessary to disable the Folder Redirection setting specified in the Highly Managed (User) GPO. This is achieved – through the supplied Kiosk GPOs – by redirecting the appropriate folders back to the local user profile location; this is, in essence, the same as disabling Folder Redirection.

**Internet Explorer Configuration**

There are two types of Internet Explorer Group Policy settings: the standard Windows registry settings and a collection of registry settings and files used to configure Internet Explorer. The standard settings are located in the Group Policy Object Editor under Administrative Templates\Windows Components\Internet Explorer, and the configuration settings are located in User Configuration\Windows Settings\Internet Explorer Maintenance.

The Internet Explorer Maintenance settings can be set in two modes: **policy mode** or **preference mode**. Policy mode is enforced and automatically resets any settings users might change (if they have the appropriate permissions) when Group Policy is applied.

| **Note** |
| --- |
| Like all registry-based Group Policy settings, Internet Explorer Maintenance policy mode settings reapply only when the GPO changes. Unlike most registry-based Group Policy settings, configuring an Internet Explorer Maintenance setting does not prevent the user from changing that setting. |

Preference mode sets initial default values that the user can change, subject to other Group Policy settings that affect the user. The preference settings are only applied again when the administrator makes changes to the preference settings. To allow users to change these preferences, they must be able to access Internet Options on the Tools menu. You allow users access by configuring settings in the Group Policy Object Editor under Computer (or User) Configuration\Administrative Templates\Windows Components\Internet Explorer.

You cannot use policy and preference modes together in a single GPO. If you need both modes, you must use two separate

GPOs. The included scenarios are configured using policy mode, so you might need to create an additional GPO using preference mode for your environment.

**Kiosk Scenario Configuration**
The Kiosk scenario uses a single account that is a member of the Domain Users group (all new accounts in a domain are added to this group) with no special privileges. To enable the use of this account with no user intervention, the AutoLogon feature is used. At startup, the operating system logs on automatically using the account and password specified in the registry key below.

**Kiosk User Account Configuration**
The account used by the Kiosk scenario should be configured as follows:

- Password never expires
- User cannot change password

To configure the account for auto logon, a tool that is part of the Windows XP PowerToys can be used to specify the user name and password. For more information about the PowerToys, see http://go.microsoft.com/fwlink/?LinkId=101706.

**Specifying the Kiosk Application**
The packaged GPOs specify Internet Explorer as the auto launch application for both the TaskStation and Kiosk scenarios. This is handled by enabling the \User Configuration\Administrative Templates\System\Custom User Interface Group Policy setting. The value used for this policy (for both scenarios) is:

%programfiles%\internet explorer\iexplore.exe –k

This has the result of automatically launching Internet Explorer (in full screen mode because of the –k switch) when a user logs on. In effect, the policy is used to replace Windows Explorer as the shell. By updating the Custom User Interface Group Policy setting, you can dictate the application to be launched in the TaskStation and Kiosk scenarios in your own environment.

**Resetting Kiosk Settings to a Default State**
In some cases, you might want to reset the Kiosk environment to a known state. Although Kiosk users are prevented from making most changes to a Kiosk-based computer, a few application-specific settings cannot easily be managed by using Group Policy settings. For example, if a user resizes the Internet Explorer window, the window starts up in that size for all subsequent users.

You can use a mandatory user profile to reset the Kiosk settings. To do this, use the following procedure:

1. Log on to the user account and configure the appropriate settings.
2. Log off of the user account and then log on as an Administrator.
3. Copy the profile to a local or network directory and then rename the profile root to OldName.man.
4. Modify the user object and specify this directory as the profile path.

After you carry out this procedure, if a Kiosk user logs on, the computer settings reflect the settings defined in the mandatory profile.

**Disk Maintenance**
Applications used on a Kiosk-based computer can write data to the disk drive. To prevent the disk drive from filling up, set a disk quota that leaves at least 100 megabytes (MB) free on the system disk.

You should consider using the disk quota in conjunction with a scheduled script that removes older temporary files each night. If the Kiosk application creates a lot of temporary files, the script might also need to run disk defragmentation to maintain system performance.

**Disabling Logoff Capability for Kiosk Users**
Kiosk users cannot log off the Kiosk account by pressing **Ctrl+Alt+Del** or by using the **Start** menu. When the computer starts up, it automatically logs on to the Kiosk account.

**Important**

In the Kiosk scenario, Kiosk users are prevented from logging off; however, in the Kiosk GPOs provided with this white paper, logoff capability is enabled because it makes testing easier. Therefore, before deploying the scenario, you need to disable the logoff feature.

A disadvantage of disabling the logoff feature is that an administrator cannot easily log on to the computer. The administrator cannot restart the computer from the console because shutdown and restart are disabled for the kiosk user. To resolve this, you can use one of the following solutions:

**Solution 1**

1. Restart the computer by doing one of the following:

   - Execute a remote restart using **shutdown.exe**.

     Perform a hardware reset or power off of the computer (this solution is not recommended because it could lead to data loss or system malfunction).

2. When the computer restarts, hold down the **Shift** key to bypass the automatic logon feature and access the standard logon dialog box.

**Solution 2**

In this option, the logon feature remains enabled. The administrator logs off from the Kiosk account and then holds down the Shift key to bypass the automatic logon feature. The disadvantage to this method is that a user could do the first part of this operation. Although they would be unable to log on, this would leave the logon dialog box displayed and render the Kiosk computer unusable until it is restarted.

# Switching Between Scenarios

Updated: May 3, 2004

Applies To: Windows Server 2003 with SP1

Joining a particular scenario is relatively simple – move the appropriate computer and user accounts into OUs to which the appropriate scenario GPOs have been linked. For example, if a user is to experience the Multi-User scenario, his or her account must exist in an OU to which the Multi-User (User) GPO has been linked and must log on to a computer in an OU to which the Multi-User (Computer) GPO has been linked.

In general, moving between scenarios is simply a matter of moving computers and users into the appropriate OUs. However, you might need to do some additional work to complete the transition between scenarios related to security settings and Roaming User Profiles.

Note that moving users between OUs requires a logon to ensure that this is reflected and that the appropriate GPOs are applied. Similarly, moving a computer to a different OU requires that the computer is restarted for the new OU to be recognized.

**Security Settings**
A number of security settings "tattoo" the registry – once applied through a GPO, they remain active even when the GPO is moved out of scope for the target computer or user (by unlinking the GPO, moving the account from an affected OU, or disabling the GPO). Therefore, simply switching a computer or user account to an OU associated with a different scenario will result in some settings from the original scenario remaining. This is particularly evident when transitioning to a scenario with fewer security settings than the original.

There are a number of options to address this issue:

- Ensure that the GPOs associated with the new scenario explicitly disable/enable security settings that have been set in the GPOs associated with the original scenario. For example, if a security setting is configured in a GPO for the original scenario, the GPO for the new scenario must configure that security setting, even if the security setting isn't directly relevant to the new scenario. While this makes for a more deterministic application of these settings (the eventual result of the security setting is independent of the configuration in the original scenario), this does result in all GPOs needing to include the superset of all possible security settings, which can be cumbersome to manage and track.

- Temporarily move the computer and user accounts to a "clean up" OU that explicitly sets all security settings to a default state. After these have been implemented (allowing Group Policy to refresh by waiting at least 120 minutes or by using the **gpupdate** command), the accounts are moved to the appropriate OUs for the new scenario. One drawback with this approach is the potential for a delay to ensure that the temporary policy settings are applied to the computer and user accounts. Additionally, it is necessary for the user account be used to log on at least once to ensure that the "clean up" GPOs associated with user-based security settings are applied.

- As an administrator on the target machine, manually remove the security settings that no longer apply. This is clearly the most labor-intensive approach, requires significant knowledge of how each security setting is implemented, and is generally not an option with a significant number of computers.

**Roaming User Profiles**
The Roaming User Profile attribute for a user (the location of the roaming profile, if set) is stored in the user account object within Active Directory. Due to the order in which profiles are applied, as related to the application of Group Policy, this parameter cannot be set through Group Policy. As such, if a user moves between scenarios where the use of Roaming User Profiles changes (for example, where the initial scenario uses a Roaming User Profile but the target scenario does not), then it is necessary to update the user object to reflect this change.

# Extending the Scenarios

Updated: May 3, 2004

Applies To: Windows Server 2003 with SP1

You can use the common scenarios GPOs as a starting point for your own custom scenarios. For more information about the features and capabilities of Group Policy, see the *Designing a Managed Environment* book in the *Windows Server 2003 Deployment Kit*. For more information, see the Microsoft Web site (http://go.microsoft.com/fwlink/?linkid=18341).

**Software Distribution through Group Policy**
The scenarios do not implement any form of software distribution, although this is a feature of Group Policy. By creating .MSI packages and associating them with targeted GPOs, it is possible to manage applications using Group Policy, including support for initial deployment, transforms, and "self-healing" installations (detection and automatic repair of missing components such as DLLs). Group Policy enables you to automatically install and maintain software installation on target computers or make it available for user installation.

**Software Restriction Policies**
Software restriction policies, new with Windows XP and Windows Server 2003, provide a policy-driven mechanism that enables you to identify the programs that are running on computers in your domain, and to control their ability to run. By using software restriction policies, you can:

- Control what programs run on your system. For example, you can apply a rule that does not allow certain file types to run in the mail attachment directory of your e-mail program if you are concerned about users receiving viruses through e-mail.
- Run only digitally signed scripts.
- Allow users to run only specific files on multi-user computers. For example, if you have multiple users who use a single computer, you can set up software restriction policies and Access Control List settings so that users cannot make changes to the computer.
- Decide who can add trusted publishers to a computer.
- Control whether software restriction policies affect all users or only certain users who use a computer.
- Prevent any files from running on a local computer. For example, if you are aware of a known virus, you can disallow a hash of that virus so that the computers in your domain cannot run that program.

**Creating Default OUs for New Machine and User Accounts**
By default, all new computer or user accounts are created in the Computer or User containers, respectively. Because these are not OUs, it is not possible to link GPOs to them. However, using two new tools provided with Windows Server 2003, you can specify that all new accounts will be created in specific OUs. You do this by first creating OUs for new user and computer accounts and then running Redirusr.exe (for user accounts) and/or Redircmp.exe (for computer accounts) once for each domain. From this point, all new user and computer accounts will be placed in the targeted OUs. These tools are included on the Windows Server 2003 CD. You can run either of these tools or both of them.

For more details, see article 324949, "Redirecting the Users and Computers Containers in Windows Server 2003 Domains," in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?linkid=4441).

# Appendix A: GPO Scenario Policy Settings

Updated: May 3, 2004

Applies To: Windows Server 2003 with SP1

The Group Policy settings for each scenario (GPOs for both computer and user policy settings) are documented in the accompanying spreadsheet, CommonScenarios.xls. Using Excel's column-filtering capability, the spreadsheet allows you to easily browse through the settings associated with each scenario.

In addition, HTML-based GPO reports are provided in the **<installdir>\GPO-Reports** directory. One report exists for each GPO provided with CommonScenarios.msi and provides a good deal of information about each GPO.

**Scenario Comparison Table**

Table 2 lists the feature characteristics of each scenario.

**Table 2. Scenario Features**

| | **Lightly Managed** | **Mobile** | **Multi-User** | **AppStation** | **TaskStation** | **Kiosk** |
|---|---|---|---|---|---|---|
| Number of users | Multiple | 1 | Multiple | Multiple | Multiple | 1 (anonymous) |
| User profile type | Roaming | Roaming | Roaming | Roaming | Roaming | Local |
| Profile persistence at logoff | Cached | Cached | Removed at logoff | Cached | Removed at logoff | N/A |
| Folder Redirection | My Documents and AppData | My Documents and AppData | My Documents and AppData | My Documents and AppData | My Documents and AppData | No |
| User can customize | Almost all settings | Some or most settings | Some settings | Few settings | None | None |
| Task bar and Start Menu | Yes | Yes | Yes | Yes | No | No |
| Assigned Applications | Multiple | Multiple | Multiple | Few | 1 (usually computer assigned) | 1 (computer assigned) |
| Published applications | Yes | Yes | Yes | No | No | No |
| Security context | User or Power User | User or Power User | User | User | User | User |
| Based on security template | Secure Workstation | Secure Workstation | Highly Secure Workstation | Highly Secure Workstation | Highly Secure Workstation | Highly Secure Workstation |

**Notes:**

- The scenarios are based on the security templates listed; however, in each scenario, the templates have been modified.
- The following significant modifications are made for compatibility reasons:
- Mandatory digital signing of SMB traffic is disabled.
    - Mandatory encryption of secure channel communications is disabled.
    - LAN Manager Authentication Level is not specified.

**Permissions Needed for Folder Redirection**

When setting up folder redirection, it is recommended that you create the root share only on the server, and let the system create the folders for each user. For the best experience, set the share permissions to **Full Control** for the security groups you're redirecting, and set the NTFS permissions to **Full Control** on this folder, subfolders, and files.

If you must create folders for the users, ensure that you set the correct permissions. Tables 3, 4, and 5 below show the default and minimum permissions required for folder redirection.

**Table 3. NTFS Permissions Needed for Root Folder**

| User account | Folder redirection defaults | Minimum permissions needed |
|---|---|---|
| Creator/owner | Full Control, this folder, subfolders, and files | Full Control, this folder, subfolders, and files |
| Local Administrator | Full Control, this folder, subfolders, and files | Full Control, this folder, subfolders, and files |
| Everyone | Full Control, this folder, subfolders, and files | List Folder/Read data, Create Files/Write Data, Create Folders/Append Data - This Folder only |
| Local System | Full Control, this folder, subfolders, and files | Full Control, this folder, subfolders, and files |

**Table 4. Share level (SMB) Permissions Required for Root Folder**

| User account | Folder redirection defaults | Minimum permissions needed |
|---|---|---|
| Everyone | Full Control | Everyone - no permissions.<br><br>Use security group that matches the users who will need to put data on share. |

**Table 5. NTFS Permissions Required for each User's Redirected Folder**

| User account | Folder redirection defaults | Minimum permissions needed |
|---|---|---|
| *%User Name%* | Full Control, owner of folder | Full Control, owner of folder |
| Local System | Full Control | Full Control |
| Everyone | Traverse Folder, Read Attributes, Read Extended Attributes, and Read Permissions | Everyone - no permissions |

# Appendix B: Running CommonScenarios.msi

Updated: March 2, 2005

Applies To: Windows Server 2003 with SP1

This white paper comes with a number of supporting files – spreadsheets, GPO backups, and HTML-based Group Policy reports. These are installed by the installation package CommonScenarios.msi.

| **Note** |
| --- |
| You can download the CommonScenarios.msi installation package, which includes this document and supporting files, from the Microsoft Download Center. |

When you install this package, the files listed in Table 6 are copied into the **%programfiles%\Microsoft\CommonScenarios** directory and a new menu – **Group Policy Common Scenarios** – is created on **Start/Programs**.

**Table 6. Files Installed by CommonScenarios.msi Package**

| Directory | FileName | Description |
| --- | --- | --- |
| \Documentation | CommonScenariosWS2003.doc | This white paper. |
| \Documentation | CommonScenariosWS2003.xls | Spreadsheet listing each setting specified for all scenarios. |
| \Environment | CommonScenarios.xml | File representing sample environment for common scenarios and for use by CreateEnvironmentFromXML script. |
| \GPO-Backups | [GUID] | One subdirectory for each GPO included in the common scenarios. |
| \GPO-Reports | [GPO Name].htm | HTML-based report for each GPO (generated from GPMC). |
| \Scripts | CreateCommonScenarios.cmd | Command file to install a sample OU structure, create the common scenarios GPOs, and link GPOs. |

# Key Archival and Management in Windows Server 2003

Updated: May 1, 2010

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Updated: December 6, 2004

| Tip |
| --- |
| An updated version of this information is on the TechNet Wiki as Active Directory Certificate Services PKI - Key Archival and Management. |

By David B. Cross and Avi Ben-Menahem

Windows Server 2003, Enterprise Edition introduces several new features in the area of Public Key Infrastructure (PKI) technologies and certification authorities (CAs). One area of new functionality is private key archival, recovery, and management. This white paper covers best practices and procedural steps in a key recovery strategy as well as migration procedures for moving from a Microsoft Exchange Key Management Server (KMS) environment to a Windows Server 2003 certification authority.

For information about upcoming enhancements to key archival and recovery, see Key Archival and Recovery in Windows Server 2008 (http://go.microsoft.com/fwlink/?LinkID=92523).

**On This Page**

- Introduction
- Understanding Manual Key Archival
- Understanding Automatic Key Archival
- Understanding User Key Recovery
- Implementing Key Archival Walkthrough
- Migrating Exchange KMS to Windows Server 2003 CA
- Troubleshooting - Key Archival and Management in Windows Server 2003
- Appendix A: Certificate Request Structure
- Appendix B: Additional Information
- Appendix C: Useful Commands

**Introduction**

Windows Server 2003, Enterprise Edition introduces significant advancements in the area of data protection and private key recovery. Windows 2000 introduced the capability for data recovery with the implementation of Encrypting File System (EFS). EFS in both Windows 2000 and Windows Server 2003 supports the use of Data Recovery Agents (DRAs) to decrypt files that have been encrypted by other users. With the expanded functionality of the Windows Server 2003 Certificate Services to offer key archival and recovery services, an enterprise may choose to implement different strategies based on the needs for data protection and data recovery.

Microsoft first offered key archival and recovery features in the Exchange Server 4.0 product line through the KMS component of the Exchange Server. The KMS can act as a Registration Authority (RA) to Microsoft Certification Services to provide user registration, key archival, key recovery, and certificate publishing capabilities to an Exchange Server e-mail and collaboration system. The KMS allows an administrator to recover the lost or corrupted encryption private keys of a Microsoft Outlook® user and generate a new signing key. The Outlook client as well as many other Secure/Multipurpose Internet Mail Extensions (S/MIME)–enabled mail clients support the use of separate signing and encryption key pairs. This method helps to isolate an

organization from non-repudiation issues. For more information about Key Management Server and Windows PKI interoperability, see Appendix B: Additional Information.

The Windows Server 2003 key archival solution also provides migration flexibility to organizations that desire to migrate their existing Exchange 2000 KMS solution to a more integrated archival solution in the Windows Server 2003 CA or for those customers who have public key certificates from third-party CAs. The Windows Server 2003 PKI solution allows import and migration of third-party public keys and certificates into the Windows Server 2003 CA as an escrow solution as well.

Windows Server 2003 key archival can be performed in two different ways: manual key archival and automatic key archival. Manual key archival refers to a process where users manually export private keys from their keys store and send them to a CA Administrator who in turn imports them to the protected CA database. Automatic key archival is done as part of the certificate enrollment process. It is possible to mark certificate templates to require key archival. In such a case, the private key will be sent to the CA as part of the certificate request and will be archived automatically by the CA. Manual and automatic key archival are discussed in depth later in this document.

**Understanding Key Archival and Recovery**

Key recovery implies that the private key portion of a public-private key pair may be archived and recovered. Private key recovery does not recover any data or messages. It merely enables a user to retrieve lost or damaged keys, or for an administrator to assume the role of a user for data access or data recovery purposes. In many applications, data recovery cannot occur without first performing key recovery. Figure 1 demonstrates a typical key archival and recovery scenario.

**Figure 1: Key Archival and Recovery**

1. The user requests a certificate from a CA and provides a copy of the private key as part of the request. The CA which is processing the request archives the encrypted private key in the CA database and issues a certificate to the requesting user.

2. The issued certificate can be used by an application such as EFS to encrypt sensitive files.

3. If at some point the private key is lost or damaged, the user can contact the company's Certificate Manager to recover the private key. The Certificate Manager, with the help of the Key Recovery Agent (KRA), recovers the private key, stores it in a protected file format, and sends it back to the user.

4. Once the user stores the recovered private key in the user's local keys store, it can be used by an application such as EFS to decrypt previously encrypted files or to encrypt new ones.

**Understanding EFS Data Recovery**

Encrypting a file always includes a risk that it cannot be read again. The owner of the private key, without which a file cannot be decrypted, might leave the organization without decrypting all of his or her files. Worse yet, he or she might intentionally or accidentally encrypt critical shared files so that no one else can use them. A user's profile might be damaged or deleted, meaning that the user no longer has the private key needed to decrypt encrypted files. Data recovery is one of the methods used for recovering files or data when encrypted files cannot be decrypted. By implementing data recovery and DRAs, every encrypted file's encryption key (FEK) is encrypted by using the DRA's public key in addition to the user's public key. By using the associated private key, any designated DRA can decrypt any encrypted file within the scope of the EFS recovery policy. Figure 2 demonstrates encrypted file format when data recovery is implemented.

**Figure 2: File Encryption Using Data Recovery**

For more information about Data Recovery, see Appendix B: Additional Information.

**Understanding When to Use Data Recovery versus Key Recovery**

There is no definitive answer of whether key recovery or data recovery should be used over the other option. Both solutions have technical advantages and disadvantages and the decision to use one or both is subjective. Both are viable solutions separately and in summation. This section is written solely to identify some of the key advantages and disadvantages so that an organization may make an informed decision.

Key recovery should be used when the policy of a given company or enterprise permits the private keys and certificates of a given user(s) to be retrieved. Key archival and recovery imply that a person other than the original user may gain access to the private keys of another user. If a company or enterprise does not permit a person other than the original requester to ever have access to private keys of other users, key archival and recovery should not be used.

Data recovery should be used when a company or enterprise requires the ability to recover data, but not access to the individual private keys of a user. For example, when private key recovery is provided, new operations can be performed when using the key, not just data decryption.

Data recovery and key recovery should not be used when a company or enterprise wants to protect data from all parties except the original user. If data should not be accessed or recovered by any person other than the author/owner, neither data recovery nor key recovery processes should be implemented.

**Table 1: Key Recovery versus Data Recovery**

| | Key Recovery | Data Recovery |
|---|---|---|
| Certificates re-enrollment is not required. | X | |
| Existing certificates revocation is not required. | X | |
| Administrators do not have access to the user's private key. | | X |
| Non-repudiation assurance. | | X |
| Re-Encryption of all previously encrypted data is NOT required. | X | |

**Key Recovery Best Practice**

Some key best practices should be followed when implementing key archival and recovery in an organization. First, key recovery by an administrator implies impersonation and that administrators who perform key archival should be highly trusted. Implementation of operations of a key archival and recovery solution should be carefully planned and monitored for security purposes.

**Other Best Practices**

The following additional best practices are also recommended:

- If a key is known to be compromised, it should be immediately revoked and never used again.
- Keys or certificates that are used to secure high-value transactions, or are identified as high-value certificates should not be recovered except under extreme circumstances.
- Private keys that are used for signing should never be archived or recovered as this introduces non-repudiation issues.

- When a key has been compromised or lost, it should be revoked before allowing key recovery. Despite key compromise, it may be necessary to recover a key for the purpose of decrypting old data and encrypting with a new key.
- Issue the least number of certificates and key pairs possible to ease key management and reduce user confusion.
- Issue encryption certificates with longer lifetimes than signing certificates.
- Issue only one valid key pair for a given application purpose at one time.
- Develop a recovery process that combines role separation of Certificate Managers and KRAs.
- Minimize the number of CAs that archive keys for a certificate purpose, that is, if possible, do not archive keys for users across a large number of CAs as recovery operations become confusing.
- If performing key archival over the Certification Services Web enrollment pages, it is important to use Secure Sockets Layer (SSL) on the enrollment Web site to protect the enrollment traffic from tampering or malicious interception.
- Use roaming user profiles if possible to reduce user confusion, accidental key loss, and the need for manual import and export operations to enable key roaming.

**Requirements**

Key archival and recovery using a Windows Server 2003 CA has several technical dependencies.

- Enrollment requires the Certificate Management Protocol using CMS (CMC) protocol, which is only available in Windows XP client, Windows Server 2003 clients, and through the xenroll.dll ActiveX control in the CA Web enrollment interface. Through the Web enrollment interface, Windows 2000 and Windows Millennium Edition may enroll for certificates with key archival.

  | **Note** |
  | --- |
  | Version 2 templates and key archival are not available to Windows 2000 Microsoft Management Console (MMC) enrollment. |

  | **Note** |
  | --- |
  | Windows 2000 and Windows Millennium Edition require that the key be marked for export during key archival enrollment. |

- Active Directory® must have the Windows Server 2003 schema extensions.
- Mandating key archival requires a version 2 certificate template.
- Key archival is only available on a CA running Windows Server 2003, Enterprise Edition.
- Only a Microsoft Enterprise Certification Authority may be used.

| **Note** |
| --- |
| Clients running down-level operating systems, such as Windows NT® 4.0 or Windows 98, will not be able to view certificate templates that allow key archival in the Web enrollment interface. |

# Understanding Manual Key Archival

Updated: December 6, 2004

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Manual key archival is supported on the Windows Server 2003 CA as a separate operation from enrollment while still offering centralized key archival. Users may export their private keys into *.pfx files [Public Key Certificate Standard (PKCS) #12 format] or through Outlook into the *.epf format. The following section describes the procedure to export private keys manually from a Windows client so that they may be manually archived on the CA. This is especially useful for users who have enrolled with third-party CAs that do not support key archival.

**Exporting Keys and Certificates**

Keys and certificates may be exported on Windows clients by one of two methods.

- PKCS #12 (*.pfx file) export from the Certificates MMC snap-in on Windows 2000 or Windows Server 2003
- *.epf file format from the Outlook 2000 or Outlook 2002 client

If a user has enrolled for Exchange Advanced Security with version 1 certificates (first offered with Exchange 5.0 Key Management Server), direct export from Outlook into the *.epf file format will be necessary. X.509 version 1 certificates and keys may not be exported into PKCS #12 format on the Windows client.

If only X.509 version 3 certificates have been used, the PKCS #12 format may be used.

**Exporting Keys from the MMC**

**To export the certificate and private key while logged in as the user**

1. Click the **Start** button, and then click **Run**.
2. Type **mmc.exe** and press **Enter**.

   An empty MMC shell appears.
3. Select the **Console** menu, and then select **Add/Remove Snap-in**.

   A dialog box appears with a list of all the snap-ins that have been added to this MMC shell.
4. Click **Add**.

   A list appears with all the registered snap-ins on the current machine.
5. Click the **Certificates** snap-in and click **Add**, choose **My User Account**, and then click **Finish**.
6. In the **Add Standalone Snap-in** dialog box, click **Close**. In the **Add/Remove Snap-in** dialog box, click **OK**.

   The MMC now contains the personal certificate store for the currently logged-on user.
7. Expand the tree view of the certificate store. Click through **Certificates - Current User, Personal**, and then **Certificates**. When you click the **Certificates** folder on the left, the right-hand pane will display a list of all the certificates for the currently logged on user.
8. Right-click the certificate intended for export.
9. Choose **All Tasks**, and then **Export** on the **Context** menu.

   A wizard will guide you through the export process.
10. Click **Yes**, **export the private key**, and then click **Next**.

When exporting a private key, the *.pfx file format is used. The *.pfx file format is based on the PKCS #12, which is used to specify a portable format for storing or transporting a user's private keys, certificates, and miscellaneous secrets. For more information about the PKCS #12, see Appendix B: Additional Information.

11. Select the appropriate check boxes, and then click **Next**.

    As a best practice, strong private key protection should also be used as an extra level of security on the private key when exporting. The private key should be deleted only if you are performing archival and will no longer use the key on that machine.

12. The *.pfx file format (PKCS #12) allows a password to protect the private key stored in the file. Choose a strong password, and then click **Next**.

13. The last step is to save the actual *.pfx file. The certificate and private key can be exported to any writeable device, including a network drive or disk. After typing or browsing for a file name and path, click **Next**.

Once the *.pfx file and private key have been exported, the file should be secured on a stable media and transferred in a secure manner to the CA on which the key will be imported in accordance with the organization's security guidelines and practices.

**Exporting Keys from Outlook**

**To export a key from Outlook**

1. In Outlook, click the **Tools** menu, and then select **Options**. Click the **Security** tab, and then click **Import/Export** (Figure 3).

**Figure 3: Outlook Security Options**

2. Click **Export your Digital ID** to a file, and then complete the **Filename**, **Password**, and **Confirm** (password confirmation) text boxes (Figure 4).

**Figure 4: Outlook Import/Export Digital ID Options**

3. Copy this file to a location accessible by the server or manually transport it using a disk.

#### Importing a Key Manually on a CA

### To import a key manually on a CA

- On the certificate server, open a command prompt window, and run the following command.

  **C:\CertUtil.exe –f –importKMS <name of file>**

| **Note** |
| --- |
| The –f flag is required when the key and certificate pair have not been issued from the CA in question. |

The file may be in one of three formats.

- KMS export file
- PKCS #12 format (*.pfx file)
- Outlook export format (*.epf)

| **Important** |
| --- |
| The previous command will work only after the CA was configured for key archival. For more information about the actions required for enabling key archival, see Implementing Key Archival Walkthrough. |

# Understanding Automatic Key Archival

Updated: December 6, 2004

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The following sections document in detail how the key archival and key recovery processes work in Windows Server 2003 as well as step-by-step guides for implementing the features in production.

**Understanding the Archival Process**

The general steps in the archival of a user's private key are described in the following steps and in Figure 5.

1. The client finds CAs in Active Directory (enrollment services container in the configuration partition).
2. The client makes an authenticated Distributed Component Object Model (DCOM) connection to the CA and requests the CA's Exchange certificate (encryption certificate).
3. The CA sends the exchange certificate to the client.
4. The client validates that the CA's exchange certificate has been signed by the same key as the CA signing certificate and performs a revocation status check. This ensures that only the intended CA may decrypt the certificate request containing the private key.
5. The client encrypts the private key corresponding to the request with the CA exchange certificate public key, builds a CMC request, and sends a CMC full PKI request to the CA.
6. The CA validates that the encrypted private key cryptographically pairs with the public key in the certificate request.
7. The CA validates the signature on the request with the public key in the request.
8. The CA encrypts the private key from the user request with a random Triple Data Encryption Standard (3DES) symmetric key and then encrypts the symmetric key with one or more KRA public keys.
9. The CA saves the encrypted key binary large object (BLOB) containing the encrypted private key and the symmetric key encrypted with one or more KRA public keys to the CA database.
10. The CA processes the certificate request normally.
11. The CA responds to the client with a CMC full PKI response.

| **Note** |
| --- |
| Only RSA Security encryption keys may be archived in the CA database. Signature only keys as well as non-RSA key pairs will not be archived. Denied and resubmitted requests will also not archive private keys. |

**Figure 5: The Protocol for Key Archival**

**Certificate Request**
A certificate request can be driven from at least three different sources in Windows Server 2003. The sources built into the operating system are the Web browser (Internet Explorer), the certificate enrollment wizard, and auto-enrollment. All three methods call xenroll.dll (Microsoft Enrollment Control), which provides various methods to support certificate request generation and certificate installation. One of the formats the certificate request uses is the CMC format for certificate requests, which supports an optional encrypted data payload. Technically, any client that supports the CMC protocol may enroll with an Enterprise CA and request that the private key be archived by the CA. The CA enforces the archival option through a template flag. For more information about the CMC request format, see Appendix A: Certificate Request Structure.

**CA Exchange Certificate Retrieval**
Before the private key can be encrypted and delivered to the CA server, the client must first retrieve the CA's exchange certificate. The CA exchange certificate is an encryption certificate for the Certification Authority that can be used by clients to encrypt their private keys as part of their certificate request. The CA exchange certificate is issued by the CA itself where the subject and issuer are almost the same. However, the subject contains a suffix to distinguish the certificate from a root CA. Getting the CA exchange certificate can be accomplished using the existing ICertRequest::GetCACertificate method. The caller of the ActiveX xenroll.dll control will need to retrieve this certificate and verify it prior to calling xenroll.dll to create the request and to encrypt the private key. Xenroll will also perform this action. The client will verify that the exchange certificate is signed by the same key that issued the CA certificate; this step is performed to provide additional security and to prevent man-in-the-middle attacks. For that reason, a CA may not use a certificate issued by another CA for an exchange certificate.

**CA Exchange Certificate Generation**
A Windows Server 2003 CA will automatically generate a short-lived exchange certificate for use of the key archival mechanisms. By default, if the CA Exchange template is available, it will be used for extensions and the validity and overlap periods. If the validity and overlap periods in the registry differ from the template, the registry values are rewritten, so there will be consistent behavior if the template is unavailable in the future. If the template is not available, hard-coded extensions will be used along with the registry validity and overlap period settings.

If the following registry flag is configured using certutil.exe, the template must be available or the attempt to generate a CA Exchange certificate will fail. In addition, the machine object of the CA (LOCAL SYSTEM) must have Enroll access to the template. This flag is not currently set by setup; it must be manually applied.

**certutil –setreg ca\CRLFlags +CRLF_USE_XCHG_CERT_TEMPLATE**

The CA Exchange certificate template has a default expiration of one week and a template overlap period of one day. Note that the previous settings apply to both enterprise and stand-alone CAs.

**Restricting Key Archival**
Windows Server 2003 may be effectively prevented from archiving private keys through the use of qualified subordination and policy constraints. When submitting and processing a request to a parent or root CA for a subordinate CA certificate, the parent CA may exclude the key archival policy in the subordinate CA. For more information about Qualified Subordination, see Appendix B: Additional Information.

**Private Key Payload**
For Windows Server 2003 clients and servers, the encrypted private key is stored in an unauthenticated attribute as a Cryptographic Message Syntax (CMS) EnvelopedData object. This poses no concern from a security perspective as the private key is later validated to cryptographically match the public key in the certificate request, which is also signed by the same private key. For more information about the format and object structure, see Appendix A: Certificate Request Structure.

**Key Verification**
The CA must check that the encrypted private key is cryptographically associated with the public key in the certificate request. Because the client encrypted the private key using the public key from the CA's exchange certificate, the CA can decrypt the private key payload contained in the request. For encryption keys, the CA encrypts randomly generated data with the public key in the request, and then decrypts the data with the private key passed in the unauthenticated attributes of the CMC request. The decrypted data is verified against the original random data. If any of the validation steps fail, or if the data does not match, the request is rejected. For signing keys, the CA will reject the request and will not archive a key that is marked for signature only.

To verify the cryptographic association between the public and private keys, the CA loads the key pair into a cryptographic service provider (CSP) that supports the specified algorithms. The CA will use the default-enhanced RSA CSP on the CA by default or a hardware CSP, if available. Both the encrypted private key material payload and the private key loaded into the server-based CSP are securely discarded since the private key will be archived using a different key controlled by a recovery agent and is not available for the CA after verification of the payload. The decrypted private key memory is zeroed out prior to freeing the memory.

**Key Encryption**
Once the private key has been successfully verified, the CA must then encrypt the private key and archive it for future recovery. The CA will not encrypt the private key using its own key(s) to provide separation between the recovery agent role and the CA administrator role. The certificate request process and certificate issuance are completed after key archival has occurred. For more information about role separation, see Configuring the CA to Allow Key Archival.

The private key will be encrypted by the CA using a dynamically generated symmetric key that is itself encrypted using a public key from a KRA certificate (or certificates) configured on the CA. Each certificate request and private key archival operation will generate a new random 3DES symmetric key using the same CSP that was used to generate the CA signing key. This ensures that a hardware security module (HSM) can be used to generate the long-term keys that protect the individual private keys. The symmetric key algorithm is 3DES by default and cannot be changed.

If multiple recovery agents are associated with the CA, the symmetric key will be encrypted individually with each recovery agent's public key to allow any one recovery agent to perform a recovery operation. The actual KRA(s) used may randomly vary if a round-robin selection of KRAs is chosen. For example, if a CA Administrator configures four KRA certificates on a CA for use, but requires a minimum of two KRAs to be used, when the CA service starts, a random start point in the KRA list is chosen. Two of the four KRAs will be chosen from that start list start point and then for each subsequent archival operation, the list order will be incremented by two. Therefore, a round robin affect is achieved for all key archival operations. These encrypted keys along with the issued certificate will be collectively referred to as the recovery BLOB and are stored as a PKCS #7–encrypted BLOB in the database.

**Key Archival**
The private key database is the same as the database used to store the certificate requests. The Windows Server 2003 Certification Authority database has been extended to support storing the encrypted private key along with the associated encrypted symmetric key and issued certificate. The recovery BLOB will be stored in the same row as the signed certificate request and any other information the CA persists in its database for each request transaction. The actual encrypted BLOB is stored as an encrypted PKCS #7 BLOB. For more information about the format and object structure, see Appendix A: Certificate Request Structure.

The Microsoft Certification Authority uses the Microsoft Jet database engine upon which various Jet utilities may be used for maintenance purposes.

# Understanding User Key Recovery

Updated: December 6, 2004

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

A recovery operation is initiated by an end-entity that has lost access to a private key. The key recovery process is explained in Figure 6.

**Figure 6: Key Recovery Process**

The following are the key recovery steps.

1. The Certificate Manager (CA Officer) locates and retrieves the user's encrypted private key from the CA database. The encrypted BLOB(s) is protected by access control lists (ACLs) to ensure that only a valid Certificate Manager is able to copy the BLOB from the database. Since it is encrypted with the KRA's public key, the Certificate Manager cannot extract the user's private key but it can retrieve it from the CA. The encrypted PKCS #7 BLOBs in the database contain the Issuer name and serial number of each KRA certificate for KRA identification purposes. Once extracted, the Certificate Manager sends it to the appropriate KRA for decryption. For more information about the format and structure of the recovery BLOB, see Appendix A: Certificate Request Structure.

2. The KRA decrypts the user's private key and stores it in a password-protected file format (PKCS #12) and sends it to the user.

3. The user imports the key to the user's local, protected, keys store.

It is at the discretion of organizational policy whether a KRA and a Certificate Manager may be combined into one role or separate roles. For better security, it is recommended that the Certificate Manager and the KRA roles be separated. Because the Windows Server 2003 Certification Authority supports role separation, an organization could easily implement a two-step process to recover the private key(s) of a user.

**Understanding Role Separation**

Role-based administration is used to organize CA administrators into separate, predefined task-based roles. It is recommended that the management roles are distributed among several individuals in your organization to ensure that a single individual cannot compromise PKI services. Role separation enables one person to audit the actions of another person.

The Common Criteria PKI management roles in Windows Server 2003 include the following:

1. **CA Administrator** Configures and maintains the CA, designates other CA administrators and certificate managers, and renews CA certificates.

2. **Certificate Manager** Approves or denies certificate enrollment requests and revokes issued certificates.

3. **Backup Operator** Performs backups of the CA database, the CA configuration, and the CA's private and public key pair (also known as a key pair).

4. **Auditor** Defines what events are audited for Certificate Services and reviews the security log in Windows Server 2003 for success and failure audit events that are related to Certificate Services.

| **Note** |
| --- |
| Role-based administration is supported by both Windows Server 2003 Enterprise CAs and stand-alone CAs running Windows Server 2003, Enterprise Edition or Windows Server 2003, Datacenter Edition. |

To help determine role separation, you can use the Common Criteria specification, which defines security standards for all forms of network security and includes specifications for managing PKIs.

For more information about Role-Separation and Common Criteria, see Appendix B: Additional Information.

**Understanding the Key Recovery Agent Role**
KRAs are Information Technology (IT) administrators who can decrypt users' archived private keys. An organization can assign KRAs by issuing KRA certificates to designated administrators and configure them on the CA. The KRA role is not one of the default roles defined by the Common Criteria specifications but a virtual role that can provide separation between Certificate Managers and the KRAs. This allows the separation between the Certificate Manager, who can retrieve the encrypted key from the CA database but not decrypt it, and the KRA, who can decrypt private keys but not retrieve them from the CA database. For more information about how to implement Key Recovery Agents, see Implementing Key Archival Walkthrough.

**Key Recovery Agent Certificate**
A new certificate template exists in the Windows Server 2003 schema to support the KRA role. This certificate will use a unique Extended Key Usage extension to identify a KRA certificate. A Windows Server 2003 Certification Authority will only use certificates that have been properly formatted as per the following information, although it is not necessary for the certificate to contain the Microsoft-specific extensions.

KRA certificates, when issued by an Enterprise CA, are automatically published in the configuration container of Active Directory. The actual certificates are published to the userCertificate attribute of the KRA object when issued to an IT administrator. The location in the configuration container is as follows:

**(CN=KRA,CN=Public Key Services,CN=Services,CN=Configuration,DC=<domainname>)**.

The KRA certificate contains the following X.509v1 fields.

- Version
- Serial Number
- Signature Algorithm
- Valid From
- Valid To
- Subject
- Issuer
- Public Key

The KRA certificate contains the following X.509v3 extensions identified in RFC 3280.

- Authority Key Identifier
- Subject Key Identifier
- Authority Information Access
- Key Usage
- Subject Alternative Name
- CDP (CRL Distribution Point)
- Extended Key Usage (Key Recovery Object Identifier = 1.3.6.1.4.1.311.21.6)
- Application Policies (Policy Identifier = Key Recovery Agent)

The KRA certificate will contain the following X.509v3 extensions specific to Microsoft.

- Certificate Template Name
- Certificate Template Information

| **Note** |
| --- |
| None of the extensions is marked as critical; however, the Key Recovery Object Identifier must exist in the Extended Key Usage extension for the certificate to be used. |

**Understanding the Key Recovery Process**

Users may require their private keys to be recovered for a multitude of reasons. Key recovery from a Windows Server 2003 CA may be accomplished using the command-line tool, certutil.exe.

The recovery of a private key is a manual process that requires the user(s) to contact an administrative authority to perform the necessary processes. It should be a best practice of any organization to

1. Validate the identity of a user requesting key recovery.
2. Separate the roles of CA Officer and KRA as a minimum of two physical persons.
3. Develop a mechanism to securely deliver the private keys and passwords to end users. Examples could include e-mail of the *.pfx file and leaving a voice mail with the password for the *.pfx file for the user. Discussion of these best practices is beyond the scope of this white paper.

**Finding Recovery Candidates**

A CA Officer (Certificate Manager) can perform recovery of private key(s) using the CN (CommonName), UPN (UserPrincipalName), down-level name (domainname\username), certificate serial number of the certificate, or an SHA1 (Secure Hash algorithm) hash (thumbprint) of the certificate. The process is known as finding candidate certificates for recovery.

Examples:

- User1@nwtraders.com (denotes UPN)
- nwtraders\user1 (denotes the down-level name)
- Users\nuser1 (denotes a user in the default users container of Active Directory)
- User1 (denotes the CN)
- <serial number of the certificate>
- <SHA1 hash (thumbprint) of certificate>

**Finding Recovery Candidates by Using Command-Line Tools**

To recover a user using their CN, type the following command.

**Certutil -getkey <cn of user> outputblob**

If only one certificate has been issued to that user, that certificate and private key will be generated into the specified <outputblob> file. If more than one certificate has been issued to that CN, certutil.exe will list the serial number(s) of all the certificates issued to that CN on a specific Certification Authority.

Example:

```
"user1.nwtraders.com\CA1"

Serial Number: 1464be10000000000007
Subject: CN=user1, CN=Users, DC=nwtraders, DC=com
NotBefore: 1/13/2001 11:51 AM
NotAfter: 1/13/2002 11:51 AM
Template: KeyA, KeyArchival
Cert Hash(sha1): a2 7f 77 bc 2f 7b eb 26 bd 3e ed 43 b8 2a 24 04
2e 55 b8 64

Serial Number: 1464fcbc000000000008

Subject: CN=user1, CN=Users, DC=nwtraders, DC=com
NotBefore: 1/13/2001 11:51 AM
NotAfter: 1/13/2002 11:51 AM
Template: KeyA, KeyArchival
Cert Hash(sha1): 21 bd 88 2c 2a 84 0c e5 57 7b 2a bf f0 43 4b b3
ed bf 02 5a
```

Once the actual serial number of the certificate is known, the command may be run again with the serial number instead of the CN to retrieve the actual recovery BLOB.

| **Important** |
| --- |
| If a CA Administrator has configured the server to use, for example, three of a possible five available KRAs, certutil –recoverkey will list the three KRAs that were used to encrypt the selected subject's private key. At the time of archival, the three KRAs were randomly selected (out of five possible) by the CA to encrypt the subject's private key. To perform the recovery operation, it will be necessary to have one of any of the KRAs listed by certutil -recoverkey. |

#### Finding Recovery Candidates by Using the Certification Authority MMC Snap-In

A CA Officer may determine the serial number of a certificate that has been archived.

**To determine the serial number of an archived certificate**

1. Log on to a CA or a Windows XP Professional machine that has the **Administration Tools** pack installed as a CA Officer who has **Certificate Management** authority of the user(s) in question.
2. On the **Administrative Tools** menu, open **Certification Authority**.
3. In the console tree, expand **Certification Authority**, and then click **Issued Certificates**.
4. On the **View** menu, click **Add/Remove Columns**.
5. In the **Add/Remove Columns** dialog box, in the **Available Column list**, select **Archived Key**, and then click **Add**.

   Archived Key should now appear in the Displayed Columns listing.
6. Click **OK**.
7. In the details pane, scroll to the right and ensure that the last issued key has a value in the Archived Key column.
8. Double-click the user certificate.
9. Click the **Details** tab
10. Write down the serial number of the certificate (do not include spacing between digit pairs). This is required for recovery.
11. Click **OK**.
12. Close **Certification Authority**.

**Command-Line Key Recovery**
Command line key recovery is done by using the certutil.exe command-line tool. This tool is installed by default on the certificate server and it can be installed separately on a Windows XP Professional or Windows Server 2003 machine as part of the Windows Server 2003 Administration Tool Pack. The certutil.exe command structure was designed to perform batch and scripted processes.

**Recovery Using the Certificate Serial Number**
Once the serial number(s) is known, key recovery can occur through the certutil.exe command- line tool.

### To recover private key(s)

1. Open a command-prompt window.

2. At the command prompt, type **Certutil -getkey ################### outputblob** where **###################** is the serial number of the certificate that should be recovered and outputblob is the file name of the encrypted BLOB that is extracted from the CA database.

3. If a specific CA is to be targeted instead of all Enterprise CAs in the forest, use the following syntax.

   **Certutil -config <machine name\CA name> -getkey ################### outputblob**

4. The outputblob file is a PKCS #7 file containing the KRA certificate(s) and the user certificate with its entire certificate chain. The inner content is an encrypted PKCS #7 structure containing the private key [encrypted to the KRA certificate(s)].

5. To decrypt the PKCS #7 encrypted BLOB, the logged on user must have the private key of one or more of the KRAs for the target encrypted BLOB. If the CA Officer is not a Key Recovery Agent, the CA Officer must transfer the encrypted BLOB file to a user that holds a KRA private key for further processing.

6. At the command prompt, type the following command:

   **Certutil -recoverkey outputblob user.pfx –p password** where:

   - outputblob is the encrypted PKCS #7 file to be decrypted.
   - user.pfx is the output file name for the user private keys in PKCS #12 format.
   - password is the password for the *.pfx file.

   The PKCS #12 format allows for the private key file to be protected with a password. Certutil.exe will prompt the KRA for a password when generating the PKCS #12 file.

   The system will search for a valid private key in the store of the logged in user that corresponds to a valid KRA certificate that was used to encrypt the recovery BLOB. If the user does not have the proper private key in their local store, they will receive an error.

7. Enter and confirm a password for the file that cannot be randomly guessed. The user should be given the password through a secure out-of-band mechanism that is separate from the file itself to ensure strong security in the recovery process.

| **Note** |
| --- |
| An event log message will be generated when a private key is recovered from the database. The event log message will be similar to the following: |

```
Event Type: Success Audit
Event Source: Security
```

```
Event Category: Object Access
Event ID: 787
Date:  2/19/2001
Time:  5:23:45 PM

User:  NWTRADERS\User1

Computer: SERVER1

Description: Certificate Services retrieved an archived key.
Request ID 12
```

**Recovery Batch File**

The certutil.exe –getkey command is an advanced tool that can be used with explicit commands and also build batch file syntax to perform a complete recovery operation. The following is the command-line syntax for certutil.exe –getkey.

Usage:

**CertUtil -GetKey [Options] SearchToken [RecoveryBlobOutFile]**

**Retrieve archived private key recovery blob**

**SearchToken**—Used to select the keys and certificates to be recovered.

**RecoveryBlobOutFile**—Output file containing a certificate chain and an associated private key, still encrypted to one or more KRA certificates.

If the following command is performed using any of the previous SearchToken criteria, the certutil.exe tool will output the complete syntax that can be used.

Example:

**certutil -v -getkey user1@northwindtraders.com >myBatchfile.bat**

Outputfile:

```
@goto start
Querying northwind5.nwtraders.com\TestCA9....................

"northwind5.nwtraders.com\TestCA9"
  Serial Number: 611e23c200030000000e
  Subject: E=user1@nwtraders.com, CN=user1, CN=Users, DC=nwtraders, DC=com
  UPN:user1@nwtraders.com
  NotBefore: 1/12/2002 1:24 PM

@goto exit
CertUtil: -GetKey command FAILED: 0x8002802c (-2147319764)
CertUtil: Ambiguous name.
```

The following is an explanation of the previous syntax, which can be run by Certificate Managers that hold a valid KRA private key.

1. The tool finds all possible CAs that are registered in Active Directory. Then, it will query each CA for keys that have been archived for the specified user.

   ```
   @goto start
   Querying northwind5.nwtraders.com\TestCA9.....................
   ```

2. The tool will show the archived keys found for the user on each CA that is queried. It will list the most important details on each archived key found that will be useful for Certificate Managers and administrators.

   ```
   "northwind5.nwtraders.com\TestCA9"
     Serial Number: 611e23c200030000000e
     Subject: E=user1@nwtraders.com, CN=user1, CN=Users, DC=nwtraders, DC=com
     UPN:user1@nwtraders.com
     NotBefore: 1/12/2002 1:24 PM
     NotAfter: 1/12/2003 1:24 PM

     Cert Hash(sha1): d6 41 99 e7 e7 24 73 34 02 41 53 2d 29 11 a8 3b e6 aa 12 2f

     Serial Number: 6131f9c300030000000f
     Subject: E=user1@nwtraders.com, CN=user1, CN=Users, DC=nwtraders, DC=com
     UPN:user1@nwtraders.nttest.microsoft.com
     NotBefore: 1/12/2002 1:45 PM
     NotAfter: 1/12/2003 1:45 PM
     Template: EFS2
     Version: 3
     Cert Hash(sha1): 1a cc 8d 26 7f 9f 70 6c 65 05 a0 84 8c 4c e9 b7 b4 6c 66 a3
   ```

3. The tool will retrieve the encrypted recovery BLOB(s) from the CA. Note that the administrator must be a Certificate Manager for the recovered user(s) on the CA.

   ```
   @echo Version 3 certificates and keys:
   CertUtil -config "northwind5.nwtraders.com\TestCA9" -getkey
   611e23c200030000000e "user1-611e23c200030000000e.rec"

   CertUtil -config "northwind5.nwtraders.com\TestCA9" -getkey
   6131f9c300030000000f "user1-6131f9c300030000000f.rec"
   ```

4. The tool will decrypt the recovery BLOB(s) and generate *.pfx files (PKCS #12 format) for each recovered key and set a random password as denoted after the –p parameter. Note that the administrator must have a valid KRA private key to perform this step.

   ```
   CertUtil -p "UQcYLsJ(57s]FuBl" -recoverkey -user "user1-611e23c200030000000e.rec" "
   ```

```
CertUtil -p "UQcYLsJ(57s]FuBl" -recoverkey -user "user1-611e23c200030000000e.rec"
user1-611e23c200030000000e.p12"

CertUtil -p "UQcYLsJ(57s]FuBl" -recoverkey -user "user1-6131f9c300030000000f.rec" "
user1-6131f9c300030000000f.p12"
```

5. The tool will merge the multiple *.pfx files (if applicable) into a single *.pfx file to simplify the process for the user installing recovered keys. The certutil.exe –MergePFX command is automatically used to perform this process.

```
CertUtil -p "UQcYLsJ(57s]FuBl,iG1-bOt&tqdvJiu1" -MergePFX -user "user1-
611e23c200030000000e.p12,user1-6131f9c300030000000f.p12" "user1.p12"
```

6. The tool will clean up any temporary files used during the process.

```
@del user1-611e23c200030000000e.rec
@del user1-611e23c200030000000e.p12
@del user1-6131f9c300030000000f.rec
@del user1-6131f9c300030000000f.p12
@echo PASSWORD: "iG1-bOt&tqdvJiu1"

@goto exit
```

Note that the following output is expected when the user has multiple archived keys.

```
CertUtil: -GetKey command FAILED: 0x8002802c (-2147319764)
CertUtil: Ambiguous name.
```

This output implies that a full key recovery could not be performed because the command line was not specific enough to retrieve a specific recovery BLOB.

**CA Officer Does Not Have a KRA Certificate**

As mentioned previously, a CA Officer need not also hold a KRA certificate. In the case where the CA Officer does not hold a valid KRA certificate and only has permissions to retrieve a recovery BLOB, running certutil.exe –getkey <serial number> with no output file name will list the certificate hashes (thumbprints) of all of the KRA(s) that may be used to decrypt (recover) the recovery BLOB in question. The CA Officer can then determine which KRA(s) may be used and send the recovery BLOB to one of the valid KRA(s).

The previous procedure is extremely useful in an organization that has a round-robin selection of KRA(s) when archiving private keys. In a round-robin archival, it may be difficult to always predict which KRA(s) were used to encrypt any specific private key of a user. It is probably a good best practice to keep the list of all KRA certificates hashes accessible so that they may be readily identified in the previous scenario.

The following certutil command may be used to list all the information from Active Directory, including KRA certificate hashes.

**Certutil.exe –DS – v > c:\output.txt**

| **Note** |
| --- |
| This command will dump all PKI information and certificates from Active Directory and may be more usable when placing the output in a text file as shown previously. |

**Setting the Timeout Option**

When keys are recovered from a CA using the command line or the key recovery tool, the recovery tool(s) will build a complete chain for the end-entity certificate, if possible. Sometimes a chain may not be able to be built after a long time due to infrastructure changes, CA certificate availability, and so on; the tool may also timeout when trying to build these chains. The certutil –recoverkey command and other commands that verify chains or construct *.pfx files accept a –t MilliscondCount option. This allows key recovery to avoid a 15-second timeout for each user key when building a chain. Fetching the certificate specified in the AIA extension Uniform Resource Locators (URLs) can time out when the recovered keys are associated with expired encryption certificates and the CAs have been decommissioned. For more information about certificate chains and status, see Appendix B: Additional Information.

**Using the Key Recovery Tool**

The key recovery tool is a Windows Server 2003 Resource Kit tool for recovering keys from a Windows Server 2003 CA

instead of using the certutil.exe command-line tool.

The tool may be launched from the command line by running krecover.exe. The tool is dependent on the existence of the certutil.exe and other binaries, which are available by default in Windows Server 2003 and in the Administration tool pack of Windows XP Professional. The tool is also dependent on one dynamically linked library (crutredir.dll), which is installed by the resource kit.

When launched, the tool will look similar to the following:

**Figure 7: Key Recovery Tool Interface**

The tool will automatically enumerate the forest for the currently logged on user and identify Enterprise CAs that may have archived private keys stored. The tool will filter out the following from the list of available CAs.

- CAs that are not Enterprise CAs
- CAs that are not running Windows Server 2003, Enterprise Edition
- CAs that are running Windows 2000
- CAs that the current user does not have CA Administrator or CA Manager permissions for

The following are several options enabled by the tool.

- **Search**—Allows a Certificate Manager to search for archived keys for a user based on several search criteria options.
- **Recover**—Allows a Certificate Manager who holds a KRA private key to recover a user from a CA database.
- **Show KRA**—Displays the valid KRA certificates that may decrypt the user private key.
- **Retrieve BLOB**—Allows a Certificate Manager to retrieve the encrypted user's private key from the database for the purpose of transferring to a KRA.
- **Decrypt BLOB**—Allows a KRA to decrypt and create a *.pfx file for an encrypted BLOB retrieved from the database by a Certificate Manager.

If the user does not have adequate permissions on the CA to recover a user or is not a Certificate Manager, an error similar to the following will be displayed.

**Figure 8: Failed to enumerate the KRA certificates Error Message**

**Recovering a Specific User's Keys**

To recover the private key(s) of a specific user, enter a user name and click **List** to list all the certificates for that user with an archived key. In the **User Name** field, enter the user name (as described previously), or domain\user_name, or user_name@northwindtraders.com—any input that is valid for the certutil -getkey command.

| **Important** |
| --- |
| For the key recovery tool to recover a key for a user, the same permissions apply as in the certutil.exe command-line as described in the previous section. |

If no key(s) is found for the selected user on the selected CA(s), the following dialog box will appear.

**Figure 9: No archived keys were found Message**

– or –

**Figure 10: No archived keys were found Message**

Here, you can select one or more certificates to be recovered, and then click **Recover**. If you select more than one certificate, you will be prompted if you want all the keys to be recovered in a single *.pfx file, or if you want separate *.pfx files for every certificate.

**Figure 11: Single or Separate *.pfx Prompt Message**

In either case, you will be prompted for a destination for the *.pfx file. The dialog box looks like the following:

**Figure 12: Output File Dialog Box**

When saving a *.pfx file, the tool will prompt for a location to save the *.pfx file and require a password to be set on the PKCS #12 file. When recovering a single private key, the default name for the *.pfx file will be the certificate serial number that corresponds to the private key. The output file name may be changed.

If the tool cannot recover a key for a user, the following dialog box will be displayed.

**Figure 13: Recovery Failure Message**

If you do not have a valid certificate and private key for a KRA that was used to encrypt and archive the private key of the user on the CA, the following error will be displayed.

**Figure 14: Invalid Certificate and Private Key Message**

**Recovering Version 1 and Version 3 Certificates**

A Windows Server 2003 CA may be used to archive both X.509, and version 1 and version 3 certificates as detailed previously. The key recovery tool allows recovery of both types, although x.509 version 1 certificates must be exported separately as they may only be exported in the *.epf format for Outlook. The Windows Server 2003 CA supports the following version 1 certificates and keys to be imported and exported from the database.

- Profile Version=2, CAST=3, Protection=40, EPFALG_CAST_MD5
- Profile Version=2, CAST=3, Protection=64, EPFALG_CAST_MD5
- Profile Version=3, HashCount=0, Protection=128, EPFALG_RC2_SHA
- Profile Version=3, Protection=128, EPFALG_3DES

If no version 1 certificates are in the recovery selection, the user will not be prompted any differently. If one x.509 version 1 certificate is in the selection, the user will be prompted for an *.epf file name for export. If more than one x.509 version1 certificate is selected, the user will be prompted whether the user would like one *.epf file or separate *.epf files for each key recovered. X.509 version 1 certificates will be recovered first and then the x.509 version 3 certificates will be recovered. If both version 1 and version 3 certificates have been selected, the user will be prompted twice whether the certificates should be

recovered in a single file or separate files. X.509 version 1 and version 3 certificates may not be recovered in a single file together.

**Importing Recovered Keys**

The following steps would be performed by an end user who has received the recovered key file (*.pfx file) and associated password from an administrator. It is assumed that the password and associated file have been transmitted to the user in a method consistent with the organization's security policy.

**To import a recovered key for an individual user**

1. Log on as the user who needs to recover their private key(s).
2. Click the **Start** button, and then click **Run**.
3. Type **mmc.exe**, and then press **Enter**. An empty MMC shell starts up.
4. Select the **Console** menu, and then click **Add/Remove Snap-in**. A dialog box appears with a list of all the snap-ins that have been added to this MMC shell.
5. Click **Add**.

   A list appears with all the registered snap-ins on the current machine.
6. Double-click the **Certificates** snap-in, choose **My User Account**, and then click **Finish**.
7. In the **Add Standalone Snap-in** dialog box, click **Close**, and then click **OK** in the **Add/Remove Snap-in** dialog box.

   The MMC now contains the personal certificate store for the user.
8. Expand the tree view of the certificate store. Click **Certificates**, **Current User**, **Personal**, and then **Certificates**.
9. In the console tree, right-click **Personal**, click **All Tasks**, and then click **Import**.
10. In the **Certificate Import Wizard** dialog box, click **Next**.
11. On the **Files to Import** page, in the **File name** box, type the name and path of the recovered key file (*.pfx), and then click **Next**.
12. On the **Password** page, in the **Password** box, type the password for the key file, and then click **Next**.
13. On the **Certificate Store** page, click **Automatically select the certificate store based on the type of certificate**, and then click **Next**.
14. On the **Completing the Certificate Import Wizard** page, click **Finish**. The wizard will report that the import was successful.

| **Note** |
| --- |
| A *.pfx file can also be selected (double-click) to invoke the certificate import wizard. |

# Implementing Key Archival Walkthrough

Updated: December 6, 2004

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The first step in enabling key archival on a CA is enrolling for one or more KRA certificates.

**Enrolling a Key Recovery Agent**
The first step is to enroll KRAs for KRA Certificates. The following section explains the steps for enrolling a KRA.

**Configuring the Certificate Templates**
A certificate template suitable for creating KRA certificates is installed in Active Directory. By default, only an Enterprise Administrator or a Domain Administrator may request a KRA certificate as defined by the default ACLs on the KRA certificate template. The certificate template ACLs can be viewed in the Certificate Templates MMC snap-in; in addition, using the Certificate Templates MMC snap-In, certificate templates can be cloned or edited.

| **Note** |
| --- |
| Only a domain with the Windows Server 2003 schema will support version 2 templates and only a Windows Server 2003, Enterprise Edition may issue a version 2 template certificate. |

**To configure a certificate template**

1. Log on as an Enterprise or Domain Administrator to the CA machine.

2. Click the **Start** button, click **Run**, and then type **certtmpl.msc**.

3. Click **OK**.

**Figure 15: Certificate Templates MMC Snap-In**

4. In the details pane, double-click **Key Recovery Agent**.

5. In the **Key Recovery Agent Properties** dialog box, click the **Security** tab.

**Figure 16: Key Recovery Agent Template Properties**

6. Add the appropriate user(s) or group(s) with both Read and Enroll permission.

7. Click **OK** to close the dialog box.

Next, the Certification Authority must be configured to issue this type of certificate.

**Certificate Template Permissions**
For a user or a computer to enroll for a certificate template, it must have appropriate permissions [access control entries (ACEs)] set on the template in Active Directory. A user or computer must have both Enroll and Read permissions to enroll for a selected certificate template. The Read permission allows the template to be discovered by the user and the Enroll permission is enforced by the enterprise CA when a user requests a certificate for a selected template. The enterprise CA must also have Read permissions on a template to enumerate the template in the directory and issue certificates based on that template. Normally, the enterprise CA is included in the Authenticated Users group, which has Read permissions by default on a template.

The Full Control permission is given to Enterprise Administrators by default on installation of a fresh Windows Server 2003 domain. If a domain has been upgraded from Windows 2000, Enterprise Administrators will not have this permission by default and the Full Control permission allows a user to set or modify the permissions on a selected template.

The Autoenroll permission is set on a template when a user or computer wants to automatically enroll for a selected certificate template. The Autoenroll permission is needed in addition to the Enroll permission for a user to enroll for a given certificate template.

The Write permission allows a user to modify the contents of a certificate template. Note that only a version 2 certificate with a Windows Server 2003 schema may be modified and version 1 certificate templates may only have the ACLs modified.

**Smart Card Support**
Smart cards are supported for use in conjunction with KRA certificates. It may be necessary to use a smart card and CSP that supports at least an 8-KB smart card to enroll for a KRA certificate on a smart card. If a smart card does not have adequate memory to support a KRA certificate, the following error will be generated on enrollment.

**Error: 0x80100028**

**An attempt was made to write more data than would fit in the target object**

All recovery operations are supported using a Smartcard. The system will prompt the recovery agent to insert an appropriate Smartcard when the key is needed to decrypt the recovery BLOB.

**Configuring an Enterprise CA to Issue KRA Certificates**
An Enterprise CA must be configured to issue a KRA certificate.

**To configure an EnterpriseCA to issue a KRA certificate**

1. On the **Administrative Tools** menu, open the **Certification Authority** snap-in.

2. In the console tree, expand **Certification Authority**, and then click **Certificate Templates**.

3. Right-click the **Certificate Templates** node, click **New**, and then click **Certificate Template to Issue**.

4. In the **Select Certificate Template** dialog box, click **Key Recovery Agent**, and then click **OK**.

5. Close the **Certification Authority** MMC snap-in.

6. The last manual step is to add the Certification Authority machine account to the Pre-Win2K Compatible Access group in every domain in which users will be using key archival. If this mandatory step is not performed, a CA Officer may not be able to manage groups of users. The Pre-Win2K Compatible Access group allows the CA to enumerate a user account and determine the group membership for CA Manager's capability.

**Enrolling a User with a KRA Certificate**

A user may enroll for a certificate with a CA by using the Certificates MMC snap-in or through the CA Web pages. In the case of the KRA template, the template is marked to be "pended" by the CA, which requires that the certificate request be approved first by a CA Administrator or a Certificate Manager before it is issued. Pended certificate requests may only be retrieved through the Web enrollment interface or through the auto-enrollment process. For more information, see Appendix B: Additional Information.

| **Important** |
| --- |
| It is strongly recommended not to automatically enroll KRA certificates as this may cause confusion for CA Administrators when automatic enrollment is unintentionally initiated resulting in additional KRA certificates in Active Directory. |

**KRA Web Enrollment**

**To enroll through a Web page**

1. Connect to the CA using a Web URL, for example:

   http://<CA Machine Name>/Certsrv

   | **Note** |
   | --- |
   | The Microsoft Certification Authority uses an ActiveX control known as xenroll.dll, which can be downloaded to client browsers that support ActiveX controls. Windows XP and Windows Server 2003 clients both ship with the ActiveX control pre-installed. |

   A Web site will open allowing you to request a certificate.

2. Select **Request a Certificate**.

3. On the next Web page, select **Advanced Certificate Request**.

4. Select **Create and submit a request to this CA**.

5. The next page will allow the user to select various configuration options, including the type of certificate to request. Choose **Key Recovery Agent** as the Certificate Template.

| ⚠Caution |
| --- |
| A key size of 8192 or larger may take several hours to generate on the client. (Key pairs are always generated by the client CSP, not the CA.) This may slow public key operations on the CA when keys are archived. Key sizes of 2048 are much more reasonable for standard security needs; a key size of 8192 is used only as an example. |

The keys should be marked as exportable. This will enable an administrator (KRA) to export the private keys from the local store of the workstation to a disk or other medium for safe storage. Strong private key protection is also recommended, as this will require a password to be used when accessing the private key.

6. When finished, click **Submit**.

   The Web page will show that the request is being generated. When the key generation and request is complete, if the request had included Enable strong private key protection, a dialog box will appear showing that a protected item is being created (KRA private key).

**Figure 17: Private Key Security Level Dialog Box**

The dialog box will present the opportunity to set the security level on the private key. If the workstation will be used for KRA operations and the private key is to be kept in the protected store, it is recommended that the security level be set to High. This will ensure that access to the private key will require a separate password.

**Figure 18: Private Key Security Level Dialog Box**

7. Click **Next**.

**Figure 19: Private Key Security Level Dialog Box**

8. Choose a password, confirm it, and then click **Finish**.

**Figure 20: Private Key Security Level Dialog Box**

9. Click **OK** to confirm. The Web page will appear and offer a link to install the certificate. If the Certification Authority is configured to set all certificate requests to pending, the user will have to return to the Web link to install the certificate after the CA administrator or a CA Officer has approved the request.

| **Important** |
| --- |
| The user may have to return to the Web link using the same machine that was used to generate the request. This is due to the fact that certificate pending information is stored as a browser cookie. If auto-enrollment is enabled in Active Directory for the user, the user will not be required to actually return to the Web page. The auto-enrollment process will automatically retrieve the certificate for the user when available. For more information about the auto-enrollment process, see the Certificate Auto-Enrollment in Windows XP white paper in Appendix B: Additional Information. |

| **Important** |
| --- |
| If the issuing CA is in a hierarchy, a second option will appear on the Web page to download the entire path (certificate chain). You should choose to download the entire chain. |

The default KRA certificate template requires that the certificate request be pended and not issued automatically. When a certificate request is pended, a CA Officer (Certificate Manager) must manually issue the certificate, assuming that the request was valid. Pending certificate requests can be issued through the Certification Authority MMC and by selecting the pending request node.

The Certificate Manager (or administrator of the server, if role separation is not enabled) can right-click the certificate request

and choose to issue or deny the request. For more information about Certificate Managers, see Configuring Certificate Managers.

After the certificate has been issued, the user (KRA) can return to the Web pages to retrieve the pending request.

The user should select **View the status of a pending certificate request**.

The Web page will display all the pending requests for that user that have been requested from that machine. As mentioned previously, this is managed through Web browser cookies. The user should select the appropriate certificate.

The last page allows the user to install the selected certificate and private key into the local MY store of the user.

#### Configuring the CA to Allow Key Archival

This section details the steps required to configure the CA to allow key archival.

Note: If the Certification Authority is enabled to enforce role separation, only a CA Administrator may configure KRAs on a CA. Role separation is enabled through the registry and only a local server administrator may configure the registry. The easiest way to enable the CA for role separation is to use the certutil.exe command-line tool:

**certutil -setreg ca\RoleSeparationEnabled 1**

It is necessary to stop and start certificate services for the setting to take affect.

| **Note** |
| --- |
| Certutil.exe and other tools may be installed on a Windows XP Professional machine by installing the Administrative Tools (adminpak.msi) that are found in the \i386 directory on all Windows Server 2003 CD-ROM media. |

#### Enabling a Key Recovery Agent

**To enable a KRA**

1. Log on as Administrator of the server or CA Administrator, if role separation is enabled.
2. On the **Administrative Tools** menu, open **Certification Authority**.
3. In the console tree, select the CA.
4. Right-click the CA name, and then click **Properties**.
5. Click the **Recovery Agents** tab.

**Figure 21: Recovery Agents Tab**

6. To enable key archival, click **Archive the key**.

7. By default, the CA will only use one KRA. However, a KRA certificate must first be selected for the CA to begin archival. To select a KRA certificate, click **Add**.

   The system will find valid KRA certificates and display the available KRA certificates.

   KRA certificates are normally published to Active Directory by an Enterprise CA when enrollment occurs. KRA certificates are stored under the KRA container in the Public Key Services branch of the configuration partition in Active Directory. Since a CA may issue multiple KRA certificates, each KRA certificate will be added to the multi-valued userAttribute attribute of the CA object.

8. Select one certificate and click **OK**. You may view the highlighted certificate to ensure that you have selected the intended certificate.

**Figure 22: Recovery Agents Tab**

9. After one or more KRA certificates have been added, click OK to enable key archival on the CA. However, Certificate Services must be stopped and started to enable the use of the selected KRAs. KRA certificates are only processed at service start.

**Configuring Certificate Managers**

To recover the private keys of a user, the CA enforces that a person be a Certificate Manager (if defined) and also holds a private key for a valid KRA certificate. As a best practice, most organizations separate these two roles. By default, the CA Administrator is a Certificate Manager for all users unless otherwise explicitly defined. A KRA is not necessarily a CA Officer (Certificate Manager). They may be segmented as separate roles. A KRA is defined as a person who holds a private key for a valid KRA certificate.

A CA Officer is defined as a Certificate Manager who has the security permission on the CA to Issue and Manage Certificates. The security permissions are configured on a CA using the Security tab on the CA Properties in the Certification Authority MMC snap-in.

**Figure 23: Security Tab**

A CA Administrator can define more specific CA Officer Roles on a Certification Authority by using the Certificate Managers Restrictions tab. By default, any user or group that has the permission to Issue and Manage Certificates is also a CA Officer and can issue, revoke, or export a recovery BLOB for any other user who has been issued a certificate from that CA.

**Figure 24: Certificate Managers Restrictions Tab**

A CA Administrator can define that individual CA Officers have the ability to issue, revoke, and recover certificates for defined sets of user(s) and group(s) by selecting the Restrict certificate managers option. Once the option has been selected, a CA Administrator may define CA Officers' roles as required.

| **Important** |
| --- |
| Once this is complete, it is also necessary to add the machine account of the CA to the Pre W2K Compatible Access Group of every domain in which users will be archived and recovered. This is necessary to provide proper group membership enumeration for role restriction enforcement when performing recovery functions. Certificate Managers will not be able to recover users unless this task is performed first in every user domain. |

**Configuring User Templates**

To enable a user template for key archival, select the template that should enforce key archival and select the Archive subject's encryption private key check box. Once the check box has been selected, the CA will always enforce key archival for that template.

**Figure 25: Request Handling Tab**

| **Note** |
| --- |
| A Windows Server 2003 CA will not allow archival of a key marked for signature only and will reject the request, even if sent programmatically to the CA. |

# Migrating Exchange KMS to Windows Server 2003 CA

Updated: December 6, 2004

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The following are the summary steps for migrating Exchange 2000 Server KMS to a Windows Server 2003 certification authority.

1. If running Exchange 5.5 KMS, upgrade to Exchange 2000.
2. Configure Windows Server 2003 CA for key archival.
3. Ensure that the certificate is available for database migration.
4. Enable the foreign certificate import option on the CA, if necessary.
5. Export the Exchange KMS database.
6. Import the Exchange database into the CA.

**Important**

Before migrating KMS to a Windows Server 2003 CA, it is important to consider the version 1 CRL that is published by the Exchange KMS for Outlook clients in the Exchange Global Address List (GAL). If KMS is migrated to a Windows Server 2003 CA, the v1 certificates can no longer be revoked and it is recommended that a KMS migration is only performed when all V1 certificates are expired and/or are no longer being issued by KMS. If x.509 version 3 certificates are being issued by KMS with a Windows 2000 CA, the existing CA will need to be maintained to publish CRL(s) until all the original certificates issued by KMS have expired.

**Creating an Export Certificate**

When a KMS migration to a Windows Server 2003 CA is performed, the export file from the KMS must be encrypted with a public key certificate and then subsequently decrypted by the Windows Server 2003 CA. The CA may or may not have an encryption certificate available to be used for this process. It is absolutely critical that an encryption certificate and private key be installed in the machine store (local machine) of the CA to facilitate KMS migration. Since the process runs as SYSTEM, any encryption certificate and private key available in the machine store may be used.

To view the certificates installed in the local machine store, open the Certificates MMC console for the local machine and view the certificates under the Personal store. A Secure Sockets Layer (SSL) or machine authentication certificate will suffice for use in this scenario. The certificate corresponding to the private key that will be used should be manually exported and made available during the KMS migration process. For more information about certificate enrollment and exporting certificates, see the Windows Server 2003 help files. If importing a certificate and key to be used by the CA (*.pfx file), ensure that the certificate is marked for export when importing on the CA. Otherwise, the CA may not be able to use the key and certificate for key import purposes.

**Important**

The export certificate used by the KMS should not have a key size greater than 1024 bits as this may cause errors on import to the Windows Server 2003 CA.

**Important**

A Windows Server 2003 always has an Exchange certificate (encryption certificate) available for the purpose of key archival. Do not attempt to use this certificate for the purpose of migrating the KMS database as it will not be usable by the CA for this purpose.

**Enabling Foreign Certificates Import**

If the KMS contains x.509 version 1 certificates and private keys, and/or if the KMS was not configured to use the same CA with

Windows 2000, the foreign certificate import option must be enabled on the Windows Server 2003 CA.

**Foreign Certificate Import**

By default, a CA does not allow certificates (or keys) to be imported on the CA that were issued by another CA. A CA must be enabled to accept certificates and keys into the database that were issued by a foreign CA. (An Exchange 5.5 KMS issuing version 1 certificates is also considered a foreign CA.)

### To import a foreign CA

1. Run the following command in a command-prompt window on the CA.

   **certutil –setreg ca\KRAFlags +KRAF_ENABLEFOREIGN**

2. Once that has competed, restart the service.

| **Important** |
| --- |
| When foreign certificates are being imported on a CA, the –f switch must be used with certutil to inform the CA that the keys and certificates will be foreign. The command line would be as follows |

**Certutil.exe –f –importKMS [name of import file]**

**Exporting Users' Keys from Exchange 2000 KMS**

| **Important** |
| --- |
| Before an export of data from the KMS occurs, a full backup of the KMS should be performed and validated before continuing. An export of data from a KMS is destructive and will remove the keys from the KMS database. |

| **Important** |
| --- |
| If the KMS or the CA is online when the export occurs, the KMS will attempt to revoke all version 3 certificates that are exported. If this occurs, it is important to re-enroll all users immediately with the Windows Server 2003 CA to allow continued S/MIME encryption operations. Otherwise, take the CA offline, so the KMS export operation will not revoke the existing certificates. |

### To perform the export operation on the KMS

1. Start the Exchange System Manager.

2. Point to the **Advanced Security** node, right-click **Key Manager**, click **All Tasks**, and then click **Export Users**.

3. In the **Key Management Service password** box, type the password (the default password for KMS is "password"), and then click **OK**.

The Exchange KMS Key Export Wizard will start.

4. Click **Next**.

5. Click **Browse** to select the Certificate that will be used to encrypt the export file. This is the certificate file created in the previous section.

6. Browse for the certificate that will be used to encrypt the export file to the CA. This is the certificate created in the previous section. Click Open.

7. On the Encryption Certificate screen, click Next.

8. When this screen appears, use **Windows Explorer** to find and open the certificate that you chose from the screen in step 6. You will need to validate this certificate with the **Exchange KMS Key Export Wizard**.

9. Copy the first eight characters from the Certificate thumbprint field in the certificate chosen to encrypt the KMS export file (Figure 33).

10. Type the first eight characters of the certificate thumbprint in the **Thumbprint** field (Figure 34), and then click **Next**.

11. Type the name of the export file (Figure 35). Do not type in a path, only the file name. It will be saved in the following location by default. This is based on the default installation for Exchange.

    **C:\program files\exchsrvr\KMSDATA**

    This file will not have an extension.

12. Click **Next**.

13. You may select an alphabetic list of users or select by mailbox store, server, or administrative group.

14. In this case, select all of the administrative groups, and then click **Next**.

15. To start the Export process after selecting the users or administrative group(s), click **Next**.

The records will be exported. On average, approximately 100 records will be exported a minute. The actual performance will vary depending on the hardware configuration.

16. When complete, click **Next**.

17. The results will be displayed. Click **Finish**.

> **Note**
> If large numbers of users are exported, KMS may generate multiple export files and split the exported keys across the multiple files. In this case, all export files should be re-imported to the new CA.

The export file will be located in the following folder.

**C:\program files\exchsrvr\KMSDATA**

18. Copy the KMS export file to the server that will accept the import file.

**Importing Users' Keys**

The Windows Server 2003 CA allows not only key archival, but also certificate and key importation to the CA database. Certificate and key importation is important in providing migration services for Exchange KMS as well as for providing migration and escrow operations for certificates that were enrolled using a third-party CA. The Windows Server 2003 CA supports both certificate import as well as key import. Certificate import does not require that key archival be enabled on the CA, but key import does.

**To import users' keys**

1. Log in as the CA Administrator.

2. Open a command prompt window.

3. Change to a directory containing the KMS import file.

4. Run the following command.

   **CertUtil.exe –f –importkms <name of export file>**

   The output will indicate the status of the import process and the number of user keys imported and archived to the CA. The number of imported user keys should match the output from the KMS. The following is a sample successful output.

```
Processing KMS exports from:
    O=microsoft,C=US

KMS export file signature verifies
```

```
Lock box opened, symmetric key successfully decrypted
.................................

Users: 6

Ignored signature certificates: 25
Certificates with keys: 17
Foreign certificates imported: 17
Certificates imported: 17

Keys: 17
Keys archived: 17
CertUtil: -ImportKMS command completed successfully.
```

# Troubleshooting - Key Archival and Management in Windows Server 2003

Updated: December 6, 2004

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Troubleshooting KRA Configuration**

This section identifies a number of common mistakes in configuring the KRAs on a CA. The most common error in archiving user private keys on a CA is that the CA is either not configured for key archival or does not have any valid KRA certificate(s) added.

1. The number of recovery agents required by the CA must be less than or equal to the number of available KRA certificates. If an invalid number of recovery agents is entered, the following error message will appear.

**Figure 42: Invalid Number of Recovery Agents Error Message**

2. If an error occurs in trying to validate the KRA certificate when Certificate Services is started, the Recovery Agents tab on the Certification Authority will show that the selected KRA certificate is invalid. This can occur due to a corrupted certificate, corrupted registry entry, deleted certificate, revoked certificate, and so on. Figure 43 shows an example of a corrupted certificate or registry entry on the Recovery Agents tab as shown in the Status column of the selected KRA.

**Figure 43: Invalid KRA Certificate on the Recovery Agents Tab**

3. Similarly, a revoked KRA certificate will also show an error on the Recovery Agents tab when Certificate Services is stopped and started. The error will be displayed in the status column of the KRAs certificates listing.

**Figure 44: Revoked KRA Certificate on the Recovery Agents Tab**

**Loading KRA Certificates**

When certificate services starts on a Certification Authority, the CA attempts to load the KRA(s) defined by the CA Administrator. If the CA is unable to load one or more KRA(s), event log messages will be generated; however, certificate services will continue to start. If the CA is unable to load a KRA(s) successfully as defined by a CA Administrator, the CA will deny all requests for key archival and not issue any certificates that have key archival defined in the certificate template. The following event log messages may appear in the Certification Authority's Application Log when an error occurs in loading KRA certificates. The event log messages indicate that action is required by a CA Administrator to properly configure or reconfigure KRAs.

Event Type: Error

Event Source: CertSvc

Event Category: None

Event ID: 83

Date: 12/20/2000

Time: 8:24:24 AM

User: N/A

Computer: SERVER1

Description:

Certificate Services encountered an error loading key recovery certificates. Requests to archive private keys will not be accepted. The system cannot find the file specified.
0x80070002 (WIN32: 2)

This is a global error that can be caused by one of several conditions.

- The Certification Authority cannot open the KRA store on the local machine.
- The Certification Authority cannot find a corresponding certificate in the KRA store on the local machine that matches the hash of a certificate set in the registry as a KRA.
- The registry has been edited incorrectly or is corrupted.

- The count of KRA certificate hashes in the registry equals zero.
- A certificate hash in the registry corresponds to a certificate in the KRA store that is not a KRA certificate type.
- The KRA certificates are revoked, expired, or invalid.

Event Type: Error

Event Source: CertSvc

Event Category: None

Event ID: 82

Date: 12/27/2000

Time: 9:05:25 AM

User: N/A

Computer: SERVER1

Description:

Certificate Services could not load any valid key recovery certificates. Requests to archive private keys will not be accepted.

This error is usually caused when none of the certificates specified in the user interface (UI) (which corresponds to the registry) is a valid KRA certificate. This event log message is usually accompanied by the previous global event log message.

Event Type: Error

Event Source: CertSvc

Event Category: None

Event ID: 84

Date: 1/24/2003

Time: 08:49:27

User: N/A

Computer: SERVER1

Description:

Certificate Services will not use key recovery certificate 6 because it could not be verified for use as a Key Recovery Agent. CN=User1, OU=Users, DC=nwtraders, DC=com The revocation function was unable to check revocation because the revocation server was offline. 0x80092013 (-2146885613)

This error usually occurs when the CA receives an error when retrieving the CRL to check the status of the KRA certificate.

Event Type: Error

Event Source: CertSvc

Event Category: None

Event ID: 98

Date: 1/24/2003

Time: 08:49:28

User: N/A

Computer: SERVER1

Description:

Certificate Services encountered errors validating configured key recovery certificates. Requests to archive private keys will no longer be accepted.

Event Type: Error

Event Source: CertSvc

Event Category: None

Event ID: 85

Date: 12/27/2000

Time: 9:05:25 AM

User: N/A

Computer: SERVER1

Description:

Certificate Services ignored key recovery certificate 0 because it could not be loaded. Cannot find object or property. 0x80092004 (-2146885628)

This error usually occurs when a specific KRA certificate cannot be found in the KRA store on the local machine of the Certification Authority. Specifically, a KRA certificate has been specified in the UI or registry, and the certificate has been deleted or corrupted in the KRA store. This event log message is usually accompanied by a more global event log message.

**KRA Certificate Status**
When certificate services starts on a Certification Authority, the CA attempts to load the configured KRA(s). The CA must validate the status of each KRA certificate. If the CA is unable to retrieve a current CRL for each KRA certificate, the CA will not be able to load and use that KRA.

The following event log message will be logged in the application event log of the CA.

Event Type: Error

Event Source: CertSvc

Event Category: None

Event ID: 84

Date: 1/12/2001

Time: 11:47:23 AM

User: N/A

Computer: SERVER1

Description:

Certificate Services ignored key recovery certificate 1 because it could not be verified for use as a Key Recovery Agent. CN=User1, OU=Users, DC=nwtraders, DC=com The revocation function was unable to check revocation because the revocation server was offline.

0x80092013 (-2146885613)

**Importing Exchange KMS Export File**
The Windows Server 2003 CA may fail during the importation of the KMS data file if the key size used for the export certificate is greater than 1024 bits in size. The Windows Server 2003 CA may fail with the following message when a key size of greater than 1024 bits is used.

Processing KMS exports from:

CN=Certification Authority, OU=Test, O=Contoso, C=US

KMS export file signature verifies

CertUtil: -ImportKMS command FAILED: 0x80070057 (WIN32: 87)

CertUtil: The parameter is incorrect.

**User Enrollment Errors**
A user certificate request for a template that requires key archival will be denied if one of the following conditions exists.

- No KRA has been defined on the CA.
- No KRA can be successfully loaded. (KRA certificates are revoked, expired, and so on.)
- The minimum number of KRA certificates defined by the CA Administrator cannot be loaded.

If the user enrolls through a Web page, the following text will display on the Web page.

Your request failed. An error occurred while the server was processing your request.

Contact your administrator for further assistance.

**Request Mode**:

newreq - New Request **Disposition**:

(never set) **Disposition message**:

(none) **Result**:

Cannot archive private key. The certification authority is not configured for key archival. 0x8009400a (-2146877430) **COM Error Info**:

CCertRequest::Submit Cannot archive private key. The certification authority is not configured for key archival. 0x8009400a (-2146877430) **LastStatus**:

Cannot archive private key. The certification authority is not configured for key archival. 0x8009400a (-2146877430) **Suggested Cause**:

No suggestions.

If enrolling through the MMC, the following error will be displayed.

**Figure 45: Incorrect Certificate Request Error Message**

The CA will also log the following error to the application event log of the CA.

Event Type: Error

Event Source: CertSvc

Event Category: None

Event ID: 21

Date: 1/12/2001

Time: 4:23:39 PM

User: N/A

Computer: SERVER1

Description:

Certificate Services could not process request 16094 due to an error: Cannot archive private key. No valid key recovery agent is defined for this certification authority. 0x8009400b (-2146877429). The request was for NWTRADERS\User1.

If the CA is unable to retrieve a current CRL for the CA itself or any of its parent CA(s), it will be unable to issue a certificate when a user submits a request. If the CA does not have a valid CRL for itself, the following error message will be displayed in the application event log of the CA.

Event Type: Warning

Event Source: CertSvc

Event Category: None

Event ID: 53

Date: 1/6/2001

Time: 11:24:05 AM

User: N/A

Computer: SERVER1

Description:

Certificate Services denied request 1471 because the revocation function was unable to check revocation because the revocation server was offline. 0x80092013 (-2146885613). The request was for CN=user1, OU="Test", O="NWTraders", L=Redmond, S=WA, C=US, E=user1@nwtraders.com. Additional information: Denied by Policy Module

**Certificate Template Not Supported by the CA**
If a user tries to enroll with a CA for a template that is not supported by that CA, the following event log message will be entered in the CA application event log.

Event Type: Warning

Event Source: CertSvc

Event Category: None

Event ID: 53

Date: 1/16/2001

Time: 2:07:02 PM

User: N/A

Computer: SERVER1

Description:

Certificate Services denied request 8 because the requested certificate template is not supported by this CA. 0x80094800 (-2146875392). The request was for NWTRADERS\Administrator. Additional information: Denied by Policy Module The request was for certificate template (1.3.6.1.4.1.311.21.8.4144336743.1329436349.2065260953.3989445610.1.27) that is not supported by the Certificate Services policy.

**Client CSP Does Not Permit Key Export**
For the client enrollment process to generate and send a private key to the CA, the key must be marked as exportable when the key is generated. If the certificate template is not set to allow key exportable or if the third-party CSP (if applicable) does not support exportable keys, enrollment will fail and the enrollment wizard will return an error that the key is not exportable. Third-party CSPs may report varying errors, such as “catastrophic failure”, when this occurs. If a Windows 2000 or Windows Millennium Edition client performs enrollment with key archival, the following error may appear if the key is not marked for export.

0x80090009 - NTE_BAD_FLAGS

**Note**

If the CSP supports the one-time flag for key archival, known as (CRYPT_ARCHIVABLE), the key export flag is not required. The Microsoft default software CSPs support this flag. However, Windows 2000 and Windows Millennium Edition clients do not support this flag and must allow the key to be exported for enrollment to work with key archival.

**Certification Authority CSP Not Supported for Key Archival Functions**

If a software or hardware CSP is not capable of performing the symmetric and public operations for encrypting the private key(s) of users in the CA database, the CA will log an event in the application event log:

Event Type: Warning

Event Source: CertSvc

Event Category: None

Event ID: 86

Date: 12/27/2001

Time: 8:13:54 AM

User: N/A

Computer: NORTHWIND5

Description:

Certificate Services could not use the provider specified in the registry for encryption keys. The keyset is not defined. 0x80090019 (-2146893799)

For more information, see the Help and Support Center at http://go.microsoft.com/fwlink/events.asp

Event Type: Warning

Event Source: CertSvc

Event Category: None

Event ID: 88

Date: 12/27/2001

Time: 8:13:54 AM

User: N/A

Computer: NORTHWIND5

Description:

Certificate Services switched to the default provider for encryption keys.

For more information, see the Help and Support Center at http://go.microsoft.com/fwlink/events.asp

To verify which CSP the CA is using for encryption operations associated with key archival, run the following command from the CA.

**Certutil –getreg ca\EncryptionCSP\Provider**

**Certificate and Key Import Issues**

If the CA has not been configured for key archival or if the CA has not been configured for foreign key import, the following error will occur when attempting to import a KMS export file or a foreign key import. Note that the keys were not archived in the following message.

```
Processing KMS exports from:
    O=microsoft, C=US
KMS export file signature verifies
Lock box opened, symmetric key successfully decrypted
CertUtil: Invalid Signature.
```

```
CertUtil: Invalid Signature.
CertUtil: Invalid Signature.
CertUtil: Invalid Signature.
CertUtil: Invalid Signature.
CertUtil: Invalid Signature.
CertUtil: Invalid Signature.
CertUtil: Invalid Signature.
CertUtil: Invalid Signature.
CertUtil: Invalid Signature.
CertUtil: Invalid Signature.
CertUtil: Invalid Signature.
CertUtil: Invalid Signature.
CertUtil: Invalid Signature.
CertUtil: Invalid Signature.
CertUtil: Invalid Signature.
CertUtil: Invalid Signature.
CertUtil: Invalid Signature.

Users: 6

Ignored signature certificates: 25
Certificates with keys: 17
Certificates not imported: 17

Keys: 17
Keys not archived: 17
CertUtil: -ImportKMS command completed successfully.
```

**Troubleshooting Key Recovery Issues**

**Unable to Recover User**

If a CA performing key archival is also enabled for role separation with specific Certificate Manager restrictions, a Certificate Manager may not be able to recover a user certificate until the machine account of the CA has been added to the Pre W2K Compatible Access Group of the domain in which the recover user belongs. This is a necessary requirement for the CA to enumerate the group memberships of Certificate Managers and recovered users to ensure that proper restrictions are enforced.

**Missing KRA Certificate in the CA Registry**

If one of the recipient KRA certificates from the HKEY_LOCAL_MACHINE KRA certificate store on the Certification Authority is deleted, key recovery tools, such as certutil –getkey, will fail because the server cannot find the KRA certificate to include in the recovery BLOB. The following error message will be displayed when this error occurs.

```
certutil -getkey "1b 4a b7 1e 00 00 00 00 00 1d"
Querying server1.nwtraders.com\CA1............

"server1.nwtraders.com\CA1"
   1b4ab71e00000000001d  CN="Users

Administrator"
CertUtil: -GetKey command FAILED: 0x80092004 (-2146885628)
CertUtil: Cannot find object or property
```

Note that the KRA certificate must be available in the registry on the CA, not the machine where the recovery tool(s) are used.

# Appendix A: Certificate Request Structure

Updated: December 6, 2004

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

This appendix provides additional detailed information about the key archival process regarding the certificate request structure.

**ASN.1 Structure**
A certificate request for key archival to the CA is a CMC Full PKIRequest message as specified in RFC 2797. The ASN.1 structure used by the Windows Server 2003 CA is demonstrated in Figure 46.

**Figure 46: CMC Request Message**

**Understanding the PKCS #7 Message Content Structure**
The first section of the CMC message contains a PKCS #7 message that has the relevant elements for generating a certificate request.

**Understanding the controlSequence TaggedAttribute Element**
The TaggedAttribute element in the message contains the following information.

- Extensions—The Extensions section of the TaggedAttribute element contains the following extensions.
    - Application Policies
    - Template Information
    - Key Usage
    - Enhanced Key Usage
- Attributes—The Attributes section of the TaggedAttribute element contains the following data.
    - Common Name
    - Template Name to be used
    - Hash of the encrypted private key BLOB
- Other request information

**Understanding the reqSequence TaggedRequest Element**
The reqSequence TaggedRequest element contains a nested PKCS #10 message. This message contains the user's public key in addition to other information relevant for generating the certificate.

**Understanding the cmsSequence TaggedContentInfo Element**
The cmsSequence TaggedContentInfo element can contain nested PKCS #7 and CMC messages. In a standard archival request, this element is not used.

**Understanding the otherMsgSequence OtherMsg Element**
Not Used

**Understanding the Signatures Structure**
The signatures section of the CMC message contains one or more signatures used to sign the request. The following is an example of the signatures section.

```
Signer Count: 1

Signer Info[0]:
Signature matches request Public Key
CMSG_SIGNER_INFO_CMS_VERSION(3)
CERT_ID_KEY_IDENTIFIER(2)
    0000  81 92 56 3a c4 31 f8 82  0c 54 c9 d0 98 4f d8 c5
    0010  34 63 9e cc
Hash Algorithm:
    Algorithm ObjectId: 1.3.14.3.2.26 sha1
    Algorithm Parameters: NULL
Encrypted Hash Algorithm:
    Algorithm ObjectId: 1.2.840.113549.1.1.1 RSA
    Algorithm Parameters: NULL
Encrypted Hash:
    0000  c1 ae 90 a7 a3 0b 52 66  ea c4 d0 04 17 2e 94 95
    0010  14 20 06 ...
```

**Understanding the Authenticated Attributes Structure**
The authenticated attributes section contains additional authenticated attributes, such as Content Type, Message Digest, and Client Information. The following is an example of the authenticated attributes section.

```
Authenticated Attributes[0]:
  3 attributes:
  Attribute[0]: 1.2.840.113549.1.9.3 (Content Type)
    Value[0][0]:
    Unknown Attribute type
    1.3.6.1.5.5.7.12.2 CMC Data
  Attribute[1]: 1.2.840.113549.1.9.4 (Message Digest)
    Value[1][0]:
    Unknown Attribute type
    Message Digest:
        5e 1f 0f f0 28 a4 fe 91 0d c2 2f 1a 18 78 7e 2e 10 7f 17 39
  Attribute[2]: 1.3.6.1.4.1.311.21.20 (Client Information)
    Value[2][0]:
    Unknown Attribute type
    Client Id: = 1
    XECI_XENROLL -- 1
    User: CONTOSO0\avibm
    Machine: dcross-stress.contoso.com
    Process: certreq
```

**Understanding the Unauthenticated Attributes Structure**
The unauthenticated attributes section contains the encrypted private key. The private key is contained in an enveloped PKCS #7 message that is encrypted to the CA's exchange key. Since this is an unauthenticated attribute, the SHA1 hash of the PKCS #7 message is included as one of the attributes of the controlSequence TaggedAttribute attributes.

The following is an example of the unauthenticated attributes section.

```
Unauthenticated Attributes[0]:
  1 attributes:

  Attribute[0]: 1.3.6.1.4.1.311.21.13 (Encrypted Private Key)
    Value[0][0]:
    Unknown Attribute type
================ Begin Nesting Level 1 ================
```

```
PKCS7 Message:
  CMSG_ENVELOPED(3)
  CMSG_ENVELOPED_DATA_PKCS_1_5_VERSION(0)
  Content Type: 1.2.840.113549.1.7.1 PKCS 7 Data

PKCS7 Message Content:
0000    d4 a6 31 b6 5a ee 62 90  cc 17 b1 7a 6a 0d 40 9a
..1.Z.b....zj.@.
0010    33 fd 11 14 0b ae 12 bd  3b 32 b8 73 af cc 1b 76

```

**Performing Binary Export for a Request**

To view and decode a CMS key archival request from a Windows Server 2003 CA, it is necessary to do a binary export directly from the CA database. A binary export can be easily achieved through the Certification Authority MMC snap-in or by using the certutil.exe command-line tool.

**Binary Request Export Using the Certification Authority MMC Snap-In Walkthrough**

**To export a binary request using the Certification Authority MMC Snap-in**

1. Log on to the CA machine using a CA Administrator account.

2. Open the **Certification Authority** MMC snap-in.

3. Click the **Issued Certificates** folder.

4. If the binary request column has not been previously added to the database view, it must be added to support a binary request export. To add a column to the view, click **View** on the menu bar, and then select the **Add/Remove Columns** menu option.

5. In the **Add/Remove Columns** dialog box, select the **Binary Request** field in the **Available Columns** list box on the left.

6. Click **Add**, and then click **OK**.

Next, a binary request can be exported.

1. Select a request from the issued certificates view, and then click the **Action** menu.

2. Select **Export Binary Data** on the **All Tasks** menu.

3. In the **Export Binary Data** dialog box, choose **Binary Request** as the column you want to export.

4. Click **OK**.

The data will be exported into ASCII format that can be opened in Notepad using notepad.exe.

| **Note** |
| --- |
| Following the previous steps will generate a dump of the certificate archival request only; it does not include the private key material. To dump a full certificate archival request including the private key material, follow the command-line option. |

**Binary Request Export Using the CertUtil.exe Command-Line Tool Walkthrough**

To use the certutil.exe to view the certificate request including private key material, a request file has to be generated first.

**To generate a request file**

1. Run Notepad.exe.

2. Paste the following certificate request information into Notepad.

   [Version]

Signature= "$Windows NT$"

[NewRequest]

Subject = "CN=Test Subject"

KeySpec = 1

Exportable = FALSE

PrivateKeyArchive = TRUE

[RequestAttributes]

CertificateTemplate = EFS

| **Note** |
| --- |
| Make sure that the CA is configured for key archival before starting this process. In this example, the EFS template is used; this should be changed to an existing certificate template that allows private key archival. |

3. Save the file as **CertificateRequest.inf**, and then close **Notepad**.

4. Open the command-line window.

5. Type the following command.

   **Certreq –new CertificateRequest.inf CertificateRequest.req**

   **Notes**:

   - This command will prompt you to select the CA to fetch the CA exchange certificate from, and to encrypt the private key to.

   - This command will write the request to a file named by the last argument on the command line: CertificateRequest.req.

   - To avoid using the CA selection dialog, you can specify the CA via -config **CAMachineDNSName\CACertCommonName** before or after the –new option.

6. Type the following command.

   **certreq -submit CertificateRequest.req KeyArchival.cer KeyArchival. p7b KeyArchival.rsp**

   This command will prompt you to select the CA to submit the request to.

   **Notes**:

   - This command will write the newly issued certificate, a PKCS7 containing only the issued certificate and chain, and the full CMC response to files named by the last three arguments on the command line: KeyArchival.cer, KeyArchival.p7b, and KeyArchival.rsp, respectively.

   - To avoid the U/I, you can specify the CA via -config **CAMachineDNSName\CACertCommonName** before or after the **–submit**.

7. Type the following command.

   **certreq -accept KeyArchival.rsp**

   This command verifies the response, installs the certificate, and associates it with the private key.

8. Type the following command.

   **Certutil –privatekey –dump CertificateRequest.req >CertificateRequest.txt**

   This command will generate a dump of the certificate archival request into the CertificateRequest.txt file.

9. Type the following command.

   **Certutil –privatekey –dump KeyArchival.rsp >CertificateResponse.txt**

   This command will generate a dump of the certificate archival response into the CertificateResponse.txt file.

For non-Windows Server 2003 clients or servers enrolling to a Windows Server 2003 CA, the format of the request may be different. The reason is that non-Windows Server 2003 platforms may not support CMC data structures and, therefore, may not be able to encode the request information inside a PKIData object. Instead, the request information may be inside the Data body but not encoded as a PKIData object.

| **Note** |
| --- |
| certreq.exe and other tools may be installed on a Windows Server 2003 Professional machine by installing the Administrative Tools (adminpak.msi) that are located in the \i386 directory on all Windows Server 2003 CD-ROM media. |

**CMC Request and Response Examples**

```

**Recovery BLOB Structure**

When stored in the CA database, the private key is stored as a PKCS #7 message, encrypted with a 3DES symmetric key that is encrypted to the KRA(s) public key as a column in the CA database. When the recovery BLOB is retrieved by the certutil –getkey command, the encrypted PKCS #7 and the KRA certificate hashes are retrieved from the database. Also, the encrypted PKCS #7 is wrapped inside a signed PKCS #7 to allow collecting the previous certificates and attaching them to the signed PKCS #7. The PKCS #7 is not protected with a password since it is already protected by the public key of the recovery agent(s). The outer PKCS #7 wrapper can contain the certificate chains for the recovery agent(s) and the end-entity to facilitate the recovery operations and construction of the end-entity PKCS #12 file. Figure 47 illustrates the recovery BLOB structure.

The recovery BLOB consists of wrapping the encrypted PKCS #7 in the database in another (signed) PKCS #7 to allow a number of certificates to be included in the recovery BLOB. The returned certificates include the full chain of the user certificate being recovered, the chain of the signing CA certificate (which may differ from the CA certificate under which the user certificate was issued), and the KRA certificates to which the key was encrypted. The szOID_ARCHIVED_KEY_CERT_HASH(1.3.6.1.4.1.311.21.16) is an attribute containing the SHA-1 hash of the certificate for the key being recovered, attached as an authenticated attribute to the CA signature of the recovery BLOB. This allows certutil -recoverkey recoveryblobfile to also display the Subject name of the KRA certificate(s) used to protect the private key BLOB.

**Figure 47: Recovery BLOB**

**ASN.1 Structure**

The following is the ASN.1 structure of the PKCS #7 EnvelopedData object.

```
EnvelopedData ::= SEQUENCE {

version                    Version,

recipientInfos             RecipientInfos,

encryptedContentInfo       EncryptedContentInfo

}
```

Storing the recovery BLOB as an enveloped PKCS #7 enables a recovery agent to retrieve the recovery BLOB from the CA database. The recovery agent's private key is used to decrypt the EncryptedContentInfo to extract the PKCS #12 data. The following is the ASN.1 structure of the EncryptedContentInfo body.

```
EncryptedContentInfo ::= SEQUENCE {

contentType                    ContentType,

contentEncryptionAlgorithm     ContentEncryptionAlgorithmIdentifier,

encryptedContent[0]            IMPLICIT EncryptedContent OPTIONAL

}
```

By definition, there can be multiple recovery agent certificates specified by RecipientInfo, where IssuerAndSerialNumber is used to disambiguate between multiple recovery agent certificates. Only the recovery agent certificates included in the RecipientInfo body of the enveloped PKCS #7 object can be used to recover the archived key material. The following is the ASN.1 structure of the RecipientInfo body.

```
RecipientInfo ::= SEQUENCE {

version                    Version,

issuerAndSerialNumber      IssuerAndSerialNumber,

keyEncryptionAlgorithm     KeyEncryptionAlgorithmIdentifier,

encryptedKey               EncryptedKey

}
```

# Appendix B: Additional Information

Updated: December 6, 2004

# Appendix C: Useful Commands

Updated: December 6, 2004

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

The following commands are available with certutil.exe in the Windows Server 2003 Administration Tools pack in performing key archival and recovery functions.

- **certutil – ImportKMS** accepts a *.pfx, *.epf, or a KMS export file, and archives the contents in the CA database.
- **certutil –ConvertEPF** converts a *.pfx (PKCS #12) file to a *.epf-formatted file for import into Outlook.
    - *certutil –ConvertEPF* and *–MergePFX* are similar in that they both accept a comma-separated list of input files that are merged and placed in the output file. Input files for both commands may be *.pfx files, *.epf files, or a mixture of the two.
    - The –cast parameter should be used to specify the CAST encryption algorithm.
    - The –silent option may be specified to suppress the UI.
- **certutil –ImportPFX** accepts a *.pfx or a *.epf file, and installs the certificates and keys into the HKLM (local machine) MY store. If the –User parameter is specified, the key and certificate will be imported into the HKCU (user profile) MY store. The CSP to be used may also be overridden by specifying the name with the –csp parameter.
- **certutil –getkey** retrieves the archived private key recovery BLOB from the CA database.
- **certutil –recoverkey** recovers the archived private key.
- **certutil –verifykeys** verifies the private/public key pair.

# ADFS Operations Guide

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

This Operations Guide provides administering and troubleshooting information for Active Directory Federation Services (ADFS) in the Microsoft® Windows Server™ 2003 R2, Enterprise Edition, and Microsoft Windows Server 2003 R2, Datacenter Edition, operating systems (for Federation Service, Federation Service Proxy, and ADFS Web Agent components); and the Microsoft Windows Server 2003 R2, Standard Edition, operating system (for ADFS Web Agent components).

# Introduction to Administering ADFS

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Active Directory Federation Services (ADFS) is a component in Microsoft® Windows Server™ 2003 R2 that provides Web single-sign-on (SSO) technologies that allow the authentication of a user to multiple Web applications over the life of a single online session. ADFS accomplishes SSO by securely sharing digital identity and entitlement rights, or claims, across security and enterprise boundaries.

ADFS provides a robust environment that requires few frequent maintenance tasks. However, in operating a federation environment, you might have to perform certain tasks on a regular basis and others only as needed. This guide provides information and instructions for performing such tasks.

**Planning for ADFS Operations**

Operating Active Directory Federation Services (ADFS) consists of tasks and procedures for updating configurations for ADFS components as well as the installed applications and Windows components, including Windows Certificate Services, Internet Information Services (IIS), Active Directory directory service, and Active Directory Application Mode (ADAM).

When managing ADFS operations, you will need to update configurations for the ADFS components, including the ADFS servers (including federation servers and federation server proxies), ADFS Trust Policy, ADFS Web Agents, ADFS partnerships, ADFS account stores, and ADFS claims.

Before you begin, prepare a plan that establishes a baseline operating environment and addresses operational needs and actions.

To plan your ADFS operations environment, perform the following tasks:

- Assess your IT environment and establish a baseline.
- Determine your operational needs.

**Assess Your IT Environment and Establish a Baseline**

- Understand the details of the federated Web sites and partners that the ADFS deployment must support to effectively and securely operate ADFS servers. For information about planning for specific ADFS scenarios, see the Active Directory Federation Services Design Guide (http://go.microsoft.com/fwlink/?LinkId=63486).
- Review any service specifications that were produced during the planning and deployment process, along with any service-level requirements defined in service level agreements between partner IT organizations.

You will need to understand the following environmental conditions and requirements when you establish your operations baseline and to accommodate growth and modifications to your IT environment:

- Supported partners: When using ADFS, you are usually working with partner organizations. When establishing identity federation, determine the organizations with which you want to form a partnership. After a baseline ADFS deployment is in place, operating with partners involves adding partners, deleting partners, and updating partner information. Changes to partnerships can be required for a variety of reasons. For example, your ADFS deployment might require partnership updates if your partner changes its business significantly, your organization becomes part of a larger organization or a federation of organizations, or your organization is acquired by a different company. In any scenario where you are federating identities from multiple domains, you will need to be aware of the domains (partners) that you are currently supporting and all additional domains that represent potential partners.
- Supported application types: Some ADFS applications require access to operating system resources, while others are "claims aware." It is important to understand the type of applications that ADFS will support so that administration requirements can be formulated.
- Logical and physical architectural diagrams or deployment topology: You will need to know whether ADFS is working in a set of farmed servers or a single server. You must understand where your network deploys firewalls and proxies. You

must also be aware of the location of resources and whether the users are accessing resources from within your organization or from outside the organization, or both.

- Certificate and trust information: You should understand how the certificates in the environment have been acquired and used. For example, it is important to understand whether the certificates follow a chain up to a root certification authority (CA) and how your certificates are obtained so that you can address certificate renewals. It is important to understand how certificate revocation works in your environment.

- User account management requirements: You must understand how users gain access to resources in your environment, whether external users have access to resources in your domain, and whether you have enabled fine-grained control or are leveraging groups to dictate access control.

Data for these conditions provide a starting point for establishing a baseline for the operations environment and for setting the proper level of service.

**Determine Operational Needs**
Performing operations require that tasks are assigned to the appropriate server administrators on the teams that support the ADFS deployment. The ADFS operations team must establish processes for managing the following ADFS components and their related configurations:

- Federation Service:

    - If you find that the federation server or server farm is not meeting scalability, performance, or reliability requirements, you can add an additional federation server.

    - If you want to monitor access or diagnose failures, you can modify certain logging settings at the federation server.

    - Many federation server tasks encompass establishing and managing partnerships, resources, and accounts, as explained later in this topic.

- Federation Service Proxy (optional):

    - If you find that the federation server proxy or server farm is not meeting scalability, performance, or reliability requirements, you can add an additional federation server proxy.

    - You might add a proxy to an existing deployment as part of enabling Internet access to your existing resources.

    - If the client authentication model changes, you can change the federation server proxy to handle this authentication model.

- Federated application(s):

    - When you add a new Web application that is protected by ADFS--for example, if your organization has a new Web site for purchase order management--you will need to add the application to the ADFS deployment.

    - When the type of user information that the application requires to make its decisions changes, you will need to update claims in your ADFS deployment.

    - When the URL for the application changes, you will need to update URLs in your ADFS deployment.

- Partnerships:

    - When establishing a new relationship due to acquisitions, mergers, business contracts, and so on, you will need to add and remove partnerships in your ADFS deployment.

    - When changing an existing business relationship, you might need to update properties in your ADFS partnership.

- Accounts:
    - In federated scenarios where the application is a Windows NT token-based application, you will need to manage resource groups in the resource partner.
    - When you establish a new relationship, you will need to add additional accounts to your account store.
    - When additional users and groups need access to an existing application, you will need to add these accounts to your account store.

**When to Use This Guide**
You should use this guide when:

- You have ADFS deployed in a test or production environment.
- You want to add or remove ADFS components.
- You want to make changes to the configuration of ADFS components.
- You want to add or remove Web applications that authenticate through ADFS.

This guide assumes a basic understanding of ADFS, how it works, and why your organization uses it to federate Web applications. You should also have a thorough understanding of how ADFS is deployed and managed in your organization, including an understanding of the mechanism your organization uses to configure and manage ADFS settings. To learn about ADFS concepts and scenarios, see the following ADFS documentation:

- Overview of ADFS (http://go.microsoft.com/fwlink/?LinkId=63491)
- Active Directory Federation Services (ADFS) (http://go.microsoft.com/fwlink/?LinkId=57765)
- Active Directory Federation Services Design Guide (http://go.microsoft.com/fwlink/?LinkId=63486)

This guide can be used by organizations that have deployed Microsoft Windows Server 2003 R2. It includes information that is relevant to different roles within an IT organization, including IT operations management and administrators. It contains high-level information that is required to plan an ADFS operations environment. This information provides management-level knowledge of ADFS and the IT processes required to operate it.

In addition, this guide contains more detailed procedures that are designed for operators who have varied levels of expertise and experience. Although the procedures provide operator guidance from start to finish, operators must have a basic proficiency with the Microsoft Management Console (MMC) and snap-ins and know how to start administrative programs and access the command line. If operators are not familiar with ADFS, it might be necessary for IT planners or IT managers to review the relevant operations in this guide and provide the operators with parameters or data that must be entered when the operation is performed.

**How to Use This Guide**
The operations areas are divided into the following types of content:

- Tasks pertain to group-related procedures and provide general guidance for achieving the goals of an objective. In this guide, "Managing ADFS Web Agents and Applications" is an example of a task.
- Procedures provide step-by-step instructions for completing tasks. In this guide, "Add an ADAM account store" is an example of a procedure topic.

If you are an IT manager who will be delegating tasks to operators within your organization, you will want to:

- Read through the tasks to determine whether you need to install tools before operators perform the procedures for each

task.

- Before assigning tasks to individual operators, ensure that you have all the tools installed where operators can use them.

- When necessary, create "tear sheets" for each task that operators perform in your organization. Cut and paste the task and its related procedures into a separate document, and then either print these documents or store them online, depending on the preference of your organization.

**Technologies and Terminology Used in This Guide**

Active Directory Federation Services (ADFS) uses terminology from several different technologies, including certificate services, Internet Information Services (IIS), Active Directory, Active Directory Application Mode (ADAM), and Web Services (WS*).

For more information about these technologies, see:

- Certificate services: Public Key Infrastructure for Windows Server 2003 (http://go.microsoft.com/fwlink/?LinkId=19936) and Public Key Infrastructure (http://go.microsoft.com/fwlink/?LinkId=54917).

- IIS: Windows Server Internet Information Services (IIS) (http://go.microsoft.com/fwlink/?LinkId=63492).

- Active Directory: Active Directory Collection in the Microsoft Windows Server 2003 Technical Reference on (http://go.microsoft.com/fwlink/?LinkId=63494).

- ADAM: Active Directory Application Mode Technical Reference (http://go.microsoft.com/fwlink/?LinkId=63506).

- Web Services: Security Specifications (http://go.microsoft.com/fwlink/?LinkId=44191).

For a list of ADFS terms and definitions, see Terminology used in ADFS (http://go.microsoft.com/fwlink/?LinkId=63507).

# Managing ADFS Components

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Active Directory Federation Services (ADFS) has three components:

- Federation Service: Functions as a security token service and routes authentication requests from external user accounts in partner organizations and clients on the Internet.
- Federation Service Proxy: Functions as a proxy for the Federation Service in a perimeter network. This component is optional in an ADFS deployment.
- ADFS Web Agent: Provides authorization (consumes security tokens) and either allows or denies access to two types of Web applications, as follows:
    - Claims-aware applications: Makes authorization decisions based on claims.
    - Windows NT token-based applications: Uses Windows-based authorization mechanisms.

The following objectives are part of managing ADFS components:

- Managing the Federation Service
- Managing the Federation Service Proxy (Optional)
- Managing ADFS Web Agents and Applications
- Backing Up ADFS Components

**See Also**
**Other Resources**
Understanding ADFS Components

# Managing the Federation Service

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

The Federation Service component of Active Directory Federation Services (ADFS) functions as a security token service. The act of installing the Federation Service component on a computer makes that computer a federation server.

The following objectives are part of managing the Federation Service:

- Managing a Federation Server Farm
- Managing Trust Policy on Federation Servers
- Managing Certificates Used by Federation Servers

**See Also**
**Concepts**
Managing the Federation Service Proxy (Optional)
Managing ADFS Web Agents and Applications
Backing Up ADFS Components

# Managing a Federation Server Farm

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

To provide load-balancing of security services in larger Active Directory Federation Services (ADFS) deployments, you can install additional federation servers. A Federation Service must be able to verify tokens issued by all federation servers in that farm. To accomplish this verification, the Federation Service uses verification certificates. Therefore, implementing a server farm requires you to configure verification certificates in the shared trust policy for every token-signing certificate that is in use by any server in the farm.

The following properties are shared by all federation servers in a server farm:

- TrustPolicy.xml file: This file contains the information for a Federation Service. This file must be accessible to all servers in the server farm, either by location in a shared directory or by using a file distribution method that ensures the replication of updates, such as Distributed File System (DFS).

- Certificate: Federation servers in the farm can each use a different token-signing certificate, or they can all use the same certificate. When using the same certificate, every federation server must have its own local copy of that certificate configured in the certificate store, with access to the private key.

- Account store: All servers recognize the same Active Directory domain or Active Directory Application Mode (ADAM) store for user authentication.

The following tasks for managing a Federation Service server farm are described in this objective.

- Changing the Location of the ADFS Directory

- Implementing a Server Farm of Federation Servers

- Adding a New Federation Server

- Removing a Federation Server

Distributed File System (DFS)

# Changing the Location of the ADFS Directory

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

To change the Active Directory Federation Services (ADFS) directory to another location, you can perform the following procedure on a federation server or federation server proxy. The default location for the directory is C:\ADFS.

| **Important** |
| --- |
| Microsoft does not support changing the location of the ADFS directory. If you alter its location, we cannot guarantee that you can upgrade normally to future versions of Windows operating systems or that ADFS will function after you upgrade. |

To complete this procedure, you must finish all of the following steps in the order that they are presented:

1. Copy the contents of the ADFS directory to the new location.
2. Change the virtual directory path in Internet Information Services (IIS) Manager.
3. Modify the registry to point to the new ADFS directory.

| **Caution** |
| --- |
| Incorrectly editing the registry may severely damage your system. Before making changes to the registry, back up any valued data on the computer. |

### Administrative credentials

Membership in **Administrators**, or equivalent, is the minimum required to complete this procedure. Review details about using the appropriate accounts and group memberships at Local and Domain Default Groups (http://go.microsoft.com/fwlink/?LinkId=83477).

#### Copy the contents of the ADFS directory to the new location

1. Start Windows Explorer, and then create a new directory named ADFS in the desired location on the computer.
2. Copy the contents of the C:\ADFS directory (including subfolders) to the new location.

| **Important** |
| --- |
| If you plan to upgrade the Windows Server operating system to a newer version in the future, leave the C:\ADFS directory intact. To do so, copy, rather than move, the directory to the new location. |

#### Change the virtual directory path in IIS Manager

1. Click **Start**, point to **Administrative Tools**, and then click **Internet Information Services (IIS) Manager**.
2. Double-click *YourComputerName***(local computer)**, double-click **Web Sites**, and then double-click **Default Web Site**.
3. In the list of virtual directories, right-click **adfs**, and then click **Properties**.
4. On the **Virtual Directory** tab, in **Local path**, type the path to the new ADFS\STS directory, and then click **OK**.

   For example, if you want to move the directory to D:, type **d:\adfs\sts** in **Local path**.

#### Modify the registry to point at the new ADFS directory

1. Open Registry Editor (Regedit.exe).
2. Navigate to the **HKEY_LOCAL_MACHINE_SYSTEM\Microsoft\WebSSO** registry key.
3. Right-click **InitialDirectory**, click **Modify**, under **Value data**, type the path to the new ADFS directory, and then click

**OK**.

For example, if you want to move the directory to D:, then type **d:\adfs** in **Value data**.

4. Close Registry Editor.

# Implementing a Server Farm of Federation Servers

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

You can implement a server farm of servers that are running the Federation Service component of Active Directory Federation Services (ADFS) by appropriately installing and configuring token-signing certificates. Use the following options when installing the certificate and the Federation Service to implement a federation server farm:

- During installation of the token-signing certificate for a server, if you select the option to install the certificate into the local certificate store, the certificate becomes available during installation of the Federation Service.
- During installation of the Federation Service, the Windows Components Wizard provides options that affect how the token-signing certificate is configured:
    - Select token-signing certificate: You can use this option to select the installed token-signing certificate from the local certificate store.
    - Use an existing trust policy: If you select this option, ADFS automatically adds the public portion of the selected token-signing certificate to the shared trust policy of the Federation Service as the verification certificate.

Use the following methods for installing and sharing certificates to implement a federation server farm:

- Use a separate token-signing certificate for each server and generate the respective verification certificates during Federation Service installation:
    - Install a separate token-signing certificate on each server.
    - During Federation Service installation, select the installed certificate and the shared trust policy.
- Share both public and private portions of the same certificate by using an image of the server:
    - Install a token-signing certificate on one server.
    - During Federation Service installation, select the installed certificate and the shared trust policy.
    - Create an image of this server and use this image to create all additional servers in the server farm.
- Share both public and private portions of the same certificate by importing the certificate file that is provided by a public certification authority (CA) into the local certificate store.
    - Obtain a token-signing certificate from a public CA.
    - Use physical media to import the certificate into the local certificate store of each server.
    - During Federation Service installation, select the CA-provided token-signing certificate and the shared trust policy file.
- Share both public and private portions of the same certificate by exporting the private key:
    - Install a single token-signing certificate from an enterprise CA on a server and export the private key. This method requires that the token-signing certificate was generated and placed directly into the local certificate store by the enterprise CA and that private keys were marked as exportable.
    - Export the private key certificate to a file and protect it accordingly.

- Prior to Federation Service installation, import the exported private key certificate into the local certificate store on each additional server.

- During Federation Service installation, select the imported certificate and the shared trust policy. It is not necessary to export the public key because the trust policy is shared.

Completion of this task is accomplished during the course of Adding a New Federation Server.

Managing Token-signing Certificates
Rolling Over a Token-signing Certificate

# Adding a New Federation Server

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When you want to add a new federation server to an existing Active Directory Federation Services (ADFS) deployment, you must configure the server as an application server, install and configure certificates, and install the Federation Server component of ADFS according to the method of implementing a server farm that you are using. You can also set event logging according to server needs.

**Task requirements**

You need the following to perform the procedures for this task:

| **Note** |
| --- |
| If an existing server image is being used to prepare the additional federation server, procedures in this task are not required. Use your imaging software to create a new federation server. |

- An installed Secure Sockets Layer (SSL) certificate. For information about how to acquire SSL certificates, see Obtaining Server Certificates (http://go.microsoft.com/fwlink/?LinkId=62479).
- If the token-signing certificate is shared among servers in the server farm, an existing token-signing certificate for the Federation Service.
- An existing Federation Service.
- The location of the shared Trustpolicy.xml file for the Federation Service.

To complete this task, perform the following procedures:

1. Install prerequisite applications.
2. If an existing token-signing certificate private key is shared among the servers in the server farm, go to step 3.

   If a new token-signing certificate is to be installed into the local certificate store on the new server, install a token-signing certificate on the new server, as follows:

   - If you are using Microsoft Certificate Services as an enterprise certification authority (CA), obtain a new client authentication certificate. For more information about obtaining a client authentication certificate, see Submit an advanced certificate request via the Web to a Windows Server 2003 CA (http://go.microsoft.com/fwlink/?LinkId=64020). Specify installing the certificate into the local certificate store.
   - If you are using a different enterprise CA or a public CA, follow the instructions provided by the CA.
   - Alternatively, Create a self-signed, token-signing certificate.
3. Configure the token-signing certificate according to the method of server farm implementation you are using:

   - If you installed a separate token-signing certificate into the local certificate store and are not sharing the private key, no other certificate configuration is required prior to Federation Service installation.
   - If you are sharing the public and private portions of the same certificate that has been provided by a public certification authority (CA), import the certificate to the local certificate store prior to Federation Service installation. For instructions to import the certificate, see Import a certificate (http://go.microsoft.com/fwlink/?linkid=20040).

- If you are sharing the public and private portions of the same exportable certificate that has been provided by an enterprise CA, import the private key into the local certificate store by performing the following procedures prior to Federation Service installation:

  Export the private key portion of a token-signing certificate.

  Import a certificate from the Microsoft Web site (http://go.microsoft.com/fwlink/?linkid=20040).

4. Install the Federation Service on an additional federation server

5. Configure event logging on a federation server

# Install prerequisite applications

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Active Directory Federation Services (ADFS) requires that the following applications be installed on a computer running Windows Server 2003 R2, Enterprise Edition, or Windows Server 2003 R2, Standard Edition, (only for servers hosting the ADFS Web Agent) so that the computer can host the Federation Service, Federation Service Proxy, or ADFS Web Agent components of ADFS:

- Internet Information Services (IIS)
- Microsoft .NET Framework 2.0
- Microsoft ASP.NET (required for claims-aware applications only)

When you add the Application Server Windows component, these three applications are installed.

**Administrative credentials**

To complete this procedure, you must be a member of the local Administrators group.

**To add the Application Server Windows component**

1. Click **Start**, point to **Control Panel**, and then click **Add or Remove Programs**.
2. In **Add or Remove Programs**, click **Add/Remove Windows Components**.
3. In the **Windows Components Wizard**, select the **Application Server** check box, and then click **Next**.
4. On the **Completing the Windows Components Wizard** page, click **Finish**.

# Create a self-signed, token-signing certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

You can use the following procedure to create a self-signed, code-signing certificate that also creates and installs a private key. To perform this procedure, use the Makecert.exe utility. Makecert.exe is available in the Microsoft .NET Framework 2.0 Software Development Kit (SDK) (x86) (http://go.microsoft.com/fwlink/?LinkId=79548).

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To create a self-signed, token-signing certificate**

1. Open a command prompt.
2. Type the appropriate **makecert** syntax.
   - Example command:

**makecert -r -pe -n "CN=CertForADFS" -b 01/01/2006 -e 01/01/2007 -eku 1.3.6.1.5.5.7.3.3 -ss my -sr localMachine -sky exchange -sp "Microsoft RSA SChannel Cryptographic Provider" -sy 12 "CertForADFS.cer"**

| **Note** |
| --- |
| Track certificate expiration dates to make sure that certificates are replaced before they expire. You can do this using the Active Directory Federation Services snap-in for certificates of the current organization and also for partners that you configure in the trust policy. |

# Export the private key portion of a token-signing certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Every federation server in an Active Directory Federation Services (ADFS) server farm must have access to the private key of the token-signing certificate. If you are implementing a server farm of federation servers that share a single, exportable private key certificate that is issued by an enterprise certification authority (CA), the private key portion of the existing token-signing certificate must be exported to make it available for importing into the certificate store on the new server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To export the private key of a token-signing certificate**

1. Click Start, point to Administrative Tools, and then click **Active Directory Federation Services**.
2. Right-click **Federation Service**, and then click **Properties**.
3. On the **General** tab, click **View**.
4. In the **Certificate** dialog box, click the **Details** tab.
5. On the **Details** tab, click **Copy to File**.
6. On the **Welcome to the Certificate Export Wizard** page, click **Next**.
7. On the **Export Private Key** page, select **Yes, export the private key**, and then click **Next**.
8. On the **Export File Format** page, select **Personal Information Exchange = PKCS #12 (.PFX)**, and then click **Next**.
9. On the **Password** page, type and confirm the password that is required to share the token-signing certificate. You will need this password when you select the exported token-signing certificate when installing the Federation Service.
10. On the **File to Export** page, specify the certificate file, and then click **Next**.
11. On the **Completing the Certificate Export Wizard** page, click **Finish**.
12. Validate the success of your export by confirming that the file you specified is created at the specified location.

| **Important** |
| --- |
| So that this certificate can be imported to the local certificate store on the new server, you must transfer the file to physical media and protect its security during transport to the new server. It is extremely important to guard the security of the private key. |

13. Import the exported certificate into the certificate store on the new server prior to installing the Federation Service. For information about how to import the certificate, see Import a certificate (http://go.microsoft.com/fwlink/?linkid=20040).

Implementing a Server Farm of Federation Servers

# Install the Federation Service on an additional federation server

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When you install an additional federation server in a server farm, you add the Federation Service component of Active Directory Federation Services (ADFS) and use the trust policy file that is used by other federation servers in the server farm. A token-signing certificate must have been installed or imported into the local certificate store. The trust policy file must also be available on the network.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To install the Federation Service component of ADFS on an additional server**

1. Click **Start**, point to **Control Panel**, and then click **Add or Remove Programs**.
2. In **Add or Remove Programs**, click **Add/Remove Windows Components**.
3. In the Windows Components Wizard, select the **Active Directory Services** check box, and then click **Details**.
4. In the **Active Directory Services** dialog box, select the **Active Directory Federation Services (ADFS)** check box, and then click **Details**.
5. In the **Active Directory Federation Services (ADFS)** dialog box, select the **Federation Service** check box, and then click **OK**. If a message appears stating that ASP.NET 2.0 was not previously enabled, click **Yes** to enable it, and then click **OK**.
6. In the **Active Directory Services** dialog box, click **OK**.
7. In the Windows Components Wizard, click **Next**.
8. On the **Federation Service** page, click **Select token signing certificate**, and then click **Select** to select the appropriate token-signing certificate from the local certificate store.
9. In the **Select Certificate** dialog box, click the exported token-signing certificate, and then click **OK**.
10. Under **Trust policy**, click **Use an existing trust policy**, and then click **Browse**.
11. In the **Browse** dialog box, click the shared TrustPolicy.xml file, and then click **Open**.
12. If you are prompted for the location of the installation files, navigate to *R2 Installation Folder*\cmpnents\r2, and then click **OK**.
13. On the **Completing the Windows Components Wizard** page, click **Finish**.

Export the private key portion of a token-signing certificate

# Configure event logging on a federation server

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Servers that are running the Federation Service component of Active Directory Federation Services (ADFS) log ADFS Federation Service events in the Application event log. These events report information about the operation of the components of the local organization and the partner organizations that are covered by a trust policy.

| **Note** |
| --- |
| When it is manually configured, ADFS also can log debug information. Debug logs are located in *%systemdrive%*\ADFS\logs. For more information about how to configure debug logging, see Configuring ADFS Servers for Troubleshooting (http://go.microsoft.com/fwlink/?LinkId=74970). |

The following types of events are available and enabled by default in ADFS:

- **Error:** Information about a significant problem of which the user should be aware, usually involving a loss of functionality or data.
- **Warning:** Indicates a problem that is not immediately significant, but that may signify conditions that could cause future issues.
- **Info:** Information about a significant, successful operation.
- **Success audit:** Indicates an audited security event when an audited access attempt is successful; for example, a successful logon attempt.
- **Failure audit:** Indicates a security event that occurs when an audited access attempt fails; for example, an inbound token was not valid.
- **Detailed success:** A success audit event with detailed information about each token involved in the transaction, including claims information.
- **Detailed failure:** A failure audit event with detailed information about each token involved in the transaction, including claims information.

You can select the levels that you want to enable and disable.

| **Note** |
| --- |
| Audit object access must be turned on for success or failure to allow the Federation Service to log errors. For more information, see Audit object access (http://go.microsoft.com/fwlink/?LinkId=79749). |

### Administrative credentials

To complete this procedure, you must be a member of the Administrators group on the local computer.

#### To change the event types that are logged by ADFS

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click the **Trust Policy** node, and then click **Properties**.
3. Scroll to the **Event Log** tab.
4. Under **Event log level**, click to select and deselect event log types, and then click **OK**.

# Removing a Federation Server

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When you no longer need a server that is running the Federation Service component of Active Directory Federation Services (ADFS), perform the following procedures:

- Remove the Federation Service ADFS component, as described in Remove an ADFS component.
- If you have a federation server farm and the trust policy is shared on the network, disconnect the mapped network drive for the connection to the shared trust policy folder.
- Delete the token-signing certificate from the certificate store. For information about how to delete a certificate from a certificate store, see Delete a certificate (http://go.microsoft.com/fwlink/?LinkId=62715.
- If this is the only instance of the Federation Service, do the following:
    - Notify the partner that this issuer is no longer valid and tell them to remove the partner node for this Federation Service, as described in Removing ADFS Partners.
    - Decommission the Web server and change the authentication for any Web applications.

# Remove an ADFS component

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If you want to remove a server that is running the Federation Service or Federation Service Proxy component of Active Directory Federation Services (ADFS) from a Federation Service, use the following procedure to remove the respective ADFS component.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To remove an ADFS component**

1. Click **Start**, point to **Control Panel**, and then click **Add or Remove Programs**.
2. In **Add or Remove Programs**, click **Add/Remove Windows Components**.
3. In the Windows Components Wizard, select the **Active Directory Services** check box, and then click **Details**.
4. In the **Active Directory Services** dialog box, select the **Active Directory Federation Services (ADFS)** check box, and then click **Details**.
5. In the **Active Directory Federation Services (ADFS)** dialog box, clear the **Federation Service** check box or the **Federation Service Proxy** check box, and then click **OK**.
6. In the **Active Directory Services** dialog box, click **OK**.
7. In the Windows Components Wizard, click **Next**.
8. On the **Completing the Windows Components Wizard** page, click **Finish**.

# Managing Trust Policy on Federation Servers

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

The Active Directory Federation Services (ADFS) trust policy file defines the set of parameters that a Federation Service requires to identify partners, certificates, account stores, claims, and various properties of these entities that are associated with the Federation Service.

**Task requirements**

You need the following to perform the procedures for this task:

- Active Directory Federation Services MMC snap-in
- TrustPolicy.xml file located in %systemdrive%\ADFS

The following procedures for managing trust policy on federation servers are described in this task. Use these procedures on an as-needed basis.

- Change the Federation Service trust policy location
- Change the Federation Service URI
- Change the Federation Service endpoint URL
- Configure the Federation Service default Web pages
- Change the primary display name for a trust policy
- Change a claims transform module
- Change the token lifetime for a Federation Service
- Change the trust policy refresh period
- Change the Windows domain trust cache refresh period

**See Also**
**Concepts**

# Change the Federation Service trust policy location

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

The TrustPolicy.xml file contains data that defines a Federation Service in Active Directory Federation Services (ADFS). By sharing the folder that contains this file, you make the data available to other federation servers in a federation server farm that comprises the Federation Service.

If the location of the TrustPolicy.xml file changes, make sure that you update the location on each server in the Federation server farm.

Perform this procedure on a federation server that hosts the TrustPolicy.xml file you want to move. After copying the TrustPolicy.xml file to its new location, update the path on each server in the server farm, and then delete the old TrustPolicy.xml file.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the location of the trust policy file**

1. Copy the TrustPolicy.xml file from its current location to its new location and share the folder appropriately. (The default location for TrustPolicy.xml is *%systemdrive%*\ADFS).
2. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
3. Right-click **Federation Service**, and then click **Properties**.
4. On the **General** tab, replace the text in **Trust policy file** with the new path to the TrustPolicy.xml file, or click **Browse** to select it.
5. Confirm the new path in **Trust policy file**, and then click **OK**.
6. Repeat steps 2 through 5 on each federation server in the server farm.
7. After successfully reconfiguring each federation server with the new trust policy location, delete the original trust policy file.

# Change the Federation Service URI

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

In Active Directory Federation Services (ADFS), the Federation Service Uniform Resource Identifier (URI) uniquely identifies a Federation Service. This URI also identifies the federation server farm membership of the federation server. URIs are case-sensitive.

In a federated scenario, the URI that is specified in the properties of the Trust Policy node of a Federation Service also identifies the Federation Service in the properties of the respective account or resource node in the partner organization. Therefore, if you change the URI of a partner Federation Service, you must change its value in the corresponding partner node in the trust policy of the other partner. If the partners are in separate organizations, you must communicate this change to the administrator who makes these changes.

URI values must match according to standard URI comparison rules, as described in Request for Comments (RFC) 3986, "Uniform Resource Identifier (URI): Generic Syntax" (http://go.microsoft.com/fwlink/?LinkId=65481).

| **Note** |
| --- |
| Changes to the Federation Service URI are received by federation servers in the Federation Service through the shared TrustPolicy.xml file. However, this change must be made manually in the corresponding Federation Service of the partner organization. During this time, users who have already signed on using the URI will have to authenticate again if they return to the same Federation Service, such as when they try to access another site. The contents of the cookie in the access token, which lasts 10 hours by default, will no longer match the Federation Service. For this reason, the user will be prompted again for credentials |

Perform the following procedure on a federation server in the Federation Service whose URI you want to change.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the Federation Service URI in the Trust Policy properties**

1. On the federation server whose Federation Service URI you want to change, click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, right-click **Trust Policy**, and then click **Properties**.
3. On the **General** tab, in **Federation Service URI**, type the new URI, and then click **OK**.

The URI value must also be updated in the properties of the corresponding resource or account partner node in the partner Federation Service.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the Federation Service URI in the account partner or resource partner properties**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, and then double-click **Account Partners** if you are logged on to the resource federation server, or double-click **Resource Partners** if you are logged on to the account federation server.
3. Right-click the account or resource partner whose Federation Service URI has changed, and then click **Properties**.
4. On the **General** tab, in **Federation Service URI**, type the new URI, and then click **OK**.

| **Note** |
| --- |
| This URI must match the URI in the trust policy of the corresponding partner organization according to standard URI comparison rules. |

# Change the Federation Service endpoint URL

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

In Active Directory Federation Services (ADFS), the Federation Service endpoint Uniform Resource Locator (URL) is the single location, or "public URL," that is used to contact all federation servers in a server farm. If the public name changes, you must change the Federation Service endpoint URL.

The Federation Service endpoint URL that is specified in the properties of the Trust Policy node of one Federation Service also identifies the Federation Service in the properties of the respective account or resource node in the partner organization. For example, for the account partner Federation Service in an ADFS deployment that has both a resource partner and an account partner, the Federation Service endpoint URL that is specified in the properties of the account partner node on the respective resource federation server must match the Federation Service endpoint URL in the Trust Policy properties on the account federation server. Consequently, if you change the endpoint URL of the Federation Service on the Trust Policy node, an administrator in the partner organization must also change the Federation Service endpoint URL on the corresponding account partner node.

If you install the Federation Service Proxy component of ADFS in a perimeter network, the Federation Service endpoint URL must point to the Federation Service Proxy that forwards requests to the Federation Service. In this case, the Federation Service endpoint URL contains the URL of the Federation Service Proxy rather than the partner Federation Service.

| **Note** |
| --- |
| Changes to the Federation Service endpoint URL are received by federation servers through the shared TrustPolicy.xml file. However, this change must be made manually in the trust policy of the corresponding partner organizations. |

### Administrative credentials

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the Federation Service endpoint URL**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, right-click **Trust Policy**, and then click **Properties**.
3. On the **General** tab, in **Federation Service endpoint URL**, select the domain portion of the URL, replace the selected text with the new URL, and then click **OK**.

Perform the following procedure on the federation server where you are updating the Federation Service URL on the respective account partner or resource partner after it has been changed in the trust policy for the home Federation Service.

### Administrative credentials

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the Federation Service endpoint URL in the account partner or resource partner**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, and then double-click **Account Partners** if you are logged on to the resource federation server, or double-click **Resource Partners** if you are logged on to the account federation server.
3. Right-click the account or resource partner whose Federation Service endpoint URL has changed, and then click **Properties**.
4. On the **General** tab, in **Federation Service endpoint URL**, select the domain portion of the URL, replace the selected text with the new endpoint URL, and then click **OK**.

# Configure the Federation Service default Web pages

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When a Web resource is protected by Active Directory Federation Services (ADFS), three .aspx files specify the default Web pages that are presented before and after access to the resource:

- clientlogon.aspx: This page is presented by the Federation Service or Federation Service Proxy for collecting credentials from the user. It may be in the form of the current Windows credentials using Windows Integrated authentication or Basic authentication, or it might provide for forms-based user name and password entry.

- discoverclientrealm.aspx: This page is presented by the resource Federation Service or Federation Service Proxy when the realm of the client is not known.

- signout.aspx: This page is presented by the resource Federation Service or Federation Service Proxy after the user signs out of the resource Web page.

The default location of these files on federation servers and federation server proxies is %systemdrive%\ADFS\sts\ls.

You can change the names of these files, but the location of the files must be %systemdrive%\ADFS\sts\ls or a subdirectory of this location. Use Windows Explorer to change the file names or locations, and then change their location in the Active Directory Federation Services snap-in.

Perform this procedure on a federation server or federation server proxy.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the Federation Service default Web pages**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click **Federation Service** on a federation server, or **Federation Service Proxy** on a federation server proxy, and then click **Properties**.
3. On the **Web Pages** tab, change the names of the files in **Client logon page**, **Account partner discovery page**, or **Client logoff page**, and then click **OK**.
4. Validate the effect of the change by performing an action on the Web application. Verify that you receive the new logon page.

| **Note** |
| --- |
| In certain cases (for example, when you are using existing facilities offered by ADFS and IIS for authentication), you might additionally need to copy IIS settings related to authentication, as well as the auth directory (%systemdrive%\ADFS\sts\ls\auth*) where ADFS stores the different files that leverage IIS authentication. For example, ...\auth\integrated stores files that are used for integrated authentication using Windows credentials. Similarly, ...\auth\sslclient stores files that are used for SSL authentication. |

# Change the primary display name for a trust policy

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Each Federation Service in an Active Directory Federation Services (ADFS) deployment has a primary display name. The discoverclientrealm.aspx page displays these names during logon so that the user can select the correct account realm for his organization.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the primary display name for a trust policy**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, right-click the **Trust Policy** node, and then click **Properties**.
3. Click the **Display Name** tab.
4. In **Display name for this trust policy**, type the new primary display name, and then click **OK**.

# Change a claims transform module

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

You can configure servers that are running the Federation Service component of Active Directory Federation Services (ADFS) to use a claims transform module to manage claims. If you use a claims transform module and you make a change to the class name that the transform module uses, use the following procedure to make the change in the trust policy.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the claims transform module**

1. On the federation server whose transform module you want to change, click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, right-click **Trust Policy**, and then click **Properties**.
3. In the **Trust Policy Properties** dialog box, click the right arrow to scroll to the **Transform Module** tab, and then click the **Transform Module** tab.
4. In **DLL file**, type the path to the dynamic-link library (DLL) file, or click **Browse** to select it.
5. In **Class name**, type the namespace-qualified class name that the transform module will use, and then click **OK**.

**See Also**
**Concepts**
Configure a claims transform module

# Change the token lifetime for a Federation Service

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Each server that is running the Federation Service component of Active Directory Federation Services (ADFS) issues Security Assertion Markup Language (SAML) tokens. These security tokens are transferred between clients and federation servers within authentication cookies. Authentication cookies can be issued by both the Federation Service and the ADFS Web Agent.

| **Note** |
| --- |
| At the Federation Service, the security token in an authentication cookie holds the organization claims for the client. For more information about SAML tokens, see WS-Federation: Passive Requestor Profile (http://go.microsoft.com/fwlink/?LinkId=64813). |

After the Federation Service validates the client once, the authentication cookie is written to the client. Further authentication takes place through use of the cookie rather than through repeated authentication of the client credentials. In this way, the authentication cookie facilitates single sign-on (SSO). The period of time that this authentication cookie can be used by the client is configurable in the trust policy of the Federation Service as the "token lifetime."

| **Note** |
| --- |
| Authentication cookies are not used by federation server proxies. For more information about federation server proxies, see Federation Service Proxy (http://go.microsoft.com/fwlink/?LinkId=62784). |

The default value for token lifetime is 600 minutes, or 10 hours. The minimum value is one minute.

| **Caution** |
| --- |
| If you set the token lifetime value too low, the SSO experience of extranet users is degraded. Users will be forced to authenticate again in a forms-based logon as soon as the cookie expires. Only internal corporate users who use integrated authentication will continue to experience single sign-on. |

### Administrative credentials

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the token lifetime for a trust policy**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click the **Trust Policy** node, and then click **Properties**.
3. Scroll to the **Advanced** tab, and then click the **Advanced** tab.
4. In **Token lifetime (minutes)**, type or scroll to a new number of minutes, and then click **OK**.

**See Also**
**Concepts**
Change the trust policy refresh period
Change the Windows domain trust cache refresh period
Change the token lifetime for an application

# Change the trust policy refresh period

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Each Active Directory Federation Services (ADFS) component uses the trust policy refresh period to determine how often the component checks for changes to the trust policy, and loads the trust policy if it has changed. The default value for this setting is 60 minutes. The minimum value is five minutes.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the trust policy refresh period**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click **Trust Policy**, and then click **Properties**.
3. Scroll to the **Advanced** tab, and then click the **Advanced** tab.
4. In **Trust policy refresh period (minutes)**, type or scroll to a new number of minutes, and then click **OK**.

# Change the Windows domain trust cache refresh period

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

On a server that is running the Federation Service component of Active Directory Federation Services (ADFS), the refresh period of the Windows domain trust cache specifies how often the Federation Service refreshes Windows trust information. The default value is 60 minutes.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the refresh period for the Windows domain trust cache**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click **Trust Policy**, and then click **Properties**.
3. Scroll to the **Advanced** tab, and then click the **Advanced** tab.
4. In **Windows domain trust cache refresh period (minutes)**, type or scroll to a new number of minutes, and then click **OK**.

# Managing Certificates Used by Federation Servers

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Servers that are running the Federation Service component of Active Directory Federation Services (ADFS) are required to use the following types of certificates:

- Secure Sockets Layer (SSL) server authentication certificates: Federation servers use SSL server authentication certificates to secure Web services traffic for communication with Web clients and federation server proxies. If you use a standalone certification authority (CA) specifically for your ADFS deployment, you need to manually request, download, and install SSL certificates. These certificates are requested and installed through the Internet Information Services (IIS) snap-in. For more information about using SSL certificates, see Configuring Secure Sockets Layer (http://go.microsoft.com/fwlink/?LinkId=62785) and Obtaining Server Certificates (http://go.microsoft.com/fwlink/?linkid=62479).

- Token-signing certificates: Each federation server uses a token-signing certificate to digitally sign all security tokens that it produces. A token-signing certificate can be any certificate that has a digital signature key usage (KU), such as a server authentication certificate or code-signing certificate. Enhanced key usage (EKU) is not required for token-signing certificates. For best results, use a certificate other than the SSL server authentication certificate that you installed on the federation server. Token-signing certificates are installed differently, depending on the server farm method, as follows:

    - For the first server in the Federation Service, a token-signing certificate must be requested and installed. You can install a token-signing certificate by connecting to an enterprise CA, a public CA (for example, Verisign), or by creating a self-signed certificate. For information about installing token-signing certificates when using Microsoft Certificate Services as your enterprise CA, see Submit an advanced certificate request via the Web to a Windows Server 2003 CA (http://go.microsoft.com/fwlink/?linkid=64020). For information about installing a token-signing certificate from a public CA, contact your public CA. For information about creating self-signed certificates, see Create a self-signed, token-signing certificate.

    - For additional federation servers within a single server farm, you can reuse the same token-signing certificate by sharing its private key, or you can create a unique certificate for each server. When multiple certificates are used, each server in that farm signs tokens with a unique private key. However, you must configure each server with the public keys from all servers in that farm by adding public keys for all certificates to the trust policy as verification certificates.

- Verification certificates: Verification certificates are the public key portion of the token-signing certificates of federation servers, and are used to ensure that the security token was issued by a trusted federation server and that it was not modified. Each federation server requires a verification certificate for every token-signing certificate that should be accepted when presented to that federation server, including its own token-signing certificate. In a federated scenario, verification certificates are also associated with each account partner to verify tokens that claim to be issued by that partner's federation server(s). In farmed scenarios where each federation server uses a different token-signing certificate, there must be a verification certificate that corresponds to each of those servers. If all token-signing certificates that are issued to a set of federation servers are issued by the same CA, you can use the exported public key of that CA certificate for the verification certificate in the trust policy and for use by partners.

The following tasks for managing certificates on federation servers are described in this objective.

- Managing Token-signing Certificates

- Managing Verification Certificates

- Rolling Over a Token-signing Certificate

# Managing Token-signing Certificates

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Servers that are running the Federation Service component of Active Directory Federation Services (ADFS) in an account Federation Service require token-signing certificates to sign security tokens that the servers produce. You can view and change the current certificate as needed. You can also manage the certificate revocation list (CRL) to ensure that only valid certificates are in use in the Federation Service.

**Task requirements**

You need the following to perform the procedures for this task:

- A Federation Service in an account role
- A certification authority or the ability to create self-signed certificates
- Active Directory Federation Services snap-in

To complete this task, perform the following procedures on an as-needed basis:

- Create a self-signed, token-signing certificate
- View the current token-signing certificate
- Turn CRL checking on or off
- Export the public key portion of a token-signing certificate
- Export the private key portion of a token-signing certificate
- Change the token-signing certificate that a federation server uses

# Create a self-signed, token-signing certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

You can use the following procedure to create a self-signed, code-signing certificate that also creates and installs a private key. To perform this procedure, use the Makecert.exe utility. Makecert.exe is available in the Microsoft .NET Framework 2.0 Software Development Kit (SDK) (x86) (http://go.microsoft.com/fwlink/?LinkId=79548).

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To create a self-signed, token-signing certificate**

1. Open a command prompt.
2. Type the appropriate **makecert** syntax.
   - Example command:

**makecert -r -pe -n "CN=CertForADFS" -b 01/01/2006 -e 01/01/2007 -eku 1.3.6.1.5.5.7.3.3 -ss my -sr localMachine -sky exchange -sp "Microsoft RSA SChannel Cryptographic Provider" -sy 12 "CertForADFS.cer"**

| **Note** |
| --- |
| Track certificate expiration dates to make sure that certificates are replaced before they expire. You can do this using the Active Directory Federation Services snap-in for certificates of the current organization and also for partners that you configure in the trust policy. |

**Concepts**
Rolling Over a Token-signing Certificate
Rolling Over a Client Authentication Certificate

# View the current token-signing certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Each Active Directory Federation Services (ADFS) federation server uses a token-signing certificate to digitally sign all security tokens that it produces. You can view the certificate to check its expiration date, revocation status, and other details.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To view the current token-signing certificate**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click **Federation Service**, and then click **Properties**.
3. On the **General** tab, under **Token-signing certificate**, click **View**.
4. On the **General** tab in the **Certificate** property sheet, assess the validity of the certificate by noting the **Valid from** and **to** dates, and whether the certificate has a private key associated with it, and then click **OK** twice.

# Turn CRL checking on or off

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Certificate revocation list (CRL) checking is the process of searching for revoked certificates on a server. Active Directory Federation Services (ADFS) uses the Cryptographic Application Programming Interface (CAPI) to validate token-signing certificates and to verify that they have been revoked. In ADFS, CRL checking is used only for token-signing certificates. It is turned on by default for federation servers and ADFS-enabled Web servers.

You can use the script that is provided at the end of this topic to turn CRL checking on or off on a per-organization basis to meet your specific security requirements. Depending on how the script is configured, it can turn CRL verification on or off for the organization itself, which applies to both the federation server and the Web server, or for an account partner.

| **Caution** |
| --- |
| Turning CRL checking off is not a security best practice, and it has the potential to compromise your ADFS infrastructure. However, some organizations may choose to disable CRL checking or configure it to behave in a certain way. |

Using this script will not affect CRL settings for Secure Sockets Layer (SSL) certificates that are defined in Internet Information Services (IIS) Manager. The IIS metabase uses the MD_CERT_NO_REVOC_CHECK setting to validate SSL client authentication certificates and server authentication certificates that are sent to a Web server. This IIS setting is not used by clients to validate ADFS token-signing certificates or by ADFS servers to validate partner certificates. For more information about how to disable CRL checking for SSL certificates using IIS, see SSL and Certificates (IIS 6.0) (http://go.microsoft.com/fwlink/?LinkId=73717) on the Microsoft Web Site.

| **Note** |
| --- |
| In scenarios in which ADFS servers do not have connectivity to a CRL distribution point on the Internet and the SSL certificates and token-signing certificates that are assigned to those servers were issued by a public certification authority (CA), you may have to disable CRL checking settings in both IIS (using the topic in the previous paragraph) and in ADFS (using this script) on each of the servers. Otherwise, disabling both of these settings simultaneously is not required. |

Before communication between an ADFS server and a Web browser client can occur, an SSL channel must be established between the ADFS server and the client. For more information about establishing an SSL channel, see SSL and Certificates (IIS 6.0) (http://go.microsoft.com/fwlink/?LinkId=73717) on the Microsoft Web Site.

For more information about certificate revocation, see Certificate Revocation and Status Checking (http://go.microsoft.com/fwlink/?linkid=27081) and RevocationFlags Enumeration (http://windowssdk.msdn.microsoft.com/en-us/library/system.web.security.singlesignon.revocationflags.aspx) on the Microsoft Web site.

The following table briefly describes the various arguments that are used in the script.

| | |
| --- | --- |
| Usage | TpCrlChk.vbs TrustPolicy.xml TrustRealmUri RevocationFlags |

| | |
|---|---|
| Arguments | • TrustPolicy.xml—Full path to the trust policy file<br>• TrustRealmUri—Uniform Resource Identifier (URI) of the trust realm whose setting must be changed<br>• RevocationFlags—One of the following:<br>  • None<br>  • CheckEndCert<br>  • CheckEndCertCacheOnly<br>  • CheckChain<br>  • CheckChainCacheOnly<br>  • CheckChainExcludeRoot<br>  • CheckChainExcludeRootCacheOnly |
| Examples | • Cscript TpCrlChk.vbs TrustPolicy.xml 5—Sets the revocation flags to CheckChainExcludeRoot, which is the recommended default.<br>• Cscript TpCrlChk.vbs TrustPolicy.xml 0—Sets the revocation flags to None, which means no revocation checking will be done. |

**Script Text**

```
'Option Explicit

Dim tpf ' Trust policy factory

# Export the public key portion of a token-signing certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

A token-signing certificate is used by an Active Directory Federation Services (ADFS) federation server to digitally sign all security tokens that it produces. Verification certificates are used by the server that receives the token to validate that the security token was issued by a trusted federation server and that the token was not modified. To provide verification certificates to servers that will be processing tokens issued by the trusted federation servers, you can export the public key portion of the token-signing certificate of a federation server that issues the tokens.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To export the public key portion of a token-signing certificate**

1. Click Start, point to Administrative Tools, and then click **Active Directory Federation Services**.
2. Right-click **Federation Service**, and then click **Properties**.
3. On the **General** tab, under **Token-signing certificate**, click **View**.
4. In the **Certificate** dialog box, click the **Details** tab.
5. On the **Details** tab, click **Copy to File**.
6. On the **Welcome to the Certificate Export Wizard** page, click **Next**.
7. On the **Export Private Key** page, make sure that **No, do not export the private key** is selected, and then click **Next**.
8. On the **Export File Format** page, select **DER encoded binary X.509 (.CER)**, and then click **Next**.
9. On the **File to Export** page, specify the certificate file in **File name**, and then click **Next**.

   | **Note** |
   | --- |
   | So that this certificate can be imported to other federation servers as a verification certificate, you will need to securely transfer the file to administrators in your organization and in the partner organization. |

10. On the **Completing the Certificate Export Wizard** page, click **Finish**.
11. Validate success by checking to see that the file you specified was created at the specified location.

# Export the private key portion of a token-signing certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Every federation server in an Active Directory Federation Services (ADFS) server farm must have access to the private key of the token-signing certificate. If you are implementing a server farm of federation servers that share a single, exportable private key certificate that is issued by an enterprise certification authority (CA), the private key portion of the existing token-signing certificate must be exported to make it available for importing into the certificate store on the new server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To export the private key of a token-signing certificate**

1. Click Start, point to Administrative Tools, and then click **Active Directory Federation Services**.
2. Right-click **Federation Service**, and then click **Properties**.
3. On the **General** tab, click **View**.
4. In the **Certificate** dialog box, click the **Details** tab.
5. On the **Details** tab, click **Copy to File**.
6. On the **Welcome to the Certificate Export Wizard** page, click **Next**.
7. On the **Export Private Key** page, select **Yes, export the private key**, and then click **Next**.
8. On the **Export File Format** page, select **Personal Information Exchange = PKCS #12 (.PFX)**, and then click **Next**.
9. On the **Password** page, type and confirm the password that is required to share the token-signing certificate. You will need this password when you select the exported token-signing certificate when installing the Federation Service.
10. On the **File to Export** page, specify the certificate file, and then click **Next**.
11. On the **Completing the Certificate Export Wizard** page, click **Finish**.
12. Validate the success of your export by confirming that the file you specified is created at the specified location.

| **Important** |
| --- |
| So that this certificate can be imported to the local certificate store on the new server, you must transfer the file to physical media and protect its security during transport to the new server. It is extremely important to guard the security of the private key. |

13. Import the exported certificate into the certificate store on the new server prior to installing the Federation Service. For information about how to import the certificate, see Import a certificate (http://go.microsoft.com/fwlink/?linkid=20040).

Implementing a Server Farm of Federation Servers

# Change the token-signing certificate that a federation server uses

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Each Active Directory Federation Services (ADFS) federation server uses a token-signing certificate to digitally sign all security tokens that it produces. Only one token-signing certificate can be in effect on a federation server. If you have installed a new token-signing certificate on a federation server and you want that certificate to be used, you will need to select that certificate in ADFS.

Perform this procedure on the account or resource federation server whose token-signing certificate you want to change.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the token-signing certificate on a federation server**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click **Federation Service**, and then click **Properties**.
3. On the **General** tab, under **Token-signing certificate**, click **Select**.
4. In the **Select Certificate** dialog box, click the token-signing certificate you want to use, and then click **OK**.
5. In the **Federation Service Properties** dialog box, click **OK**.

   In certain cases, the Federation Service might be running in a different account and you will be prompted to allow this account to have access to the private key. Based on your deployment, give access to the private key for this account.
6. In the **Federation Server Configuration** message box, click **Yes** to add the new certificate to the verification certificates in the trust policy.

   If you have already added this certificate to the trust policy as the verification certificate, you will not be prompted to add this new certificate.
7. On the **General** tab, under **Token-signing certificate**, click **View** to check that the selected certificate is being used.

Rolling Over a Token-signing Certificate

# Managing Verification Certificates

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Servers that are running the Federation Service component of Active Directory Federation Services (ADFS) in a resource Federation Service require verification certificates to validate the security tokens that are produced by any trusted federation servers, including the same federation server.

In a federated scenario, federation servers in a resource partner also re-sign certificates. Therefore, federation servers in an account resource partner must also have verification certificates for certificates that are signed by resource federation servers.

You can add, remove, and view these certificates as needed.

**Task requirements**

You need the following to perform the procedures for this task:

- A federated ADFS deployment
- Exported token-signing certificate
- Active Directory Federation Services snap-in

To complete this task, perform the following procedures on an as-needed basis:

- Add a verification certificate to the trust policy
- Add a verification certificate to an account partner
- View the current verification certificate
- Remove a verification certificate

**See Also**
**Concepts**

# Add a verification certificate to the trust policy

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When a token-signing certificate is replaced on a server that is running the Federation Service component of Active Directory Federation Services (ADFS), the public key portion of the new token must be added as a verification certificate to federation servers that receive tokens from that Federation Service.

This procedure is not usually necessary because the verification certificate is added to the trust policy automatically when you select a token-signing certificate for use by the server. Use this procedure under the following conditions:

- You are restoring an old trust policy from a version that predates the **Valid from** date of the token-signing certificated.
- You answered "No" to the question of whether to add the verification certificate to the trust policy in the procedure to Change the token-signing certificate that a federation server uses.

### Administrative credentials

To complete the procedure in this topic, you must be a member of the Administrators group on the local computer.

**To add a verification certificate to the trust policy**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, right-click **Trust Policy**, and then click **Properties**.
3. Click the **Verification Certificates** tab, and then click **Add**.
4. In the **Browse for Verification Certificate file** dialog box, locate the certificate file that you want to add.
5. Select the certificate file, and then click **Open**.
6. In the **Trust Policy Properties** dialog box, click **OK**.

# Add a verification certificate to an account partner

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When a token-signing certificate is replaced on a server that is running the Federation Service component of Active Directory Federation Services (ADFS), you must export the new token to a file and then add the token to the trust policy that is used by federation servers that receive tokens from that Federation Service. In addition, if the Federation Service is acting in the account role, the verification certificate must be added to the account node in the respective resource partner.

After you export the public portion of the token-signing certificate, use the following procedure to add it as the verification certificate on the account node in the resource partner.

| **Note** |
| --- |
| To prevent downtime, do not remove the existing verification certificate until the new token-signing certificate has been added on the originating federation server. To prevent the need for re-authentication, wait 10 hours (the default lifetime for an access token) or until all access tokens have expired. |

### Administrative credentials

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To add a verification certificate to an account partner**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click Trust Policy, double-click Partner Organizations, double-click Account Partners, right-click the account partner, and then click **Properties**.
3. Click the **Verification Certificates** tab, and then click **Add**.
4. In the **Browse for Verification Certificate file** dialog box, locate the certificate file that you want to add.
5. Select the certificate file, and then click **Open**.
6. In the **Trust Policy Properties** dialog box, click **OK**.

# View the current verification certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

In Active Directory Federation Services (ADFS), verification certificates are used to verify that a security token was issued by a valid federation server and that it was not modified. A verification certificate is an exported copy of the token-signing certificate of any trusted federation server.

Use this procedure to view the certificate when you want to see the information about the verification certificate that is currently being used by a federation server. For example, use this procedure if you want to ensure that the certificate is good, view the server that issued the certificate, or view its date of expiration.

**Administrative credentials**

To complete this procedure , you must be a member of the Administrators group on the local computer.

**To view a verification certificate**

1. On a federation server that hosts the Federation Service for which you want to view verification certificates, click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, right-click **Trust Policy**, and then click **Properties**.
3. Click the **Verification Certificates** tab.
4. Click the certificate that you want to view, and then click **View**.

# Remove a verification certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

After you add a new verification certificate on a server that is running the Federation Service component of Active Directory Federation Services (ADFS), you must remove the old verification certificate. Removing an old verification certificate is part of the prescribed certificate rollover process by which you replace token-signing and verification certificates in a manner that prevents downtime. Use this procedure in accordance with the instructions in "Rolling Over a Token-signing Certificate."

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To remove a verification certificate**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Remove the certificate as follows:
   - If you are removing the verification certificate from the trust policy on an account or resource federation server, double-click **Federation Service**, right-click the **Trust Policy** node, and then click **Properties**.
   - If you are removing the verification certificate from the account partner on a trusting resource federation server, double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, double-click **Account Partners**, right-click the account partner node, and then click **Properties**.
3. Click the **Verification Certificates** tab.
4. Click the certificate that you want to remove, click **Remove**, and then click **OK**.

# Rolling Over a Token-signing Certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When you need to replace a token-signing certificate on a server that is running the Federation Service component of Active Directory Federation Services (ADFS), either due to expiration or suspicion of tampering, use the procedures in this task to roll over the certificate in a manner that eliminates any significant lapse of certificate validity on the servers.

Configure the public key of every certificate that you replace as a verification certificate on any other servers in the same federation server farm. This configuration occurs automatically when you select the token-signing certificate for use on the server. In addition, if the Federation Service is acting in the account role, the certificate must be configured as a verification certificate for the account partner by any trusting resource partners. To accomplish this configuration, you must export the public key of the certificate to make it available for adding to the account partner.

When the same token-signing certificate is shared among multiple servers in a server farm, the private key of the new token-signing certificate must be exported and then imported on all other servers in the server farm. If a different token-signing certificate is installed on each server in the federation server farm, this additional import step is not required and each server uses a unique private key. The public key is always shared as the verification certificate through the trust policy.

**Task requirements**

You need the following to perform the procedures for this task:

- If you are using self-signed certificates, you can use the makecert.exe utility, which is available for download on the Microsoft Web site.
- Active Directory Federation Services MMC snap-in.

To complete this task, perform the following procedures:

1. Install a new token-signing certificate, as follows:
    - If you are using Microsoft Certificate Services as an enterprise certification authority (CA), obtain a new code signing certificate according to the instructions in "Submit an advanced certificate request via the Web to a Windows Server 2003 CA" (http://go.microsoft.com/fwlink/?linkid=64020. Specify installing the certificate into the local certificate store.
    - If you are using a different enterprise CA or a public CA, follow the instructions provided by the CA.
    - Alternatively, Create a self-signed, token-signing certificate.
2. Configure the private key, if needed, on all servers in a server farm where federation servers use the same private key, as follows:
    - If you are implementing a server farm of federation servers that share a single, exportable private key certificate that is issued by an enterprise certification authority (CA) directly into the certificate store, first use the procedure Export the private key portion of a token-signing certificate to make it available for importing into the local certificate stores of the other servers in the farm. Then, on all other servers in the farm, import the exported certificate into the local store.
    - If you are implementing a server farm of federation servers that share a single, exportable private key certificate that is issued by a public certification authority (CA), import the certificate into the local certificate store.

    For information about how to import the certificate into the certificate store, see Import a certificate (http://go.microsoft.com/fwlink/?linkid=22763).

3. If the server is acting in the account role, do the following:

    a. On the federation server for which you obtained a new token-signing certificate in step 1, use the procedure Export the public key portion of a token-signing certificate to create a file that can be used as a verification certificate.

    b. Provide the exported certificate to the resource partner and instruct the resource partner to perform the procedure Add a verification certificate to an account partner to configure the account partner with the new verification certificate.

    c. Confirm that the partner organization has added the new verification certificate.

4. Select the new verification certificate to Change the token-signing certificate that a federation server uses. Newly issued tokens will now use this certificate. This procedure also adds the verification certificate to the trust policy. Perform this procedure as follows:

    - If you are sharing the same token-signing certificate among all servers in the server farm, perform this procedure on one federation server in the server farm.

    - If you are using separate token-signing certificates for each server in the server farm, perform this procedure on each federation server in the server farm.

5. Inform the partner organizations that it is safe to remove the original verification certificate.

6. On all servers on which you selected the new verification certificate in step 4, remove verification certificates, as follows:

    a. Use the procedure Remove a verification certificate to remove the old verification certificate from the trust policy.

    | **Note** |
    | --- |
    | To prevent the need for users who have already logged on to be authenticated again,, wait 10 hours (the default lifetime of an access token for the Federation Service) or until all access tokens have expired before you remove the existing verification certificate. |

    b. In the case of a Federation Service in the account role, instruct the resource partner to remove the old verification certificate from the account partner in the resource Federation Service. In this case, follow the same procedure but use the **Verification Certificates** tab in the account partner node properties instead of the **Trust Policy** node properties.

7. Delete the old token-signing certificate from the certificate store. For information about how to delete a certificate from a certificate store, see Delete a certificate (http://go.microsoft.com/fwlink/?linkid=62715).

Rolling Over a Client Authentication Certificate

# Create a self-signed, token-signing certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

You can use the following procedure to create a self-signed, code-signing certificate that also creates and installs a private key. To perform this procedure, use the Makecert.exe utility. Makecert.exe is available in the Microsoft .NET Framework 2.0 Software Development Kit (SDK) (x86) (http://go.microsoft.com/fwlink/?LinkId=79548).

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To create a self-signed, token-signing certificate**

1. Open a command prompt.
2. Type the appropriate **makecert** syntax.
   - Example command:

**makecert -r -pe -n "CN=CertForADFS" -b 01/01/2006 -e 01/01/2007 -eku 1.3.6.1.5.5.7.3.3 -ss my -sr localMachine -sky exchange -sp "Microsoft RSA SChannel Cryptographic Provider" -sy 12 "CertForADFS.cer"**

| **Note** |
| --- |
| Track certificate expiration dates to make sure that certificates are replaced before they expire. You can do this using the Active Directory Federation Services snap-in for certificates of the current organization and also for partners that you configure in the trust policy. |

Rolling Over a Token-signing Certificate
Rolling Over a Client Authentication Certificate

# Export the public key portion of a token-signing certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

A token-signing certificate is used by an Active Directory Federation Services (ADFS) federation server to digitally sign all security tokens that it produces. Verification certificates are used by the server that receives the token to validate that the security token was issued by a trusted federation server and that the token was not modified. To provide verification certificates to servers that will be processing tokens issued by the trusted federation servers, you can export the public key portion of the token-signing certificate of a federation server that issues the tokens.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To export the public key portion of a token-signing certificate**

1. Click Start, point to Administrative Tools, and then click **Active Directory Federation Services**.
2. Right-click **Federation Service**, and then click **Properties**.
3. On the **General** tab, under **Token-signing certificate**, click **View**.
4. In the **Certificate** dialog box, click the **Details** tab.
5. On the **Details** tab, click **Copy to File**.
6. On the **Welcome to the Certificate Export Wizard** page, click **Next**.
7. On the **Export Private Key** page, make sure that **No, do not export the private key** is selected, and then click **Next**.
8. On the **Export File Format** page, select **DER encoded binary X.509 (.CER)**, and then click **Next**.
9. On the **File to Export** page, specify the certificate file in **File name**, and then click **Next**.

   | **Note** |
   | --- |
   | So that this certificate can be imported to other federation servers as a verification certificate, you will need to securely transfer the file to administrators in your organization and in the partner organization. |

10. On the **Completing the Certificate Export Wizard** page, click **Finish**.
11. Validate success by checking to see that the file you specified was created at the specified location.

Add a verification certificate to an account partner

# Export the private key portion of a token-signing certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Every federation server in an Active Directory Federation Services (ADFS) server farm must have access to the private key of the token-signing certificate. If you are implementing a server farm of federation servers that share a single, exportable private key certificate that is issued by an enterprise certification authority (CA), the private key portion of the existing token-signing certificate must be exported to make it available for importing into the certificate store on the new server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To export the private key of a token-signing certificate**

1. Click Start, point to Administrative Tools, and then click **Active Directory Federation Services**.
2. Right-click **Federation Service**, and then click **Properties**.
3. On the **General** tab, click **View**.
4. In the **Certificate** dialog box, click the **Details** tab.
5. On the **Details** tab, click **Copy to File**.
6. On the **Welcome to the Certificate Export Wizard** page, click **Next**.
7. On the **Export Private Key** page, select **Yes, export the private key**, and then click **Next**.
8. On the **Export File Format** page, select **Personal Information Exchange = PKCS #12 (.PFX)**, and then click **Next**.
9. On the **Password** page, type and confirm the password that is required to share the token-signing certificate. You will need this password when you select the exported token-signing certificate when installing the Federation Service.
10. On the **File to Export** page, specify the certificate file, and then click **Next**.
11. On the **Completing the Certificate Export Wizard** page, click **Finish**.
12. Validate the success of your export by confirming that the file you specified is created at the specified location.

| **Important** |
| --- |
| So that this certificate can be imported to the local certificate store on the new server, you must transfer the file to physical media and protect its security during transport to the new server. It is extremely important to guard the security of the private key. |

13. Import the exported certificate into the certificate store on the new server prior to installing the Federation Service. For information about how to import the certificate, see Import a certificate (http://go.microsoft.com/fwlink/?linkid=20040).

# Add a verification certificate to an account partner

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When a token-signing certificate is replaced on a server that is running the Federation Service component of Active Directory Federation Services (ADFS), you must export the new token to a file and then add the token to the trust policy that is used by federation servers that receive tokens from that Federation Service. In addition, if the Federation Service is acting in the account role, the verification certificate must be added to the account node in the respective resource partner.

After you export the public portion of the token-signing certificate, use the following procedure to add it as the verification certificate on the account node in the resource partner.

| **Note** |
| --- |
| To prevent downtime, do not remove the existing verification certificate until the new token-signing certificate has been added on the originating federation server. To prevent the need for re-authentication, wait 10 hours (the default lifetime for an access token) or until all access tokens have expired. |

### Administrative credentials

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To add a verification certificate to an account partner**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click Trust Policy, double-click Partner Organizations, double-click Account Partners, right-click the account partner, and then click **Properties**.
3. Click the **Verification Certificates** tab, and then click **Add**.
4. In the **Browse for Verification Certificate file** dialog box, locate the certificate file that you want to add.
5. Select the certificate file, and then click **Open**.
6. In the **Trust Policy Properties** dialog box, click **OK**.

Remove a verification certificate

# Change the token-signing certificate that a federation server uses

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Each Active Directory Federation Services (ADFS) federation server uses a token-signing certificate to digitally sign all security tokens that it produces. Only one token-signing certificate can be in effect on a federation server. If you have installed a new token-signing certificate on a federation server and you want that certificate to be used, you will need to select that certificate in ADFS.

Perform this procedure on the account or resource federation server whose token-signing certificate you want to change.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the token-signing certificate on a federation server**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click **Federation Service**, and then click **Properties**.
3. On the **General** tab, under **Token-signing certificate**, click **Select**.
4. In the **Select Certificate** dialog box, click the token-signing certificate you want to use, and then click **OK**.
5. In the **Federation Service Properties** dialog box, click **OK**.

   In certain cases, the Federation Service might be running in a different account and you will be prompted to allow this account to have access to the private key. Based on your deployment, give access to the private key for this account.
6. In the **Federation Server Configuration** message box, click **Yes** to add the new certificate to the verification certificates in the trust policy.

   If you have already added this certificate to the trust policy as the verification certificate, you will not be prompted to add this new certificate.
7. On the **General** tab, under **Token-signing certificate**, click **View** to check that the selected certificate is being used.

Rolling Over a Token-signing Certificate

# Remove a verification certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

After you add a new verification certificate on a server that is running the Federation Service component of Active Directory Federation Services (ADFS), you must remove the old verification certificate. Removing an old verification certificate is part of the prescribed certificate rollover process by which you replace token-signing and verification certificates in a manner that prevents downtime. Use this procedure in accordance with the instructions in "Rolling Over a Token-signing Certificate."

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To remove a verification certificate**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Remove the certificate as follows:
   - If you are removing the verification certificate from the trust policy on an account or resource federation server, double-click **Federation Service**, right-click the **Trust Policy** node, and then click **Properties**.
   - If you are removing the verification certificate from the account partner on a trusting resource federation server, double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, double-click **Account Partners**, right-click the account partner node, and then click **Properties**.
3. Click the **Verification Certificates** tab.
4. Click the certificate that you want to remove, click **Remove**, and then click **OK**.

# Managing the Federation Service Proxy (Optional)

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

The Federation Service Proxy component of Active Directory Federation Services (ADFS) functions as a proxy in a perimeter network (also known as demilitarized zone, extranet, or screened subnet) for the Federation Service. The Federation Service Proxy component is not a required component in an ADFS deployment.

The act of installing the Federation Service Proxy component on a computer makes that computer a federation server proxy. Federation server proxies forward requests to federation servers that are not accessible from the Internet.

The following tasks for managing the Federation Service Proxy are described in this objective.

- Managing a Federation Server Proxy Farm
- Managing Certificates Used by Federation Server Proxies

**See Also**
**Concepts**
Managing the Federation Service
Managing ADFS Web Agents and Applications
Backing Up ADFS Components

# Managing a Federation Server Proxy Farm

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

To provide load-balancing of proxy services in larger Active Directory Federation Services (ADFS) deployments, you can install additional federation server proxies to create server farms. When multiple federation server proxies are deployed in the same perimeter network or demilitarized zone, you must configure Federation Service Proxy (FSP) verification certificates in the trust policy for every Federation Service that is protected by the Federation Service Proxy. This configuration implements the federation service proxy farm.

The following tasks for managing a federation server proxy farm are described in this objective.

- Changing the Location of the ADFS Directory
- Adding a New Federation Server Proxy
- Removing a Federation Server Proxy

**See Also**
**Concepts**
Managing a Federation Server Farm

# Changing the Location of the ADFS Directory

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

To change the Active Directory Federation Services (ADFS) directory to another location, you can perform the following procedure on a federation server or federation server proxy. The default location for the directory is C:\ADFS.

| **Important** |
| --- |
| Microsoft does not support changing the location of the ADFS directory. If you alter its location, we cannot guarantee that you can upgrade normally to future versions of Windows operating systems or that ADFS will function after you upgrade. |

To complete this procedure, you must finish all of the following steps in the order that they are presented:

1. Copy the contents of the ADFS directory to the new location.
2. Change the virtual directory path in Internet Information Services (IIS) Manager.
3. Modify the registry to point to the new ADFS directory.

| **Caution** |
| --- |
| Incorrectly editing the registry may severely damage your system. Before making changes to the registry, back up any valued data on the computer. |

### Administrative credentials

Membership in **Administrators**, or equivalent, is the minimum required to complete this procedure. Review details about using the appropriate accounts and group memberships at Local and Domain Default Groups (http://go.microsoft.com/fwlink/?LinkId=83477).

#### Copy the contents of the ADFS directory to the new location

1. Start Windows Explorer, and then create a new directory named ADFS in the desired location on the computer.
2. Copy the contents of the C:\ADFS directory (including subfolders) to the new location.

| **Important** |
| --- |
| If you plan to upgrade the Windows Server operating system to a newer version in the future, leave the C:\ADFS directory intact. To do so, copy, rather than move, the directory to the new location. |

#### Change the virtual directory path in IIS Manager

1. Click **Start**, point to **Administrative Tools**, and then click **Internet Information Services (IIS) Manager**.
2. Double-click *YourComputerName***(local computer)**, double-click **Web Sites**, and then double-click **Default Web Site**.
3. In the list of virtual directories, right-click **adfs**, and then click **Properties**.
4. On the **Virtual Directory** tab, in **Local path**, type the path to the new ADFS\STS directory, and then click **OK**.

   For example, if you want to move the directory to D:, type **d:\adfs\sts** in **Local path**.

#### Modify the registry to point at the new ADFS directory

1. Open Registry Editor (Regedit.exe).
2. Navigate to the **HKEY_LOCAL_MACHINE_SYSTEM\Microsoft\WebSSO** registry key.
3. Right-click **InitialDirectory**, click **Modify**, under **Value data**, type the path to the new ADFS directory, and then click

**OK**.

For example, if you want to move the directory to D:, then type **d:\adfs** in **Value data**.

4. Close Registry Editor.

# Adding a New Federation Server Proxy

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When you have an existing Active Directory Federation Services (ADFS) deployment and you want to add a new federation server proxy, you must configure the server as an application server, install and configure certificates, and then install the Federation Server Proxy component of ADFS. You can also set event logging according to server needs.

Unlike farmed federation servers, farmed sets of federation server proxies are not required to share certificate private keys, but must share the certificate public key with the Federation Service that they protect.

However, you must export the public key from each federation server proxy and add this key to the shared trust policy of the Federation Service as an FSP verification certificate.

During installation, you configure the federation server proxy with the DNS host name of the protected Federation Service. This name is added automatically to create the FS URL, which the federation service proxy uses to communicate with the Federation Service.

**Task requirements**

You need the following to perform the procedures for this task:

- An installed Secure Sockets Layer (SSL) certificate. For information about how to acquire SSL certificates, see Obtaining Server Certificates (http://go.microsoft.com/fwlink/?linkid=62479).
- An existing Federation Service.
- The Domain Name System (DNS) host name of the Federation Service that this federation server proxy will protect.
- An installed client authentication certificate for the Federation Service Proxy. For information about installing client authentication certificates when using Microsoft Certificate Services as your enterprise certification authority (CA), see Submit an advanced certificate request via the Web to a Windows Server 2003 CA (http://go.microsoft.com/fwlink/?linkid=64020).

To complete this task, perform the following procedures:

1. Install prerequisite applications
2. Install the Federation Service Proxy on an additional federation server proxy
3. Export the public key portion of a client authentication certificate
4. Add a Federation Service Proxy certificate to the trust policy
5. Configure event logging on a federation server proxy

**See Also**
**Concepts**
Rolling Over a Client Authentication Certificate

# Install prerequisite applications

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Active Directory Federation Services (ADFS) requires that the following applications be installed on a computer running Windows Server 2003 R2, Enterprise Edition, or Windows Server 2003 R2, Standard Edition, (only for servers hosting the ADFS Web Agent) so that the computer can host the Federation Service, Federation Service Proxy, or ADFS Web Agent components of ADFS:

- Internet Information Services (IIS)
- Microsoft .NET Framework 2.0
- Microsoft ASP.NET (required for claims-aware applications only)

When you add the Application Server Windows component, these three applications are installed.

**Administrative credentials**

To complete this procedure, you must be a member of the local Administrators group.

**To add the Application Server Windows component**

1. Click **Start**, point to **Control Panel**, and then click **Add or Remove Programs**.
2. In **Add or Remove Programs**, click **Add/Remove Windows Components**.
3. In the **Windows Components Wizard**, select the **Application Server** check box, and then click **Next**.
4. On the **Completing the Windows Components Wizard** page, click **Finish**.

# Install the Federation Service Proxy on an additional federation server proxy

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When you install the Federation Service Proxy component of Active Directory Federation Services (ADFS) on an additional server in a federation server proxy server farm, you identify the protected Federation Service by its DNS host name and select the installed client authentication certificate.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To install the Federation Service Proxy component of ADFS on an additional federation server proxy**

1. Click **Start**, point to **Control Panel**, and then click **Add or Remove Programs**.
2. In **Add or Remove Programs**, click **Add/Remove Windows Components**.
3. In the Windows Components Wizard, select the **Active Directory Services** check box, and then click **Details**.
4. In the **Active Directory Services** dialog box, select the **Active Directory Federation Services (ADFS)** check box, and then click **Details**.
5. In the **Active Directory Federation Services (ADFS)** dialog box, select the **Federation Service Proxy** check box, and then click **OK**. If a message appears stating that ASP.NET 2.0 was not previously enabled, click **Yes** to enable it, and then click **OK**.
6. In the **Active Directory Services** dialog box, click **OK**.
7. In the Windows Components Wizard, click **Next**.
8. On the **Federation Service** page, click **Select client authentication certificate**, and then click **Select** to select the installed certificate.
9. In the **Select Certificate** dialog box, click the client authentication certificate, and then click **OK**.
10. If you are prompted for the location of the installation files, navigate to *R2 Installation Folder*\cmpnents\r2, and then click **OK**.
11. On the **Completing the Windows Components Wizard** page, click **Finish**.

**See Also**
**Concepts**
Export the public key portion of a client authentication certificate
Add a Federation Service Proxy certificate to the trust policy

# Export the public key portion of a client authentication certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

The public key portion of a client authentication certificate for the federation server proxy must be added to the trust policy on a federation server so that the Federation Service can authenticate the federation server proxy. By exporting the public key portion of the client authentication certificate, you create a file that can be imported into the trust policy. You can use the following procedure on the federation server proxy computer to export the public key portion of its client authentication certificate.

**To export the public key portion of a client authentication certificate**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click **Federation Service Proxy**, and then click **Properties**.
3. On the **General** tab, under **FSP client authentication certificate**, click **View**.
4. In the **Certificate** dialog box, click the **Details** tab, and then click **Copy to File**.
5. On the **Welcome to the Certificate Export Wizard** page, click **Next**.
6. On the **Export Private Key** page, ensure that **No, do not export the private key** is selected, and then click **Next**.
7. On the **Export File Format** page, ensure that **DER encoded binary X.509 (.CER)** is selected, and then click **Next**.
8. On the **File to Export** page, type or browse to the location and file name that you want to use for the exported certificate, and then click **Next**.
9. On the **Completing the Certificate Export Wizard** page, verify that the information that you provided is accurate, and then click **Finish**.
10. In the **Certificate Export Wizard** dialog box, click **OK**.
11. In the **Certificate** dialog box, click **OK**.
12. In the **Federation Service Properties** dialog box, click **OK**.

Checklist: Installing a federation server proxy
Certificate requirements for federation server proxies

# Add a Federation Service Proxy certificate to the trust policy

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

So that the Federation Service can authenticate the federation server proxy, the public key portion of the client authentication certificate for the federation server proxy must be added to the trust policy on a federation server with which the federation server proxy communicates. You can use the following procedure to add the client authentication certificate for the federation server proxy from a file that you have exported.

| **Note** |
| --- |
| The Trust Policy user interface (UI) in the Active Directory Federation Services snap-in refers to client authentication certificates for federation service proxies as **Federation Service Proxy (FSP) certificates**. |

The Federation Service Proxy certificate should chain to a trusted root in the Federation Service. Perform this procedure on a federation server that hosts the trust policy to which you want to add a Federation Service Proxy certificate.

**To add a Federation Service Proxy certificate to the trust policy**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click **Trust Policy**, and then click **Properties**.
3. On the **FSP Certificates** tab, click **Add**.
4. In the **Browse for Federation Service Proxy Certificate file** dialog box, navigate to the certificate file that you want to add, select the certificate file, and then click **Open**.
5. In the **Trust Policy Properties** dialog box, click **OK**.

**See Also**
**Concepts**

# Configure event logging on a federation server proxy

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Federation servers log Active Directory Federation Services (ADFS) Federation Service events in the Application and Security event logs. On a federation server proxy, events in the Application log contain additional information about errors regarding contact with the Federation Service. In addition, when a federation server proxy is in effect, the Federation Service events contain information about the proxy certificates that are used.

Use the following procedure to specify the level of events that you want to be logged on a server that is running the Federation Service Proxy. Event logging for a federation server proxy is set in the web.config file. By default, this file is located in %systemdrive%\ADFS\sts. You can apply the following logging types in the Web.config file:

- **Error:** Information about a significant problem of which the user should be aware, usually involving a loss of functionality or data.
- **Warning:** Indicates a problem that is not immediately significant, but that may signify conditions that could cause future issues.
- **Info:** Information about a significant, successful operation.
- **SuccessAudit:** Indicates an audited security event that occurs when an audited access attempt is successful, for example, a successful logon attempt.
- **FailureAudit:** Indicates a security event that occurs when an audited access attempt fails; for example, authentication failed.
- **DetailedSuccess:** A success audit event with detailed information about each token involved in the transaction, including claims information.
- **DetailedFailure:** A failure audit event with detailed information about each token involved in the transaction, including claims information.
- **Everything:** Enables all logging levels.

Use the following procedure to configure event logging levels on a federation server proxy. Perform this procedure on the federation server proxy.

| **Note** |
| --- |
| For security events to be registered, object access auditing must be enabled in the security policy. For more information, see Configuring ADFS Servers for Troubleshooting (http://go.microsoft.com/fwlink/?LinkId=79242). |

### Administrative credentials

To complete this procedure, you must have Read-Write access to the web.config file.

**To configure event logging for a federation server proxy using the web.config file**

1. In Notepad, open the web.config file in %systemdrive%\ADFS\sts.
2. Search for **<logonserver>**.
3. Add the **<auditlevel>** XML element under **<logonserver>**, as follows:

   **<auditlevel>** *Value* **</auditlevel>**

   Where *Value* is one of the following, or the combined values of two or more:

   - Error = 1

# Removing a Federation Server Proxy

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When you no longer need a federation server proxy in an Active Directory Federation Services (ADFS) deployment, remove ADFS and the client authentication certificate.

To complete this task, perform the following procedures:

- Remove the Federation Service Proxy ADFS component, as described in Remove an ADFS component.
- Delete the client authentication certificate from the certificate store. For information about how to delete a certificate from a certificate store, see Delete a certificate (http://go.microsoft.com/fwlink/?linkid=62715).
- Use the procedure Remove a Federation Service Proxy (FSP) certificate from the trust policy to remove the corresponding FSP certificate from any Federation Service trust policy that references it.

# Remove an ADFS component

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If you want to remove a server that is running the Federation Service or Federation Service Proxy component of Active Directory Federation Services (ADFS) from a Federation Service, use the following procedure to remove the respective ADFS component.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To remove an ADFS component**

1. Click **Start**, point to **Control Panel**, and then click **Add or Remove Programs**.
2. In **Add or Remove Programs**, click **Add/Remove Windows Components**.
3. In the Windows Components Wizard, select the **Active Directory Services** check box, and then click **Details**.
4. In the **Active Directory Services** dialog box, select the **Active Directory Federation Services (ADFS)** check box, and then click **Details**.
5. In the **Active Directory Federation Services (ADFS)** dialog box, clear the **Federation Service** check box or the **Federation Service Proxy** check box, and then click **OK**.
6. In the **Active Directory Services** dialog box, click **OK**.
7. In the Windows Components Wizard, click **Next**.
8. On the **Completing the Windows Components Wizard** page, click **Finish**.

# Remove a Federation Service Proxy (FSP) certificate from the trust policy

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When a new client authentication certificate has been added to a server that is running the Federation Service Proxy component of Active Directory Federation Services (ADFS), or when you remove a federation server proxy from a server farm, the public portion of the client authentication certificate (the FSP certificate) must be removed from the trust policy of the Federation Service.

Perform the following procedure on a federation server to remove an FSP certificate from the trust policy.

**Administrative credentials**

To complete the procedure in this topic, you must be a member of the Administrators group on the local computer.

**To remove a Federation Service Proxy authentication certificate**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, right-click **Trust Policy**, and then click **Properties**.
3. Click the **FSP Certificates** tab.
4. Click the certificate that you want to remove, and then click **Remove**, and then click **OK**.

# Managing Certificates Used by Federation Server Proxies

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Servers that are running the Federation Service Proxy component of Active Directory Federation Services (ADFS) are required to use the following types of certificates:

- Secure Sockets Layer (SSL) server authentication certificates: Federation server proxies use SSL server authentication certificates to secure Web services traffic for communication with Web clients. Federation server proxies are usually exposed to computers on the Internet that are not included in your enterprise public key infrastructure (PKI). For this reason, you should use a server authentication certificate that is issued by a public (third-party) certification authority (CA) (for example, Verisign). For more information about using SSL certificates, see Configuring Secure Sockets Layer (http://go.microsoft.com/fwlink/?linkid=62785) and Obtaining Server Certificates (http://go.microsoft.com/fwlink/?linkid=62479).

- SSL client authentication certificates: Each federation server proxy uses a client authentication certificate to authenticate to the Federation Service. You can use any certificate with client authentication enhanced key usage (EKU) and that chains to a trusted root CA on the federation server as a client authentication certificate for the federation server proxy. In addition, you must explicitly add the client authentication certificate to the trust policy. However, only the federation server proxy stores the private key that is associated with the federation server proxy client authentication certificate. You can install a client authentication certificate by connecting to an enterprise CA or by creating a self-signed certificate.

  | **Important** |
  | --- |
  | Do not use a certificate that was issued by your enterprise CA for client authentication of an Active Directory user (especially a domain administrator) because the private key is stored on the federation server proxy. Storing such a private key on the federation server proxy allows an administrator or other successful attacker to assume the identity that the certificate represents. |

  For information about installing client authentication certificates when using Microsoft Certificate Services as your enterprise CA, see "Submit an advanced certificate request via the Web to a Windows Server 2003 CA" (http://go.microsoft.com/fwlink/?linkid=64020). For information about creating self-signed certificates, see Create a self-signed, token-signing certificate.

### Task requirements

You need the following to perform the procedures for this task:

- Active Directory Federation Services MMC snap-in

The following procedures for managing certificates on federation server proxies are described in this task. Use these procedures on an as-needed basis.

- Managing Client Authentication Certificates

- Rolling Over a Client Authentication Certificate

# Managing Client Authentication Certificates

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Servers that are running the Federation Service Proxy component of Active Directory Federation Services (ADFS) require Secure Sockets Layer (SSL) client authentication certificates to authenticate to the Federation Service.

**Task requirements**

You need the following to perform the procedures for this task:

- A certification authority or the ability to create self-signed certificates
- A server that is running the Federation Service Proxy component of ADFS
- Active Directory Federation Services snap-in

To complete this task, perform the following procedures on an as-needed basis:

- Create a self-signed, token-signing certificate
- View the current client authentication certificate
- Export the public key portion of a client authentication certificate
- Add a Federation Service Proxy certificate to the trust policy
- Change the client authentication certificate that a federation server proxy uses

Rolling Over a Client Authentication Certificate

# Create a self-signed, token-signing certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

You can use the following procedure to create a self-signed, code-signing certificate that also creates and installs a private key. To perform this procedure, use the Makecert.exe utility. Makecert.exe is available in the Microsoft .NET Framework 2.0 Software Development Kit (SDK) (x86) (http://go.microsoft.com/fwlink/?LinkId=79548).

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To create a self-signed, token-signing certificate**

1. Open a command prompt.
2. Type the appropriate **makecert** syntax.
   - Example command:

**makecert -r -pe -n "CN=CertForADFS" -b 01/01/2006 -e 01/01/2007 -eku 1.3.6.1.5.5.7.3.3 -ss my -sr localMachine -sky exchange -sp "Microsoft RSA SChannel Cryptographic Provider" -sy 12 "CertForADFS.cer"**

| **Note** |
| --- |
| Track certificate expiration dates to make sure that certificates are replaced before they expire. You can do this using the Active Directory Federation Services snap-in for certificates of the current organization and also for partners that you configure in the trust policy. |

# View the current client authentication certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

An Active Directory Federation Services (ADFS) federation server proxy requires you to install a client authentication certificate. You can view the certificate if you want to check its expiration date, revocation status, and other details.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To view the current Federation Service Proxy client authentication certificate**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click **Federation Service Proxy**, and then click **Properties**.
3. On the **General** tab, under **FSP client authentication certificate**, click **View**.
4. After viewing the certificate, click **OK** twice.

Change the client authentication certificate that a federation server proxy uses

# Export the public key portion of a client authentication certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

The public key portion of a client authentication certificate for the federation server proxy must be added to the trust policy on a federation server so that the Federation Service can authenticate the federation server proxy. By exporting the public key portion of the client authentication certificate, you create a file that can be imported into the trust policy. You can use the following procedure on the federation server proxy computer to export the public key portion of its client authentication certificate.

**To export the public key portion of a client authentication certificate**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click **Federation Service Proxy**, and then click **Properties**.
3. On the **General** tab, under **FSP client authentication certificate**, click **View**.
4. In the **Certificate** dialog box, click the **Details** tab, and then click **Copy to File**.
5. On the **Welcome to the Certificate Export Wizard** page, click **Next**.
6. On the **Export Private Key** page, ensure that **No, do not export the private key** is selected, and then click **Next**.
7. On the **Export File Format** page, ensure that **DER encoded binary X.509 (.CER)** is selected, and then click **Next**.
8. On the **File to Export** page, type or browse to the location and file name that you want to use for the exported certificate, and then click **Next**.
9. On the **Completing the Certificate Export Wizard** page, verify that the information that you provided is accurate, and then click **Finish**.
10. In the **Certificate Export Wizard** dialog box, click **OK**.
11. In the **Certificate** dialog box, click **OK**.
12. In the **Federation Service Properties** dialog box, click **OK**.

# Add a Federation Service Proxy certificate to the trust policy

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

So that the Federation Service can authenticate the federation server proxy, the public key portion of the client authentication certificate for the federation server proxy must be added to the trust policy on a federation server with which the federation server proxy communicates. You can use the following procedure to add the client authentication certificate for the federation server proxy from a file that you have exported.

| **Note** |
| --- |
| The Trust Policy user interface (UI) in the Active Directory Federation Services snap-in refers to client authentication certificates for federation service proxies as **Federation Service Proxy (FSP) certificates**. |

The Federation Service Proxy certificate should chain to a trusted root in the Federation Service. Perform this procedure on a federation server that hosts the trust policy to which you want to add a Federation Service Proxy certificate.

**To add a Federation Service Proxy certificate to the trust policy**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click **Trust Policy**, and then click **Properties**.
3. On the **FSP Certificates** tab, click **Add**.
4. In the **Browse for Federation Service Proxy Certificate file** dialog box, navigate to the certificate file that you want to add, select the certificate file, and then click **Open**.
5. In the **Trust Policy Properties** dialog box, click **OK**.

# Change the client authentication certificate that a federation server proxy uses

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

In Active Directory Federation Services (ADFS), the federation server proxy uses a client authentication certificate to communicate securely with the federation server. If you have installed a new client authentication certificate on a federation server proxy and you want that certificate to be used, you will need to select that certificate in ADFS.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the client authentication certificate on a federation server proxy**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click **Federation Service Proxy**, and then click **Properties**.
3. On the **General** tab, under **FSP client authentication certificate**, click **Select**.
4. In the **Select Certificate** dialog box, click the client authentication certificate that you want to use, and then click **OK**.
5. In the **Federation Service Proxy Properties** dialog box, click **OK**.
6. If the certificate is not trusted by any of the trusted toot certification authorities, after you click **OK**, a Federation Service message box appears, stating: "The Federation Service is running as an account that does not have access to the certificate private key. Do you want to grant permission to this account to read the private key?" Click **Yes** so that the certificate is trusted.
7. On the **General** tab, under **Token-signing certificate**, click **View** to check that the selected certificate is being used.

# Rolling Over a Client Authentication Certificate

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When a client authentication certificate must be replaced on a server that is running the Federation Service Proxy component of Active Directory Federation Services (ADFS), use the procedures in this task to roll over the certificate in a manner that eliminates any significant lapse of certificate validity on the servers.

After a new client authentication certificate is installed on the first federation server proxy, the public portion of the client authentication certificate must be exported and added to the trust policy for the Federation Service.

**Task requirements**

You need the following to perform the procedures for this task:

- If you are using self-signed certificates, you can use the makecert.exe utility, which you can download from http://go.microsoft.com/fwlink/?linkid=63617.
- Active Directory Federation Services MMC snap-in.

To complete this task, perform the following procedures:

1. Install a new token-signing certificate, as follows:
   a. If you are using Microsoft Certificate Services as an enterprise certification authority (CA), obtain a new client authentication certificate according to the instructions in "Submit an advanced certificate request via the Web to a Windows Server 2003 CA" (http://go.microsoft.com/fwlink/?linkid=64020). Specify installing the certificate into the local certificate store.
   b. If you are using a different enterprise CA or a public CA, follow the instructions provided by the CA.
   c. Alternatively, use the procedure Create a self-signed, token-signing certificate.
2. On the federation server for which you obtained a new client authentication certificate in step 1, use the procedure Export the public key portion of a client authentication certificate to create a file that can be used as an FSP verification certificate.
3. Make the exported certificate file available to the Federation Service administrator who must add it to the trust policy.
4. Instruct the administrator to use the procedure Add a Federation Service Proxy certificate to the trust policy to the trust policy to add the exported certificate to the trust policy of the Federation Service that this federation server proxy is protecting.
5. On a federation server proxy, use the procedure Change the client authentication certificate that a federation server proxy uses to select the new certificate.
6. To remove the old FSP verification certificate from the Federation Service, inform the Federation Service administrator to use the procedure Remove a Federation Service Proxy (FSP) certificate from the trust policy.
7. Delete the old client authentication certificate from the certificate store. For information about how to delete a certificate from a certificate store, see Delete a certificate (http://go.microsoft.com/fwlink/?linkid=62715).

# Change the client authentication certificate that a federation server proxy uses

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

In Active Directory Federation Services (ADFS), the federation server proxy uses a client authentication certificate to communicate securely with the federation server. If you have installed a new client authentication certificate on a federation server proxy and you want that certificate to be used, you will need to select that certificate in ADFS.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the client authentication certificate on a federation server proxy**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click **Federation Service Proxy**, and then click **Properties**.
3. On the **General** tab, under **FSP client authentication certificate**, click **Select**.
4. In the **Select Certificate** dialog box, click the client authentication certificate that you want to use, and then click **OK**.
5. In the **Federation Service Proxy Properties** dialog box, click **OK**.
6. If the certificate is not trusted by any of the trusted toot certification authorities, after you click **OK**, a Federation Service message box appears, stating: "The Federation Service is running as an account that does not have access to the certificate private key. Do you want to grant permission to this account to read the private key?" Click **Yes** so that the certificate is trusted.
7. On the **General** tab, under **Token-signing certificate**, click **View** to check that the selected certificate is being used.

# Remove a Federation Service Proxy (FSP) certificate from the trust policy

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When a new client authentication certificate has been added to a server that is running the Federation Service Proxy component of Active Directory Federation Services (ADFS), or when you remove a federation server proxy from a server farm, the public portion of the client authentication certificate (the FSP certificate) must be removed from the trust policy of the Federation Service.

Perform the following procedure on a federation server to remove an FSP certificate from the trust policy.

**Administrative credentials**

To complete the procedure in this topic, you must be a member of the Administrators group on the local computer.

**To remove a Federation Service Proxy authentication certificate**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, right-click **Trust Policy**, and then click **Properties**.
3. Click the **FSP Certificates** tab.
4. Click the certificate that you want to remove, and then click **Remove**, and then click **OK**.

# Managing ADFS Web Agents and Applications

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

ADFS Web Agents are Active Directory Federation Services (ADFS) components that consume security tokens and either allow or deny a user access to a Web application. ADFS Web Agents are available for two types of Web applications:

- ADFS Web Agent for Windows NT token-based applications: Internet Information Services (IIS) applications that use traditional Windows native authorization mechanisms. This type of application does not use ADFS claims.
- ADFS Web Agent for claims-aware applications: Applications that have been written to use ADFS claims for authorization.

The following tasks for managing ADFS Web Agents and applications are described in this objective.

- Installing and Removing ADFS Web Agents
- Adding and Configuring a Windows NT Token-based Application
- Adding and Configuring a Claims-aware Application
- Managing Security for Web Applications

**See Also**

Controlling Access to Web-based Applications

# Installing and Removing ADFS Web Agents

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

You can add and remove Active Directory Federation Services (ADFS) Web Agents on servers that are running Internet Information Services (IIS).

**Task requirements**

You need the following to perform the procedures of this task:

- To add the ADFS Web Agent for Windows NT token-based application, the Web server must have a Secure Sockets Layer (SSL) server authentication certificate installed.

The following procedures are provided in this task:

- Install the ADFS Web Agent component of ADFS
- Remove the ADFS Web Agent component of ADFS

**See Also**
**Concepts**
Adding and Configuring a Windows NT Token-based Application
Adding and Configuring a Claims-aware Application

# Install the ADFS Web Agent component of ADFS

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

You can add an Active Directory Federation Services (ADFS) Web Agent to a Web server in a resource partner organization. You use the same procedure to add either the ADFS Web Agent for Windows NT token–based applications or the ADFS Web Agent for claims-aware applications. This action makes that server an ADFS-enabled Web server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To add an ADFS Web Agent to a Web server**

1. Click **Start**, point to **Control Panel**, and then click **Add or Remove Programs**.
2. In **Add or Remove Programs**, click **Add/Remove Windows Components**.
3. In the **Windows Components Wizard**, select the **Active Directory Services** check box, and then click **Details**.
4. In the **Active Directory Services** dialog box, select the **Active Directory Federation Services (ADFS)** check box, and then click **Details**.
5. In the **Active Directory Federation Services (ADFS)** dialog box, click **ADFS Web Agents**, and then click **Details**.
6. In the **ADFS Web Agents** dialog box, select Web Agent subcomponents as follows, and then click **OK**:
   - To add ADFS Web Agent support for applications that can process ADFS claims directly for authorization, select the **Claims-aware applications** check box.

     | **Note** |
     | --- |
     | If your Web server will host only claims-aware applications, do not select the **Windows NT token–based applications** check box. |

   - To add ADFS Web Agent support for applications that require Windows native authorization mechanisms (that is, for applications that do not directly consume ADFS claims), select the **Windows NT token–based applications** check box.

     | **Note** |
     | --- |
     | If your Web server will host only Windows NT token–based applications, do not select the **Claims-aware applications** check box. |

7. In the **Active Directory Federation Services (ADFS)** dialog box, click **OK**.
8. In the **Active Directory Services** dialog box, click **OK**.
9. In the Windows Components Wizard, click **Next**.
10. If you are prompted for the location of installation files, navigate to *R2 installation files*\cmpnents\r2, and then click **OK**.
11. On the **Completing the Windows Components Wizard** page, click **Finish**.

# Remove the ADFS Web Agent component of ADFS

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If you no longer want to use Active Directory Federation Services (ADFS) for authenticating and authorizing a Windows NT token-based application or claims-aware application, or both, you can remove one or both ADFS Web Agents from a Web server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To remove an ADFS Web Agent**

1. Click **Start**, point to **Control Panel**, and then click **Add or Remove Programs**.
2. In **Add or Remove Programs**, click **Add/Remove Windows Components**.
3. In the **Windows Components Wizard**, select the **Active Directory Services** check box, and then click **Details**.
4. In the **Active Directory Services** dialog box, select the **Active Directory Federation Services (ADFS)** check box, and then click **Details**.
5. In the **Active Directory Federation Services (ADFS)** dialog box, click **ADFS Web Agents**, and then click **Details**.
6. In the **ADFS Web Agents** dialog box, clear the Web Agent subcomponent check box for the Web agent subcomponent or subcomponents that you want to remove, and then click **OK**.
7. In the **Active Directory Federation Services (ADFS)** dialog box, click **OK**.
8. In the **Active Directory Services** dialog box, click **OK**, and then, in the **Windows Components Wizard**, click **Next**.
9. On the **Completing the Windows Components Wizard** page, click **Finish**.

# Adding and Configuring a Windows NT Token-based Application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If you have applications that use the Active Directory Federation Services (ADFS) Web Agent for Windows NT token-based applications for authorization, you can configure them in Internet Information Services (IIS) Manager. Use the ADFS Web Agent tab in the properties pages for the following IIS nodes:

- Web Sites node: Use this node to configure the Federation Service URL. Clients are directed to the Federation Service URL when they contact the associated Federation Service.
- *SiteName* nodes and virtual directories: Use this node to enable the ADFS Web agent for Windows NT token-based applications and to configure cookies and the Return URL. The Return URL directs clients to the application page after successful authentication.

**Task requirements**

You need the following to perform the procedures for this task:

- Active Directory Federation Services MMC snap-in
- Internet Information Services (IIS) Manager MMC snap-in
- Regedit.exe

To complete this task, perform the following procedures:

1. Add a new Windows NT token-based application to the Federation Service
2. Enable or disable a Web application
3. Set the cookie path for a Windows NT token-based application
4. Set the cookie domain for a Windows NT token-based application
5. Set the Federation Service URL for a Windows NT token-based application
6. Set the return URL for a Windows NT token-based application
7. Configure event logging for a Windows NT token-based application
8. Configure authentication methods for a federated application

**See Also**

# Add a new Windows NT token-based application to the Federation Service

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When you configure your Active Directory Federation Services (ADFS)–enabled Web server to host a Windows NT token–based application, you must add a reference to that application in the trust policy so that you can specify application properties for the Federation Service. You can use the following procedure to add a new Windows NT token–based application to the Federation Service. You perform this procedure on a federation server in the resource partner.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To add a Windows NT token–based application to the Federation Service**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, right-click **Applications**, point to **New**, and then click **Application**.
3. On the **Welcome to the Add Application Wizard** page, click **Next**.
4. On the **Application Type** page, click **Windows NT token–based application**, and then click **Next**.
5. On the **Application Details** page, in **Application display name**, type the name of the application.
6. In **Application URL**, type the Uniform Resource Locator (URL) for your application—for example, https://www.treyresearch.net/*ApplicationName*/—and then click **Next**.

   | **Note** |
   | --- |
   | The value in **Application URL** on this property page must match precisely the **Return URL** value that you specify in the **ADFS Web Agent** tab for the Windows NT token-based application (on the ADFS-enabled Web server). |

7. On the **Accepted Identity Claim** page, click one of the following identity claim types, based on the needs of your application, and then click **Next**:
   - **User principal name (UPN)**
   - **E-mail**
8. On the **Enable this Application** page, ensure that the **Enable this application** check box is selected, and then click **Next**.
9. On the **Completing the Add Application Wizard** page, click **Finish**.

# Enable or disable a Web application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Web applications are enabled by default when you create them in the Active Directory Federation Services (ADFS) snap-in. You can disable an application if it is currently enabled. If you disable an application, access to the application is prevented.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To enable or disable a Web application**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, and then double-click **Applications**.
3. Right-click the application you want to enable or disable and do one of the following:
   - If the application is disabled and you want to enable it, click **Enable**.
   - If the application is enabled and you want to disable it, click **Disable**.

| **Note** |
| --- |
| You can also perform this procedure by right-clicking the application, clicking **Properties**, and then selecting or clearing the **Enabled** check box. |

# Set the cookie path for a Windows NT token-based application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

The cookie path specifies the location within an Internet Information Services (IIS) Web site virtual directory for which cookies will be sent in response to an application request by an Active Directory Federation Service (ADFS) client. If no cookie path is set, the default path points to a location that depends on whether a cookie domain is set, as follows:

- Cookie domain is set: The path continues from / below the domain that applies for the requested address on the basis of the cookie domain.
- No cookie domain is set: The path continues from / below the domain specified in the Federation Service Uniform Resource Identifier (URI).

If you specify a cookie path (for example, /test01), the cookie is sent for requests under that path (for example, /test01, /test01/index.html, /test01/test05/, and so on).

The cookie path setting is configured in the ADFS Web Agent for an application. For a Windows NT token-based application, configure the ADFS Web Agent in IIS.

Perform this procedure on a Web server in the resource Federation Service.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To set the cookie path for a Windows NT token-based application**

1. Click **Start**, point to **Administrative Tools**, and then click **Internet Information Services (IIS) Manager**.
2. Double-click *YourComputerName* **(local computer)**, and then double-click **Web Sites**.
3. Right-click your Web site, and then click **Properties**.
4. On the **ADFS Web Agent** tab, in **Cookie path**, change the path as needed, and then click **OK**.

**Concepts**
Set the cookie domain for a Windows NT token-based application

# Set the cookie domain for a Windows NT token-based application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

You can use the cookie domain setting to share an application at a higher level than the domain level that is specified in the Federation Service Uniform Resource Identifier (URI). In this way, you can expand the scope of requests for which a cookie will be sent.

If you do not configure a cookie domain, cookies are sent only for requests where the domain that is specified matches the domain in the Federation Service Uniform Resource Identifier (URI). For example, if no cookie domain is set and the domain in the Federation Service URI is Sales.Adatum.com, cookies are sent for only requests where the request URL matches Sales.Adatum.com. However, if you set Adatum.com as the cookie domain, cookies are sent for Sales.Adatum.com plus requests for any other domain with the suffix Adatum.com. For example, cookies are also sent for Northwest.Adatum.com.

The cookie domain setting is configured in the ADFS Web Agent for an application. For a Windows NT token-based application, configure the ADFS Web Agent in Internet Information Services (IIS).

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To set the cookie domain for a Windows NT token-based application**

1. Click **Start**, point to **Administrative Tools**, and then click **Internet Information Services (IIS) Manager**.
2. Double-click *YourComputerName* **(local computer)**, and then double-click **Web Sites**.
3. Right-click your Web site, and then click **Properties**.
4. On the **ADFS Web Agent** tab, in **Cookie domain**, change the domain as needed, and then click **OK**.

# Set the Federation Service URL for a Windows NT token-based application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

The Federation Service Uniform Resource Locator (URL) in Active Directory Federation Services (ADFS) defines the URL that is used for all Web sites and Web applications on a Web server where an ADFS Web Agent is enabled. If the Federation Service URL for a Web server that hosts a Windows NT token-based application changes, you must update the ADFS Web Agent in Internet Information Services (IIS).

Perform this procedure on a Web server in the resource Federation Service.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To set the Federation Service URL for a Windows NT token-based application**

1. Click **Start**, point to **Administrative Tools**, and then click **Internet Information Services (IIS) Manager**.
2. Double-click *YourComputerName* **(local computer)**, right-click **Web Sites**, and then click **Properties**.
3. On the **ADFS Web Agent** tab, in **Federation Service URL**, change the URL as needed, and then click **OK**.

# Set the return URL for a Windows NT token-based application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

The return Uniform Resource Locator (URL) in Active Directory Federation Services (ADFS) is configured on the ADFS Web Agent on a Web server to reflect the URL that opens a requested Web application. If this URL changes for a Windows NT token-based application, you must change its value in Internet Information Services (IIS).

The return URL must match the application URL that you configure in the properties of the application in the resource Federation Service. Therefore, if you change one, you must change the other.

Perform this procedure on an ADFS Web server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To set the return URL for a Windows NT token-based application**

1. Click **Start**, point to **Administrative Tools**, and then click **Internet Information Services (IIS) Manager**.
2. In the console tree, double-click *WebServerName* **(local computer)**, double-click **Web Sites**, right-click any application or site (typically, the **Default Web Site**), and then click **Properties**.
3. On the **ADFS Web Agent** tab, in **Return URL (Uniform Resource Locator)**, type the URL for the application, and then click **OK**.
4. If you have not already done so, change the application URL to match the new value of the return URL.

# Configure event logging for a Windows NT token-based application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

On a Web server that is running the Active Directory Federation Services (ADFS) Web Agent for Windows NT token–based applications, you can configure the types of events that you want to be logged for Windows NT token–based applications.

| **Note** |
| --- |
| Event logging is enabled differently for Windows NT token–based applications and claims-aware applications. |

Use the following procedure to specify the types of events that you want to be logged for Windows NT token–based applications in the Application event log on the ADFS-enabled Web server. You set event logging for Windows NT token–based applications in the registry of the Web server.

| **Caution** |
| --- |
| Editing the registry incorrectly may damage your system severely. Before you make changes to the registry, back up any valued data on the computer. |

### Administrative credentials

To complete this procedure, you must be a member of the Administrators group on the local computer.

#### To configure event logging for Windows NT token–based applications

1. Open Regedit. Click **Start**, click **Run**, type **regedit**, and then click **OK**.
2. Navigate to:

   **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ifssvc\ Parameters**
3. Right-click **Parameters**, click **New**, and then click **DWORD Value**.
4. In the new value file name box, type the following, and then press Enter:

   **ADFSEvent**
5. Double-click the new entry, and then, in **Value data**, provide a value for one of the following levels, or add values to configure multiple levels, and then click **OK**:
   - Warning: 0x01
   - Information: 0x02
   - Success: 0x04
   - Failure: 0x08

# Configure authentication methods for a federated application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

By default, a Web application that you configure in Active Directory Federation Services (ADFS) accepts any of the following authentication methods:

- Windows Integrated authentication (also referred to as Windows NT Challenge/Response authentication): A secure form of authentication because the user name and password are hashed before they are sent across the network.

- User name and password authentication (also called Basic authentication): A widely used, industry-standard method for transmitting user names and passwords across the network in an unencrypted form.

- Certificate or Secure Sockets Layer / Transport Layer Security (SSL/TLS) client authentication: A form of digital identification for your server and for clients that request information from your server. Its function is similar to that of a passport, or other official identity card, that identifies the person carrying it. Certificates are part of the SSL features in Internet Information Services (IIS) that establish a secure connection for sensitive information.

If you want to use a specific authentication method or methods, you can use the following procedure to select one or more methods that will apply to users of the application. You perform this procedure on a resource federation server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To configure authentication methods for a federated application**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, double-click **Applications**, right-click the application whose authentication methods you want to change, and then click **Properties**.
3. On the **Authentication Methods** tab, to select from the available authentication methods, do one of the following:
   - To allow all possible authentication methods in the list, select the **Any** check box.
   - To allow one or more of the available authentication methods, clear the **Any** check box, and then select one or more of the available methods.
4. When you finish selecting authentication methods, click **OK**.

# Adding and Configuring a Claims-aware Application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

You can configure the Active Directory Federation Services (ADFS) Web Agent for claims-aware applications by using the Web.config file in the Web application directory (typically \Inetpub\wwwroot*virtualDirectoryName*) on the Web server.

**Task requirements**

You need the following to perform the procedures for this task:

- You must have access to trust policy properties for the resource Federation Service.
- You must have access to the Web.config file for the Web application.
- Active Directory Federation Services MMC snap-in
- Internet Information Services (IIS) Manager MMC snap-in
- Notepad or other text editor

To complete this task, perform the following procedures:

- Add a new claims-aware application to the Federation Service
- Enable or disable a Web application
- Set the cookie path for a claims-aware application
- Set the cookie domain for a claims-aware application
- Set the Federation Service URL for a claims-aware application
- Set the return URL for a claims-aware application
- Set the application URL for an application
- Configure event logging for a claims-aware application
- Configure authentication methods for a federated application

# Add a new claims-aware application to the Federation Service

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When you configure your Active Directory Federation Services (ADFS)–enabled Web server to host a claims-aware application, you must add a reference to that application in the trust policy so that you can specify application properties for the Federation Service. You can use the following procedure to add a new claims-aware application to the Federation Service. You perform this procedure on a federation server in the resource partner.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To add a new claims-aware application to the Federation Service**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, right-click **Applications**, point to **New**, and then click **Application**.
3. On the **Welcome to the Add Application Wizard** page, click **Next**.
4. On the **Application Type** page, click **Claims-aware application**, and then click **Next**.
5. On the **Application Details** page, in **Application display name**, type the name of the application.
6. In **Application URL**, type the Uniform Resource Locator (URL) for your application—for example, https://www.treyresearch.net/*ApplicationName*/—and then click **Next**.

   | **Note** |
   | --- |
   | The value in **Application URL** on this property page must match precisely the Return URL value (in **<returnurl> </returnurl>**) that you specify in the web.config file of the claims-aware application (on the ADFS-enabled Web server). |

7. On the **Accepted Identity Claims** page, select the check boxes for the claim types that will be recognized by your claims-aware application, and then click **Next**.
8. On the **Enable this Application** page, ensure that the **Enable this application** check box is selected, and then click **Next**.
9. On the **Completing the Add Application Wizard** page, click **Finish**.

# Enable or disable a Web application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Web applications are enabled by default when you create them in the Active Directory Federation Services (ADFS) snap-in. You can disable an application if it is currently enabled. If you disable an application, access to the application is prevented.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To enable or disable a Web application**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, and then double-click **Applications**.
3. Right-click the application you want to enable or disable and do one of the following:
   - If the application is disabled and you want to enable it, click **Enable**.
   - If the application is enabled and you want to disable it, click **Disable**.

# Set the Federation Service URL for a claims-aware application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

The Federation Service Uniform Resource Locator (URL) in Active Directory Federation Services (ADFS) defines the URL that is used for all Web sites and Web applications on a federation Web server where the ADFS Web Agent is enabled. If the Federation Service URL for a Web server that hosts a claims-aware application changes, you must update the ADFS Web Agent by editing the Web.config file for the application.

**Administrative credentials**

To complete this procedure, you must have read-write access to the Web.config file.

**To set the Federation Service URL for a claims-aware application using the Web.config file**

1. In Notepad or other text editor, open the Web.config file that is in the Web application directory (typically \Inetpub\wwwroot*ApplicationName*) on the Web server.
2. Search for **<fs>**.
3. In the current entry (for example, https://adfsresource.trey.net/adfs/fs/federationserverservice.asmx), select the domain name portion of the URL, and then replace the name with a different fully qualified domain name.
4. Save and close the Web.config file.

# Set the return URL for a claims-aware application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

The return Uniform Resource Locator (URL) in Active Directory Federation Services (ADFS) that you configure in the ADFS Web Agent on a Web server reflects the URL that opens a requested Web application. If this URL changes for a claims-aware application, you must change its value in the Web.config file.

The return URL must match the application URL that you configure in the properties of the application in the resource Federation Service. Therefore, if you change one, you must change the other.

### Administrative credentials

To complete this procedure, you must have read-write access to the Web.config file.

**To set the return URL for a claims-aware application using the Web.config file**

1. In Notepad or other text editor, open the Web.config file that is in the Web application directory (typically \Inetpub\wwwroot*ApplicationName*) on the Web server.
2. Search for **<returnurl>**.
3. In the current entry, select the portion of the URL that is changing, and then type the new value.
4. Save and close the Web.config file.
5. If you have not already done so, change the application URL to match the new value of the return URL.

# Set the cookie path for a claims-aware application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

The cookie path specifies the location within an Internet Information Services (IIS) Web site virtual directory for which cookies will be sent in response to an application request by an Active Directory Federation Service (ADFS) client. If no cookie path is set, the path defaults to a location that depends on whether a cookie domain is set, as follows:

- Cookie domain is set: / below the domain that applies for the requested address on the basis of the cookie domain.
- No cookie domain is set: / below the domain specified in the Federation Service Uniform Resource Identifier (URI).

If you specify a cookie path (for example, /test01), the cookie is sent for requests under that path (for example, /test01, /test01/index.html, /test01/test05/, and so on).

The cookie path setting is configured in the ADFS Web Agent for an application. For a claims-aware application, configure the ADFS Web Agent in the Web.config file.

**Administrative credentials**

To complete this procedure, you must have read-write access to the Web.config file.

**To set the cookie path for a claims-aware application using the Web.config file**

1. In Notepad or other text editor, open the Web.config file that is in the Web application directory (typically \Inetpub\wwwroot*ApplicationName*) on the Web server.
2. Search for the opening tag string **<cookies**.
3. In the current entry for **<path>**, select the existing path and replace it by typing the new path. If the path entry does not exist, type a new one (for example: **<path>https://**).
4. Save and close the Web.config file.

# Configure event logging for a claims-aware application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Use the following procedure to specify the level of events that you want to be logged for claims-aware applications in the Application event log on the Web server that is protected by Active Directory Federation Services (ADFS).You set event logging for claims-aware applications in the Web.config file for the application.

You can apply the following event logging settings in the web.config file:

- **Error:** An alert that provides information about a significant problem of which the user should be aware, usually involving a loss of functionality or data.
- **Warning:** An alert that indicates a problem that is not immediately significant but that may signify conditions that could cause future issues.
- **Info:** An alert that provides information about a significant, successful operation.
- **SuccessAudit:** A security event that occurs when an audited access attempt succeeds, for example, a successful logon attempt.
- **FailureAudit:** A security event that occurs when an audited access attempt fails, for example, a failed attempt to open a file.
- **DetailedSuccess:** A success audit event that provides detailed information about each token that is involved in the transaction, including claims information.
- **DetailedFailure:** A failure audit event that provides detailed information about each token that is involved in the transaction, including claims information.
- **Everything:** Enables all logging levels.

### Administrative credentials

To complete this procedure, you must have Read-Write access to the Web.config file.

#### To configure event logging for a claims-aware application

1. In Notepad, open the Web.config file in the directory that stores the claims-aware application.
2. Search the file for <websso>.
3. Add or change the **<auditlevel>** entry under **<websso>**, as follows:

   **<auditlevel>** *Value* **</auditlevel>**

   Where *Value* is one of the following or the combined values of two or more:

   - Error = 1
   - Warning = 2
   - Info = 4
   - SuccessAudit = 16
   - FailureAudit = 32
   - DetailedSuccess = 64

- DetailedFailure = 128
- Everything = 247

4. Save and close the web.config file.

# Configure authentication methods for a federated application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

By default, a Web application that you configure in Active Directory Federation Services (ADFS) accepts any of the following authentication methods:

- Windows Integrated authentication (also referred to as Windows NT Challenge/Response authentication): A secure form of authentication because the user name and password are hashed before they are sent across the network.

- User name and password authentication (also called Basic authentication): A widely used, industry-standard method for transmitting user names and passwords across the network in an unencrypted form.

- Certificate or Secure Sockets Layer / Transport Layer Security (SSL/TLS) client authentication: A form of digital identification for your server and for clients that request information from your server. Its function is similar to that of a passport, or other official identity card, that identifies the person carrying it. Certificates are part of the SSL features in Internet Information Services (IIS) that establish a secure connection for sensitive information.

If you want to use a specific authentication method or methods, you can use the following procedure to select one or more methods that will apply to users of the application. You perform this procedure on a resource federation server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To configure authentication methods for a federated application**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, double-click **Applications**, right-click the application whose authentication methods you want to change, and then click **Properties**.
3. On the **Authentication Methods** tab, to select from the available authentication methods, do one of the following:
   - To allow all possible authentication methods in the list, select the **Any** check box.
   - To allow one or more of the available authentication methods, clear the **Any** check box, and then select one or more of the available methods.
4. When you finish selecting authentication methods, click **OK**.

# Managing Security for Web Applications

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

You can use a common set of procedures to manage security for Web applications that are protected by Active Directory Federation Services (ADFS) Web Agents for both Windows NT token-based applications and claims-aware applications.

**Task requirements**

You need the following to perform the procedures for this task:

- You must have the following information about how to control access to the application:
    - The appropriate authentication methods.
    - The security token protection methods.
    - The appropriate security token lifetime.
- Active Directory Federation Services (ADFS) MMC snap-in.
- The Web.config file located in %systemdrive%\ADFS\sts on a federation server.

To complete this task, perform the following procedures on an as-needed basis:

- Configure authentication methods for a federated application
- Configure the security token protection method for a federated application
- Change the token lifetime for an application
- Configure a policy page for a Web site

# Configure authentication methods for a federated application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

By default, a Web application that you configure in Active Directory Federation Services (ADFS) accepts any of the following authentication methods:

- Windows Integrated authentication (also referred to as Windows NT Challenge/Response authentication): A secure form of authentication because the user name and password are hashed before they are sent across the network.

- User name and password authentication (also called Basic authentication): A widely used, industry-standard method for transmitting user names and passwords across the network in an unencrypted form.

- Certificate or Secure Sockets Layer / Transport Layer Security (SSL/TLS) client authentication: A form of digital identification for your server and for clients that request information from your server. Its function is similar to that of a passport, or other official identity card, that identifies the person carrying it. Certificates are part of the SSL features in Internet Information Services (IIS) that establish a secure connection for sensitive information.

If you want to use a specific authentication method or methods, you can use the following procedure to select one or more methods that will apply to users of the application. You perform this procedure on a resource federation server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To configure authentication methods for a federated application**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, double-click **Applications**, right-click the application whose authentication methods you want to change, and then click **Properties**.
3. On the **Authentication Methods** tab, to select from the available authentication methods, do one of the following:
   - To allow all possible authentication methods in the list, select the **Any** check box.
   - To allow one or more of the available authentication methods, clear the **Any** check box, and then select one or more of the available methods.
4. When you finish selecting authentication methods, click **OK**.

# Configure the security token protection method for a federated application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Security tokens that are received by Active Directory Federation Services (ADFS) federation servers are protected during transit by one of two methods:

- Public Key Infrastructure (PKI): A PKI is implemented as a hierarchy of certification authorities that verify identities. When a PKI is in place, a signature is embedded into the token that protects the token from tampering.

- Domain service account: A domain service account, which is identified by a service principal name (SPN), runs under an account that is trusted for delegation and that can impersonate a client to gain access to resources. By default, this account is the Internet Information Services (IIS) application pool identity that hosts a claims-aware application and the identity of the ADFS Web Agent Authentication Service that hosts a Windows NT token–based application. When a token is transferred in a domain service account with this setting, the token contains a binary Kerberos V5 signature for the configured SPN. This signature protects the token from tampering.

You can use the following procedure to change the security token protection method for a federated application on a resource federation server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the security token protection method for a federated application**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Trust Policy**, double-click **My Organization**, and then double-click **Applications**.
3. Right-click the application whose security token protection method you want to change, and then click **Properties**.
4. On the **General** tab, under **Security token protection method**, do one of the following, and then click **OK**:
   - If your deployment uses certificates that are issued by a certification authority (CA), select **Public Key Infrastucture (PKI)**.
   - If your deployment does not use certificates that are issued by a CA, select **Domain service account** and then, in **service principal name (SPN) of service account**, type the SPN of the account.

Determine your security token protection method

# Change the token lifetime for an application

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

The token lifetime for an Active Directory Federation Services (ADFS) Web application indicates the time during which the security token contained in an ADFS authentication cookie remains in effect for the application. You can change this value in the application properties.

Perform this procedure on a resource federation server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the token lifetime for an application**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Trust Policy**, double-click **My Organization**, and then double-click **Applications**.
3. Right-click the application whose token lifetime you want to change, and then click **Properties**.
4. On the **Advanced** tab, in the **Token lifetime (minutes)** box, type or scroll to a new number of minutes, and then click **OK**.

**See Also**
**Concepts**
Change the token lifetime for a Federation Service

# Configure a policy page for a Web site

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

In a Web site that is protected by Active Directory Federation Services (ADFS), you can configure a policy page that will be provided to users who request a token for some or all resource partners. The policy page notifies the user of special protections that are in place. To configure the policy page, use the sample policy.aspx file in %systemdrive%\ADFS\SampleFiles to create an .aspx page that contains the appropriate text, and then use the following procedure to configure the Web.config file to open the page during logon.

Perform this procedure on an account federation server or account federation server proxy.

**Administrative credentials**

To complete this procedure, you must have read-write access to the Web.config file.

**To configure a policy page using the Web.config file**

1. Use Notepad or other text editor to open the Web.config file that is located in %systemdrive%\ADFS\sts on the federation server.
2. Search for **<forms>** under **<logonserver>**.
3. Add or change the <policy> entry under <forms>, as follows:

   **<policy>** *PathToPolicyFileName* **.aspx</policy>**
4. Save and close the Web.config file.

| **Note** |
| --- |
| This setting takes effect immediately for all users that subsequently reach the account Federation Service. However, users who already have a token and do not return to the Federation Service until that token expires are not affected. |

Enable enhanced identity privacy

# Backing Up ADFS Components

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Backing up Active Directory Federation Services (ADFS) components to preserve a snapshot of ADFS state is critical for ensuring a recovery option in the event of lost data or hardware failure.

ADFS state is maintained in the following places:

- TrustPolicy.xml file. The default location is *%systemdrive%*\adfs\sts.
- Web.config and other files under *%systemdrive%*\ADFS\..., especially any customized Web pages (*%systemdrive%*\ADFS\sts\ls).
- IIS metabase files (MetaBase.xml and MBSchema.xml) in *%systemroot%*\System32\Inetsrv (included in system state backup).
- Windows registry (included in system state backup).
- Custom transform module (.dll) or files related to the custom transform module.

Always back up system state on any federation server, federation server proxy, or Web server that you are backing up. System state contains the following components:

- System startup (boot) files. These files are required for Windows Server 2003 to start.
- System registry.
- IIS settings.
- Class registration database of component services. The Component Object Model (COM) is a binary standard for writing component software in a distributed systems environment.
- Windows Clustering or Certificate Services, if installed.

Use the following table to identify components to back up on servers that are running ADFS components.

| ADFS Component Running on Server | Files and Components to Back Up |
|---|---|
| Federation Service | • TrustPolicy.xml file<br>• Web.config and other files under *%systemdrive%E*\ADFS\...<br>• System state<br>• Custom transform module (.dll) and related files, if any |
| Federation Service Proxy | • Web.config and other files under *%systemdrive%*\ADFS\...<br>• System state |

| | |
|---|---|
| ADFS Web Agent | • *%systemdrive%*\ADFS\...<br>• System state |

| **Note** |
|---|
| For a claims-aware application, ADFS settings are contained in the Web.config file. For a Windows NT token-based application, ADFS settings are contained in the IIS metabase files. |

**Task requirements**

You need the following to perform the procedures for this task:

- Backup software

To complete this task, perform the following procedures:

- Back up ADFS components on a federation server, federation server proxy, or Web server

# Back up ADFS components on a federation server, federation server proxy, or Web server

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

This procedure provides instructions for using Ntbackup.exe to create a backup for Active Directory Federation Services (ADFS) components on federation servers, federation server proxies, and Web servers that are running the ADFS Web Agent. Ntbackup is available on all servers that are running Windows Server 2003. However, you can use any backup software to back up the components identified in Backing Up ADFS Components.

**Administrative credentials**

To complete this procedure, you must be a member of the Backup Operators group on the local computer.

**To back up ADFS components**

1. To start the Windows Server 2003 backup utility, click **Start**, click **Run**, type **ntbackup**, and then click **OK**.

| **Note** |
| --- |
| This procedure provides steps for backing up in Wizard Mode. By default, the **Always Start in Wizard Mode** check box is selected in the Backup or Restore Wizard. If the **Welcome to the Backup Utility Advanced Mode** page appears, click **Wizard Mode** to open the Backup or Restore Wizard. |

2. On the **Welcome to the Backup or Restore Wizard** page, click **Next**.
3. On the **Backup or Restore** page, click **Back up files and settings**, and then click **Next**.
4. On the **What to Back Up** page, click **Let me choose what to back up**, and then click **Next**.
5. On the **Items to Back Up** page, double-click **My Computer**.
6. In the expanded list below **My Computer**, expand **Local Disk (*DRIVE*:)** and make selections by placing check marks in the boxes for each directory that you want to back up, according to the ADFS component that is running on the server (see the table in Backing Up ADFS Components).
7. In the list below **My Computer**, place a check mark in the **System State** box, and then click **Next**.
8. On the **Backup Type, Destination, and Name** page, browse to select a location to save the backup, and type a name for the backup.
9. On the **Completing the Backup or Restore Wizard** page, click **Finish**.

Backing Up ADFS Components

# Managing ADFS Partnerships

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When an Active Directory Federation Services (ADFS) deployment supports a Web resource that must be accessed by other organizations across the Internet, you must manage the partnership between your organization and a partner organization. You can add and remove partners and configure the properties that allow users in the account partner to access resources and that allow the resource Web applications to appropriately recognize, authenticate, and authorize those users.

The following tasks for managing ADFS partnerships are described in this objective:

- Adding a New Account Partner
- Adding a New Resource Partner
- Configuring Windows Trust for Account and Resource Partners
- Removing ADFS Partners

**See Also**
**Other Resources**
Partner organizations

# Adding a New Account Partner

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

You can use the New Account Partner wizard to add an account partner to the resource Federation Service in Active Directory Federation Services (ADFS). This wizard allows you to create an account partner that requires manual configuration of the trust policy or imports an existing policy file that is provided (exported) by an existing federation server in the account partner, as follows:

- Manually configure the trust policy: If the corresponding account partner organization has not installed ADFS yet or does not plan to provide you with an exported policy file, create the account partner to use the values that you provide. To do so, you must have the following information about the account partner Federation Service:

  - Display name: The name of the account partner Federation Service. This name appears in the list of realms that is presented to clients that request access to a Web site that is protected by ADFS authentication and authorization.

  - Federation Service Uniform Resource Identifier (URI): Uniquely identifies the Federation Service, and identifies this server as a member of the account Federation Service, in the form **urn:federation:***OrganizationName*.

  - Federation Service endpoint Uniform Resource Locator (URL): The URL that will be used by clients to access a Web server in this Federation Service, in the form **https://***FullyQualifiedDomainName***/adfs/ls/**. If a federation server proxy is installed, the fully qualified domain name should be the host name of the federation server proxy. If no federation server proxy is installed, the fully qualified domain name should be the name you are using to represent federation servers in the account Federation Service.

- Import a trust policy file: When you import a policy file when creating an account partner, the properties of the new account partner are automatically entered in the trust policy by the New Account Partner wizard. This information is derived from the account Federation Service trust policy file, thereby eliminating configuration errors. To import a policy file, the account partner must have exported its generic policy file or partner policy file and provided you with the file or its shared location.

**Task requirements**

You need the following to perform the procedures for this task:

- Active Directory Federation Services snap-in running on a federation server.

To complete this task, perform the following procedures, as needed:

- Add a new account partner by manually configuring the trust policy

- Export an account or resource policy file to a partner organization

- Add a new account partner by importing an existing policy file

**See Also**
**Concepts**
Adding a New Resource Partner

# Add a new account partner by manually configuring the trust policy

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

To add a new account partner in Active Directory Federation Services (ADFS) and manually configure the trust policy, perform the following procedure on a resource federation server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To add a new account partner by manually configuring the trust policy**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. In the console tree, double-click **Federation Service**, **Trust Policy**, and **Partner Organizations**.
3. Right-click **Account Partners**, point to **New**, and then click **Account Partner**.
4. On the **Welcome to the Add Account Partner Wizard** page, click **Next**.
5. On the **Import Policy File** page, click **No**, and then click **Next**.
6. On the **Account Partner Details** page, do the following, and then click **Next**
   - In **Display name**, type the display name of the account partner.
   - In **Federation Service URI**, type the Uniform Resource Identifier (URI) of the account partner Federation Service.
   - In **Federation Service endpoint URL**, type the endpoint Uniform Resource Locator (URL) as follows:

     **With a Federation Service Proxy:** If the Federation Service Proxy is installed on servers in a perimeter network of the account domain, use the fully qualified domain name (FQDN) of any federation server proxy.

     **Without a Federation Service Proxy:** If your deployment does not use federation server proxies, use the FQDN of the account partner Federation Service.
7. On the **Account Partner Verification Certificate** page, type the path to the verification certificate, or browse to it, and then click **Next**.
8. On the **Federation Scenario** page, do one of the following, and then click **Next**:
   - If you are establishing a federated trust with another organization or you do not want to use an existing forest trust, click **Federated Web SSO**, and then go to step 10.
   - If you are establishing a federated trust within the same organization when both sides already share a forest trust, click **Federated Web SSO with Forest Trust**.
9. On the **Federated Web SSO with Forest Trust** page, do one of the following, and then click **Next**:
   - To accept users in all domains that are trusted by the account partner, click **All Active Directory domains and forests**. Any user that can authenticate to the account partner will be accepted.
   - To accept user accounts that are located in some of the domains that are trusted by the account partner, click **The following Active Directory domains and forests**. Then, in **New, trusted Active Directory domain or forest**, type the name of a domain or forest, and then click **Add**. Only users from the specified domains will be accepted.
10. On the **Account Partner Identity Claims** page, select one or more identity claims to share with the resource partner,

and then click **Next**:

- If the resource partner requires user principal name (UPN) claims to make authorization decisions, select the **UPN Claim** check box.

| **Important** |
| --- |
| When UPN claims or e-mail claims are used to make authorization decisions, it is essential that each account partner use a unique UPN suffix or e-mail suffix. If two account partners use the same UPN suffix or e-mail suffix, it might not be possible to identify users uniquely. This condition might allow a user from one account partner to receive the permissions that are intended for a user in another account partner. This condition might also introduce a significant security weakness because an administrator can intentionally create user accounts to impersonate users from one of your other account partners. |

| **Note** |
| --- |
| If you selected the **Federated Web SSO with Forest Trust** scenario, the **UPN Claim** option is selected and not configurable because UPN claims are required for this scenario. |

- If the resource partner requires e-mail claims to make authorization decisions, select the **E-mail Claim** check box.

- If the resource partner requires common name claims to make authorization decisions, select the **Common Name Claim** check box.

11. If you selected **UPN Claim** as an identity claim, on the **Accepted UPN Suffixes** page, type the accepted suffix, click **Add**, and then click **Next**. You may click to accept **All UPN suffixes** if you selected the **Federation Web SSO with Forest Trust** option.
12. If you selected **E-mail Claim** as an identity claim, on the **Accepted E-mail Suffixes** page, type the accepted suffix, click **Add**, and then click **Next**. You may click to accept **All E-mail suffixes** if you selected the **Federation Web SSO with Forest Trust** option.

| **Note** |
| --- |
| Common name claims require no additional information. |

13. On the **Enable this Account Partner** page, if you do not want to enable the account partner now, clear the **Enable this account partner** check box, and then click **Next**.
14. To add the new account partner and close the wizard, click **Finish**.

# Export an account or resource policy file to a partner organization

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If you have created an Active Directory Federation Services (ADFS) resource or account partner in your side of a federated partnership, you can export a trust policy file that has information about both your Federation Service and the Federation Service of the respective account or resource partner Federation Service. The policy file contains the following information that the prospective partner can use to configure its Federation Service trust policy:

- Resource Display Name
- Resource URI
- Resource Federation Server Proxy URL
- Account Display Name
- Account URI
- Account Federation Server Proxy URL
- Account Verification Certificate

For example, if you are a resource partner, you can export your partner policy file and provide it to the account partner organization. When the account partner adds a resource partner for your organization and selects the option to import your policy file, the Add Resource Partner wizard uses the imported file to automatically update the trust policy with the correct information for both organizations.

Perform this procedure on a federation server that hosts the account or resource partner that represents the Federation Service whose policy file you are exporting. The **Export Policy** command in the Active Directory Federation Services snap-in creates the file with the name and location that you provide.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To export an account or resource policy file**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Trust Policy**, double-click **Partner Organizations**, and then double-click **Account Partners** or **Resource Partners**, depending on the federation server role.
3. Right-click the account or resource partner, and then click **Export Policy**.
4. In the **Export Partner Policy** dialog box box, click **Browse** to browse to the location for the partner policy file (or type the path and file name in **Policy file Location**, and then click **OK**).
5. In the **Save As** dialog box, click **Save** and then click **OK**.
6. Notify the partner organization and make the exported file available to the partner organization.

**See Also**
**Concepts**
Export a generic policy file to a partner organization

# Add a new account partner by importing an existing policy file

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If you have received an exported Active Directory Federation Services (ADFS) trust policy file from the account partner organization, perform the following procedure on a resource federation server to automatically configure the new account partner by importing the policy file.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To add a new account partner by importing an existing policy file**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. In the console tree, double-click **Federation Service**, double-click **Trust Policy**, and then double-click **Partner Organizations**.
3. Right-click **Account Partners**, point to **New**, and then click **Account Partner**.
4. On the **Welcome to the Add Account Partner Wizard** page, click **Next**.
5. On the **Import Policy File** page, click **Yes**. In **Partner interoperability policy file**, type or browse to the policy file that you want to import, and then click **Open**.
6. On the **Federation Scenario** page, do one of the following, and then click **Next**:
   - If you are establishing a federated trust with another organization or you do not want to use an existing forest trust, click **Federated Web SSO**, and then go to step 8.
   - If you are establishing a federated trust within the same organization when both sides already share a forest trust, click **Federated Web SSO with Forest Trust**.
7. On the **Federated Web SSO with Forest Trust** page, do one of the following, and then click **Next**:
   - To accept users in all domains that are trusted by the account partner, click **All Active Directory domains and forests**. Any user that can authenticate to the account partner will be accepted.
   - To accept user accounts that are located in some of the domains that are trusted by the account partner, click **The following Active Directory domains and forests**. Then, in **New, trusted Active Directory domain or forest**, type the name of a domain or forest, and then click **Add**. Only users from the specified domains will be accepted. If you need to remove a domain or forest, click **Remove**.
8. On the **Account Partner Identity Claims** page, select one or more identity claims to share with the resource partner, and then click **Next**:
   - If the resource partner requires user principal name (UPN) claims to make authorization decisions, select the **UPN Claim** check box.

| **Important** |
| --- |
| When UPN claims or e-mail claims are used to make authorization decisions, it is essential that each account partner use a unique UPN suffix or e-mail suffix. If two account partners use the same UPN suffix or e-mail suffix, it might not be possible to uniquely identify users. This condition might allow a user from one account partner to receive the permissions that are intended for a user in another account partner. This condition might also introduce a significant security weakness because an administrator can intentionally create user accounts to impersonate users from one of your other account partners. |

| **Note** |
| --- |

| |
|---|
| If you selected the **Federated Web SSO with Forest Trust** scenario, the **UPN Claim** option is selected and not configurable because UPN claims are required for this scenario. |

- If the resource partner requires e-mail claims to make authorization decisions, select the **E-mail Claim** check box.
- If the resource partner requires common name claims to make authorization decisions, select the **Common Name Claim** check box.

9. If you selected **UPN Claim** as an identity claim, on the **Accepted UPN Suffixes** page, type the accepted suffix, click **Add**, and then click **Next**. You may click to accept **All UPN suffixes** if you selected the **Federation Web SSO with Forest Trust** option.
10. If you selected **E-mail Claim** as an identity claim, on the **Accepted E-mail Suffixes** page, type the accepted suffix, click **Add**, and then click **Next**. You may click to accept **All E-mail suffixes** if you selected the **Federation Web SSO with Forest Trust** option.

| **Note** |
|---|
| Common name claims require no additional information. |

11. On the **Enable this Account Partner** page, if you do not want to enable the account partner now, clear the **Enable this account partner** check box, and then click **Next**.
12. To add the new account partner and close the wizard, click **Finish**.

Export an account or resource policy file to a partner organization
Add a new account partner by manually configuring the trust policy

# Adding a New Resource Partner

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

You can use the New Resource Partner wizard to add a resource partner to the account Federation Service. This wizard allows you to create a resource partner that requires manual configuration of the trust policy or imports an existing policy file that is provided (exported) by an existing federation server, as follows:

- Manually configure the trust policy: If the corresponding resource partner organization does not plan to provide you with an exported policy file, create the resource partner to use the values that you provide. To do so, you must have the following information about the resource partner:

    - Display name: The name the resource partner uses to identify itself.

    - Federation Service Uniform Resource Identifier (URI): Uniquely identifies the Federation Service, and identifies this server as a member of the account Federation Service, in the form **urn:federation:***OrganizationName*.

    - Federation Service endpoint Uniform Resource Locator (URL): The URL that will be used by clients to access a server in this Federation Service, in the form **https://***FullyQualifiedDomainName***/adfs/ls/**

- Import a policy file: When you import a policy file during resource partner creation, the properties of the new resource partner are automatically entered in the trust policy by the New Resource Partner wizard according to the information in the resource policy file, thereby eliminating configuration errors. To import a policy file, the resource partner must have exported its generic policy file or partner policy file and provided you with the file or its shared location.

**Task requirements**

You need the following to perform the procedures for this task:

- Active Directory Federation Services snap-in running on a federation server.

To complete this task, perform one of the following procedures:

- Add a new resource partner by manually configuring the trust policy

- Add a new resource partner by importing an existing policy file

# Add a new resource partner by manually configuring the trust policy

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

To add a new resource partner in Active Directory Federation Services (ADFS) and manually configure the trust policy, perform the following procedure on an account federation server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To add a new resource partner by manually configuring the trust policy**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. In the console tree, double-click **Federation Service**, **Trust Policy**, and **Partner Organizations**.
3. In the console tree, right-click **Resource Partners**, point to **New**, and then click **Resource Partner**.
4. On the **Welcome to the Add Resource Partner Wizard** page, click **Next**.
5. On the **Import Policy File** page, ensure that **No** is selected, and then click **Next**.
6. On the **Resource Partner Details** page, do the following, and then click **Next**:
   - In **Display name**, type the display name of the resource partner.
   - In **Federation Service URI**, type the Uniform Resource Identifier (URI) for the resource partner Federation Service.
   - In **Federation Service endpoint URL**, type the endpoint Uniform Resource Locator (URL) of the resource partner Federation Service.
7. On the **Federation Scenario** page, do one of the following, and then click **Next**:
   - If you are establishing a federated trust with another organization or you do not want to use an existing forest trust, click **Federated Web SSO**.
   - If you are establishing a federated trust within the same organization when both sides already share a forest trust, click **Federated Web SSO with Forest Trust**.
8. On the **Resource Partner Identity Claims** page, select one or more identity claims to share with the resource partner, and then click **Next**:
   - If the resource partner requires user principal name (UPN) claims to make authorization decisions, select the **UPN Claim** check box.

     | **Note** |
     | --- |
     | If you selected the **Federated Web SSO with Forest Trust** scenario, the **UPN Claim** option is selected and not configurable because UPN claims are required for this scenario. |

   - If the resource partner requires e-mail claims to make authorization decisions, select the **E-mail Claim** check box.
   - If the resource partner requires common name claims to make authorization decisions, select the **Common Name Claim** check box.
9. If you selected **UPN Claim** as an identity claim, on the **Select UPN Suffix** page, do one of the following, and then click

**Next**:

- To pass all UPN suffixes through without replacing them, click **Pass all UPN suffixes through unchanged**.
- To replace all UPN suffixes with a different suffix, click **Replace all UPN suffixes with the following**, and then type the suffix that you want to use to replace all UPN suffixes.

10. If you selected **E-mail Claim** as an identity claim, on the **Select E-mail Suffix** page, do one of the following, and then click **Next**:

    - To pass all e-mail suffixes without replacing them, click **Pass all E-mail suffixes through unchanged**.
    - To replace all e-mail suffixes with a different suffix, click **Replace all E-mail suffixes with**, and then type the suffix that you want to use to replace all e-mail suffixes.

| **Note** |
| --- |
| Common name claims require no additional information. |

11. On the **Enable this Resource Partner** page, if you do not want to enable the resource partner now, clear the **Enable this resource partner** check box, and then click **Next**.
12. To add the new resource partner and close the wizard, click **Finish**.

Add a new resource partner by importing an existing policy file

# Export an account or resource policy file to a partner organization

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If you have created an Active Directory Federation Services (ADFS) resource or account partner in your side of a federated partnership, you can export a trust policy file that has information about both your Federation Service and the Federation Service of the respective account or resource partner Federation Service. The policy file contains the following information that the prospective partner can use to configure its Federation Service trust policy:

- Resource Display Name
- Resource URI
- Resource Federation Server Proxy URL
- Account Display Name
- Account URI
- Account Federation Server Proxy URL
- Account Verification Certificate

For example, if you are a resource partner, you can export your partner policy file and provide it to the account partner organization. When the account partner adds a resource partner for your organization and selects the option to import your policy file, the Add Resource Partner wizard uses the imported file to automatically update the trust policy with the correct information for both organizations.

Perform this procedure on a federation server that hosts the account or resource partner that represents the Federation Service whose policy file you are exporting. The **Export Policy** command in the Active Directory Federation Services snap-in creates the file with the name and location that you provide.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To export an account or resource policy file**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Trust Policy**, double-click **Partner Organizations**, and then double-click **Account Partners** or **Resource Partners**, depending on the federation server role.
3. Right-click the account or resource partner, and then click **Export Policy**.
4. In the **Export Partner Policy** dialog box box, click **Browse** to browse to the location for the partner policy file (or type the path and file name in **Policy file Location**, and then click **OK**).
5. In the **Save As** dialog box, click **Save** and then click **OK**.
6. Notify the partner organization and make the exported file available to the partner organization.

Export a generic policy file to a partner organization

# Add a new resource partner by importing an existing policy file

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If you have received a policy file from your resource partner organization that you can import, perform the following procedure on the account federation server on which you are creating the new resource partner.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To add a new resource partner by importing an existing policy file**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. In the console tree, double-click **Federation Service**, **Trust Policy**, and **Partner Organizations**.
3. Right-click **Resource Partners**, point to **New**, and then click **Resource Partner**.
4. On the **Welcome to the Add Resource Partner Wizard** page, click **Next**.
5. On the **Import Policy File** page, do the following, and then click **Next**:
   - Click **Yes**.
   - In **Partner interoperability policy file**, browse to or type the location of the resource partner policy file.
6. On the **Federation Scenario** page, do one of the following, and then click **Next**:
   - If you are establishing a federated trust with another organization or you do not want to use an existing forest trust, click **Federated Web SSO**.
   - If you are establishing a federated trust within the same organization when both sides already share a forest trust, click **Federated Web SSO with Forest Trust**.
7. On the **Resource Partner Identity Claims** page, select one or more identity claims that the account partner will provide to the resource partner, and then click **Next**:
   - If the resource partner requires user principal name (UPN) claims to make authorization decisions, select the **UPN Claim** check box.

     | **Note** |
     | --- |
     | If you selected the **Federated Web SSO with Forest Trust** scenario, the **UPN Claim** option is selected and not configurable because UPN claims are required for this scenario. |

   - If the resource partner requires e-mail claims to make authorization decisions, select the **E-mail Claim** check box.
   - If the resource partner requires common name claims to make authorization decisions, select the **Common Name Claim** check box.
8. If you selected **UPN Claim** as an identity claim, on the **Select UPN Suffix** page, select one of the following, and then click **Next**.
   - To pass all UPN suffixes through without replacing them, click **Pass all UPN suffixes through unchanged**.
   - To replace all UPN suffixes with a different suffix, click **Replace all UPN domain suffixes with the following**, type the suffix that you want to use to replace all UPN suffixes, and then click **Add**.

9. If you selected **E-mail Claim** as an identity claim, on the **Select E-mail Suffix** page, do one of the following, and then click **Next**:

   - To pass all e-mail suffixes without replacing them, click **Pass all e-mail suffixes through unchanged**.

   - To replace all UPN suffixes with a different suffix, click **Replace all E-mail suffixes with**, and then type the suffix that you want to use to replace all e-mail suffixes.

| **Note** |
| --- |
| Common name claims require no additional information. |

10. On the **Enable this Resource Partner** page, if you do not want to enable the resource partner now, clear the **Enable this resource partner** check box, and then click **Next**.

11. To add the new resource partner and close the wizard, click **Finish**.

Add a new resource partner by manually configuring the trust policy

# Configuring Windows Trust for Account and Resource Partners

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

An Active Directory Federation Services (ADFS) deployment in a federated scenario can be configured with or without a Windows trust relationship. In a Federated Web single sign-on (SSO) scenario, a federation trust is created between the two partners, but a Windows trust relationship, if one exists between the two partners, is not used. In a Federated Web SSO with Forest Trust scenario, an organization that has a Windows trust relationship between the two Active Directory forests (the resource forest trusts the account forest) configures ADFS partners to use the Windows trust relationship.

The Windows trust between the forests of the two partners (either a forest trust between two Windows Server 2003 forests or an external trust between Windows Server 2003 or Windows 2000 Server domains in each forest) must be enabled for ADFS by both the resource partner and the account partner. The account partner must be configured to select the domains that are to be included in the trust relationship. You must also configure the resource partner in the account Federation Service.

**Task requirements**

You need the following to perform the procedures for this task:

- A Windows trust between the two partners (two Windows Server 2003 forests or an external trust between Windows Server 2003 or Windows 2000 Server domains in each forest), where the resource forest or domain has a trust relationship with the account forest or domain.
- A federation server in each partner organization.
- The Active Directory Federation Services snap-in.

This task provides procedures to begin using or discontinue Windows trust in both partners:

- Configure an account partner to use Windows trust
- Configure a resource partner to use Windows trust
- Discontinue Windows trust for an account partner
- Discontinue Windows trust for a resource partner

Administering Domain and Forest Trusts

# Configure an account partner to use Windows trust

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

You must configure the account partner to select the domains that are to be included in the trust relationship. For example, if a Windows Server 2003 forest trust is in place from the resource partner forest to the account partner forest, the trust is transitive to all domains in the trusted account forest.

If you want to grant access to resources in the resource forest to users in only some domains in the account forest, you can specify only those domains. Otherwise, you can allow all trusted domains (all domains in the account forest and any forest that is trusted by the account forest) to be granted access.

Use the following procedure to enable Windows trust for the account partner that will participate in the Federated Web SSO with Forest Trust design scenario.

Perform this procedure on a federation server in the resource partner organization.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To configure an account partner to use Windows trust**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, and then double-click **Account Partners**.
3. Right-click the account partner that you want to configure to use Windows trust, and then click **Properties**.
4. On the **Windows Trust** tab, click **Use Windows trust relationship**.
5. In **Trusted Active Directory domains and forests**, do one of the following, and then click **OK**:
   - Click **All Active Directory domains and forests** if you want to allow users in all trusted domains in the account partner forest and in any forest that is trusted by the account partner forest, and then click **OK**.
   - Click **Specified Active Directory domains and forests (press Enter to separate entries)** if you want to name only the domains where you want to allow federated access. Type a domain name, press ENTER, and then repeat this action to add each domain in the account partner forest and in any other trusted forests for the users that you want to grant access to resources.

# Configure a resource partner to use Windows trust

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Use the following procedure to enable Windows trust for a resource partner in an Active Directory Federation Services (ADFS) Federated Web SSO with Forest Trust scenario.

| **Note** |
| --- |
| When you enable the Windows trust option in the account Federation Service, you are sending actual security identifiers (SIDs) to the resource partner organization over the Internet, which may be a security risk. These SIDs are packaged in the ADFS Security Assertion Markup Language (SAML) token. Therefore, enable this option only when you are using the Federated Web SSO with Forest Trust design. This design is meant to establish secure communication within the same organization. |

Perform this procedure on an account federation server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To configure a resource partner to use Windows trust**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, and then double-click **Resource Partners**.
3. Right-click the resource partner for which you want to configure Windows trust, and then click **Properties**.
4. On the **General** tab, click **Use Windows trust relationship for this partner**, and then click **OK**.

# Discontinue Windows trust for an account partner

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If you want to stop using Windows trust for an account partner in an Active Directory Federation Services (ADFS) scenario, you can configure the account partner to not use the Windows trust relationship.

Perform this procedure on a resource federation server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To discontinue using Windows trust for an account partner**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, and then double-click **Account Partners**.
3. Right-click the account partner for which you want to stop using Windows trust, and then click **Properties**.
4. On the **Windows Trust** tab, clear the **Use Windows trust relationship** check box, and then click **OK**.

# Discontinue Windows trust for a resource partner

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If you want to stop using Windows trust for a resource partner, you can configure the resource partner to not use the Windows trust relationship.

Perform this procedure on an account federation server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To discontinue using Windows trust for a resource partner**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, and then double-click **Resource Partners**.
3. Right-click the resource partner for which you want to stop using Windows trust, and then click **Properties**.
4. On the **General** tab, clear the **Use Windows trust relationship for this partner** check box, and then click **OK**.

# Removing ADFS Partners

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

A resource partner in an Active Directory Federation Services (ADFS) deployment can have more than one account partner, and vice versa. When a partner organization is to be removed from the federation, you must remove the partner node in the trust policy on the other side of the ADFS partnership. The partner that is being removed from the federation must remove its federation servers and federation server proxies, as well. For information about removing servers that are running ADFS components, see Managing ADFS Components.

**Task requirements**

You need the following tool to perform the procedures for this task:

- Active Directory Federation Services MMC snap-in

To complete this task, perform the following procedures:

- Delete an existing account partner
- Delete an existing resource partner
- Managing ADFS Components

# Delete an existing account partner

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Use this procedure to delete the account partner node for an account partner that is no longer a member of your Active Directory Federation Services (ADFS) deployment.

Perform this procedure on a federation server in the resource Federation Service.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To delete an account partner**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, and then double-click **Account Partners**.
3. Right-click the account partner you want to delete, and then click **Delete**.
4. In the **Delete Account Partner** dialog box, click **Yes** to confirm the deletion.

# Delete an existing resource partner

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Use this procedure to delete the resource partner node for a resource partner that is no longer a member of an Active Directory Federation Services (ADFS) deployment.

Perform this procedure on a federation server in the account Federation Service.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To delete a resource partner**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, and then double-click **Resource Partners**.
3. Right-click the resource partner you want to delete, and then click **Delete**.
4. In the **Delete Resource Partner** dialog box, click **Yes** to confirm the deletion.

# Managing Partner Relationships

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

In an Active Directory Federation Services (ADFS) partnership, you can manage privacy aspects of the partner experience, export your trust policy for a partner, and manage resource (impersonation) accounts. You can also enable or disable a partner when you need to temporarily suspend the partnership.

**Task requirements**

You need the following to perform the procedures for this task:

- Active Directory Federation Services MMC snap-in.

To complete this task, perform the following procedures on an as-needed basis:

- Enable enhanced identity privacy
- Export a generic policy file to a partner organization
- Export an account or resource policy file to a partner organization
- Enable or disable a resource partner
- Enable or disable an account partner
- Configure resource account optionsr

# Enable enhanced identity privacy

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Enhanced identity privacy is an optional setting that you can configure on a resource partner in the account Federation Service in an Active Directory Federation Services (ADFS) deployment. This setting hashes the user-name portion of outgoing user principal name (UPN) claims and e-mail claims. It substitutes the common name with a random value. If you select the **Enable enhanced identity privacy** option in ADFS, the resource partner will not be able to correlate identity claims to personally identifiable user information.

The enhanced identity privacy setting affects the information that is sent in identity claims, based on the claim type that is being used to transfer the user identity, as follows:

- UPN and e-mail claim types: The user component of the UPN and e-mail name is hashed, replacing the user component in the identity claim of the security token. In this way, each resource partner can uniquely identify each user without revealing their true identity.

- Common name claim types: The common name identity claim is populated with a randomly generated, globally unique identifier (GUID), which ensures that the identity claim is unique per session with the resource partner and that multiple sessions by the same user cannot be tracked.

Enable this setting if you want to:

- Prevent collusion between partners in correlating identity claims to personally identifiable user information.

- Prevent simple dictionary attacks against the user-name hash.

For more information about the effects of enhanced identity privacy, see Partner organizations (http://go.microsoft.com/fwlink/?LinkId=62227).

Perform this procedure on an account federation server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To enable enhanced identity privacy on a resource partner**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, and then double-click **Resource Partners**.
3. Right-click the resource partner that will begin using enhanced identity privacy, and then click **Properties**.
4. On the **General** tab, click **Enable enhanced identity privacy**, and then click **OK**.

Configure a policy page for a Web site

# Export a generic policy file to a partner organization

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

To begin an Active Directory Federation Services (ADFS) federated partnership with another organization, prior to adding resource and account partners, you can export a generic policy file that the other organization can use to configure your organization as either its account or resource partner. For example, if you are administering a resource organization, you can export a generic policy file that the account organization can use to configure your organization as its resource partner in ADFS. You must make the file available to the partner organization, which can then import the file.

The exported generic policy file contains the following information:

- Your organization's display name
- Federation Service endpoint URL
- Federation Service URI
- Verification certificate (for an exported account partner only)

When the partner organization imports this policy file when adding a resource or account partner that represents your organization, the wizard (Add Resource Partner Wizard or Add Account Partner Wizard) automatically configures the new partner with the correct information for your organization, eliminating the possibility of mistyping the various required identifiers.

Perform this procedure on a federation server that hosts the policy file you want to share with another organization that will become a partner in a federated partnership. The **Export Policy** command in the Active Directory Federation Services snap-in creates the file with the name and location that you provide.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To export a generic policy file**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click **Trust Policy**, and then click **Export Policy**.
3. In the **Export Generic Partner Policy** dialog box, click **Browse** to browse to the location for the generic policy file (or type the path and file name in **Policy file Location**, and then click **OK**).
4. In the **Save As** dialog box, in **File name**, type a name for the generic trust policy file, click **Save**, and then click **OK**.
5. Make the exported file available to the partner organization.

**See Also**
**Concepts**
Export an account or resource policy file to a partner organization

# Export an account or resource policy file to a partner organization

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If you have created an Active Directory Federation Services (ADFS) resource or account partner in your side of a federated partnership, you can export a trust policy file that has information about both your Federation Service and the Federation Service of the respective account or resource partner Federation Service. The policy file contains the following information that the prospective partner can use to configure its Federation Service trust policy:

- Resource Display Name
- Resource URI
- Resource Federation Server Proxy URL
- Account Display Name
- Account URI
- Account Federation Server Proxy URL
- Account Verification Certificate

For example, if you are a resource partner, you can export your partner policy file and provide it to the account partner organization. When the account partner adds a resource partner for your organization and selects the option to import your policy file, the Add Resource Partner wizard uses the imported file to automatically update the trust policy with the correct information for both organizations.

Perform this procedure on a federation server that hosts the account or resource partner that represents the Federation Service whose policy file you are exporting. The **Export Policy** command in the Active Directory Federation Services snap-in creates the file with the name and location that you provide.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To export an account or resource policy file**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Trust Policy**, double-click **Partner Organizations**, and then double-click **Account Partners** or **Resource Partners**, depending on the federation server role.
3. Right-click the account or resource partner, and then click **Export Policy**.
4. In the **Export Partner Policy** dialog box box, click **Browse** to browse to the location for the partner policy file (or type the path and file name in **Policy file Location**, and then click **OK**).
5. In the **Save As** dialog box, click **Save** and then click **OK**.
6. Notify the partner organization and make the exported file available to the partner organization.

**See Also**
**Concepts**
Export a generic policy file to a partner organization

# Enable or disable a resource partner

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Active Directory Federation Services (ADFS) resource partners are enabled by default when you create them in the Active Directory Federation Services snap-in. If a resource partner is currently enabled, you can disable it. If a resource partner is currently disabled, you can enable it.

Perform this procedure on an account federation server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**ToTo enable or disable a resource partner**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, and then double-click **Resource Partners**.
3. Right-click the resource partner you want to enable or disable and do one of the following:
   - If the resource partner is disabled and you want to enable it, click **Enable**.
   - If the resource partner is enabled and you want to disable it, click **Disable**.

| **Note** |
| --- |
| You can also perform this procedure by right-clicking the resource partner, clicking **Properties**, and then selecting or clearing the **Enable this partner** check box. |

# Enable or disable an account partner

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Active Directory Federation Services (ADFS) account partners are enabled by default when you create them in the Active Directory Federation Services snap-in. If an account partner is currently enabled, you can disable it. If an account partner is currently disabled, you can enable it.

Perform this procedure on a resource federation server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**ToTo enable or disable an account partner**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, and then double-click **Account Partners**.
3. Right-click the account partner you want to enable or disable and do one of the following:
   - If the account partner is disabled and you want to enable it, click **Enable**.
   - If the account partner is enabled and you want to disable it, click **Disable**.

| **Note** |
| --- |
| You can also perform this procedure by right-clicking the account partner, clicking **Properties**, and then selecting or clearing the **Enable this partner** check box. |

# Configure resource account options

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

By adjusting resource account options in the resource Federation Service, resource partner administrators can refine how access control for federated users is administered and delegated on an account partner–by–account partner basis. Use the following procedure to adjust resource account options .

| **Note** |
| --- |
| We recommend that you first review information about each resource account option before you modify the default resource account setting. For more information about resource account options, see Select the optimal resource account option. |

Perform this procedure on a resource federation server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To configure resource account options**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, and then double-click **Account Partners**.
3. Right-click the account partner whose resource account behavior you want to change, and then click **Properties**.
4. Click the **Resource Accounts** tab.
5. Select one of the following options for using resource accounts for this account partner, and then click **OK**:
   - **Resource accounts exist for all users** (Resource group claim mappings are not checked.)
   - **Resource accounts exist for some users (prefer resource account)** (First, check for resource accounts. If they do not exist, use the resource groups in the token.)
   - **Resource accounts exist for some users (prefer groups in token)** (First, process resource groups in tokens. If none exist, check for resource accounts.)
   - **No resource accounts exist for this account partner** (Check only for resource groups in tokens.)

Map an organization group claim to a resource group

# Managing Accounts and Account Stores

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Active Directory Federation Services (ADFS) uses account stores to log on users and extract security claims for those users. You can configure multiple account stores for a single Federation Service and define their priority. The Federation Service uses Lightweight Directory Access Protocol (LDAP) to communicate with account stores.

ADFS supports two types of account stores: Active Directory account stores and Active Directory Application Mode (ADAM) account stores. Only one Active Directory account store can be used for an ADFS deployment. However, you can use multiple ADAM account stores.

Enabling and disabling an account store is the same procedure for both types of account stores.

- Enable or disable an account store

The following tasks for managing account stores are described in this objective.

- Managing Active Directory Account Stores
- Managing ADAM Account Stores
- Using Multiple Account Stores

**See Also**
**Other Resources**
Account Stores

# Enable or disable an account store

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If an account store needs to be taken offline temporarily, you can disable the store in Active Directory Federation Service (ADFS) to stop authentication requests by federation servers. If you have disabled an account store in ADFS and you want to enable it, you can use the same procedure to enable the store.

Perform this procedure on an account federation server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To enable or disable an account store**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, and then double-click **Account Stores**.
3. Right-click the account store you want to enable or disable and do one of the following:
   - If the account store is disabled and you want to enable it, click **Enable**.
   - If the account store is enabled and you want to disable it, click **Disable**.

| **Note** |
| --- |
| You can also perform this procedure by right-clicking the account store, clicking **Properties**, and then selecting or clearing the **Enable this account store** check box. |

# Managing Active Directory Account Stores

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Active Directory Federation Services (ADFS) is tightly integrated with Active Directory. ADFS retrieves user attributes and authenticates users against Active Directory. ADFS also uses Windows Integrated Authentication and security tokens that Active Directory creates.

Management of the Active Directory account store is limited to adding, removing, and enabling or disabling the account store.

**Task requirements**

You need the following tool to perform the procedures for this task:

- Active Directory Federation Services MMC snap-in.

To complete this task, perform the following procedures on an as-needed basis:

- Add an Active Directory account store
- Remove an Active Directory account store
- Enable or disable an account store

**See Also**
**Other Resources**
Account Stores

# Add an Active Directory account store

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If user and computer accounts that require access to a resource that is protected by Active Directory Federation Services (ADFS) are stored in Active Directory, you must add Active Directory as an account store on a federation server in the Federation Service that authenticates the accounts.

An Active Directory forest can have only one Active Directory instance. Therefore, you can add only one Active Directory store for the respective Federation Service.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To add an Active Directory account store**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, right-click **Account Stores**, point to **New**, and then click **Account Store**.
3. On the **Welcome to the Add Account Store Wizard** page, click **Next**.
4. On the **Account Store Type** page, ensure that **Active Directory** is selected, and then click **Next**.
5. On the **Enable this Account Store** page, ensure that the **Enable this account store** check box is selected, and then click **Next**.
6. On the **Completing the Add Account Store Wizard** page, click **Finish**.

**See Also**
**Concepts**
Add an ADAM account store

# Remove an Active Directory account store

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Use this procedure to delete the Active Directory account store node for an Active Directory Federation Services (ADFS) Federation Service that no longer uses an Active Directory account store.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To delete the Active Directory account store node**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, and then double-click **Account Stores**.
3. Right-click **Active Directory**, and then click **Delete**.
4. In the **Delete Account Store** dialog box, click **Yes** to confirm the deletion.

# Managing ADAM Account Stores

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Active Directory Application Mode (ADAM) provides data storage and retrieval for directory-enabled applications, without the dependencies that are required for Active Directory. A Federation Service can use multiple ADAM account stores when they are needed to accommodate sets of users for different applications. To differentiate between ADAM stores, the Federation Service assigns a unique value to each ADAM store in the trust policy, in the form of the uniform resource identifier (URI).

**Task requirements**

You need the following to perform the procedures for this task:

- An ADAM instance
- ADAM ADSI Edit
- Ldp, a Windows Server 2003 Support Tool, available in the SUPPORT\TOOLS folder on the Windows Server 2003 operating system CD.
- Active Directory Federation Services MMC snap-in

To complete this task, perform the following procedures on an as-needed basis:

- Prepare an ADAM instance for use with ADFS
- Add an ADAM account store
- Change the server name or IP address for an ADAM account store
- Change the display name for an ADAM account store
- Change the port number for an ADAM account store
- Change the search base for an ADAM account store
- Change the user name attribute for an ADAM account store
- Enable or disable TLS and SSL for an ADAM account store

Account Stores

# Prepare an ADAM instance for use with ADFS

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Before you can use an Active Directory Application Mode (ADAM) instance as an account store in your Active Directory Federation Services (ADFS) deployment, you must perform two preliminary procedures:

- Set an attribute to enable user accounts
- Configure the member attribute with the federation server security identifier (SID) to enable federation servers to search the ADAM store

**Enable ADAM User Accounts**

On ADAM instances running on Windows Server 2003, where local or domain password policy restrictions are in effect, the ADAM user account is disabled by default. Before you can enable the user account, you must set a password that meets the password policy restrictions that are in effect. This rule does not apply to ADAM instances running on Windows XP Professional.

To enable user accounts, set the msDS-UserAccountDisabled attribute value to **False**. Be sure that the user account has been configured with a userPassword attribute value that meets policy requirements.

Use the following procedure to enable a user account in the ADAM account store.

### Administrative credentials

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To enable an ADAM user account**

1. Open ADAM ADSI Edit and connect to the ADAM instance.
2. Right-click an ADAM user, and then click **Properties**.
3. In the **Attribute** column, click **msDS-UserAccountDisabled**, and then click **Edit**.
4. Click **False**, and then click **OK** twice.

   If an ADAM-ADSIEdit message appears stating that the password cannot be updated because the value does not meet requirements for the domain, right-click the user account and click **Reset Password**. Then repeat this procedure.

**Configure the Federation Server SID**

To enable federation servers to search the ADAM account store, you need to add the machine account SID of the account federation server to the member attribute in the Readers role of the ADAM instance.

Use the following procedures to prepare ADAM for searches by federation servers.

- Obtain the machine account SID of the federation server
- Add the SID to the member attribute in ADAM

### Administrative credentials

To complete this procedure, you must be a member of the Domain Users group in the Active Directory domain of the federation server.

**To obtain the SID of the federation server**

1. Open Ldp and connect and bind to the Active Directory domain to which the federation server is joined.
2. On the **View** menu, click **Tree**.
3. Expand the tree to locate the computer object of the federation server.

4. Double-click the computer object and view the properties in the results pane.
5. Make a note of the value in **1>objectSid**.

Perform the next procedure to add the SID you obtained to the member attribute in ADAM.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To add the federation server SID to the member attribute for an ADAM instance**

1. In Ldp, connect and bind to the ADAM instance.
2. On the **View** menu, click **Tree**.
3. Double-click the ADAM instance and then double click the **CN=Roles** container.
4. Right-click the **CN=Readers** container, and then click **Modify**.
5. In **Attribute**, type **member**.
6. In **Values**, type the SID value as follows, and then click **Enter**:

   **<SID=** *objectSIDValue* **>**
7. Click **Run** to modify the attribute, and then click **Close**.

# Add an ADAM account store

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If you use multiple Active Directory Application Mode (ADAM) stores for user accounts that require access to one or more Web applications that are protected by Active Directory Federation Services (ADFS), you can add the ADAM account stores to the Federation Service.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To add an ADAM account store**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, right-click **Account Stores**, point to **New**, and then click **Account Store**.
3. On the **Welcome to the Add Account Store Wizard** page, click **Next**.
4. On the **Account Store Type** page, ensure that **Active Directory Application Mode (ADAM)** is selected, and then click **Next**.
5. On the **ADAM Store Details** page, in **Account store display name**, type the name of the ADAM account store as you want it to be displayed in the Active Directory Federation Services snap-in user interface (UI).
6. In **Account store URI**, type the Uniform Resource Identifier (URI) for the ADAM account store, and then click **Next**.

| **Note** |
| --- |
| The account store URI uniquely identifies the ADAM instance among multiple ADAM account stores. |

7. On the **ADAM Server Settings** page, do the following, and then click **Next**:
   a. In **ADAM server name or IP address**, type the name or IP address of the ADAM server.
   b. In **Port number**, type the TCP/IP port number for the account service. Accept the default of 389 unless Active Directory is installed on the same server, in which case you must use a different port.
   c. In **LDAP search base distinguished name**, type the distinguished name of the ADAM instance.
   d. In **User name LDAP attribute**, type the name of the user name attribute that users provide during logon (for example, **userPrincipalName** or **sAMAccountName**).
8. On the **Identity Claims** page, select one or more identity claims that will be provided by the account store, and then click **Next**:
   a. If the account store provides user principal name (UPN) identity claims, select the **User Principal Name (UPN)** check box, and then type the Lightweight Directory Access Protocol (LDAP) attribute name to which UPN identity claims map (the attribute whose value is the user's UPN, usually **userPrincipalName**).
   b. If the account store provides e-mail identity claims, select the **E-mail** check box, and then type the LDAP attribute name to which e-mail identity claims map (the attribute whose value is the user's a-mail name, usually **userPrincipalName**).
   c. If the account store provides a common name identity claim, select the **Common Name** check box, and then type the LDAP attribute name to which the common name identity claim maps (the attribute whose value is the user's common name, usually **displayName**).

9. On the **Enable this Account Store** page, ensure that the **Enable this account store** check box is selected, and then click **Next**.
10. On the **Completing the Add Account Store Wizard** page, click **Finish**.

# Change the server name or IP address for an ADAM account store

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If the name or IP address of the server that hosts an Active Directory Application Mode (ADAM) instance changes, you must change the corresponding server setting in the properties of the ADAM account store in Active Directory Federation Services (ADFS).

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the server name or IP address for an ADAM account store**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, and then double-click **Account Stores**.
3. Right-click the ADAM account store whose server name or IP address you want to change, and then click **Properties**.
4. On the **Settings** tab, in **Server name or IP address**, replace the existing server name or IP address with the new value, and then click **OK**.

# Change the display name for an ADAM account store

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

The ADAM display name identifies the ADAM store to the user during logon. You can change this name in Active Directory Federation Services (ADFS), if needed.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the URI for an ADAM account store**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, and then double-click **Account Stores**.
3. Right-click the ADAM account store whose display name you want to change, and then click **Properties**.
4. On the **General** tab, in **Display name**, type the new display name, and then click **OK**.

# Change the port number for an ADAM account store

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If the communication port that is used by an Active Directory Application Mode (ADAM) instance changes on the host server, you must change the corresponding server setting in the properties of the ADAM account store in Active Directory Federation Services (ADFS). The default port for Lightweight Directory Access Protocol (LDAP) traffic is 389, and ADAM uses this port if a different port is not specified. However, if Active Directory is subsequently installed on the server that hosts the ADAM store, the ADAM port conflicts with the Active Directory port and must be changed for ADAM.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the port number for an ADAM account store**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, and then double-click **Account Stores**.
3. Right-click the ADAM account store whose port number you want to change, and then click **Properties**.
4. On the **Settings** tab, in **Port number**, replace the existing port number with the new value, and then click **OK**.

# Change the search base for an ADAM account store

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

An Active Directory Application Mode (ADAM) store is discovered through a Lightweight Directory Access Protocol (LDAP) search. The search base for an ADAM account store specifies the top node from which the LDAP search for the ADAM instance is to be performed. Typically, the search base is the top node in the directory tree. However, if you want to reduce the search time, you can specify a more restricted path. For example, the search base distinguished name DC=Adatum,DC=com begins searching at Adatum and searches all domains in the path that contains Adatum.com. If the ADAM instance is located on a server in DomainB.DomainA.Adatum.com, you can avoid searching through Adatum and DomainA by specifying the search base of DC=DomainB,DC=DomainA,DC=Adatum.com.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the search base for an ADAM account store**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, and then double-click **Account Stores**.
3. Right-click the ADAM account store whose search base you want to change, and then click **Properties**.
4. On the **Settings** tab, in **Search base Distinguished Name (DN)**, replace the existing distinguished name with the new value, and then click **OK**.

**See Also**

# Change the user name attribute for an ADAM account store

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Active Directory Federation Services (ADFS) can provide authentication for users whose accounts are stored in an Active Directory Application Mode (ADAM) partition. To process user credentials, ADFS must be configured to recognize ADAM users by the attribute that the user provides when logging on to the Web site. This attribute is typically **userPrincipalName** or **sAMAccountName**.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the search base for an ADAM account store**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, and then double-click **Account Stores**.
3. Right-click the ADAM account store whose user name attribute you want to change, and then click **Properties**.
4. On the **Settings** tab, in **User name attribute**, replace the existing attribute with the new attribute, and then click **OK**.

**See Also**
**Concepts**

# Enable or disable TLS and SSL for an ADAM account store

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

By default, Transport Layer Security (TLS) and Secure Sockets Layer (SSL) protocols are not enabled for Active Directory Application Mode (ADAM) account stores in Active Directory Federation Services (ADFS). You can enable or disable these protocols as needed.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To enable or disable TLS/SSL protocols for an ADAM account store**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, and then double-click **Account Stores**.
3. Right-click the ADAM account store whose search base you want to change, and then click **Properties**.
4. On the **Settings** tab, enable or disable TLS/SSL as follows, and then click **OK**:
   - If the **Enable Transport Layer Security (TLS) and Secure Sockets Layer (SSL) protocols** check box is cleared (disabled) and you want to enable it, select the check box.
   - If the **Enable Transport Layer Security (TLS) and Secure Sockets Layer (SSL) protocols** check box is selected (enabled) and you want to disable it, clear the check box.

# Using Multiple Account Stores

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If you have multiple Active Directory Application Mode (ADAM) account stores that use Web applications that are protected by Active Directory Federation Services (ADFS), you must configure each ADAM store in the Federation Service with a unique uniform resource identifier (URI). In addition, you can set a priority for connecting to each store.

**ADAM Store URI**
Account stores are identified in Active Directory Federation Services (ADFS) by a Uniform Resource Identifier (URI). The account store URI is different from the Federation Service URI.

The URI for an Active Directory account store is always the same (urn:federation:activedirectory) because a forest has only one Active Directory store; this URI is provided automatically by the system. However, you can have multiple instances of Active Directory Application Mode (ADAM) account stores in a Federation Service. To uniquely identify ADAM stores within the trust policy, each ADAM store requires a unique URI. The URI can use a Uniform Resource Locator (URL) format, such as ldap//:*ADAMInstanceName*, or a Uniform Resource Name (URN), such as urn:federation:*ADAMInstanceName*. ADFS does not impose or check the URI format; however, ADFS does check for uniqueness.

When you use the exact ADAM instance name in the URI, ADFS searches that store first. If the URI does not contain the ADAM instance name, ADFS searches all ADAM stores until it finds a match for the user. Therefore, although ADFS accepts the ADAM account store URI as long as it is unique, you can improve efficiency of the ADAM search by including the exact ADAM instance name in the URI.

**Task requirements**

You need the following to perform the procedures for this task:

- Active Directory Federation Services MMC snap-in

To complete this task, perform the following procedures on an as-needed basis:

- Change account store priority
- Change the URI for an ADAM account store

**See Also**
**Other Resources**
Account Stores

# Change account store priority

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If you have more than one account store in a Federation Service, you can determine the order in which Active Directory Federation Services (ADFS) contacts the stores when it authenticates users. If most users are stored in one of the stores, you can set that store to have a higher priority than other stores.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the priority of an account store**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, and then double-click **My Organization**.
3. Right-click **Account Stores**, and then click **Store Priority**.
4. In the **Account Store Prioritization** dialog box, click the store in the list that you want to move to the top of the list, and then click the **Up** button repeatedly until that store is at the top of the list.
5. If you want to reposition any other stores in the list, select each store and use the **Up** and **Down** buttons as needed.
6. When all stores are in the correct priority order, click **OK**.

# Change the URI for an ADAM account store

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Active Directory Federation Services (ADFS) identifies account stores with a Uniform Resource Identifier (URI). You can change the URI in the account store properties.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the URI for an ADAM account store**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, and then double-click **Account Stores**.
3. Right-click the ADAM account store whose URI you want to change, and then click **Properties**.
4. On the **General** tab, in **URI**, type the new URI, and then click **OK**.

Enable or disable TLS and SSL for an ADAM account store

# Managing Claims and Claim Mapping

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

In an Active Directory Federation Services (ADFS) deployment, claims are statements about users that are carried within security tokens and are used by Web applications to make authorization decisions. Claims originate from either an account store or an account partner.

When administering an account store in a Federation Service, you perform the following claim management procedures:

- Create a claim that represents a user or group of users from your organization.
- Extract the claim to map it to a local security account (either a group or user) in your directory service.
- Map the claim to an outgoing identity that you name to appropriately represent the type of users in the claim. During a request for access to a resource, ADFS sends this claim to the resource Federation Service in a security token.

When administering an account partner in a resource Federation Service, you perform the following management procedures:

1. Create a claim for your organization.
2. Map an incoming claim (the name of which has been communicated to you by the account Federation Service) to your local organization claim. This claim is used by the Web server to make authorization decisions about the user or users represented by the claim.

The following tasks for managing claims are described in this objective.

- Exposing Account Store Attributes as Claims
- Mapping Claims as Part of Application Authorization
- Creating, Deleting, and Configuring Claims

**See Also**
**Other Resources**
Understanding Claims

# Exposing Account Store Attributes as Claims

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Active Directory Federation Services (ADFS) uses claims to provide specific information about users to a Web application. Claims are populated with information (attributes) from the account store that hosts the user account. For example, a claim might extract the user's name, identity, key, group, privilege, or capability. The claim is passed in the security token, which the Web server uses to make authorization decisions for access to the requested application.

An organization group claim, when used with an Active Directory Application Mode store, requires mapping the claim to an ADAM attribute.

An organization custom claim maps the claim to an attribute when used with either an ADAM store or an Active Directory store.

**Task requirements**

You must meet the following conditions to perform the procedures for this task:

- ADFS must be installed to create at least one federation server in your forest or realm.
- The Active Directory Federation Services MMC snap-in must be running on the federation server.
- Active Directory or Active Directory Application Mode (ADAM) must be available in the ADFS forest or realm.
- You must have a plan for creating claims and mapping them to the appropriate attributes of a user account in ADAM if you are managing an account Federation Service, or to a set of organization claims if you are managing a resource Federation Service.

To complete this task, perform the following procedures on an as-needed basis:

- Map an organization group claim to an ADAM attribute and value (group claim extraction)
- Map an organization custom claim to an Active Directory or ADAM user attribute (custom claim extraction)

**See Also**
**Other Resources**
Understanding Claims

# Map an organization custom claim to an Active Directory or ADAM user attribute (custom claim extraction)

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Whether you use Active Directory or Active Directory Application Mode (ADAM) as the Active Directory Federation Services (ADFS) account store for an account Federation Service, an organization custom claim maps to an administratively assigned Lightweight Directory Access Protocol (LDAP) attribute for the user that the claim identifies. This mapping is called a custom claim extraction.

For example, if the user is to be identified by position, you might create the organization custom claim Position and use the Title attribute to identify the user's position. If the Title attribute is present in the Active Directory or ADAM store, the corresponding organization custom claim is generated with the value of the Title attribute. Suppose that the Title attribute of the user account has the value "Software Engineer." In this case, the organization custom claim Position is generated for this user with the value "Software Engineer." If the Title attribute is not found for the user account, the Position claim is not generated for the user.

Perform this procedure in the account Federation Service.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To map an organization custom claim to an Active Directory or ADAM user attribute**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, double-click **Account Stores**, right-click **ADAM** or **Active Directory**, point to **New**, and then click **Custom Claim Extraction**.
3. In the **Create a New Custom Claim Extraction** dialog box, in **Attribute**, type the LDAP attribute name for the user.
4. In **Map to this Organization Claim**, select the organization custom claim to map to the attribute, and then click **OK**.

# Map an organization group claim to an ADAM attribute and value (group claim extraction)

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When you use Active Directory Application Mode (ADAM) as the Active Directory Federation Services (ADFS) account store for a Federation Service, an organization group claim maps to a Lightweight Directory Access Protocol (LDAP) attribute and value of the user account in ADAM. This mapping is called a group claim extraction. For example, suppose that the organization group claim Manager is mapped to the ADAM user account attribute **memberOf** and the value **CN=ADAMTestGroup,CN=Users,DC=adatum,DC=com**. In this case, if the ADAM store user account for the logged-on user has the **memberOf** attribute and that attribute has a value of **CN=ADAMTestGroup,CN=Users,DC=adatum,DC=com**, the organization group claim Manager is generated for the user. If both the **memberOf** attribute and the corresponding value that is specified in the group claim extraction are not present on the user account, the organization group claim is not generated.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To map an organization group claim to an ADAM attribute and value**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, double-click **Account Stores**, right-click **ADAM**, point to **New**, and then click **Group Claim Extraction**.
3. In the **Create a New Group Claim Extraction** dialog box, in **Attribute** and **Value**, type the LDAP attribute and its value, respectively.
4. In **Map to this Organization Claim**, select the organization group claim to map to the ADAM attribute and value, and then click **OK**.

# Mapping Claims as Part of Application Authorization

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Claims that are used by Active Directory Federation Services (ADFS) make it possible for an application in one organization to recognize and authorize users from a different organization or from the Internet. By creating claims to represent users in the account organization, and mapping them to a group that is recognized by the resource, you can enable authorization of users for applications that are protected by ADFS in a federated scenario.

**Task requirements**

You must meet the following conditions to perform the procedures for this task:

- ADFS must be installed to create at least one federation server in your forest or realm.
- The Active Directory Federation Services snap-in must be running on the federation server.
- Active Directory or Active Directory Application Mode (ADAM) must be available in the account forest or realm.
- You must have a plan for creating claims and mapping them to the appropriate users and groups if you are managing an account Federation Service, or to a set of local claims if you are managing a resource Federation Service.

To complete this task, perform the following procedures on an as-needed basis:

- Map an organization group claim to an Active Directory group (group claim extraction)
- Map an organization group claim to a resource group
- Create an incoming group claim mapping
- Create an incoming custom claim mapping
- Create an outgoing group or custom claim mapping
- Change the organization claim mapping of an outgoing group or custom claim
- Change the organization claim mapping of an incoming group or custom claim

Understanding Claims

# Map an organization group claim to an Active Directory group (group claim extraction)

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

When you use Active Directory as the Active Directory Federation Services (ADFS) account store for an account Federation Service, you map an organization group claim to a security group in Active Directory. This mapping is called a group claim extraction.

Perform this procedure in the account Federation Service.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To map an organization group claim to an Active Directory group**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, double-click **Account Stores**, right-click **Active Directory**, point to **New**, and then click **Group Claim Extraction**.
3. In the **Create a New Group Claim Extraction** dialog box, click **Add**, and then select the Active Directory security group that you want to map to a group claim.
4. In **Map to this Organization Claim**, select the group claim to map to the Active Directory security group, and then click **OK**.

**See Also**
**Concepts**
Map an organization group claim to an ADAM attribute and value (group claim extraction)
Map an organization custom claim to an Active Directory or ADAM user attribute (custom claim extraction)

# Map an organization group claim to a resource group

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Organization group claims in the resource Federation Service can be mapped to resource groups, which reside in Active Directory, so that federated users who have the organization group claim are treated as members of that resource group. Therefore, you must create a security group (which is the resource group) in the resource partner forest that represents the users who have the organization group claim but do not have domain user accounts in the resource partner forest. After you create the organization group claim, map the claim to the resource group that you created in the resource partner forest.

| **Note** |
| --- |
| This procedure is not required if the resource partner forest trusts the account partner forest and the Windows trust option is selected in the Active Directory Federation Services snap-in in both the account Federation Service and the resource Federation Service. |

Perform this procedure on a resource federation server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To map an organization group claim to a resource group**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, and then click **Organization Claims**.
3. In the details pane, right-click the organization group claim that requires mapping to a local group, click **Properties**, and then click the **Resource Group** tab.
4. Select the **Map this claim to the following local resource group** check box, and then click the **...** button.
5. In **Enter the object name to select**, type the name of the resource group that you want to map to the group claim, and then click **OK**.
6. In the **Group Claim Properties** dialog box, click **OK**.

When to use resource groups

# Create an incoming group claim mapping

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

In Active Directory Federation Services (ADFS), incoming group claim mappings are used in the resource Federation Service to transform group claims that are sent by an account partner into organization claims that can be used by the resource partner to make authorization decisions.

For example, an account partner might send a security token for a user that contains the group claim SalesReps. Because the resource partner cannot make authorization decisions based on the account user's membership in the SalesReps group, an incoming group claim mapping is used to map the incoming group claim that is named SalesReps in the account Federation Service to the organization group claim that is named Purchasers in the resource Federation Service. The resource itself provides access to the local security group to which the Purchasers claim is mapped.

Perform this procedure on a resource federation server. To perform this procedure, you must have created an organization group claim to which you can map the incoming claim.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To create an incoming group claim mapping**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, double-click **Account Partners**, right-click your account partner, point to **New**, and then click **Incoming Group Claim Mapping**.
3. In the **Create a New Incoming Group Claim Mapping** dialog box, in **Incoming group claim name**, type the name of the group claim that your account partner sends to you.
4. In **Organization group claim**, select the group claim that you will use in your organization to map the incoming group claim to, and then click **OK**.

Create an organization group or custom claim
Change the organization claim mapping of an incoming group or custom claim

# Create an incoming custom claim mapping

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

In Active Directory Federation Services (ADFS), an organization custom claim maps to a user attribute. Incoming custom claim mappings are used in the resource Federation Service to map custom claims that are sent by an account partner to claims that can be used by the resource partner to make authorization decisions.

For example, an account partner might send a security token for a user that contains the custom claim EmployeeID, which maps to a user attribute in the account partner directory database. Because the resource partner cannot make authorization decisions based on the account user's EmployeeID attribute value, an incoming custom claim mapping is used to map the custom organization claim EmployeeID, which is recognized in the account partner, to the organization claim CustomerID, which is recognized in the resource partner.

Perform this procedure on a federation server in the resource Federation Service. To complete this procedure, you must have created an organization custom claim to which you can map the incoming claim.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To create an incoming custom claim mapping**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, double-click **Account Partners**, right-click your account partner, click **New**, and then click **Incoming Custom Claim Mapping**.
3. In the **Create a New Incoming Custom Claim Mapping** dialog box, in **Incoming custom claim name**, type the name of the custom claim that your account partner sends to you.
4. In **Organization custom claim**, select the custom claim that you will use in your organization to map the incoming custom claim to, and then click **OK**.

# Create an outgoing group or custom claim mapping

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

In Active Directory Federation Services (ADFS), an organization claim (group or custom) in the account Federation Service must be mapped to an outgoing claim, which the resource Federation Service will receive when an account organization user is requesting access to a resource. On the resource federation server, this claim is received as an incoming claim, which is likewise configured to map to a local organization claim, which the resource Federation Service uses to make authorization decisions.

Perform this procedure on an account federation server. To perform this procedure, you must have created an organization group or custom claim to which you can map the outgoing claim.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To create an outgoing group or custom claim mapping**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, double-click **Resource Partners**, right-click the resource partner, point to **New**, and then click one of the following:

   If you are mapping a group claim, click **Outgoing Group Claim Mapping**, and then create the mapping as follows:

   a. In the **Create a New Outgoing Group Claim Mapping** dialog box, in **Organization group claims**, select the group claim in the account organization that you want to map to the outgoing claim.

   b. In **Outgoing group claim name**, type the name of the outgoing group claim that you want to send to the resource partner, and then click **OK**.

   If you are mapping a custom claim, click **Outgoing Custom Claim Mapping**, and then create the mapping as follows:

   a. In the **Create a New Outgoing Custom Claim Mapping** dialog box, in **Organization custom claims**, select the custom claim in the account organization that you want to map to the outgoing claim.

   b. In **Outgoing custom claim name**, type the name of the outgoing custom claim that you want to send to the resource partner, and then click **OK**.

# Change the organization claim mapping of an outgoing group or custom claim

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

In Active Directory Federation Services (ADFS), when you create an organization group claim or organization custom claim in an account Federation Service, you map it to an outgoing claim that is sent to the resource Federation Service. If you subsequently replace the organization claim with a different claim or want to use a different organization claim for the group or user identified in the claim, you can change the mapping of the existing outgoing claim to the new organization custom or group claim. You can also rename the outgoing custom or group claim.

Perform this procedure in the account Federation Service.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the organization claim mapping of an outgoing group or custom claim**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, double-click **Resource Partners**, and then click the resource partner whose organization claim mapping you want to change.
3. In the details pane, right-click the organization group or custom claim whose outgoing claim mapping you want to change, and then click **Properties**.
4. On the **General** tab, in **Organization group claims** or **Organization custom claims**, select the new organization group or custom claim that you want to map to the outgoing group or custom claim.
5. In **Outgoing group claim name** or **Outgoing custom claim name**, change the name, if needed, and then click **OK**.

# Change the organization claim mapping of an incoming group or custom claim

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

In Active Directory Federation Services (ADFS), when you create an organization group claim or organization custom claim in a resource Federation Service, you map it to an incoming claim that is sent from the account Federation Service. If you subsequently replace the organization claim with a different claim or want to use a different organization claim for the group or user identified in the claim, you can change the mapping of the existing incoming claim to the new organization custom or group claim. You can also rename the incoming custom or group claim.

Perform this procedure in the resource Federation Service.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the organization claim mapping of an incoming group or custom claim**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, double-click **Account Partners**, and then click the account partner whose organization claim mapping you want to change.
3. In the details pane, right-click the incoming claim whose claim mapping you want to change, and then click **Properties**.
4. On the **General** tab, in **Organization group claim** or **Organization custom claim**, select the new organization group or custom claim to which the incoming group or custom claim will map.
5. In **Incoming group claim name** or **Incoming custom claim name**, change the name, if needed, and then click **OK**.

# Creating, Deleting, and Configuring Claims

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Use the procedures in this task to create, delete, and configure auditing for Active Directory Federation Services (ADFS) organization group and custom claims. You can also configure a claims transform module and manage identity claims.

**Task requirements**

You must meet the following conditions to perform the procedures for this task:

- ADFS must be installed to create at least one federation server in your forest or realm.
- The Active Directory Federation Services snap-in must be running on the federation server.
- Active Directory or Active Directory Application Mode (ADAM) must be available in the account forest or realm.
- You must have a plan for creating claims and mapping them to the appropriate users and groups if you are managing an account Federation Service, or to a set of local claims if you are managing a resource Federation Service.

To complete this task, perform the following procedures on an as-needed basis:

- Create an organization group or custom claim
- Delete an organization group or custom claim
- Change the auditing limitation for an organization group or custom claim
- Configure a claims transform module
- Change the domain suffix for an incoming or outgoing e-mail claim
- Enable or disable an organization identity claim for an account or resource partner

Understanding Claims

# Create an organization group or custom claim

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

In Active Directory Federation Services (ADFS), an organization group claim is used by the Federation Service to represent a user's membership in a group or role. An organization custom claim is used by the Federation Service to provide custom information, such as an employee identification number, about a user. Group claims and custom claims are created in the same way. You can use the following procedure to create an organization group claim or a custom claim.

Administrators in the account Federation Service create organization group claims and custom claims to represent account users. Administrators in the resource Federation Service create corresponding organization group claims and custom claims to represent groups and users that can be recognized as resource users in the resource Federation Service. Because outgoing claims in the account Federation Service map to incoming claims in the resource Federation Service, the resource Federation Service is able to accept the credentials that are provided by the account Federation Service.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To create an organization group or custom claim**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, right-click **Organization Claims**, point to **New**, and then click **Organization Claim**.
3. In the **Create a New Organization Claim** dialog box, in **Claim name**, type a unique name that identifies the group or role for a group claim, or type the name of a custom claim.

   | **Note** |
   | --- |
   | You can create a group claim and a custom claim with the same name. |

4. If you want to limit the auditing of the claim to the claim name and omit the value, select the **Limit the auditing of this claim** check box.
5. For **Specify the claim type**, click **Group claim** or **Custom claim**, and then click **OK**.

**See Also**

# Delete an organization group or custom claim

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

If a group or user no longer requires access to a resource that is protected by Active Directory Federation Services (ADFS), you can delete the organization group claim or custom claim that represents the group or user to reduce management overhead.

For example, an account partner might have provided a group claim or custom claim to represent a capability of a group or role. If this condition changes and the group claim or custom claim is no longer valid in the resource domain, you can delete the group claim.

At the account partner, a group that existed before might no longer be valid. In this case, the corresponding group claim can be removed.

If a partner has been deleted and any claims are specific to the deleted partner, you can delete these claims as well.

Perform this procedure on a federation server in your organization.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To delete an organization group or custom claim**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, and then click **Organization Claims**.
3. In the details pane, right-click the claim to be deleted, and then click **Delete**.
4. In the **Delete group claim** message box, click **Yes** to confirm the deletion.

# Change the auditing limitation for an organization group or custom claim

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Active Directory Federation Services (ADFS) uses claims to transfer user information that is used for authorization in the resource Federation Service. By default, auditing of an organization group or custom claim is not limited, which means that both the claim name and its value are audited, or shared, when the claim is produced or mapped. If you limit the auditing of an organization group or custom claim, the ADFS audit logs indicate only the name of the claim; the value of the claim is omitted. Omitting the value protects the privacy of sensitive data, such as the groups to which a user belongs.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To change the auditing limitation on an organization group or custom claim**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **My Organization**, and then click **Organization Claims**.
3. In the details pane, right-click the organization group or custom claim whose auditing you want to change, and then click **Properties**.
4. Click to select or clear the **Limit the auditing of this claim** check box to change the existing setting.

# Configure a claims transform module

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

A claims transform module is custom code that manipulates organization, input (incoming), and output (outgoing) claims. Typically, transform modules use the corporate and input claims to produce additional output claims. However, the claim transform module can enumerate, add, delete, and modify claims in any of the claim sets.

Store the claims transform module in %systemdrive%\adfs\sts\bin. This location provides the following advantages:

- ASP.NET keeps a shadow copy of the dynamic-link library (DLL), which allows the DLL to be replaced without stopping the Federation Service, thereby preventing downtime.
- File security is inherited from the \adfs\sts directory.
- The module can be backed up along with all other Active Directory Federation Services (ADFS) files.

After you deploy the transform module to the federation server, perform the following procedure on the account federation server or resource federation server that is configured with the trust policy whose claims transform module you are configuring.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To configure a claims transform module**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, right-click the **Trust Policy** node, and then click **Properties**.
3. On the **Transform Module** tab, configure the DLL file and class name for the module as follows:
   a. **DLL file:** Click **Browse** to navigate to the DLL that implements the claim transform module, and then click **Open**.

      | **Note** |
      | --- |
      | This DLL must be a managed-code assembly. |

   b. **Class name:** Type the namespace-qualified class name that implements the claim transform interface (**IClaimTransform**, which is defined in System.Web.Security.SingleSignOn.ClaimTransforms.dll): The namespace qualified name should be of the format namespace.classname.
4. Click **OK** to save the configuration.

# Change the domain suffix for an incoming or outgoing e-mail claim

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

In Active Directory Federation Services (ADFS), an e-mail identity claim is an organization identity claim that is created when you create an account or resource partner. The e-mail identity claim is automatically mapped to the outgoing (from the account Federation Service) and incoming (to the resource Federation Service) e-mail claim. In the account Federation Service, you specify whether all domain suffixes can be sent to the resource Federation Service, or whether you will replace all domain suffixes with a specific domain suffix. In the resource Federation Service, you can specify the domain suffixes that the resource Federation Service will accept or, if your partnership does not extend across the Internet, you can accept all domain suffixes.

| **Note** |
| --- |
| To manage the properties of an identity claim, the claim must first be enabled. |

### Administrative credentials

To complete these procedures, you must be a member of the Administrators group on the local computer.

**To change the domain suffix for an outgoing e-mail identity claim in the account Federation Service**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, double-click **Resource Partners,** and then click the resource partner whose e-mail claim you want to manage.
3. In the details pane, right-click the e-mail identity claim, and then click **Properties**.
4. Under **Settings**, select **Replace all domain suffixes with** if it is not selected.
5. In **Specify the new suffix**, type the domain name suffix, and then click **OK**.

**To change the domain suffixes for an incoming e-mail identity claim in the resource Federation Service**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, double-click **Account Partners,** and then click the account partner whose e-mail claim you want to manage.
3. In the details pane, right-click the e-mail identity claim, and then click **Properties**.
4. Under **Settings**, select **Accept some domain suffixes** if it is not selected.
5. In **Accepted domains (press Enter to separate entries)**, type the domain name suffix or suffixes, and then click **OK**.

**Concepts**
Enable or disable an organization identity claim for an account or resource partner

# Enable or disable an organization identity claim for an account or resource partner

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

In Active Directory Federation Services (ADFS), organization identity claims are created when you create an account or resource partner. They are incoming claims on the resource partner and outgoing claims on the account partner. Identity claims are not enabled unless you specify the identity type (UPN, e-mail, or common name) when you create the partner. You can enable or disable organization identity claims after the partner is created.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To enable or disable an organization identity claim**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, double-click **Account Partners** or **Resource Partners**, and then click the partner whose organization identity claim you want to manage.
3. In the details pane, right-click the organization identity claim that you want to enable or disable, and then click **Properties**.
4. On the **General** tab, enable or disable the identity claim as follows, and then click **OK**:
   - To enable the claim when it is disabled, select the **Enabled** check box.
   - To disable the claim when it is enabled, clear the **Enabled** check box.

# Troubleshooting Active Directory Federation Services

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

This guide provides troubleshooting information for Active Directory Federation Services (ADFS) in the Microsoft Windows Server 2003 R2, Enterprise Edition, and Microsoft Windows Server 2003 R2, Datacenter Edition, operating systems (for Federation Service, Federation Service Proxy, and ADFS Web Agent components); and the Microsoft Windows Server 2003 R2, Standard Edition, operating system (for ADFS Web Agent components).

**In this guide**

- Verifying ADFS Computer Settings and Connectivity
- Configuring ADFS Servers for Troubleshooting
- Troubleshooting ADFS Problems

# Verifying ADFS Computer Settings and Connectivity

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Before you begin troubleshooting, you must isolate the location of the problem by performing preliminary tests to verify that your federation servers, Web servers, and client computers are communicating and that Active Directory Federation Services (ADFS) is set up and running properly.

**Verifying Settings to Locate the Point of Failure**
ADFS components are deployed among several servers, each of which requires settings that affect various server-server and client-server interactions. The best way to effectively troubleshoot and solve a problem is to find the exact location of failure between ADFS components.

To help you better understand how to locate the point of failure, the following sample scenario is provided.

**Sample Scenario**
Using this sample diagram of a client requesting access to an ADFS-protected application in a Federated Web with Single Sign-on (SSO) scenario, you can easily distinguish how ADFS servers enumerate connections. This information is meant to assist you in determining which connection point might be causing the failure. If you are already familiar with the location of the failure in your environment, skip to the section where you suspect the failure is occurring. By testing for success at each step, you can better determine where the problem lies.

For more details and instructions for implementing this sample Federated Web SSO scenario, see the ADFS Step-by-Step Guide (http://go.microsoft.com/fwlink/?linkid=63445).

| Note |
| --- |
| To improve user experience, always obtain Secure Sockets Layer (SSL) certificates for any external (Internet-facing) computers from a well-known third-party certification authority (CA). Because well-known third-party CAs are already trusted by the client browser, the user does not receive prompts that the browser does not trust the root CA certificate. |

**Verification Steps to Locate the Point of Failure**
Each topic below corresponds to a number in the preceding diagram and provides information and step-by-step procedures to help eliminate the error that is causing the failure.

1. Verify Connectivity and Initial Request from the Client

2. Verify Web Server Redirection to the Resource Federation Server

3. Verify Home Realm Discovery

4. Verify Client Authentication in the Account Domain

5. Verify Account Server Redirection to the Resource Federation Server

6. Verify Resource Server Redirection to the Web Server

**1. Verify Connectivity and Initial Request from the Client**
In this step, you verify that the ADFS client can reach the Web site on the Web server before the client has received any

previous token.

When you enter the uniform resource locator (URL) of the Web application in the client browser for the first time, the client sends an initial GET request to the ADFS Web server. The ADFS Web server does not allow the client access to the requested page at this point because the client does not have an authentication token to present to the Web server at that point. If the ADFS client fails to receive access to the page, you get an error and the URL in the browser indicates the point of failure. Common errors might be Domain Name System (DNS) failures and 401 access denied errors.

Make sure you have good connectivity and name resolution between the account and resource domains. Clients coming from the Internet should be able to locate domain controllers.

Domain controllers, federation servers, Web servers, and clients need to be able to locate each other by a fully qualified domain name (FQDN). Ping by IP address and FQDN, and use Nslookup.exe to test DNS connectivity. In addition, to make sure that all the necessary ports are open, you can download PortqryUI.exe from the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=64729

Use the following tests to verify connectivity from the client:

- Test a TCP/IP configuration by using the ping command (http://go.microsoft.com/fwlink/?LinkId=64765)
- Verify DNS server responsiveness using the **nslookup** command (http://go.microsoft.com/fwlink/?LinkId=64766)

If DNS resolution appears to be the connectivity problem, see Troubleshooting Domain Name System (http://go.microsoft.com/fwlink/?LinkId=62177). You should also check the Web server to verify that the **ASP.NET v2.0.50727** extension is set to **Allowed** using the Internet Information Services (IIS) Manager snap-in. The typical symptom that occurs when this extension is set to **Prohibited** is a ***Page cannot be displayed error*** in the browser.

**2. Verify Web Server Redirection to the Resource Federation Server**

In this step, verify that the redirect of the ADFS client to the resource federation server is occurring properly and that the client can reach the Federation Service endpoint URL.

| **Note** |
| --- |
| The Federation Service URL is used by clients to access a server in the resource Federation Service. This URL has the form **https://***FullyQualifiedDomainName***/adfs/ls/** |

The ADFS Web server issues a standard HTTP 302 REDIRECT to the client, which directs the client to the resource federation server. This redirect occurs to the resource federation server because the ADFS Web server knows about only its own federation server and requires that incoming ADFS tokens are signed by its federation server. The ADFS client is able to communicate with the resource federation server because it trusts the CA that issues the SSL server certificate for the resource federation server. As in Step 1 (Verify Connectivity and Initial Request from the Client), if the client fails to contact the resource federation server, an error appears and the URL on the browser indicates the point of failure. Common errors are DNS failures and 401 access denied. In this case, use the tests that are described in step 1.

| **Important** |
| --- |
| If the Federation Service endpoint URL value has recently been modified in the Windows NT token–based Web agent, clients may experience logon problems to Windows NT token–based applications that are located on the Web server within one hour from the time when the URL value was changed. After the one hour has passed, clients should be able to log on to the Windows NT token–based applications without problems. To avoid this one-hour delay, you can run **iisreset** from a command line immediately after the URL value changes. |

**3. Verify Home Realm Discovery**

In this step, verify that the default page is displayed in the browser and the proper home realm of the client is available in the list.

When the ADFS client first requests a resource, the resource federation server has no information about the realm of the client. The resource federation server responds to the ADFS client with an HTTP 200, which provides the Client Realm Discovery page, where the user selects the home realm from a list. The list values are populated from the display name property in the account Federation Service trust policy. This value is known to the resource Federation Service through the account partner node properties.

**The client realm discovery page fails to appear**

If the client realm discovery page fails to appear, do the following on the client computer:

1. Delete all cookies from the client browser to remove the persistent home realm cookie, if present.

2. Try again to connect to the Web site. The Web server attempts to redirect to the resource federation server.

### Administrative credentials

To complete this procedure, you must be a member of the Users group on the local computer.

**To delete all cookies in Internet Explorer**

1. In Internet Explorer, on the **Tools** menu, click **Internet Options**.
2. On the **General** tab, click **Delete Cookies**.
3. In the **Delete Cookies** dialog box, click **OK**.
4. In the **Internet Options** dialog box, click **OK**.

**Deleting cookies does not solve the problem**
If the ADFS client still fails to receive access to the realm discovery page, the problem is with the resource Federation Service because this redirection is the final step before the client is sent to the account Federation Service.

In this case, do the following:

1. Look at the URL in the Web browser of the client to determine whether the failure is occurring on the Web server or on the resource federation server.

2. If the URL still shows the Web server address and nothing further, you can assume that the issue is on the Web server. In this case, go to the next step.

3. Look at the Application log on the Web server to see what errors are logged. Review the User Action section of the event and take proper troubleshooting steps according to any errors. If these steps do not solve the problem, go to the next step.

4. Use the following procedure to confirm that the Web server can communicate with the Federation Service on the resource federation server.

   **Administrative credentials**

   To complete this procedure, you must be a member of the Administrators group on the local computer.

   **To check the Federation Service URL**

   a. On the ADFS Web server, open Internet Information Services (IIS) Manager, right-click **Web Sites**, and then click **Properties**.

   b. On the **ADFS Web Agent** tab, copy the **Federation Service URL**.

   c. Paste the URL into the browser address line, and then press Enter.

If the URL resolves properly, a Federation Service Web page appears that lists supported operations for the service.

| **Note** |
| --- |
| You might be prompted for a client authentication certificate, which is standard behavior. |

**The Federation Service URL does not resolve**
If the URL does not resolve, assuming you have verified name resolution and connectivity, the error is most likely a typing error in the Federation Service URL on the Web server. Use the following procedure to check for potential typing errors for the Windows NT token-based Web agent.

**To check the Federation Service URL of the Windows NT token-based Web agent**

1. On the ADFS Web server, open Internet Information Services (IIS) Manager, right-click **Web Sites**, and then click **Properties**.

2. On the **ADFS Web Agent** tab, check that the URL specified in the **Federation Service URL** field is typed correctly.

Use the following procedure to check for potential typing errors in the web.config file that is associated with the claims-aware application.

**To check the Federation Service URL in the web.config file**

1. Using Notepad, edit the web.config file associated with your claims-aware application.

2. Find the Federation Service URL value in the web.config file by locating the **<fs>FederationServiceURLValue</fs>** entry. Check that the value and format specified in **FederationServiceURLValue** is typed correctly. An example of the Federation Service URL located in the web.config file used in the ADFS Step-by-Step guide is **<fs>https://adfsresource.treyresearch.net/adfs/fs/federationserverservice.asmx</fs>**.

**Confirm that Web service extensions are configured properly**
Confirm that **ASP.NET v2.0.50727** (for claims-aware applications) and/or the **ADFS Web Component Extension** (for Windows NT token-based applications) are set to **Allowed** in the Internet Information Services (IIS) Manager snap-in on the ADFS Web server.

When the ADFS client successfully reaches the home realm discovery page and selects its domain, the ADFS client submits a POST back to the resource federation server that includes the home realm. In response, the resource federation server issues a 302 redirect to the ADFS client so that the client can be authenticated for its domain and receive the appropriate claims from the account federation server.

**4. Verify Client Authentication in the Account Domain**
If the address in the ADFS client browser indicates failure of client redirection from the resource federation server back to the account federation server, the client cannot be authenticated by a domain controller in the account forest. In this case, check the following:

- The value of the Federation Service endpoint URL that is configured on the account partner node in the resource Federation Service trust policy is the same value as the Federation Service endpoint URL that is configured on the Trust Policy node in the account Federation Service. These values must match.

- Whether or not the user account is configured to use the **Smart card is required for interactive logon** option in the account properties. If this option is enabled for a user account that is attempting to access an ADFS-enabled Web application, authentication to that application will not be successful.

**Disable Java Scripting**
JavaScript is used to automatically redirect the client to various points, including posting tokens. When JavaScript is disabled, the automatic redirect will be prevented and a submit button will be displayed instead. This button allows the client to walk through each step more easily as part of troubleshooting the configuration.

### Administrative credentials

To complete this procedure, you must be a member of the Users group on the local computer.

**To disable JavaScript in Internet Explorer**

1. Open Internet Explorer.

2. On the **Tools** menu, click **Internet Options**.

3. On the **Security** tab, click **Custom Level**.

4. Scroll to the **Scripting** category.

5. Under **Active scripting**, click **Disable**, and then click **OK** twice.

**Check the Federation Service endpoint URL**
Use the following procedures to check the value of the Federation Service endpoint URL on the Trust Policy node in the account Federation Service against the value on the account partner node in the resource Federation Service.

### Administrative credentials

To complete these procedures, you must be a member of the Administrators group on the local computer.

**To check the Federation Service endpoint URL in the account Federation Service**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, right-click the **Trust Policy** node, and then click **Properties**.
3. On the **General** tab, check the value in the **Federation Service endpoint URL** box. If you need to change the value, select the domain portion of the URL, replace the selected text with the new URL, and then click **OK**.

Use the following procedure to check the Federation Service endpoint URL on the account partner node in the resource Federation Service.

**To check the Federation Service endpoint URL in the resource Federation Service**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Double-click **Federation Service**, double-click **Trust Policy**, double-click **Partner Organizations**, and then double-click **Account Partners** if you are logged on to the resource federation server, or **Resource Partners** if you are logged on to the account federation server.
3. Right-click the account or resource partner whose Federation Service endpoint URL has changed, and then click **Properties**.
4. On the **General** tab, check the value in the **Federation Service endpoint URL** box. If you need to change the value, select the domain portion of the URL, replace the selected text with the new URL, and then click **OK**.

**5. Verify Account Server Redirection to the Resource Federation Server**
After the client is authenticated and the account federation server receives authorization information from the domain controller, the account federation server builds the SAML token with the claims for the user, writes the cookie to the ADFS client. The account federation server then issues a POST REDIRECT with the SAML token and the redirect URL of the resource federation server. The account federation server signs the SAML token with its token-signing certificate. The resource federation server must have been configured with a verification certificate from the account federation server. The verification certificate contains the public key portion of the token-signing certificate of the account federation server. The resource federation server requires this certificate to verify that the account federation server sent the token.

If the verification certificate from the account federation server is not installed on the resource federation server, token validation fails. Use the following procedure to check for the existence of the verification certificate on the resource federation server.

View the current verification certificate

**The verification certificate is invalid**
If the verification certificate is present but has expired, follow the steps to roll over the verification certificate.

Rolling Over a Token-signing Certificate

**The verification certificate is missing**
If the verification certificate is not present, use the following procedure to first export the public portion of the token-signing certificate on the account federation server, and then you will need to import it into the certificate store on the resource federation server.

Export the public key portion of a token-signing certificate

**6. Verify Resource Server Redirection to the Web Server**
After receiving the token from the account federation server, the following events occur:

1. Resource federation server maps the incoming claims in the token to the appropriate claims for the ADFS Web server, and then issues a token for the ADFS Web server.
2. The resource federation server writes the cookie to the ADFS client and provides the token for the ADFS Web server to the client, along with the URL for the ADFS Web server. This information is provided to the client in the form of a POST REDIRECT.
3. The resource federation server signs the token with its own token-signing certificate. The ADFS Web server uses the

public key to verify that the token is signed by the resource federation server. The ADFS Web obtains the public key by making a call to the resource federation server. By using this public key, the ADFS Web server can verify that the token is signed by the resource federation server. The ADFS Web server then allows the appropriate access to the client.

If redirection to the ADFS Web server fails, the page fails to appear. Causes for failure can include:

- The application URL in the trust policy does not match the return URL specified in the ADFS Web Agent tab on the Web server hosting the application.
- The endpoint URL is incorrect for a federation server or federation server proxy

**The application URL does not match the return URL**
If the page fails to appear with an error such as "Server Error in '/adfs' Application," use the following procedures to check that the application URL in the properties of the application node on the resource federation server matches the return URL in the ADFS Web Agent tab on the application Web site.

1. Set the return URL for a Windows NT token-based application
2. Set the return URL for a claims-aware application
3. Set the application URL for an application

You can also check the security and application logs in Event Viewer on the resource federation server and ADFS Web server for warnings and errors that provide problem-specific information.

**The endpoint URL is incorrect for a federation server proxy**
If a federation server proxy is in place in a perimeter network in the adatum.com domain, both the resource federation server in Treyresearch.net and the account federation server in Adatum.com must be configured with the location of the federation server proxy.

If you use a federation server proxy in the account domain, check the endpoint URL on both the account partner node and resource partner node on the respective federation servers. If the URL does not point to the federation server proxy, change its value. Use the procedure "To change the Federation Service endpoint URL" in the following procedure:

Change the Federation Service endpoint URL

**The client authentication certificate for the federation server proxy is not configured**
You must ensure that an SSL certificate and a client authentication certificate is installed on each server that is running the federation server proxy component. The public key portion of the client authentication certificate must be present on the account federation server and the resource federation server. If you have more than one federation server proxy, the same SSL and client authentication certificate can be shared among all federation server proxies. Alternately, you can obtain a separate SSL and client authentication certificate for each federation server proxy, export each certificate to a file, and import all of them to the Federation Service trust policy.

| **Note** |
| --- |
| When certificates are shared among servers in the same role, you export both the public and private portions of the certificates. |

In the account Federation Service, if the client is internal, the client goes directly to the account federation server and the steps, as illustrated in the sample Federated Web SSO diagram, occur. If the client requests access remotely from the Internet, the client is redirected to the federation server proxy.

Use the following information and procedures for configuring the client authentication certificate and installing its public key on the federation servers.

Managing Client Authentication Certificates

Configuring ADFS Servers for Troubleshooting

# Configuring ADFS Servers for Troubleshooting

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

This topic provides the following sections to help you configure and understand settings and logs that can aid problem-solving on Active Directory Federation Services (ADFS) servers.

- Configuring Cache Settings on ADFS servers
- Configuring ADFS Servers to Record Auditing of ADFS Events to the Security Log
- Configuration Tasks for Troubleshooting
- Understanding Default Event Logs

**Configuring Cache Settings on ADFS servers**

The following table describes all of the various ADFS-related cache settings, where they are located, the values associated with them and the ADFS components they affect.

| Cache Setting Description | Cache Setting Location | ADFS Component / Sub-Component | Configuration Parameter | Units | Default Value | Minimum Value | Maximum Value |
|---|---|---|---|---|---|---|---|
| Lifetime of an entry in the Security Assertion Markup Language (SAML) token cache | Registry(DWORD Value) | Windows NT Token-based Web Agent / ADFS Authentication Service | System\\CurrentControlSet\\Services\\IFSSVC\\Parameters**TokenCacheEntryLifetime** | Minutes | 60 minutes | 5 minutes | Maximum DWORD |
| How often the SAML token cache is scavenged | Registry (DWORD Value) | Windows NT Token-based Web Agent / ADFS Authentication Service | System\\CurrentControlSet\\Services\\IFSSVC\\Parameters**TokenCacheScavengePeriod** | Minutes | 15 minutes | 5 minutes | Maximum DWORD |
| Total number of entries in the SAML token cache | Registry (DWORD Value) | Windows NT Token-based Web Agent / ADFS Authentication Service | System\\CurrentControlSet\\Services\\IFSSVC\\Parameters**TokenCacheSize** | N/A | 10000 | 0 | Maximum DWORD |
| How long cookie cache entries are guaranteed to live | Registry (DWORD Value) | Windows NT Token-based Web Agent / ADFS Web Agent ISAPI Extension | Software\\Microsoft\\ADFS\\WebServerAgent**CookieCacheEntryLifetime** | Seconds | 5 minutes | 1 minute | 8 hours |
| How often the cookie cache is scavenged | Registry (DWORD Value) | Windows NT Token-based Web Agent / ADFS Web Agent ISAPI Extension | Software\\Microsoft\\ADFS\\WebServerAgent**CookieCacheScavengeInterval** | Seconds | 15 minutes | 1 minute | 1 hour |
| How long token-information cache entries are guaranteed to live | Registry (DWORD Value) | Federation Service and Windows NT Token-based Web Agent | System\\CurrentControlSet\\Control\\Lsa\\WebSso\\Parameters**CacheEntryLifetime** | Seconds | 1 hour | 1 minute | 10 hours |
| How often the token information cache is scavenged | Registry (DWORD Value) | Federation Service and Windows NT Token-based Web Agent | System\\CurrentControlSet\\Control\\Lsa\\WebSso\\Parameters**CacheScavengeInterval** | Seconds | 15 minutes | 1 minute | 1 hour |
| Total number of entries in the SAML token cache | Web.config (Integer) | Claims-aware Web Agent | /websso/**tokenCacheSize** | N/A | 10000 | 0 | Integer Maximum Value |

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| Lifetime of an entry in the SAML token cache | Web.config (Integer) | Claims-aware Web Agent | /websso/**tokenCacheEntryLifetime** | Minutes | 60 minutes | 5 minutes | Integer Maximum Value |
| How often the SAML token cache is scavenged | Web.config (Integer) | Claims-aware Web Agent | /websso/**tokenCacheScavengePeriod** | Minutes | 15 minutes | 5 minutes | Integer Maximum Value |
| How often the Windows trust information is updated | Trust policy (Integer) | Federation Service | **WindowsTrustCacheUpdatePeriodInMinutes** | Minutes | 60 minutes | 5 minutes | Integer Maximum Value |
| Total number of entries in the SAML token cache | Trust policy (Integer) | Federation Service | **TokenCacheCapacity** | N/A | 10000 | 0 | Integer Maximum Value |
| Lifetime of an entry in the SAML token cache | Trust policy (Integer) | Federation Service | **TokenCacheEntryLifetimeInMinutes** | Minutes | 60 minutes | 5 minutes | Integer Maximum Value |
| How often the SAML token cache is scavenged | Trust policy (Integer) | Federation Service | **TokenCacheScavengePeriodInMinutes** | Minutes | 15 minutes | 5 minutes | Integer Maximum Value |
| How often the trust policy is checked for updates (this is in addition to change notifications in the trust policy file) | Trust policy (Integer) | Federation Service | **TrustPolicyUpdatePeriodInMinutes** | Minutes | 60 minutes | 5 minutes | Integer Maximum Value |

**Configuring ADFS Servers to Record Auditing of ADFS Events to the Security Log**
All ADFS-related audits that are made specifically to the security log are considered by the system to be object access–type audits, which by default are ignored by the system. For this reason, to ensure that ADFS-related audits (specifically **Success Audits** and **Failure Audits**) appear in the Security log, you need to manually configure the Local Security Policy, using the procedure below. You must apply the steps in this procedure to all of the ADFS servers (federation servers, federation server proxies, and Web servers hosting the ADFS Web Agent) before enabling success or failure auditing in the Trust Policy properties of the ADFS snap-in. This will allow the Federation Service to log either success or failure errors.

This procedure has no effect on the events that ADFS writes to the application log.

**To configure the Windows Security Log to support auditing of ADFS events**

1. Click **Start**, point to **Administrative Tools**, and then click **Local Security Policy**.
2. Double-click **Local Policies**, and then click **Audit Policy**.
3. In the details pane, double-click **Audit object access**.
4. On the **Audit object access Properties** page, select either **Success** or **Failure**, or both, and then click **OK**.
5. Close the **Local Security Settings** snap-in.
6. At a command prompt, type **gpupdate /force** and then press ENTER to immediately refresh the local policy.

**Configure event logging for a federation server**
Use the following procedure to specify the types of events that you want to be logged on a server that is running the Active Directory Federation Service:

- Configure event logging on a federation server

**Configure event logging for a federation server proxy**
Use the following procedure to specify the types of events that you want to be logged on a server that is running the ADFS Federation Service Proxy:

- Configure event logging on a federation server proxy

**Configure event logging on a Web server**
Events logged on Web servers that are running an ADFS Web Agent are configured according to the application type that the agent supports. Event logging is configured differently for Windows NT token-based applications and claims-aware applications:

- Windows NT token-based applications: On Web servers that are running the ADFS Web Agent for Windows NT token-based applications, event logging for these applications is set in the registry on the Web server. Use the following procedure to specify the types of events that you want to be logged for Windows NT token-based applications on the Web server:

  Configure event logging for a Windows NT token-based application

- Claims-aware applications: On Web servers that are running the ADFS Web Agent for claims-aware applications, event logging for these applications is set in the Web.config file for the application. Use the following procedure to specify the types of events that you want to be logged for claims-aware applications on the Web server:

  Configure event logging for a claims-aware application

**Configuration Tasks for Troubleshooting**
Before you use advanced troubleshooting techniques to identify and solve ADFS problems, configure your computer for troubleshooting.

To configure your computer for troubleshooting, perform the following tasks:

- Configure ADFS Event Logging
- Configure ADFS Debug Logging
- Disable JavaScript
- Enable ASP.NET Debug Output
- Configure an ASP.NET Error Page

**Configure ADFS Event Logging**
You can configure event logging on federation servers, federation server proxies, and Web servers. ADFS events are logged in the Application event log and the Security event log.

| **Important** |
| --- |
| You must turn on audit object access at each of the federation servers, for ADFS-related audits to appear in the Security log. This will allow the Federation Service to log either success or failure errors. For more information about how to turn on audit object access, see Audit object access (http://go.microsoft.com/fwlink/?LinkId=62686). |

**Configure ADFS Debug Logging**
Event logs are generally descriptive, intended to help you understand what is happening. However, the default events do not always provide the level of detail that is needed for effective troubleshooting. In this case, configure ADFS debug logging.

ADFS provides several levels of debug information that are available for troubleshooting ADFS problems. Use the procedures in this section for enabling debug logging and setting appropriate debug logging levels on federation servers, federation proxy servers, and Web servers that are running ADFS Web Agents.

| **Note** |
| --- |
| Debug logging consumes space and resources on the computer. Enabling debug logging is recommended only if you are troubleshooting a problem and need more information than is provided in events. Otherwise, do not enable debug logging. |

The debug log file is located in %systemdrive%\ADFS\logs.

**Debug log filename format**
If debug logging is enabled on a federation server, the log filename in the C:\ADFS\logs directory has the following format:

adfs*yyyymmdd-hhmmss*.log

In the name of the file, the number following "adfs" represents the date of the log and the number following the dash (-) represents the beginning time of the log.

**Debug log tags**
Depending on the level of debug logging you enable, you will see the following tags in debug logs:

[INFO] - Displays information about events, such as redirects with protocol Uniform Resource Locators (URLs), token validations, or claim mappings.

[VERBOSE] - Displays information about events, such as sign-in requests, responses, token contents, Web method calls, and security identifier (SID) information.

[ERROR] - Displays events for significant problems in the debug log.

[WARNING] - Displays events, which are not necessarily significant but that may cause future problems.

[EVENTLOG] - Displays all ADFS events.

Although all information in the log file could be useful, you can look at the lines that are tagged [ERROR] and [WARNING] first to quickly assess the problem.

For example, the following section of a debug log file shows that certificate chain validation is failing.

```
----------------

2005-11-09T19:46:47 [INFO] Requesting token for https://adfsweb.treyresearch.net/ from FS using inbound token.

2005-11-09T19:46:47 [VERBOSE] Parse: Token NOT found in cache

2005-11-09T19:46:47 [VERBOSE] SAML: effectivetime = 11/09/2005 19:46:53

expirationtime = 11/09/2005 20:46:53

2005-11-09T19:46:50 [WARNING] VerifyCertChain: Cert chain did not verify - error code was 0x80092013

2005-11-09T19:46:50 [ERROR] KeyInfo processing failed because the trusted certificate does not have a a valid certificate chain. Thumbprint =
BAF02C45AF23389CC7FEC615615056021E107C3E

2005-11-09T19:46:50 [WARNING] Failing signature verification because the KeyInfo section failed to produce a key.

2005-11-09T19:46:50 [WARNING] SAML token signature was not valid: AssertionID = _cbe6e3ca-fb90-4a93-a789-b925856163d0

2005-11-09T19:46:50 [VERBOSE] Processing FS response: policy version is a9d515c1-6965-4aa7-a78e-3cfc77f0dd2a - 16

2005-11-09T19:46:50 [INFO] Token issuance request to FS failed: ValidationFailure

2005-11-09T19:53:14 [VERBOSE] Processing HTTP GET: https://adfsresource.treyresearch.net/adfs/ls/?
wa=wsignin1.0&wreply=https://ADFSWeb.TREYRESEARCH.NET/&wct=2005-11-09T19:53:13Z&wctx=https://adfsweb.treyresearch.net/default.aspx

2005-11-09T19:53:14 [VERBOSE] Received SignIn Request.

2005-11-09T19:53:14 [VERBOSE] HOMEREALM: Realm could not be determined.
```

```
2005-11-09T19:53:14 [INFO] Received signin request via query string.

2005-11-09T19:53:14 [VERBOSE] Sign In Request Dump

-------------------
```

As you can see in the log text, even the thumbprint of the certificate is provided.

You can run the following command against the .cer file of the certificate to get more information about the failure.

**certutil –v –urlfetch -verify** *CertFileName* **.cer**

#### Set ADFS debug levels on federation servers

On federation account, resource, and proxy servers, you can use the Windows UI to enable debug logging and set levels to increase the detail of feedback in the logs.

Perform the following procedure on an account or resource federation server or federation proxy server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To set ADFS debug levels on federation servers and federation proxy servers**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click **Federation Service** or **Federation Service Proxy**, and then click **Properties**.
3. On the **Troubleshooting** tab, select debug levels as appropriate, and then click **OK**.

| **Note** |
| --- |
| To see descriptions for each debug level, click **Help** on the **Troubleshooting** tab. |

#### Enable ADFS authentication package debug logging on ADFS account federation servers

The account federation server uses the ADFS authentication package (ifsAp.dll) for mapping client certificates.

Perform the following procedures on an ADFS account federation server.

**Administrative credentials**

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To enable debug logging for the ADFS authentication package on an account federation server**

1. Open Regedit.
2. Navigate to:

   **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\lsa\WebSSO\Parameters**
3. Right-click **Parameters**, click **New**, and then click **DWORD Value**.
4. In the new value file name box, type the following, and then press Enter:

   **DebugLevel**
5. Double-click the new entry and then, in **Value data**, type the following, and then click **OK**:

   **FFFFFFFF**

#### Enable ADFS debug logging on Web servers

To enable debug logging on Web servers, you need to edit the registry on the servers that you are troubleshooting.

You can enable debug logging for the following components:

- The ADFS Web Agent running on ADFS Web servers has two components:
  - ADFS Token Authentication service (ifssvc.exe), which validates incoming tokens and cookies. Debug logging creates ifssvc.log.
  - ADFS Web Agent Internet Server Application Programming Interface (ISAPI) extension (ifsext.dll), which handles the protocols that are used by ADFS to authenticate requests; and the ADFS Web Agent ISAPI filter (ifsfilt.dll), which assists the extension and enables user name logging in the Internet Information Services (IIS) log files. Debug logging creates the ifsext_StsAppPool1.log and ifsfilt_StsAppPool1.log, respectively in the %systemdrive%\ADFS\Logs directory.
- In addition, the ADFS Web Agent authentication package (ifsAp.dll) is used by Windows NT token-based applications for generating tokens when Service-for-User (S4U) is not available. Debug logging creates ifsap.log.

You can enable debug logging for each of these components in the registry on ADFS Web servers.

**Administrative credentials**

To complete these procedures, you must be a member of the Administrators group on the local computer.

**To enable debug logging for the ADFS Token Authentication service**

1. Open Regedit.
2. Navigate to:

   **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ifssvc\Parameters**
3. Right-click **Parameters**, click **New**, and then click **DWORD Value**.
4. In the new value file name box, type the following, and then press Enter:

**DebugPrintLevel**

5. Double-click the new entry and then, in **Value data**, type the following, and then click **OK**:

   **FFFFFFFF**

**To enable debug logging for the ADFS ISAPI extension and filter**

1. Open Regedit.
2. Navigate to:

   **HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\ADFS\WebServerAgent**

3. Right-click **WebServerAgent**, click **New**, and then click **DWORD Value**.
4. In the new value file name box, type the following, and then press Enter:

   **DebugPrintLevel**

5. Double-click the new entry and then, in **Value data**, type the following, and then click **OK**:

   **FFFFFFFF**

**To enable debug logging for the ADFS Web Agent authentication package (for Windows NT token-based applications)**

1. Open Regedit.
2. Navigate to:

   **HKEY_LOCAL_MACHINE_SYSTEM\CurrentControlSet\Lsa\WebSso\ Parameters**

3. Right-click **Parameters**, click **New**, and then click **DWORD Value**.
4. In the new value file name box, type the following, and then press Enter:

   **DebugLevel**

5. Double-click the new entry and then, in **Value data**, type the following, and then click **OK**:

   **FFFFFFFF**

**Disable JavaScript**
JavaScript is used to automatically redirect the client to various points, including posting tokens. When JavaScript is disabled, the automatic redirect is prevented and a submit button is displayed instead. This button allows the client to walk through each step more easily as part of troubleshooting the configuration.

### Administrative credentials

To complete this procedure, you must be a member of the Users group on the local computer.

**Disable JavaScript in Internet Explorer**

1. Open Internet Explorer.
2. On the **Tools** menu, click **Internet Options**.
3. On the **Security** tab, click **Custom Level**.
4. Scroll to the **Scripting** category.
5. Under **Active scripting**, click **Disable**, and then click **OK** twice.

**Enable ASP.NET Debug Output**
You can generate debug output for ASP.NET files by configuring the Web.config file on the computer.

| **Note** |
| --- |
| Generating debug output for ASP.Net files enable clients to view server state information that could be misused by malicious users. |

### Administrative credentials

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To enable ASP.NET debug output**

1. In Notepad, open the Web.config file in *SYSTEMDRIVE*\ADFS\sts.
2. Search for **<system.web>**.
3. Add the **<compilation debug>** entry under **<system.web>**, as follows:

   **< compilation debug="true" />**

4. Save and close the Web.config file.

**Configure an ASP.NET Error Page**
You can configure an error page to display when ASP.NET errors prohibit the opening of a page. Use the Web.config file to configure this error page.

### Administrative credentials

To complete this procedure, you must be a member of the Administrators group on the local computer.

**To configure an ASP.NET error page**

1. In Notepad, open the Web.config file in *SYSTEMDRIVE*\ADFS\sts.
2. Search for **<system.web>**.

3. Add the following entries under **<system.web>**:

   **<customErrors mode="Off" defaultRedirect="Errors.aspx">**

   **<error statusCode="404" redirect="PageNotFound.aspx" />**

   **</customErrors>**

4. Save and close the Web.config file.

**Understanding Default Event Logs**
By default, some events are logged by ADFS components in Event Viewer. The following categories of default events provide information about successful operations that are logged in the event logs and for which you will see events in Event Viewer.

- Default Events for Token-based Applications on a Web Server
- Default Events for Claims-aware Applications on a Web Server
- Default Auditing Events for Token-based Applications on a Federation Server
- Default Auditing Events for Claims-aware Applications on a Federation Server

**Default Events for Token-based Applications on a Web Server**
The following types of events appear when an ADFS client successfully receives access to the requested application Web page. These events occur in an environment similar to the sample scenario presented in Verifying ADFS Computer Settings and Connectivity.

If a Web server that is running an ADFS Web Agent is able to retrieve trust information successfully from the Federation Service, the following event is generated in the Application log on the Web server:

```
Event Type:Information
Event Source:ADFS ISAPI Extension
Event Category:None
Event ID:101
Date:11/10/2005
Time:10:45:23 AM
User:N/A
Computer:ADFSWEB
Description:
The ADFS Web Agent for Windows NT token-based applications successfully retrieved trust information from the Federation
Service.
```

The following event appears in the Security log on the ADFS Web server:

```
Event Type:Success Audit
Event Source:Security
Event Category:Logon/Logoff
Event ID:540
Date:11/10/2005
Time:10:46:17 AM
User:urn:federation:adatum\adamcar@adatum.com
Computer:ADFSWEB
Description:
Successful Network Logon:
 User Name:adamcar@adatum.com
 Domain:urn:federation:adatum
 Logon ID:(0x0,0x25E31)
 Logon Type:3
 Logon Process:
 Authentication Package:IfsAp
 Workstation Name:-
 Logon GUID:-
 Caller User Name:ADFSWEB$
 Caller Domain:TREYRESEARCH0
 Caller Logon ID:(0x0,0x3E7)
 Caller Process ID: 1568
 Transited Services: -
 Source Network Address:-
 Source Port:-
```

In the preceding event text, Caller Process ID: 1568 is the process ifssvc.exe on the ADFS Web server.

**Default Events for Claims-aware Applications on a Web Server**
You will notice the following event if the ADFS Web server is able to retrieve ADFS trust information successfully from the Federation Service.

```
Event Type:Information
Event Source:ADFS
Event Category:None
Event ID:621
Date:11/10/2005
Time:4:09:26 PM
User:N/A
Computer:ADFSWEB
Description:
The ADFS Web Agent for claims-aware applications successfully retrieved trust information from the Federation Service.
GUID: d977fee6-175b-4532-bc24-5ac54d137d57
Version: 17
Federation Service Uniform Resource Locator (URL):
https://adfsresource.treyresearch.net/adfs/fs/federationserverservice.asmx
Federation Service Uniform Resource Identifier (URI): urn:federation:treyresearch
Federation Service Endpoint URL: https://adfsresource.treyresearch.net/adfs/ls/
Federation Service Domain Account: TREYRESEARCH0\ADFSRESOURCE$
```

You will also see the following event below in the Security log.

```
Event Type:Success Audit
Event Source:ADFS ASP.NET Module Auditor
Event Category:Object Access
Event ID:560
Date:11/10/2005
Time:4:10:11 PM
User:NT AUTHORITY\NETWORK SERVICE
Computer:ADFSWEB
Description:
The client presented a valid inbound token as evidence.
Token ID: _ad5a3694-860d-4063-95a3-3b0163fad3ca
Identity: adamcar@adatum.com
```

**Default Auditing Events for Token-based Applications on a Federation Server**

Federation servers in the account and the resource domains log similar events in the security log if object access auditing is turned on. These events provide details about claims, including the time that the claim was presented and the requested user.

**Default auditing events for a token-based application on an account federation server**

The following default auditing events are logged in the Security log on the account federation server:

- Event ID 500: Indicates that a token request was received by adfsaccount.
- Event ID 510: Contains details of the resource token that was issued by adfsaccount.
- Event ID 520: Contains details of the logon accelerator token that was issued by adfsaccount.
- Event ID 550: Contains the list of claims that were retrieved from the account store.

The following sample events are generated on the federation server named adfsaccount.adatum.com, in an ADFS deployment similar to that described in Verifying ADFS Computer Settings and Connectivity.

**Event ID 500:**

```
Event Type:Success Audit
Event Source:ADFS Federation Service Auditor
Event Category:Object Access
Event ID:500
Date:11/10/2005
Time:4:10:13 PM
User:NT AUTHORITY\SYSTEM
Computer:ADFSACCOUNT
Description:
Transaction ID: {c727f983-de98-4c88-947c-06d5f914659a}

A token request was received directly by the Federation Service. The request for target 'urn:federation:treyresearch' was
approved, and one or more tokens were issued.
Target URI: urn:federation:treyresearch

A resource token was issued. Depending on the audit policy, further details of this token may be written to a 510 event
with the same transaction ID.
Token ID: _952de51d-e827-41db-8332-1afa84aa51d2
Identity: adamcar@adatum.com

A logon accelerator was issued. Depending on the audit policy, further details of this token may be written to a 520 event
with the same transaction ID.
Token ID: _b17a22ce-96af-4a59-a885-c1252872c6ea
Identity:

The client did not present a logon accelerator token as evidence.

The client presented valid credentials. Depending on the audit policy, the list of generated claims may be written to a 550
event with the same transaction ID.
Authentication method: Windows integrated authentication
Username: ADATUM0\adamcar
```

**Event ID 510:**

```
Event Type:Success Audit
Event Source:ADFS Federation Service Auditor
Event Category:Object Access
Event ID:510
Date:11/10/2005
Time:4:10:13 PM
User:NT AUTHORITY\SYSTEM

**Default Auditing Events for Claims-aware Applications on a Federation Server**

A claims-aware application generates events that are similar to the events that are generated by a token-based application.

# Troubleshooting ADFS Problems

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

Active Directory Federation Services (ADFS) scenarios rely on the interactions among several components, all of which must be configured correctly to achieve single sign-on (SSO) for ADFS clients. The components that make up an ADFS deployment include the following:

- Multiple ADFS components, including:
    - Federation Services
    - ADFS Web Agent
    - ADFS Proxy Server (optional)
- Internet Information Services (IIS) Web sites
- Active Directory or Active Directory Application Mode (ADAM) directory store
- Certificate services
- Domain Name System (DNS) infrastructure

Troubleshooting content that is included in this guide provides the information that you need to identify and solve problems that occur within and between components in an ADFS deployment. The identified problems and solutions apply to computers that are running the following software versions:

- IIS servers that are running ADFS servers, including account and resource federation servers and ADFS proxy servers: These IIS servers must be running Windows Server 2003 R2, Enterprise Edition, or Windows Server 2003 R2, Datacenter Edition.
- Domain controllers: Domain controllers must be running Windows Server 2003 R2, Windows Server 2003, or Windows 2000 Server.
- IIS servers running ADFS Web Agent: These IIS servers must be running Windows Server 2003 R2, Enterprise Edition; Windows Server 2003 R2, Datacenter Edition; or Windows Server 2003 R2, Standard Edition.

**In this section**

- A certificate has been issued to the wrong site

# A certificate has been issued to the wrong site

Updated: September 13, 2007

Applies To: Windows Server 2003 R2

This problem typically occurs when you are attempting to connect to a Web site that is configured to use Active Directory Federation Services (ADFS) for single-sign-on (SSO) authentication and authorization. For this problem, the user might see error messages, as follows:

- If the resource Federation Service certificate name does not match the resource Federation Service host name, "The page cannot be displayed" error message appears.
- If either the account Federation Service certificate name or the Web server certificate name does not match the appropriate Federation Service host name, the following Internet Explorer warning appears: "The name on the security certificate is invalid or does not match the name of the site."

**Cause**

A Secure Sockets Layer (SSL) server authentication certificate Uniform Resource Locator (URL) does not match the appropriate URLs, as follows:

- The Federation Service endpoint URL that is configured in any of the following:
  - The account Federation Service
  - The resource Federation Service
  - The Web server
- The Federation Service URL in the ADFS Web Agent

**Solution**

Perform the following checks to determine where an incorrect URL exists.

- Verify the DNS Name in the Server Authentication Certificate
- Verify the Federation Service URL in the ADFS Web Agent

**Verify the DNS Name in the Server Authentication Certificate**

Use the following procedure to verify that the Domain Name System (DNS) names in the SSL server authentication certificates for account and resource federation servers match the DNS names in the Federation Service endpoint URL for the respective account and resource Federation Services.

Perform the following procedure on a federation server in both the account and resource Federation Services.

**To verify the DNS name in the server authentication certificate for a federation server**

1. Click **Start**, point to **Administrative Tools**, and then click **Active Directory Federation Services**.
2. Right-click **Trust Policy**, and then click **Properties**.
3. Under **Federation Service endpoint URL**, note the DNS name in the first portion of the URL, and then click **Cancel**.
4. Open the server authentication certificate (*ServerName*.cer) for the federation server.
5. Make sure the DNS name in **Issued to** is the same as the DNS name in the Federation Service endpoint URL in step 3. If the names do not match, do one of the following:
   - If the **Federation Service endpoint URL** is incorrect, change the value.

- If the **Issued to** value in the certificate is incorrect, remove the current certificate, and then request and install a new SSL server authentication certificate using the correct DNS name.

Perform the following procedure on a Web server that is running an ADFS Web Agent.

**To verify the DNS name in the server authentication certificate for a Web server**

1. Click **Start**, point to **Administrative Tools**, and then click **Internet Information Services**.
2. Right-click **Web Site**, and then click **Properties**.
3. On the **Directory Security** tab, under **Secure Communications**, click **View Certificate**.
4. Make sure that the DNS name in **Issued to** is the same as the DNS name of the Web server.
5. If the names do not match, remove the current certificate, and then request and install a new SSL server authentication certificate using the correct DNS name.

For information about how to request and install SSL server authentication certificates, see Public Key Infrastructure for Windows Server 2003 on the Microsoft Web site (http://go.microsoft.com/fwlink/?LinkId=19936).

**Verify the Federation Service URL in the ADFS Web Agent**
Use the following procedure to make sure that the DNS name in the Federation Service URL on the Web server that is running the ADFS Web Agent matches the DNS name in the Federation Service endpoint URL for the resource partner Federation Service.

Check the Federation Service endpoint URL value for the resource Federation Service that you noted in the preceding procedure against the Federation Service URL that is configured in the ADFS Web Agent on the Web server. The DNS names in these two URLs must match exactly.

**To verify the Federation Service URL in the ADFS Web Agent**

1. To check the ADFS Web Agent in IIS (for Windows NT token-based applications):
   a. On the Web server, click **Start**, point to **Administrative Tools**, and then click **Internet Information Services (IIS) Manager**.
   b. Double-click *YourServerName* **(local computer)**, right-click **Web Sites**, and then click **Properties**.
   c. On the **ADFS Web Agent** tab, under **Federation Service URL**, verify that the URL path specifies **https://***DNSNameOfResourcePartner***/adfs/fs/FederationServerService.asmx**.
   d. Verify that the DNS name in the first portion of the URL matches the DNS name in **Federation Service endpoint URL** in step c.
2. To check the ADFS Web Agent in the Web.config file (for claims-aware applications):
   a. In Notepad or another text editor, open the Web.config file that is located in the application folder on the Web server.
   b. Search for **<fs>**.
   c. Verify that the URL path specifies **https://***DNSNameOfResourcePartner***/adfs/fs/FederationServerService.asmx**.
   d. Verify that the DNS name in the first portion of the URL matches the DNS name in **Federation Service endpoint URL** in step c.
3. If the path is incorrect or if the DNS name does not match the name in **Federation Service endpoint URL**, either change the Federation Service URL as needed in the ADFS Web Agent, or change the Federation Service endpoint URL in the resource Federation Service.

**See Also**

**Concepts**

Change the Federation Service endpoint URL
Set the Federation Service URL for a Windows NT token-based application
Set the Federation Service URL for a claims-aware application

# IIS 6.0 Operations Guide

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Internet Information Services (IIS) 6.0 with the Microsoft® Windows Server 2003™ operating system provides integrated, reliable, scalable, secure, and manageable Web server capabilities over an intranet, the Internet, or an extranet. IIS is a tool for creating a strong communications platform of dynamic network applications. Organizations of all sizes use IIS to host and manage Web pages on the Internet or on their intranet, to host and manage FTP sites, and to route news or mail using the Network News Transfer Protocol (NNTP) and the Simple Mail Transfer Protocol (SMTP). IIS 6.0 leverages the latest Web standards like Microsoft ASP.NET, XML, and Simple Object Access Protocol (SOAP) for the development, implementation, and management of Web applications. IIS 6.0 includes new features designed to help organizations, IT professionals, and server administrators achieve their goals of performance, reliability, scalability, and security for potentially thousands of Web sites either on a single IIS server or on multiple servers.

| **Important** |
| --- |
| To help minimize the attack surface of the server, IIS 6.0 is not installed on Windows Server 2003 by default. When you first install IIS 6.0, it is locked down — which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable these features, IIS returns a 404 error. You can enable these features through the Enabling and Disabling Dynamic Content in IIS 6.0 node in IIS Manager. For more information about how to troubleshoot 404 errors and other issues, see Troubleshooting in IIS 6.0. |

This version of IIS was designed to provide the following benefits and features.

| IIS 6.0 Feature | Description |
| --- | --- |
| Reliability | IIS 6.0 uses a new request-processing architecture and application isolation environment that enables individual Web applications to function within a self-contained worker process. This environment prevents one application or Web site from stopping another, and reduces the amount of time administrators spend restarting services to correct problems related to applications. The new environment also includes proactive Application Pool Health. |
| Scalability | IIS 6.0 introduces a new kernel-mode driver for HTTP parsing and caching, specifically tuned to increase Web server throughput and scalability of multiprocessor computers, thereby significantly increasing the following:<br>• The number of sites a single IIS 6.0 server can host<br>• The number of concurrently-active worker processes<br>Also, by Configuring Startup and Shutdown Time Limits, IIS allocates resources to active sites, as opposed to wasting resources on idle requests. |

| | |
|---|---|
| Security | IIS 6.0 provides significantly improved security over earlier versions of IIS. To reduce the attack surface of systems, IIS is not installed by default on the operating systems in the Windows Server 2003 family. Administrators must explicitly select and install IIS. IIS installs by default in a locked-down state, capable of serving only static content. Using the Web Service Extensions node, Web site administrators can Configuring IIS For Dynamic Content IIS functionality based on the individual needs of their organization. IIS 6.0 includes a variety of Security in IIS 6.0 features and technologies to help ensure the integrity of your Web and FTP site content, as well as the data transmitted through your sites. IIS security features include the following security-related tasks:<br>• Authentication in IIS 6.0<br>• Access Control with IIS 6.0<br>• IIS 6.0 Encryption<br>• Certificates_IIS_SP1_Ops<br>• Auditing in IIS 6.0 |
| Manageability | To meet the needs of a diverse set of organizations, IIS provides a variety of manageability and administration tools. Administrators can configure an IIS 6.0 server using IIS Manager, Using Command-Line Administration Scripts, or by directly Enabling Edit-While-Running in IIS 6.0. Administrators can also Administering Servers Remotely in IIS 6.0 IIS servers and sites. |
| Enhanced Development | Compared to earlier operating systems, the Windows Server 2003 family offers an improved developer experience with About ASP.NET and IIS integration. ASP.NET recognizes most ASP code while providing greater functionality for building enterprise-class Web applications that can work as a part of the Microsoft .NET Framework. Using ASP.NET allows you to take full advantage of the features of the common language runtime, such as type safety, inheritance, language interoperability, and versioning. IIS 6.0 also offers support for the latest Web standards, including XML, SOAP, and Internet Protocol Version 6 Features. |
| Application Compatibility | IIS 6.0 is compatible with most existing applications, based on feedback from thousands of customers and independent software vendors (ISVs). Also, to ensure maximum compatibility, IIS 6.0 can be configured to run in IIS 5.0 Isolation Mode in IIS 6.0. |

The IIS 6.0 Operations Guide includes the following information:

- Getting Started with IIS 6.0: Describes key features in IIS 6.0, outlines the differences between this and earlier versions of IIS, and introduces basic concepts and tools, such as how to install IIS and how to open IIS Manager.
- Common Administrative Tasks in IIS 6.0: Includes a series of short procedural topics describing how to complete routine or common IIS 6.0 tasks.
- Site Setup: Describes how to set up a new Web, FTP, SMTP, or NNTP site.
- Server Administration Guide: Includes conceptual and procedural information regarding administrative tasks performed on IIS servers and sites.
- Security in IIS 6.0: Describes how to configure your Web server to strengthen the security of your Web sites and to carry out other essential security functions.
- Performance Tuning: Describes how to maximize the performance of your IIS 6.0 solution.
- Logging Site Activity: Describes how to use operating system and IIS logs to collect information about server events, server performance, and user activity.

- Error Messages in IIS 6.0: Describes how to configure IIS to send default and custom error messages.
- Web Application Guide: Describes how to develop and manage Web applications by using ASP and ASP.NET.
- IIS 6.0 Administration Reference: Describes interfaces, objects, and data structures that are available for programming and administering IIS, as well as metabase properties.
- Troubleshooting in IIS 6.0: Describes processes for resolving issues with your IIS 6.0 installation.

# Getting Started with IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This section includes general information about key features and changes in this version of Internet Information Services (IIS). It also includes information about how to install IIS and access IIS Manager to administer IIS sites, as well as links to resources on the Web.

| **Important** |
| --- |
| To help minimize the attack surface of the server, IIS 6.0 is not installed on Windows Server 2003 by default. When you first install IIS 6.0, it is locked down -- which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable these features, IIS returns a 404 error. You can enable these features through the Enabling and Disabling Dynamic Content in IIS 6.0 node in IIS Manager. For more information about how to troubleshoot 404 errors and other issues, see Troubleshooting in IIS 6.0. |

**In This Section**

This section includes the following information:

- IIS 6.0 Features: Describes key features in this version of IIS.
- What's Changed: Describes important differences between IIS versions 4.0, 5.0, 5.1 and 6.0.
- IIS Manager: Describes how to access the IIS graphical user interface.
- Frequently Asked Questions about IIS 6.0: Answers common questions about IIS.
- Additional IIS 6.0 Resources: Provides links to information on the Web.
- Release Notes_IIS_SP1_Ops: Explains how to access late-breaking technical information, known problems, and information about how to get technical support for IIS.
- Before Configuring IIS: Discusses server configurations that should be addressed before attempting to configure IIS.
- Installing IIS: Describes various methods for installing IIS and how to add or remove components.
- Uninstalling IIS: Describes two methods for removing IIS from your server.

# IIS 6.0 Features

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS 6.0 includes new features designed to help businesses, IT professionals, and Web administrators achieve their goals of performance, reliability, scalability, and security for potentially thousands of Web sites either on a single IIS server or on multiple servers. This section describes new and notable features in IIS 6.0.

**In This Section**

- Reliability Features: Describes new modes of operation and World Wide Web Publishing Service (WWW service) processes.
- Security Features_IIS_SP1_Ops: Describes new features designed to secure your Web sites, data, and your IIS server.
- Performance Features: Describes performance and scalability features.
- Web Application Technologies: Describes the IIS 6.0 implementation of Microsoft® ASP.NET, ASP, and the ADSI provider.
- Administrative Tools and Features: Describes metabase changes and new administrative tools.
- Internet Standards: Describes support for Web and Internet standard protocols.
- Internet Protocol Version 6 Features: Describes the IIS 6.0 functionality that supports Internet Protocol Version 6 (IPv6).

# Reliability Features

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS 6.0 is more reliable than previous versions due to a new request processing architecture that provides an application isolation environment which enables individual Web applications to function within their own, self-contained worker process. The following are just a few of the improvements that make IIS 6.0 a more reliable Web administration environment.

**Modes of Operation — New**
You can configure IIS 6.0 to run in either worker process isolation mode, which runs all processes in an isolated environment, or IIS 5.0 isolation mode, in which you can run Web applications that are not compatible with worker process isolation mode. In worker process isolation mode, you can isolate anything — from an individual Web application to multiple sites — in its own self-contained World Wide Web Publishing Service (WWW service) worker process, preventing one application or site from stopping another. Separating applications or sites into separate processes simplifies a number of management tasks.

**Worker Processes — New**
In worker process isolation mode, worker processes handle all user code and are completely isolated from the core WWW service, Inetinfo.exe. Because these ISAPI applications run separately from the WWW service, an application failure prevents all services hosted by the WWW service from failing. Only the worker process that hosts the ISAPI application is affected. Worker processes can be configured to run on specific CPUs, which allows you greater control of balancing system resources.

**Multiple Application Pools — New**
Worker process isolation mode allows customers to create multiple application pools, where each application pool can have a unique configuration. Performance and reliability are enhanced because these application pools receive their requests directly from the kernel instead of from the WWW service.

**Application Pool Assignments — New**
An application pool can be configured in worker process isolation mode to serve anything from one Web application, to multiple applications, to multiple sites. Assigning an application to an application pool allows you to further isolate applications, and is as easy as configuring what pool that application should be routed to in the metabase. Sites, by default, are considered to be a simple application, where the root namespace "/" is configured as an application.

**Application Pool Queue Length Limits — New**
When running in worker process isolation mode, you can choose to limit the number of requests that should be queued for each application pool in the HTTP protocol stack (HTTP.sys). This allows you to fine-tune the environment in which your applications run by managing application pool requests and system resources.

**Web Garden Configuration on Multi-Processor Computers — New**
An application pool is associated with a specified worker process. For improved reliability, you can configure a Web garden, which is an application pool that has multiple worker processes serving the requests routed to that pool. If one worker process fails, another worker process can continue to process requests. On a computer with multiple processors, you can obtain even greater reliability by establishing affinity between worker processes and specific processors. Using processor affinity, a lock on one process does not block other processes running on the multiprocessor computer.

**Kernel-Mode Queuing — New**
The IIS 6.0 kernel-mode driver, HTTP.sys, places requests destined for application pools in a queue if a worker process in that pool fails. Because the WWW service manages the processes, the WWW service can initialize another process without causing an interruption in service to users. Requests are sent from the queue until the queue is empty or until the WWW service is stopped.

**Health Monitoring — New**
In worker process isolation mode, the WWW service monitors the health of worker processes and, if the process is unresponsive, terminates the process and replaces it with another. Health monitoring helps keep processes running and provides users with more reliable service.

**Idle Process Timeout — New**
You can control system resources by configuring application pools in worker process isolation mode to have their worker processes request a shutdown if the worker processes are idle for a configurable amount of time, such as minutes, hours, or days. You can then request a forced application startup when IIS receives a request for that application pool.

**Rapid-Fail Protection — New**

You can configure IIS in worker process isolation mode to use rapid-fail protection to automatically disable an application pool when a particular application pool suffers consecutive multiple failures.

**Orphan Worker Process — New**

A worker process that fails to respond to queries from the WWW Service Administration and Monitoring component can be configured in worker process isolation mode to "separate" from the application pool instead of being terminated, as a new worker process is started in its place. Because the process is still running, you can perform diagnostics on it. For more information, see Application Pool Health.

**Recycling Worker Processes — New**

You can configure IIS, in worker process isolation mode, to periodically restart worker processes in an application pool. When a new process is initialized, it takes over any requests to that application pool while the former worker process finishes processing its requests from the queue. Recycling worker processes allows you to manage troublesome applications, such as those with memory leaks, without interrupting service to your users.

# Security Features_IIS_SP1_Ops

Updated: August 22, 2005

Applies To: Windows Server 2003 R2, Windows Server 2003 with SP1

IIS 6.0 includes a variety of security features and technologies to ensure the integrity of your Web and FTP site content, as well as data transmitted through your sites. IIS security features cover the following security-related tasks: authentication, access control, encryption, certificates, and auditing. This topic describes new and notable security features.

| **Important** |
| --- |
| To help minimize the attack surface of the server, IIS 6.0 is not installed on Windows Server 2003 by default. When you first install IIS 6.0, it is locked down -- which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable these features, IIS returns a 404 error. You can enable these features through the Web Service Extensions node in IIS Manager. For more information about how to troubleshoot 404 errors and other issues, see Troubleshooting in IIS 6.0. |

**Digest Authentication**

Digest authentication allows robust authentication of users across proxy servers and firewalls. In addition, Anonymous authentication, Basic authentication, and Integrated Windows authentication are still available.

**Advanced Digest Authentication — New**

Advanced Digest authentication makes improvements over Basic authentication in that credentials are sent over the network as an MD5 hash and are stored as such in the Active Directory® of the domain controller. This mechanism makes it extremely difficult for intruders to discover users' passwords and does not require you to modify your applications.

**Secured Communications**

Secure Sockets Layer (SSL) 3.0 and Transport Layer Security (TLS) provide a secure way to exchange information between clients and servers. In addition, SSL 3.0 and TLS provide a way for the server to verify who the client is before the user logs on to the server. In IIS, client certificates are exposed to both ISAPI and Active Server Pages (ASP), so that programmers can track users through their sites. Also, IIS can map the client certificate to a Windows user account so that administrators can control access to system resources based on the client certificate.

**Server-Gated Cryptography**

Server-Gated Cryptography (SGC) is an extension of SSL that allows financial institutions with export versions of IIS to use strong 128-bit encryption. Although SGC capabilities are built into IIS, a special SGC certificate is required to use SGC. For more information about SGC, see Server-Gated Cryptography.

**Selectable Cryptographic Service Provider — New**

Secure Sockets Layer provides a secure way to exchange information between clients and servers. However, the CPU has to perform intensive cryptography, which degrades performance. IIS offers the Selectable Cryptographic Service Provider (CSP), which allows you to select a cryptographic provider that suits your needs. Each provider can create a public and private key for encrypting data sent to and from the Web server. The private key is stored at the server on hardware, a PCI card, a SmartCard, or in the registry — as it is for the two default providers that Microsoft installs. Storing the private key on hardware allows you to plug into hardware-based accelerator cards, that perform cryptographic computations, instead of the server. It is easy to select providers from IIS Manager to use Microsoft CryptoAPI providers or installed CryptoAPI providers from other companies. All CryptoAPIs implement the same methods so that you can switch between providers without having to change your code.

**Configurable Worker Process Identity — New**

To thwart system attackers and malicious users, you can configure application pools and therefore the worker process executing within, to run under an account with a lower level of permissions than LocalSystem. If you provide services to Internet users, you can allow your customers to upload static content and executable code. Erroneous code will not cause the World Wide Web Publishing Service (WWW service) or computer to fail. Only the application will fail.

**Security Wizards**

The following security wizards simplify server administration tasks:

- The **Web Server Certificate Wizard** simplifies certificate administration tasks, such as creating certificate requests and managing the certificate life cycle.

- The **CTL Wizard** helps you configure your certificate trust lists (CTLs). A CTL is a list of trusted certification authorities (CAs) for a particular directory. CTLs are especially useful for Internet service providers (ISPs) who have several Web sites on their server and need to have a different list of approved certification authorities for each site.

**IP and Internet Domain Restrictions**
You can assign or deny Web access to individual computers, groups of computers, or entire domains.

**Kerberos V5 Authentication Protocol Compliance**
IIS is fully integrated with the Kerberos V5 authentication protocol implemented in members of the Windows Server 2003 family, allowing you to pass authentication credentials among connected computers running Windows.

**Certificate Storage**
IIS certificate storage is now integrated with the Windows CryptoAPI storage. The Windows Certificate Manager provides a single point of entry that allows you to store, back up, and configure server certificates.

# Performance Features

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

A new generation of applications puts a greater demand on performance and scalability attributes of Web servers. Increasing the speed at which HTTP requests can be processed and allowing more applications and sites to run on one server translates directly into fewer servers needed to host a site. The following are a few of the performance improvements included in IIS 6.0.

**HTTP.sys — New**
The Hyper Text Transfer Protocol (HTTP) stack in members of the Windows Server 2003 family is implemented as a kernel-mode device driver called HTTP.sys. HTTP.sys is a new feature specific to the Windows Server 2003 family, and is a part of the networking subsystem. IIS is a user-mode process that runs in a completely different execution mode than kernel processing. HTTP.sys is a single point of contact for all incoming (server-side) HTTP requests that provides high performance connectivity for HTTP server applications. HTTP.sys is also responsible for overall connection management, bandwidth throttling, and text-based logging. HTTP.sys implements a flexible Universal Resource Identifier (URI) response cache, called flexible caching, which enables HTTP applications to cache static data and service cached HTTP requests completely in kernel mode with no transition to user mode. HTTP.sys implements a URI namespace mapping mechanism called application pools. With application pools, HTTP applications can claim portions of the URI namespace, which allows HTTP.sys to route HTTP requests directly to the appropriate HTTP applications. As a result of these changes, IIS has increased throughput and scalability of multiprocessor computers, which significantly increases:

- The number of sites a single IIS 6.0 server can host.
- The number of concurrently-active worker processes.

**ASP Disk Caching — New**
Active Server Pages (ASP) processes templates that contain ASP scripts, stores the processed templates in a cache, and serves the cached templates to clients. By default, 250 templates are cached in-memory. If a site uses ASP heavily, this in-memory template cache cannot store all the necessary templates. IIS includes a persistent cache, so templates are cached to disk if the in-memory cache does not have enough space. If the ASP page is requested again, Asp.dll doesn't need to recompile the source code and can load the compiled template from disk. Caching ASP templates enhances performance because cached ASP templates are not processed each time they are called. You can further improve performance by changing the number of cached templates for all applications with low (in process) application protection, medium (pooled) application protection, or individually for applications with high (isolated) application protection.

For more information about ASP caching, see Configuring ASP Applications.

**Asynchronous CGI — New**
IIS handles the Common Gateway Interface (CGI) implementation asynchronously, thereby removing the potential for blocked CGI processing responses.

**Capacity Planning Tracing — New**
The IIS tracing feature for capacity planning traces application workloads against ASP script resource usage, such as HTTP response/request times. You can collect and analyze event trace data under different workloads and different hardware configurations and then use this data to help you with capacity planning.

**Centralized Binary Logging — New**
Centralized Binary Logging allows multiple sites to write to a single log file in a binary, unformatted manner. This logging format improves performance, as the data does not have to be formatted in any specific manner like W3C Extended, IIS, or NCSA formats. With Microsoft SQL Server-TM- support, multiple machines can deposit logs in one centralized database.

**Quality of Service —New**
Quality of Service (QoS) encompasses the set of methods or processes that a service-based organization implements to maintain a specific level of quality. In the context of Windows, QoS is a set of service requirements that the network must meet to assure an adequate service level for data transmission. The goal of QoS is to ensure that particular sites or applications do not monopolize server resources, like memory or CPU cycles. As an administrator, you can control the level and quality of service for your users by using the IIS implementation of connection limits and timeouts, application pool queue length limits, bandwidth throttling, and process accounting.

**Bandwidth Throttling**

If the network or Internet connection used by your Web server is also used by other services such as e-mail or news, you may want to limit the bandwidth used by your Web server so that bandwidth is available for those other services. If your Web server hosts more than one Web site, you can individually throttle the bandwidth used by each site.

**CPU Monitoring**

CPU Monitoring is a tool that monitors and automatically shuts down worker processes that consume large amounts of CPU resources. CPU monitoring is enabled for individual application pools. CPU monitoring can also help you determine which sites have malfunctioning scripts or CGI processes.

**Large Memory Support for x86.0**

IIS 6.0 (HTTP.sys) can be configured to cache up to 64 GB on an x86 system if booted with /PAE and without /3GB. This is a new feature as IIS 5.0 cached in virtual memory which was capped at 3GB.

# Web Application Technologies

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The Windows Server 2003 family offers an improved developer experience with ASP.NET and IIS integration. Microsoft® ASP.NET recognizes most ASP code while providing greater functionality for building enterprise-class Web applications that can work as a part of the Microsoft .NET Framework. Using ASP.NET allows you to take full advantage of the features of the common language runtime, such as type safety, inheritance, language interoperability, and versioning. IIS 6.0 also offers support for the latest Web standards, including XML, Simple Object Access Protocol (SOAP) and Internet Protocol Version 6 (IPv6.0).

**ASP.NET -- New**
ASP.NET is a unified Web application platform that provides the services necessary to build and deploy enterprise-class Web applications and XML Web services. ASP.NET is available and is installed, by default, on the operating systems in the Windows Server 2003 family.

| **Important** |
| --- |
| This feature is not available on Windows XP 64-Bit Edition and the 64-bit versions of the Windows Server 2003 family. For more information, see "Features unavailable on 64-bit versions of the Windows Server 2003 family" in Help and Support Center for Windows Server 2003. |

ASP.NET offers a new programming model and infrastructure for more secure, scalable, and stable applications that can target any browser or device. ASP.NET is part of Microsoft .NET Framework, a computing environment that simplifies application development in the highly distributed environment of the Internet.

.NET Framework includes the common language runtime, which provides core services such as memory management, thread management, code security, and the .NET Framework class library, a comprehensive and object-oriented collection of types that developers can use to create applications. Note that ASP.NET is not supported by 64-bit systems.

**Active Server Pages**
You can create dynamic content by using server-side scripting and components to create browser-independent dynamic content. Microsoft Active Server Pages (ASP) provides an easy-to-use alternative to Common Gateway Interface (CGI) and ISAPI by allowing content developers to embed any scripting language or server component into their HTML pages. ASP provides access to all of the HTTP request and response streams, as well as standards-based database connectivity and the ability to customize content for different browsers.

**ADSI 2.0**
ADSI 2.0 provides administrators and application developers the ability to add custom objects, properties, and methods to the existing ADSI provider, giving administrators even more flexibility in configuring their sites.

**Wildcard Application Mappings**
Wildcard application mappings provide administrators the ability to configure a Web site or virtual directory to run an ISAPI application at the beginning of every request to that Web site or virtual directory, regardless of the extension of the requested file.

**Related Information**

- For more information about ASP.NET, see About ASP.NET and Creating ASP.NET Web Applications.
- For more information about Active Server Pages, see About ASP.
- For more information about ADSI 2.0, see IIS Administration Technologies in the IIS Software Development Kit (SDK) on MSDN.
- For more information about wildcard application mappings, see Installing Wildcard Application Mappings.

# Administrative Tools and Features

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

To meet the needs of a diverse set of customers, IIS provides a variety of manageability and administrative tools. Administrators can configure a server running IIS 6.0 with IIS Manager, administration scripts, or by directly editing the IIS plaintext configuration file. Administrators can also remotely administer IIS servers and sites.

**Plaintext Metabase — New**
The metabase is a repository for most IIS configuration values. Metabase reengineering has lead to dramatic improvements in server startup and shutdown times, in addition to enhancing overall metabase performance and usability. This version of IIS includes an XML metabase configuration file, which can be edited manually or programmatically. The metabase is stored in two plaintext XML files:

- MetaBase.xml contains the configuration values for IIS.
- MBSchema.xml stores the XML metabase schema and enforces correct metabase configuration.

Because both the MetaBase.xml and MBSchema.xml files are stored as plain text, they can be read using any plaintext editor.

**Storing Metabase History — New**
You can quickly revert to a previous version of the metabase, thereby preventing long service interruptions. Automatic tracking of changes to the metabase are written to disk by copying each version of the metabase file into a history folder. Each history file is identified with a unique version number, which is then available for the metabase restore processes. A new set of Admin Base Object (ABO), WMI, and ADSI methods are exposed, which allows users to enumerate and restore the metabase configuration programmatically.

**Edit Metabase File While IIS Is Running — New**
You can edit the metabase file directly while IIS is running and the changes are immediately applied to the in-memory metabase. This capability, known as *edit-while-running*, is possible because MetaBase.xml is a text file. Direct editing can be accomplished using common text tools, like Microsoft Notepad, when the edit-while-running feature is enabled.

**Import and Export Site and Application Configuration — New**
In order to propagate site and application configuration settings across multiple servers for any node level, IIS supports two Admin Base Object (ABO) methods, Import() and Export(). Using these methods, you can export one node, or an entire tree, to an XML file from any level of the metabase, along with the inherited configuration, and then import one node, or an entire tree, from an XML file, as well as the inherited configurations. In addition you can password-protect secure data with these ABO methods.

**Create Server-Independent Metabase Backups — New**
Using the BackupWithPassword() and RestoreWithPassword() methods of the ADSI IIsComputer object, you can programmatically back up or restore the metabase with a password. The session key is encrypted with an optional user-supplied password during backup and is not based on the machine key.

**Metabase Reliability — New**
Using the configuration backup/restore feature, you can create a secure or unsecured backup of your metabase. Administrators can also restore copies of the metabase to other computers through IIS Manager. These backup methods provide a way to restore only your metabase settings, not your content files.

**IIS WMI Provider — New**
The Windows Server 2003 family of products features Windows Management Instrumentation (WMI), a scalable management infrastructure, as a means to improve management of Windows servers in your environment. The IIS WMI provider provides a level of manageability that is functionally equivalent to the IIS ADSI provider, while supporting an extensible schema. Furthermore, schema extensions developed using ADSI are imported into the IIS WMI provider, making the benefits of WMI even greater. For more information about WMI, see "IIS Administration Technologies" in the IIS Software Development Kit (SDK) on MSDN.

**FTP User Isolation — New**
FTP user isolation is a solution for Internet service providers (ISP) and application service providers that need to offer their customers individual FTP directories to upload files and Web content. FTP user isolation prevents users from viewing or

overwriting other users' Web content by restricting users to their own directory. A user cannot navigate higher up the directory tree because the user's top-level directory appears as the root of the FTP service. Within the user's specific site, the user still has the ability to create, modify, or delete files and folders.

**FrontPage 2002 Server Extensions — New**
FrontPage Server Extensions provide Web-based and command-line administration for extending virtual servers. Extending virtual servers with FrontPage Server Extensions enables the site owner to author the site in FrontPage and delegate site ownership and administration credentials.

FrontPage® 2002 Server Extensions from Microsoft is an update of FrontPage 2000 Server Extensions, and includes new security features, such as roles and rights, and new features for monitoring server health and Web site usage.

**Command-Line Administration Scripts — New**
Command-line administration makes it easier to perform management tasks efficiently. IIS provides scripts for the following tasks:

- Create, delete, start, stop, and list Web sites
- Create, delete, start, stop, and list FTP sites
- Create or delete Web virtual directories
- Create or delete applications
- Export or import IIS configuration
- Back up or restore IIS configuration

**UTF-8 Logging Support — New**
IIS supports log file recording in UTF-8 that allows administrators to log their URL hits in their native language instead of English. This setting, configurable on the Web-service level, instructs the HTTP protocol stack (HTTP.sys) in which format to write the log files: UTF-8 or the local code page.

**Remote Administration**
IIS includes a variety of tools to help you remotely administer your IIS Web servers. These tools include the Remote Administration (HTML) tool, Terminal Services, and programmatic features like ADSI, WMI, and a new set of command-line administration scripts.

The IIS Remote Administration (HTML) tool allows you to remotely administer IIS across the Internet or your intranet through your Web browser.

Terminal Services is a feature of the Windows Server 2003 family of products that allows you to run 32-bit Windows applications on terminals and terminal emulators running on personal computers and other computer desktops. This enables you to remotely administer Windows services, such as IIS, as if you were at the server console. You can administrate from older legacy PCs, or even from devices such as UNIX workstations with compatible client software. However, non-Windows-based client devices require third-party add-on software.

**Centralized Administration**
Administration tools for IIS use Microsoft Management Console (MMC). MMC hosts programs, such as IIS Manager, that administrators can use to manage their servers. You can use IIS Manager from a computer running a member of the Windows Server 2003 family to administer a computer on your intranet running IIS on a Windows server product.

**Remotable Certification Object —New**
Using scripts, you can process Secure Sockets Layer (SSL) certificates on your local or a remote computer. A Component Object Model (COM) object allows you to perform the add, remove, back up, and restore functions, which circumnavigates the constraints imposed by MMC.

For more information, see Managing Server Certificates Programmatically in IIS 6.0.

# Internet Standards

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS 6.0 offers support for the latest Web standards, including HTTP 1.1, TCP/IP, FTP, SMTP, NNTP, and PICS ratings.

**Standards Based**
IIS 6.0 complies with the HTTP 1.1 standard, which includes features such as PUT and DELETE, the ability to customize HTTP error messages, and support for custom HTTP headers.

**Multiple Sites, One IP Address**
With support for host headers, you can host multiple web sites on a single server running a member of the Windows Server 2003 family with only one IP address. This is useful for Internet service providers and corporate intranets hosting multiple sites.

**IIS Extensions to FTP — New**
IIS extends FTP in two significant areas. The IIS FTP User Isolation feature allows you to contain users to their own FTP directory, thus preventing them from viewing or overwriting other users' Web content. In addition, IIS supports multiple character sets for FTP, which allows your users access to their native-language worldwide.

**UTF-8 Support — New**
Support for Unicode and UTF-8 now extends to file names and URLs. Active Server Pages (ASP) can open any file name using the Unicode file name string. UTF-8 URLs are converted to a Unicode representation and presented to ASP.

**Web Distributed Authoring and Versioning**
Web Distributed Authoring and Versioning (WebDAV) enables remote authors to create, move, or delete files, file properties, directories, and directory properties on your server over an HTTP connection.

**News and Mail**
You can use News Network Transport Protocol (NNTP) and Simple Mail Transfer Protocol (SMTP) services to set up intranet news and mail services that work in conjunction with IIS.

**PICS Ratings**
You can apply Platform for Internet Content Selection (PICS) ratings to sites that contain content for mature audiences.

**FTP Restart**
FTP Restart enables File Transfer Protocol (FTP) file downloads to be resumed without having to download the entire file again if an interruption occurs during data transfer.

**HTTP Compression**
HTTP Compression provides faster transmission of pages between the Web server and compression-enabled clients. It compresses and caches static files, and performs on-demand compression of dynamically generated files.

# Internet Protocol Version 6 Features

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This version of IIS provides Internet services to clients connecting over the next generation of Internet Protocol (IP) known as IP version 6, or IPv6. IPv6 is included with the Microsoft Windows XP networking platform and the Microsoft Windows Server 2003 family.

The Internet Server API (ISAPI) framework provides the appropriate local- and remote-host server variables for IPv6 network addresses: LOCAL_ADDR and REMOTE_ADDR. When clients connect over IPv6, these variables store the IPv6 address.

When writing applications that use the ISAPI server variables for network addressing over IPv6, remember that all buffers allocated for network address storage can be a maximum of 128 bits in size (56 character string), whereas buffers allocated for network address storage over IPv4 are limited to 32 bits (16 character string).

After the protocol stack is installed, IIS automatically begins supporting IPv6 on your Web server.

Web sites that are already running must be restarted before they begin listening for IPv6 requests. Sites created after IPv6 support is enabled automatically listen for IPv6.

**Functionality**

The IIS core functionality has not changed as a result of IPv6 support; however, only a subset of all IIS 6.0 functionality is available for IPv6.

- IIS Manager does not display IPv6 addresses as it does for IPv4 addresses.
- Bandwidth Throttling is not supported for IPv6 Web sites.
- The ServerBindings metabase property does not support storing IPv6 literal addresses (as defined in RFC 2732). This behavior limits IIS to support host-header routing only.
- The **IP Address Restrictions** feature in IIS does not support IPv6 addresses or IPv6 prefixes.
- The EnableReverseDnsLookup metabase property is not supported. Setting this property to true does not cause the REMOTE_HOST server variable to return the DNS name of the client, as it does for IPv4. REMOTE_HOST will always contain the IPv6 address regardless of the **EnableReverseDNSLookup** setting.
- Site routing based on IP addresses is not supported for IPv6. Server address with sites that are configured to route based on IPv4 addresses will not respond to IPv6 requests.
- IPv6 is enabled for all sites. You cannot configure IPv6 support at the machine level. In other words, you cannot configure individual sites to respond to IPv6 traffic while other sites on the same server respond to IPv4 traffic. It is possible, however, to limit IPv6 traffic to a specific site if that site is configured to use IP-based routing on an IPv4 address.
- Logging. IIS writes IPv6 addresses to the log file when IPv6 is enabled and client computers connect to the server using IPv6 addresses. Log parsing tools must support IPv6 address formats if they are to be used with log files for IPv6 sites.
- SSL. Due to the IP routing restriction for IPv6, IIS deployments designed for IPv6 addresses are limited to one Secure Sockets Layer (SSL) site per computer.

**Related Information**

- For information about how to install the IPv6 network protocol stack, see IPv6 and IIS 6.0.

# What's Changed

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

There are some notable and important differences in default behavior and settings between IIS 4.0, IIS 5.0, IIS 5.1, and IIS 6.0.

This topic includes the following information:

- Core Functionality and Services
- Metabase Configuration
- Administration
- Programmatic Administration
- Active Server Pages (ASP)
- ASP Hang Detection
- Security
- Performance
- IIS Utility Components
- IIS on 64-bit Versions of the Windows Server 2003 Family

The following table summarizes the important differences between versions of IIS.

| | **IIS 4.0** | **IIS 5.0** | **IIS 5.1** | **IIS 6.0** |
|---|---|---|---|---|
| **Platform** | Windows NT 4.0 | Windows 2000 | Windows XP Professional | Windows Server 2003 family |
| **Architecture** | 32-bit | 32-bit | 32-bit and 64-bit | 32-bit and 64-bit |
| **Application process model** | TCP/IP kernel<br>MTX.exe | TCP/IP kernel<br>DLLhost.exe (multiple DLL hosts in medium- or high-application isolation) | TCP/IP kernel<br>DLLhost.exe (multiple DLL hosts in medium- or high-application isolation) | HTTP.sys kernel<br>When IIS is running in IIS 5.0 isolation mode: Inetinfo.exe (for in-process applications) orDLLhost.exe (for out-of-process applications)<br>When IIS is running in Worker Process Isolation Mode: W3wp.exe (multiple worker processes) |
| **Metabase configuration** | Binary | Binary | Binary | XML |

| | | | | |
|---|---|---|---|---|
| **Security** | Windows authentication<br>SSL | Windows authentication<br>SSL<br>Kerberos | Windows authentication<br>SSL<br>Kerberos<br>Security wizard | Windows authentication<br>SSL<br>Kerberos<br>Security wizard<br>Passport support |
| **Remote administration** | HTMLA | HTMLA | No HTMLA<br>Terminal Services | Remote Administration Tool (HTML)<br>Terminal Services |
| **Cluster support** | In Windows NT 4.0 | IIS clustering | Windows support | Windows support |
| **WWW services** | IIS on Windows NT 4.0 | Personal Web Manager on Windows 9x<br>IIS on Windows 2000 | IIS optionally on Windows XP Professional | IIS on a member of the Windows Server 2003 family |

**Core Functionality and Services**

IIS 6.0 has been redesigned to take advantage of the base Windows kernel, HTTP.sys. This allows for built-in response and request caching and queuing, as well as the ability to route application process requests directly to the worker processes, which improves reliability and performance.

IIS 6.0 introduces two modes of operation in order to configure your application environments: worker process isolation mode and IIS 5.0 isolation mode. The default isolation mode upon installing IIS 6.0 depends on whether you perform a clean installation or an upgrade.

- After a clean install of IIS 6.0, IIS runs in worker process isolation mode.
- After an upgrade from an earlier version of IIS 6.0, the isolation mode is the same as configured on the previously-installed version of IIS 6.0.
- After an upgrade from IIS 5.0 or IIS 4.0, IIS 6.0 runs in IIS 5.0 isolation mode by default to maintain compatibility with your existing applications.

For information about switching from one isolation mode to the other, see Configuring Isolation Modes.

**IIS 5.0 Isolation Mode**

IIS 5.0 isolation mode manages application processes in a similar fashion to the process management in IIS 5.0: all in-process applications run inside Inetinfo.exe, and out-of-process applications run in separate DLL hosts. Some existing applications may not have been written to run concurrently, or to store session state separately from the application. Therefore, running processes in IIS 5.0 isolation mode ensures compatibility for most existing applications. The following illustration shows how application processes are handled in IIS 5.0 isolation mode.

**Worker Process Isolation Mode**

When configured to execute in worker process isolation mode, all application code runs in an isolated environment. This design removes some of the existing bottlenecks. Worker process isolation mode allows the administrator to isolate anything from an individual Web application to multiple sites in their own self-contained worker process. This prevents one application or site from stopping another. In addition, separating applications or sites into their own process space simplifies a number of management tasks, such as restarts (independent of all other sites or applications running on the system), changing a component used by the application, debugging, monitoring counters, throttling resources, and so forth. The following illustration shows how applications are managed by IIS in worker process isolation mode.

HTTP requests are routed to the correct application pool queue, which means that user mode worker processes serving an application pool pull the requests directly from the kernel and eliminate the unnecessary process hops encountered when

sending a request to an out-of-process DLL host. In IIS 6.0, there is no longer the notion of in-process applications; all necessary HTTP application run-time services, such as ISAPI extension support, are equally available in any application pool. This design prevents a malfunctioning HTTP application or Web site from disrupting other HTTP applications (or other Web sites) served from other processes on that computer. Unloading components becomes easier because with isolated application processes, the process can, if necessary, be terminated to unload all resources, with no effect on other content or applications being served from other processes. It is also beneficial to be able to leverage other operating system services available at the process level (for example CPU throttling), per application pool.

Furthermore, critical portions of worker process isolation mode that maintain the overall functioning of World Wide Web Publishing Service (WWW service) run entirely outside of the worker processes. The IIS 6.0 kernel-mode driver, HTTP.sys, which is the universal HTTP processor for Windows, and the WWW Service Administration and Monitoring component isolate the critical portions of the core Web server. Both of these components are protected and do not allow third-party code to be loaded into them. This design prevents a malfunctioning HTTP application from disrupting WWW services on the server.

For more information about isolation modes, see Application Isolation Modes.

**Metabase Configuration**
The metabase for IIS 6.0 is stored in an XML file instead of in binary format as it was in earlier versions of IIS. The location remains the same, but the ways it can be manipulated -- updated, rolled back, restored, and extended -- have changed. There are two significant files instead of one: MetaBase.xml and MBSchema.xml.

**Administration**

- In IIS 4.0, applications could either be run in the same process as the Internet service or in a separate process. In IIS 5.0 and 5.1, applications can be grouped into pooled processes for increased performance and improved scalability. For more information, see About Configuring Applications. In IIS 6.0 worker process isolation mode, applications can grouped in any number of application pools.

- The Application Mappings property sheet contains a list of Hypertext Transport Protocol (HTTP) verbs that are processed by an application that is mapped to certain file types. This list of verbs represents a change from IIS 4.0. In IIS 4.0, the list contained verbs that were *excluded*, or not processed. This change was made to accommodate new HTTP verbs as they are added to the protocol. For more information about application mappings, see Setting Application Mappings in IIS 6.0.

- Clustering is not a feature of IIS 6.0 (IISsynche.exe is not supported). Clustering is a feature of the Windows Server 2003 family. For information about Windows Clustering (MSCS), see Windows Server 2003 family Help.

- The location of custom error files has changed from IIS 4.0 to IIS 5.0.

- The Web-based Internet Services Manager (HTML) has been replaced by a Web application called the Remote Administration (HTML) tool. To remotely administer IIS by using the Remote Administration (HTML) tool, see Administering Servers Remotely in IIS 6.0.

**Programmatic Administration**
In previous versions of IIS, programmatic administration of IIS was possible with Admin Base Objects (ABO) from compiled C++ applications, or with Active Directory Services Interfaces (ADSI) from C++ or script files. IIS 6.0 includes a provider for Windows Management Instrumentation (WMI), a technology that allows administrators to control all services and applications programmatically. For more information about WMI, see "IIS Administration Technologies" in the IIS Software Development Kit (SDK) on MSDN.

**Active Server Pages**
Beginning with IIS 6.0, Microsoft Active Server Pages (ASP) can be used along with Microsoft ASP.NET. For information about configuring IIS to run ASP.NET applications, see About ASP.NET. For news on changes to ASP functionality in IIS 6.0, see Important Changes in ASP.

Because the worker process, W3wp.exe, runs as the Network Service account in IIS 6.0 worker process isolation mode, you must configure Launch and Access permissions to enable ASP debugging for Script Debugger and Visual InterDev. For more information, see Enabling ASP Debugging.

**ASP Hang Detection**
When an IIS Web site is busy, there may be instances when the maximum number of ASP threads has been spawned and some of the ASP threads are hung, resulting in degraded performance. IIS 6.0 has the ability to solve the problem of hung threads by recycling the worker process that hosts that particular instance of the ASP ISAPI extension, ASP.dll. When ASP threads are hung

in IIS 6.0, ASP.dll calls the ISAPI server support function **HSE_REQ_REPORT_UNHEALTHY**, and the WWW service recycles the worker process that hosts ASP.dll, and make an entry in the event log.

For more information about ISAPI server support functions, see **ServerSupportFunction** in the ISAPI Extension Reference at MSDN® Online.

**Security**

One of the most important changes in IIS 6.0 addresses Web server security. In order to take a more proactive stance against malicious users and attackers, IIS is not installed by default on members of the Microsoft Windows Server 2003 family.

| **Important** |
| --- |
| To help minimize the attack surface of the server, IIS 6.0 is not installed on Windows Server 2003 by default. When you first install IIS 6.0, it is locked down -- which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable these features, IIS returns a 404 error. You can enable these features through the Web Service Extensions node in IIS Manager. For more information about how to troubleshoot 404 errors and other issues, see Troubleshooting in IIS 6.0. |

With the Web Server Certificate Wizard and the CTL Wizard, you can synchronize Web and NTFS security settings, obtain and install server certificates, and create and modify certificate trust lists. You can also select a cryptographic service provider (CSP) for encrypting data with a certificate.

Other security changes in IIS 6.0 include the following:

- Disabled on upgrades: The World Wide Web Publishing Service (WWW service) is disabled on Windows Server 2003 family upgrades, unless one of the following is true:

    - You have already run the IIS Lockdown Wizard on your Windows 2000 Server before starting the upgrade process. The IIS Lockdown Wizard reduces surface attack by disabling unnecessary features, and it allows you to decide which features to enable for your site. The IIS Lockdown Wizard is available at IIS Lockdown Tool.

| **Important** |
| --- |
| If you use the WWW service, we strongly recommend that you run the IIS Lockdown Wizard on your Windows 2000 Server before upgrading to a product in the Windows Server 2003 family. The IIS lockdown Wizard will help secure your computer by disabling or removing unnecessary features that are present in your Windows 2000 Server installation. These features would otherwise have remained on your machine after upgrading, leaving your server vulnerable to attacks. |

- The registry key RetainW3SVCStatus has been added to the registry under HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W3SVC. Under RetainW3SVCStatus, you can add any value and then assign a DWORD value to it. For example, you can create the key HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W3SVC\RetainW3SVCStatus\do_not_disable with the DWORD value of 1.

- In the unattended install case, an entry "DisableWebServiceOnUpgrade = false" exists in the unattended install script.

- Disabling IIS through Group Policy: With members of the Windows Server 2003 family, domain administrators can prevent users from installing IIS on their machines.

- Running as an account with a low level of access rights: IIS worker processes run in a user context of few access rights. This drastically reduces the effect of potential attacks.

- Secure ASP: All ASP built-in functions always run as the account with very few access rights, IUSR_*computername*.

- Restriction on running executables: In order to run most executables in the system folder (such as cmd.exe) you must be a member of the Administrators group, the LocalSystem, Interactive, or Service account. This restriction limits remote access to Administrators, so anonymous users cannot run executables.

- Patch management: With patch management, administrators can get the latest security patches installed without interrupting service.

- Known extensions: IIS serves requests only to files with known file name extensions. The server rejects requests for content if the file name extension is not mapped to a known file type or to an application that services requests for that file type.

| **Note** |
| --- |
| The word *extensions* has two meanings: Either Web service extensions that enable pages to serve dynamic content, for example, .asp or .aspx; or file name extensions, which indicate the file type, such as .exe, .txt, or .inc. |

Use the **WebSvcExtRestrictionList** metabase key to lock down DLLs and executables that handle dynamic content. To lock down file name extensions, use the MimeMap feature in the IIS metabase.

- Write protection for content: Anonymous users (running as IUSR_*computername* account) are denied write access to Web content by default.

- Timeouts and limits: In IIS 6.0, settings are set to aggressive and secure defaults to minimize attacks due to timeouts and limits that were previously too generous.

- Upload data limitations: Administrators can limit the data that can be uploaded to a server.

- Buffer overflow protection: Worker processes detect and exit programs if a buffer overflow is detected.

- File verification: IIS verifies whether the requested content exists before it gives the request to a request handler (ISAPI extension).

- Index this resource: This permission is now enabled by default.

- Script source access: This permission, which allows access to the *source code* of scripts in ASP pages and other scripts, is new and is disabled by default. It is available if either the **Read** or **Write** permission is selected.

- Subauthentication: This is no longer enabled by default on a new installation of IIS 6.0. For more information, see Configuring Subauthentication.

- UNC authentication: In this version of IIS, the UNC authentication method checks for user credentials. For more information, see UNC Authentication in IIS 6.0.

- New policy: The "Prevent IIS from Installing" policy has been added to the Windows Server 2003 family of products. This policy allows a domain administrator to control which computers in the domain can install IIS. For more information, see "Group Policy" in Help and Support Center for Windows Server 2003.

- Fortezza: Support for this has been removed.

**Performance**

To limit the amount of memory allocated to ASP pages, IIS has set the default value of the AspScriptFileCacheSize Metabase Property to 250 ASP pages, and the default value of the AspScriptEngineCacheMax Metabase Property to 125 script engines. The **ASPScriptFileCacheSize** can be set higher on sites with a large set of frequently requested ASP pages. This improves performance because ASP page compilation is substantially slower than retrieving pages from cache. On a site with only a small number of frequently requested ASP pages, memory can be saved by setting this number to a smaller value.

**IIS Utility Components**

- Collaboration Data Objects for Windows NT Server (CDONTS): CDONTS has been removed from the Windows Server 2003 family. If your Web applications use CDONTS, you can convert them to Microsoft Collaboration Data Objects

(CDO). Most methods in CDONTS have matching methods in CDO, but might be named differently. For reference material for CDO in the Platform Software Developer Kit (PSDK), see Overview of CDO at MSDN Online.

- IIS utility components not installed: Ad Rotator, Browser Capabilities, Content Linker, Content Rotator, Counters, Logging Utility, My Info, Page Counter, Status, and tools are not installed with IIS 6.0. However, if you upgrade your Web server from a previous version of IIS, the utility components are not removed.

**IIS on 64-bit Versions of the Windows Server 2003 Family**

On the 64-bit versions of the Windows Server 2003 family of operating systems, IIS runs as a 64-bit application. This means that 32-bit applications cannot be called from IIS on the 64-bit versions of the Windows Server 2003 family of operating systems. For example, the Jet database engine will not convert to a 64-bit application, so you cannot use ActiveX® Data Objects (ADO) to open a Microsoft Access database from an ASP page. However, you can still use ADO to access other drivers, like SQL and Exchange.

# IIS Manager

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS Manager is a graphical interface for configuring your application pools or your Web, FTP, SMTP, or NNTP sites. With IIS Manager, you can configure IIS security, performance, and reliability features. You can add or delete sites; start, stop, and pause sites; back up and restore server configurations; and create virtual directories for better content management, to name only a few of the administrative capabilities. In previous releases of IIS, this tool was called the Internet Service Manager.

| **Important** |
| --- |
| To help minimize the attack surface of the server, IIS 6.0 is not installed on Windows Server 2003 by default. When you first install IIS 6.0, it is locked down — which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable these features, IIS returns a 404 error. You can enable these features through the **Web Service Extensions** node in IIS Manager. For more information about how to troubleshoot 404 errors and other issues, see Troubleshooting in IIS 6.0. |

**Procedures**

**To start IIS Manager**

- From the **Start** menu, point to **Administrative Tools**, and then click **Internet Information Services (IIS) Manager**.

**To start IIS Manager from the Run dialog box**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **inetmgr**, and click **OK**.

You can also access IIS from the Computer Management window. Accessing IIS in this way does not give you the range of administration options offered by IIS Manager; however, it does offer quick access and limited management options for your Web sites.

**To start IIS Manager from the Computer Management window**

1. From the **Start** menu, right-click **My Computer**, and click **Manage**.
2. In the console tree, expand the **Services and Applications** node.
3. Click **Internet Information Services**. The names and states of your Web sites appear in the details pane.
4. In the console tree, expand the **Internet Information Services** node and any subsequent Web site nodes to see a list of directories and virtual directories for that Web site.

**Related Information**

- For more information about using IIS Manager and administering IIS, see the Server Administration Guide.
- For information about administering IIS remotely, see Administering Servers Remotely in IIS 6.0.

# Frequently Asked Questions about IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

1. Why do features like FrontPage Server Extensions, WebDAV publishing, ASP, and server-side includes not work on IIS 6.0 by default?
2. What is a Web service extension and how do I use the Web Service Extensions folder?
3. How do I publish documents or Web pages?
4. How do I create a virtual directory on a Web or FTP site?
5. How do I create a Web site?
6. How do I create multiple Web sites?
7. How do I replicate Web content?
8. How do I stop and restart Internet services?
9. Where can I find information about accessibility features for disabled users?
10. How do I get technical support for IIS?
11. Can I change the name of my Web site and also redirect requests for the old site name to the new one?
12. Can I use IIS Manager to remotely administer my site through a proxy server?
13. How do I determine whether my drive is configured to use NTFS?
14. How do I convert a drive or partition formatted for the file allocation table (FAT) file system to the NTFS file system?
15. Can I set up an FTP site with different levels of access for different users?
16. How can I confirm that a server certificate is attached to a Web site?
17. Can I attach more than one server certificate to a Web site?
18. Can I attach the same server certificate to more than one site?
19. Can I attach a server certificate to an FTP site?
20. Should I create a backup copy of my server certificate?
21. How do I determine how many users are connected to my FTP service?
22. Does ASP debugging work in IIS 6.0 worker process isolation mode?
23. Why do features like FrontPage Server Extensions, WebDAV publishing, ASP, and server-side includes not work on IIS 6.0 by default?

# Why do features like FrontPage Server Extensions, WebDAV publishing, ASP, and server-side includes not work on IIS 6.0 by default?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In order to take a more proactive stance against malicious users and attackers, IIS is not installed on members of the Microsoft Windows Server 2003 family by default. Furthermore, when you initially install IIS, the service is installed in a highly secure and locked mode. By default, IIS serves only static content — meaning features like ASP, ASP.NET, server-side includes, WebDAV publishing, and FrontPage Server Extensions do not work. You can serve dynamic content and unlock these features using IIS Manager. See Configuring IIS 6.0 Web Service Extensions.

**Related Sections**

For more information, see Security in IIS 6.0.

# What is a Web service extension and how do I use the Web Service Extensions folder?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The **Web Service Extensions** folder is the user interface for the new IIS 6.0 lockdown feature. This feature is a manifest of ISAPI extensions and CGIs with user-specified permissions, meaning, administrators must set the permissions to allow specific ISAPIs and CGIs to run on your server. Administrators can also specify the names of ISAPIs or CGIs that are forbidden to run on your server. Before loading an ISAPI extension .dll file or CGI .exe file, IIS checks this manifest for the permissions on the file. If the file is permitted to run, then the request proceeds normally. If the file is not permitted to run, then IIS returns a 404.2 error response to the client machine. The HTML page for a 404.2 error looks like a standard 404 error page, so the client machine processes the request as though the file did not exist. IIS logs the 404.2 error, which administrators can view to assess problems or potential threats against the server.

**Related Sections**

For more information, see Configuring IIS For Dynamic Content.

# How do I publish documents or Web pages?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

**To publish documents or Web pages**

1. Move your files to the \Inetpub\Wwwroot directory.
2. Type **http://***servername***/***filename* in the address bar of your Internet browser to see your published files.

For more information, see Site Setup.

# How do I create a virtual directory on a Web or FTP site?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use IIS Manager to create virtual directories on your Web site. For procedural information about how to accomplish this task, see Using Virtual Directories.

# How do I create a Web site?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When you install IIS on a computer running a member of the Windows Server 2003 family, a default Web site is set up for you. You can publish your content here immediately.

# How do I create multiple Web sites?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

To create multiple Web sites, you must first ensure that each site has unique identification. To accomplish this, you need to contact your network administrator to either obtain multiple IP addresses or to assign multiple host header names. For more information, see Domain Name Resolution.

# How do I replicate Web content?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the Content Deployment service (formerly known as the Content Replication System, or CRS) to replicate content and settings across servers in a Web cluster. Content Deployment is a feature of Microsoft Content Management Server. For more information about Content Deployment service, see the Content Management Server 2002 Product Documentation on the Windows Server System Web site.

# How do I stop and restart Internet services?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Internet services are most effectively shut down and restarted differently from other Windows services. For information about stopping and restarting IIS, see Restarting IIS.

# Where can I find information about accessibility features for disabled users?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

For general information about accessibility for Windows, see "Accessibility for people with disabilities" in Help and Support Center for Windows Server 2003.

# How do I get technical support for IIS?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If IIS was pre-installed as part of an original equipment manufacturer (OEM) package, or if it was otherwise included with your personal computer purchase, you must contact the manufacturer of your computer or server for technical support. Refer to the documentation that came with your computer or server for the telephone number of the manufacturer.

If you acquired this product separately at retail, and have a technical question that you cannot answer by using the IIS 6.0 Operations Guide, see the Microsoft Help and Support Center Web site.

# Can I change the name of my Web site and also redirect requests for the old site name to the new one?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure your Web site to respond to both the old name and the new name, provided your network correctly routes both requests to your computer. This way, visitors can still reach your site by using the old name, and will be informed of the new name. For instructions on how to assign names to Web sites, see Naming Web Sites.

# Can I use IIS Manager to remotely administer my site through a proxy server?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Yes. To learn about remote administration using IIS Manager and other tools, see Administering Servers Remotely in IIS 6.0.

# How do I determine whether my drive is configured to use NTFS?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

1. In Windows Explorer, right-click the drive, and click **Properties** to open its property sheet.
2. On the **General** tab, the file system type is listed.

# How do I convert a drive or partition formatted for the file allocation table (FAT) file system to the NTFS file system?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

At the command prompt, type **convert** *drive letter:* **/FS:NTFS**.

An NTFS drive cannot be converted back to FAT. For more information, see "File systems" in Windows Help.

# Can I set up an FTP site with different levels of access for different users?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

**To limit access to only certain computers**

1. In IIS Manager, right-click the FTP site, and click **Properties**.
2. Click the **Directory Security** tab, and click **Edit**.

   You can assign or deny access to all computers or subnets except those you specify.

On an NTFS file system, you could also use a single virtual directory and set the NTFS permissions to assign or deny different types of access to different Windows user accounts. For more information, see Isolating FTP Users.

# How can I confirm that a server certificate is attached to a Web site?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

1. In IIS Manager, right-click the Web site, and click **Properties**.

2. Click the **Directory Security** tab.

3. Under **Secure communications**, if the **View Certificate** button is activated, there is a certificate attached to the Web site.

   If the button is not activated, you must attach a server certificate to the site to use the Secure Sockets Layer (SSL) features.

# Can I attach more than one server certificate to a Web site?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

No. Each Web site can have only one server certificate attached to it.

# Can I attach the same server certificate to more than one site?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Yes. A server certificate can be attached to as many Web sites as needed.

# Can I attach a server certificate to an FTP site?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

No. FTP sites do not support Secure Sockets Layer (SSL) features.

# Should I create a backup copy of my server certificate?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Yes. Your server certificate is a valuable investment, and is the key to your server's Secure Sockets Layer features. To create a backup copy of your server certificate, copy the entire certificate on to a floppy disk and store it in a safe place.

# How do I determine how many users are connected to my FTP service?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

1. In IIS Manager, right-click an FTP site, and click **Properties**.
2. On the **FTP Site** tab, click **Current Sessions**.

   The **FTP User Sessions** dialog box appears indicating the number of connected users.

For more information, see Performance Tuning.

# Does ASP debugging work in IIS 6.0 worker process isolation mode?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Yes, when you configure Launch and Access permissions to enable ASP debugging in worker process isolation mode for Script Debugger and Visual InterDev. For more information, see Enabling ASP Debugging.

# Additional IIS 6.0 Resources

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

# Release Notes_IIS_SP1_Ops

Updated: August 22, 2005

Applies To: Windows Server 2003 R2, Windows Server 2003 with SP1

The release notes for Internet Information Services (IIS) 6.0 are incorporated into the release notes for the Microsoft Windows Server 2003 family of products. For late-breaking technical information, known problems, and upgrade information, please refer to the following: readme.htm, relnotes.htm, read1st.txt, and \docs*.txt.

# Before Configuring IIS

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Before configuring IIS, it is important to understand issues users sometimes face. By addressing these issues now, you can enjoy a smoother configuration process. This topic outlines these issues and also links you to additional information that you might want to review before beginning your IIS configuration.

This topic includes the following information:

- Internet Connection Firewall
- Remote Administration
- IP Address and Domain Name Registration
- Permissions and Access Control

**Internet Connection Firewall**

The Windows Server 2003 family provides a software-based firewall to prevent unauthorized connections to your server from remote computers. The Internet Connection Firewall is disabled by default; however, if you have enabled the firewall in its default configuration after installing a member of the Windows Server 2003 family and before installing IIS, clients will not be able to connect to your server. The following procedure configures Internet Connection Firewall to allow clients to initiate Web and other IIS-related connections to your server.

**To configure Internet Connection Firewall for IIS**

1. From the **Start** menu, click **Control Panel**.
2. Double-click **Network Connections**.
3. Right-click the **Local Area Connection**, and click **Properties**.
4. Click the **Advanced** tab.
5. If you do not want to use the Internet Connection Firewall, make sure the **Protect my computer and network by limiting or preventing access to this computer from the Internet** check box is disabled, and click **OK**.
6. If you do want to use the Internet Connection Firewall, make sure the **Protect my computer and network by limiting or preventing access to this computer from the Internet** check box is enabled, and click **Settings**.
7. On the **Services** tab, enable a service to which you want to allow access to clients.
8. In the **Service Settings** dialog box that appears after enabling a service, do one of the following:
   - If you are enabling a service on the same computer on which you are working, the correct computer name is already filled in. Click **OK**.
   - If you are enabling a service on a different computer on your network, type the name or IP address of the computer hosting the service you are enabling, and click **OK**.
9. Repeat steps 7 and 8 until all the services you want accessible to clients are enabled.

**Remote Administration**

Many network administrators configure servers remotely, that is, from a computer other than the server being configured. If you are installing IIS on one server, and configuring and administering that IIS installation from a different computer, you should configure Remote Administration on the server running IIS. You can use the following tools for this purpose:

- IIS Manager: You can use IIS Manager on your server to remotely connect to and administer an intranet server running IIS 4.0, IIS 5.0, or IIS 5.1 (IIS 3.0 is not supported).

- Terminal Services: Terminal Services does not require you to install IIS Manager on the remote client computer because, once connected to the server running IIS, you use IIS Manager on the Web server as if logged on locally.

- Remote Administration (HTML) Tool: You can use the Remote Administration (HTML) tool to administer your IIS Web server from any Web browser on your intranet. This version of the Remote Administration tool runs only on servers running IIS 6.0.

For information about how to configure remote administration, see Administering Servers Remotely in IIS 6.0.

**IP Address and Domain Name Registration**
If you are configuring IIS on a server connected directly to the Internet, that is, not within a corporate network or behind a router, you must have on hand the IP address and domain name of each site you will create in this IIS configuration. For more information, see Domain Name Resolution and Hosting Multiple Web Sites on a Single Server.

If you are configuring IIS on a server within a corporate network or behind a router, you must ask the network administrator for an IP address, and if applicable, to configure the router and/or firewall to allow traffic to flow to and from the IIS server. Registering a domain name is usually not necessary in these cases because IIS servers within a corporate network are typically for Intranet use only.

When obtaining IP addresses for your Web sites, make sure they are static IP addresses. Dynamic IP addresses are not suitable for any kind of IIS configuration.

**Permissions and Access Control**
If you are configuring IIS so that it will be relying on other servers or network components, such as routers, to serve content, make sure that the other servers or network components have been configured to allow access to the IIS server, and that you have the appropriate authentication information on hand before you begin configuring IIS. For more information, see Authentication in IIS 6.0 and Access Control in IIS 6.0.

**Related Information**

- For a checklist of additional issues to consider before configuring IIS, see "Application server role: Configuring an application server" in Windows Help.

# Installing IIS

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This topic describes 3 methods for installing IIS:

- Using the Configure Your Server Wizard.
- Using Add or Remove Programs from Control Panel.
- Using unattended setup.

**Note**

You can use the Web Platform Installer (Web PI) to easily install IIS, and applications that run on IIS. The Web PI is a free, lightweight tool that lets you install IIS and related technologies such as ASP.NET, SQL Server Express, Visual Web Developer, other popular Web applications, and more. Because the Web PI installs the latest versions of available Web Platform offerings, with just a few simple clicks you can download and install any new tools or updates. To learn more about the Web PI, see Learn more and install the Web PI.

This topic also lists the directories created on install, describes the IIS initial configuration backup, and briefly describes IIS optional components.

**Important**

To help minimize the attack surface of the server, IIS 6.0 is not installed on Windows Server 2003 by default. When you first install IIS 6.0, it is locked down — which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable these features, IIS returns a 404 error. You can enable these features through the Web Services Extensions node in IIS Manager. For more information about how to troubleshoot 404 errors and other issues, see Troubleshooting in IIS 6.0.

Microsoft strongly recommends installing IIS on an NTFS-formatted drive. NTFS is a more powerful and secure file system than FAT and FAT32. For more information, see Securing Files with NTFS Permissions.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the runas command to run IIS Manager as an administrator. At a command prompt, type **runas**

**/user:***Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**.

**Procedures**

**To install IIS using the Configure Your Server Wizard**

1. From the **Start** menu, click **Manage Your Server**.
2. Under **Managing Your Server Roles**, click **Add or remove a role**.
3. Read the preliminary steps in the **Configure Your Server Wizard** and click **Next**.
4. Under **Server Role**, click **Application server (IIS, ASP.NET)** and then click **Next**.

   By default, the wizard installs and enables IIS, COM+, and DTC.
5. If you want to serve either of the optional technologies (FrontPage Server Extensions or ASP.NET), on the **Application Server Options** page, select the appropriate check boxes, and then click **Next**.

6. Read the summary and click **Next**.
7. Complete the wizard, and then click **Finish**.

| **Note** |
| --- |
| The **Configure Your Server Wizard** enables ASP.NET by default, unlike the **Add/Remove Windows components** install method below. |

For more information about the **Configure Your Server Wizard**, see "Configuring Your Server Wizard" in Windows Help.

**To install IIS, add components, or remove components using Control Panel**

1. From the **Start** menu, click **Control Panel**.
2. Double-click **Add or Remove Programs**.
3. Click **Add/Remove Windows Components**.
4. In the **Components** list box, click **Application Server**.
5. Click **Details**.
6. Click **Internet Information Services Manager**.
7. Click **Details** to view the list of IIS optional components. For a detailed description of IIS optional components, see "Optional Components" in this topic.
8. Select all optional components you wish to install.

   | **Note** |
   | --- |
   | The **World Wide Web Publishing Service** optional component includes important subcomponents like the **Active Server Pages** component and **Remote Administration (HTML)**. To view and select these subcomponents, click **World Wide Web Publishing Service** and then click **Details**. |

9. Click **OK** until you are returned to the **Windows Component Wizard**.
10. Click **Next** and complete the **Windows Component Wizard**.

**Unattended Setup**

To simplify the process of setting up IIS on multiple computers running a member of the Windows Server 2003 family, you can run setup unattended. To do this, create and use an answer file, which is a customized script that automatically answers the setup questions.

For information about how to create an answer file and to view a table of all IIS unattended setup parameters, see Appendix E: Unattended Setup.

**IIS Directories**

IIS installs the following directories:

- \InetPub
- **systemroot**\Help\IISHelp
- **systemroot**\System32\InetSrv
- **systemroot**\System32\InetSrv\MetaBack

These directories contain user content and cannot be moved. You can, however, select the location of your Wwwroot and Ftproot directories at installation by using a script during unattended setup. If you uninstall IIS, the IISHelp directory is removed. The InetPub and InetSrv directories remain on your computer.

**IIS Initial Configuration Backup**
When you first install IIS, a backup of the initial metabase configuration is automatically created in the *systemroot*\System32\InetSrv\MetaBack directory. This backup can be used to restore the IIS configuration to its state immediately following IIS installation. This is a useful tool for solving metabase corruption or configuration problems, and can help you recover a known good configuration without needing to reinstall IIS. This backup is not password protected, and can only be used to restore settings on the system on which it was created. See Backing Up and Restoring the Metabase in IIS 6.0 for information about restoring the initial IIS configuration backup.

It is strongly recommended that following IIS installation, and before any configuration changes are made, you create a password-protected backup of the IIS configuration. Unlike the automatic initial configuration backup, a password-protected backup is system independent, and can be used to restore settings on other systems running IIS 6.0. See Backing Up and Restoring the Metabase in IIS 6.0 for information about creating a password-protected backup of the IIS configuration.

**Optional Components**
IIS includes optional components that you can enable or disable at anytime through the **Add or Remove Programs** item in Control Panel, or using unattended setup. Descriptions of these components and the impact to your current IIS settings are described below.

Files for Active Server Pages (ASP), Internet Data Connector, server-side includes, and WebDav are installed, but disabled by default on a clean installation. All IIS functionality is enabled by default on an upgrade. When one of these components is selected or cleared from the **Windows Components Wizard** or by using an unattended file, the component is enabled or disabled in the WebSvcExtRestrictionList Metabase Property.

**BITS Server Extensions**
The Background Intelligent Transfer Service (BITS) is a background file transfer mechanism and queue manager, also known as a drizzle service. BITS throttles file requests to minimize bandwidth consumption and enhance the end-user experience. Enable BITS with IIS to maintain Web server quality of service. From the Windows Components Wizard, click **Details** to enable the following BITS Server components:

- **BITS Server Extensions ISAPI**: Enable this option to drizzle IIS requests with the help of the BITS server.
- **BITS Server Extensions Snap-in**: Enabling this option to access and view the BITS graphical user interface (GUI).

**Common Files**
For the sake of added security in your server environment, you may choose to deselect some of the common files. However, if you deselect the Common Files option, all of the common files are subsequently deselected and IIS will not be installed on your machine. Therefore, if you want to install IIS on your computer, leave this option selected. If you want to limit the services and components installed with IIS, deselect the individual components that are listed below the Common Files component.

**File Transfer Protocol (FTP) Server**
The File Transfer Protocol (FTP) is used to copy files to and from remote computer systems on a network that uses Transmission Control Protocol/Internet Protocol (TCP/IP).

**FrontPage 2002 Server Extensions**
FrontPage 2002 Server Extensions allow you to view and manage a Web site in a graphical user interface using FrontPage as the authoring environment. FrontPage allows you to quickly create Web sites on your server, as well as, create, edit, and post Web pages to IIS remotely. While you are creating your site, FrontPage keeps a connection open to IIS, saving and changing the Web files so you can view your site. If you choose not to install the FrontPage Server Extensions, you will have to manually copy all of your Web content, configure your settings, and in some cases, manually register applications already registered in FrontPage. Microsoft FrontPage Server Extensions are not supported for resources in Microsoft Clustering.

**Internet Information Services Manager**
IIS Manager is a graphical user interface to administer your Web site. In previous releases of IIS, this tool was called the Internet Service Manager. Without IIS Manager, you can still manage your server, but you must use coded scripts that call on the IIS APIs to create sites, applications, virtual directories, and security settings.

**NNTP Service**
Use Network News Transfer Protocol (NNTP) to distribute network news messages to NNTP servers and to NNTP clients (news readers) on the Internet. NNTP provides for the distribution, inquiry, retrieval, and posting of news articles by using a reliable stream-based transmission of news on the Internet. NNTP is designed so that news articles are stored on a server in a central database, thus users can select specific items to read. Indexing, cross-referencing, and expiration of aged messages are also provided.

If you have NNTP installed, you can view Microsoft News (NNTP) Service Help by typing **file:\\%systemroot%\help\news.chm** in your browser address bar and pressing ENTER.

**SMTP Service**

Use Simple Mail Transfer Protocol (SMTP) to set up intranet mail services that work in conjunction with IIS. SMTP is a TCP/IP protocol for sending messages from one computer to another on a network. This protocol is used on the Internet to route e-mail.

If you have SMTP installed, you can view Microsoft Mail (SMTP) Service Help by typing **file:\\%systemroot%\help\mail.chm** in your browser address bar and pressing ENTER.

**World Wide Web Publishing Service**

IIS serves pages to the Internet and the World Wide Web. This component must be installed for IIS to perform its primary service. If you do not select this option, you disable IIS.

The World Wide Web Publishing Service (WWW service) includes the following subcomponents:

- About ASP: Select to enable ASP on your server. If this option is not selected, all .asp requests return a 404 error.
- **Internet Data Connector**: Select to enable Internet Data Connector on your server. If this option is not selected, all .idc requests return a 404 error.
- Administering Servers Remotely in IIS 6.0: Select to enable remote Web administration of your IIS Web server from any Web browser on your intranet. Once you install IIS and view your Web sites through IIS Manager, IIS creates a site called **Administration**.
- **Remote Desktop Web Connection**: Select to enable connectivity to a computer's desktop from a remote location and run applications as if you were sitting at the console.
- Using Server-Side Include Directives: Select to enable server-side include files on your server. If this option is not selected, all .shtm, .shtml, and .stm requests return a 404 error.
- Web Authoring with WebDAV: Select to allow Web Distributed Authoring and Versioning (WebDAV) on your server. WebDAV is similar to File Transfer Protocol, with the exception being that WebDAV allows any WebDAV client to publish and change content in a WebDAV directory using HTTP.
- Web Site Administration: Select to install the World Wide Web Publishing Service. If this option is not selected, IIS does not run on your server.

**Related Information**

- For information about unattended setup, see "Planning for Unattended Setup" in Windows Help.

# Uninstalling IIS

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This topic describes how to uninstall IIS using either of the following 2 methods:

- Using the Configure Your Server Wizard.
- Using Add or Remove a Windows Component in Control Panel.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To uninstall IIS using the Configure Your Server Wizard**

1. From the **Start** menu, click **Manage Your Server**.
2. Under **Managing Your Server Roles**, click **Add or remove a role**.
3. Read the preliminary steps in the **Configure Your Server Wizard** and click **Next**.
4. Under **Server Role**, click **Application server (IIS, ASP.NET)** and then click **Next**.
5. In the **Role Removal Configuration** dialog, check the **Remove the application server role** check box.
6. Complete the wizard, and then click **Finish**.

**To uninstall IIS using Add or Remove a Windows Component in Control Panel**

1. From the **Start** menu, click **Control Panel**.
2. Double-click **Add or Remove Programs**.
3. Click **Add/Remove Windows Components**.
4. In the **Components** list click the **Application Server** check box.
5. Click **Next**.
6. Click **Close** when uninstallation of IIS is complete.

**Related Information**

For more information about the Configure Your Server Wizard, see "Configuring Your Server Wizard" in Windows Help.

# Common Administrative Tasks in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This section provides procedures and conceptual information for completing common administrative tasks. Some of the tasks are new to this version of IIS, others are similar to previous versions, but the procedures have changed. Some tasks remain unchanged, but may be unfamiliar to new administrators.

**In This Section**

This section includes the following information:

- Enabling Web Service Extensions: Describes the state of the default installation and how to enable Web service extensions.
- Creating Web or FTP Sites: Describes how to create Web site configurations and how to install and use FTP services.
- Creating Virtual Directories in IIS 6.0: Describes how to create virtual directories within Web and FTP sites.
- Renaming Virtual Directories: Describes how to rename virtual directories by editing the MetaBase.xml file.
- Configuring Authentication: Describes how to set up and use user authentication methods.
- Creating Application Pools in IIS 6.0: Describes how to group Web applications into application pools.
- Creating and Isolating Applications in IIS 6.0: Describes how to create and manage applications.
- Obtaining and Backing Up SSL Certificates: Describes how to set up and use Secure Sockets Layer (SSL) certification on your sites.
- Backing Up and Restoring the Metabase in IIS 6.0: Describes how to back up your site configurations.
- Redirecting Web Sites in IIS 6.0: Describes how to automatically direct users to the correct page on your site.
- Hosting Multiple Web Sites: Describes how to create and host multiple Web sites.
- Assigning Resources to Applications in IIS 6.0: Describes how to control the amount of resources an application uses.
- Controlling Access to Applications in IIS 6.0: Describes how to secure your applications with permissions and restrictions.
- Enabling ASP.NET: Describes how to take advantage of dynamic content by enabling ASP.NET.
- Enabling ASP Pages in IIS 6.0: Describes how to allow IIS to process requests for Active Server Pages.
- Saving Configurations: Describes how to save metabase and application configurations.
- Starting and Stopping Services: Describes how to start and stop IIS services.
- Configuring Recycling in IIS 6.0: Describes how to periodically restart worker processes assigned to an application pool.
- Administering Servers from the Command Line in IIS 6.0: Describes how to use powerful scripting and programming tools to access and configure settings.
- Administering Servers Remotely in IIS 6.0: Describes the tools to use to administer your sites.
- Enabling Network File System Support: Describes how to allow IIS to access files on a UNIX or Linux-based system.

# Enabling Web Service Extensions

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

To help minimize the attack surface of the server, IIS 6.0 is not installed on Windows Server 2003 by default. When you first install IIS 6.0, it is locked down — which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable these features, IIS returns a 404 error. You can enable these features through the Web Service Extensions node in IIS Manager. For more information about how to troubleshoot 404 errors and other issues, see Troubleshooting in IIS 6.0.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

### To enable Web service extensions

1. In IIS Manager, click the Web Service Extensions folder.
2. In the details pane, select the Web service extension that you want to enable, and then click **Allow**.
3. To see the properties of a Web service extension, select an extension, and then click **Properties**.

| **Important** |
| --- |
| If you choose to allow all unknown ISAPI extensions or CGI extensions to run on your Web server, your Web server could be susceptible to computer viruses or worms that exploit these technologies. Instead, select only those specific ISAPI extensions or CGI extensions that you want to run on your Web server. |

#### Related Information

- For more information about Web service extensions, see Configuring IIS For Dynamic Content.

# Creating Web or FTP Sites

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS creates a default Web site configuration on your hard disk at the time of installation. You can use the \Inetpub\Wwwroot directory to publish your Web content, or create any directory or virtual directory you choose. The File Transfer Protocol (FTP) service must be installed and started in order to create an FTP site. It is not installed by default.

Creating a Web or FTP site using IIS Manager does not create content, but merely creates a directory structure and configuration files from which to publish the content.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To use the default Web site**

1. In IIS Manager, expand the local computer, expand the **Web Sites** folder, right-click **Default Web Site**, and then click **Properties**.
2. On the **Web Site** tab, under **Web site description**, type the name of your Web site in the **Description** box.
3. Click **OK**. The name of the new site appears in IIS Manager.

**To create a new Web site**

1. In IIS Manager, expand the local computer, right-click the **Web Sites** folder, point to **New**, and then click **Web Site**. The **Web Site Creation Wizard** appears.
2. Click **Next**.
3. In the **Description** box, type the name of your site, and then click **Next**.
4. Type or click the IP address (the default is **All Unassigned**), TCP port, and host header (for example, *www.mysite.com*) for your site, and then click **Next**.

   | **Important** |
   | --- |
   | To help ensure that user requests reach the correct Web site, configure a unique identity for each site on the server by distinguishing each Web site with at least one of three unique identifiers: a host header name, an IP address, or a TCP port number. |

   | **Note** |
   | --- |
   | Using unique host header names is the preferred way to identify multiple Web sites on a single server. For more information about choosing unique identifiers, see Hosting Multiple Web Sites on a Single Server and Adding Web Sites to Your Server in the IIS 6.0 Operations Guide, which is accessible from IIS Manager. |

5. In the **Path** box, type or browse to the directory that contains, or will contain, the site content, and then click **Next**.
6. Select the check boxes for the Web site access permissions you want to assign to your users, and then click **Next**.
7. Click **Finish**.

To change these and other settings later, right-click the Web site, and click **Properties**.

**To install FTP services**

1. From the **Start** menu, click **Control Panel**.
2. Double-click **Add or Remove Programs**.
3. Click **Add/Remove Windows Components**.
4. From the **Components** list box, click **Application Server**, and then click **Details**.
5. From the **Subcomponents of Application Server** list box, click **Internet Information Services (IIS)**, and then click **Details**.
6. From the **Subcomponents of Internet Information Services** list box, select the **File Transfer Protocol (FTP) Service** check box.
7. Click **OK** twice.
8. Click **Next**. You might be prompted for the Windows Server 2003 family CD or the network install path.
9. Click **Finish**, and then click **Close**.

| **Note** |
| --- |
| IIS Manager creates a default FTP site during the FTP services installation. You can use the \Inetpub\Ftproot directory to publish your content, or you can create another directory. |

**To create a new FTP site**

1. In IIS Manager, double-click the local computer, right-click the **FTP Sites** folder, point to **New**, and then click **FTP Site**.
2. Click **Next**.
3. In the **Description** box, type the name of your site, and then click **Next**.
4. Type or click the IP address (the default is **All Unassigned**) and TCP port for your site, and then click **Next**.
5. Click the user isolation option you want, and then click **Next**.
6. In the **Path** box, type or browse to the directory that contains or will contain shared content, and click **Next**.
7. Select the check boxes for the FTP site access permissions you want to assign to your users, and then click **Next**.
8. Click **Finish**.

To change these and other settings later, right-click the FTP site, and then click **Properties**.

**Related Information**

- For more information about configuring Web sites, see Web Site Setup.
- For more information about configuring FTP sites, see FTP Site Setup.

# Creating Virtual Directories in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In most cases, the content you publish to your Web or FTP site is located in a root or home directory on your computer, such as C:\Inetpub\Wwwroot\. However, there might be instances when the content is located somewhere else, or even on a remote computer.

To publish from any directory not contained within your home or root directory, you can create a virtual directory. A virtual directory is a directory that is not contained in the home directory but appears to client browsers as though it were.

You can create a virtual directory through IIS Manager or by using Windows Explorer. Additionally, you can create a Web virtual directory by using the Iisvdir.vbs script, and a FTP virtual directory by using the Iisftpdr.vbs script.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To create a virtual directory by using IIS Manager**

1. In IIS Manager, expand the local computer, expand the **Web Sites** or **FTP Sites** folder, right-click the site or folder within which you want to create the virtual directory, point to **New**, and then click **Virtual Directory**. The **Virtual Directory Creation Wizard** appears.
2. Click **Next**.
3. In the **Alias** box, type a name for the virtual directory. (Choose a short name that is easy to type because the user types this name.)
4. Click **Next**.
5. In the **Path** box, type or browse to the physical directory in which the virtual directory resides, and then click **Next**.
6. Under **Allow the following permissions**, select the check boxes for the access permissions you want to assign to your users, and then click **Next.**

   | **Important** |
   | --- |
   | For security reasons, when selecting access permissions, consider allowing only the default Read permission. By restricting permissions in this way, you can help avoid attacks against your Web site by malicious users. For more information about setting access permissions, see Securing Virtual Directories and Access Control in Help and Support Center for Windows Server 2003. |

7. Click **Finish**. The virtual directory is created below the currently selected folder level.

**To create a virtual directory by using Windows Explorer**

1. Open Windows Explorer.
2. Right-click the folder you want to be a virtual directory, and click **Sharing and Security**.
3. Click the **Web Sharing** tab.
4. Click **Share this folder**.
5. In the **Alias** box, type the name for the virtual directory.
6. Click **OK** twice.

**To create a Web virtual directory by using the Iisvdir.vbs script**

1. From the **Start** menu, click **Run.**
2. In the **Open** box, type **cmd**, and then click **OK**.
3. At the command prompt, type the following:

   **cscript %SystemRoot%\system32\iisvdir.vbs /create** *SampleWebSite*[**/***Path*] *VirtualDirectorydrive***:***path*

   where *SampleWebSite*, *VirtualDirectory*, and *path* is the physical directory, as appropriate.

For more information about creating Web virtual directories by using the Iisvdir.vbs command and its parameters, type the following at the command prompt: **iisvdir /create /?**.

**To create an FTP virtual directory by using the Iisftpdr.vbs script**

1. From the **Start** menu, click **Run.**
2. In the **Open** box, type **cmd**, and then click **OK**.
3. At the command prompt, type the following:

   **cscript %SystemRoot%\system32\iisftpdr.vbs /create** *FTPSite*[**/***Path*] *VirtualDirectory drive***:***path*

   where *FTPSite*, *VirtualDirectory*, and *path* is the physical directory, as appropriate.

For more information about creating FTP virtual directories by using the Iisftpdr.vbs command and its parameters, type the following at the command prompt: **iisftpdr /create /?**.

**Related Information**

- For more information about Iisvdir.vbs, see Creating Web Virtual Directories Using Iisvdir.vbs.
- For more information about Iisftpdr.vbs, see Creating FTP Virtual Directories Using Iisftpdr.vbs.

# Renaming Virtual Directories

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In IIS 6.0, you cannot use IIS Manager to rename a virtual directory. Instead, you can rename a virtual directory by editing the MetaBase.xml file using a text editor, such as Microsoft Notepad.

**Note**

Always back up the metabase before editing MetaBase.xml. For information about backing up the metabase, see Backing Up and Restoring the Metabase in IIS 6.0.

**Important**

You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:***MyComputer***\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters).

**Procedures**

### To rename a virtual directory by using Notepad

1. Open MetaBase.xml in Notepad. The default location for MetaBase.xml is C:\Windows\System32\Inetsrv.
2. On the **Edit** menu, click **Find**, and then locate the virtual directory name that you want to change.
3. Replace the current virtual directory name with a new name.
4. Close the MetaBase.xml file and when prompted, save the changes.
5. In IIS Manager, right-click the local computer, and then select **All Tasks**.
6. On the **All Tasks** menu, click **Save Configuration to Disk**

**Note**

When you rename a newly created virtual directory, it takes at least two minutes for the change to appear in IIS Manager if no other changes are pending. To see the change immediately in IIS Manager, close and then reopen IIS Manager.

# Configuring Authentication

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can require users to provide a valid Microsoft® Windows® user account name and password before they access any information on your server. This identification process is called *authentication*. Authentication, like many of the features in IIS, can be set at the Web site, directory, or file level. IIS provides the following authentication methods to control access to the content on your server.

**Web Methods**

- Anonymous Authentication in IIS 6.0: Gives users access to the public areas of your Web site without prompting them for a user name or password.
- Basic Authentication in IIS 6.0: Requires a previously assigned Windows account user name and password, also known as credentials.
- Digest Authentication in IIS 6.0: Offers the same functionality as Basic authentication, while providing enhanced security in the way that a user's credentials are sent across the network.
- Advanced Digest Authentication in IIS 6.0: Collects user credentials and stores them on the domain controller as an MD5 hash, or message digest.
- Integrated Windows Authentication in IIS 6.0: Collects information through a secure form of authentication where the user name and password are hashed before being sent across the network.
- .NET Passport Authentication in IIS 6.0: Provides a single sign-in service through SSL, HTTP redirects, cookies, JavaScript, and strong symmetric key encryption.

**FTP Methods**

- Configuring Anonymous FTP Authentication: Gives users access to the public areas of your FTP site without prompting them for a user name or password.
- Configuring Basic FTP Authentication: Requires users to log on with a user name and password corresponding to a valid Windows user account.

# Creating Application Pools in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| This feature of IIS 6.0 is available only when running in worker process isolation mode. |

With IIS 6.0 running in worker process isolation mode, you can group Web applications into application pools. Application pools allow specific configuration settings to be applied to groups of applications, and the worker processes servicing those applications. Any Web directory or virtual directory can be assigned to an application pool.

By creating new application pools and assigning Web sites and applications to them, you can make your server more efficient and reliable, and your other applications always available, even when the applications in the new application pool terminate.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To create a new application pool**

1. In IIS Manager, double-click the local computer, right-click **Application Pools**, point to **New**, and then click **Application Pool**.
2. In the **Application pool ID** box, type the name of the new application pool.
3. Under **Application pool settings**, click either **Use default settings for new application pool** or **Use existing application pool as template**.
4. If you selected **Use existing application pool as template**, from the **Application pool name** list box, click the application pool to be used as a template.
5. Click **OK**.

**Related Information**

- For more information about creating application pools, see Configuring Application Pools in IIS 6.0.
- For information about configuring worker processes, see Configuring Application Pool Identity with IIS 6.0.

# Creating and Isolating Applications in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

To create an application, you designate a directory as the starting point (application root) for the application. You can then set properties for the application. Each application can have a friendly name; this name appears in IIS Manager and gives you a way to distinguish between applications. The application name is not used anywhere else.

Web sites are root-level applications by default. When you create a Web site, a default application is created at the same time. You can use this root-level application, remove it, or replace it with a new application by removing it and creating a new application.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To create an application**

1. In IIS Manager, expand the local computer, right-click the directory that is the application starting point, and then click **Properties**.
2. Click the **Home Directory**, **Virtual Directory**, or **Directory** tab.
3. In the **Application settings** section, click **Create**. If you see the **Remove** button instead of the **Create** button, an application has already been created.
4. In the **Application name** box, type a name for your application.
5. Click **OK**.

Isolating applications means configuring them to run in a process (memory space) separate from the Web server and other applications. You can run IIS 6.0 in one of two isolation modes: worker process isolation mode or IIS 5.0 isolation mode. IIS cannot run in both modes simultaneously.

Worker process isolation mode is the default mode that the server runs in on a clean installation. In this mode, you can isolate an application by adding it to an application pool that includes isolation settings. For more information about creating and configuring application pools, see Configuring Application Pools in IIS 6.0.

| **Note** |
| --- |
| Before you isolate an application, verify in which application isolation mode the computer is running. You can determine the application isolation mode in which IIS is running by the presence (worker process isolation mode) or absence (IIS 5.0 isolation mode) of the Application Pools folder. |

**To isolate an application in worker process isolation mode**

1. In IIS Manager, expand the local computer, expand the **Web Sites** folder, right-click the application you want to isolate, and click **Properties**.
2. Click the **Home Directory**, **Virtual Directory**, or **Directory** tab (depending on the application).
3. In the **Application settings** section, in the **Application pool** list box, click an application pool.
4. Click **Apply**, and then click **OK**.

IIS 5.0 isolation mode allows you to run applications in IIS 6.0 that were developed for earlier versions of IIS. Use this mode only if an application has a compatibility issue when it runs in worker process isolation mode and you cannot resolve the problem.

**To isolate an application in IIS 5.0 isolation mode**

1. In IIS Manager, expand the local computer, expand the **Web Sites** folder, right-click the application you want to isolate, and click **Properties**.
2. Click the **Home Directory**, **Virtual Directory**, or **Directory** tab (depending on the application). If you are in the directory listed as the **Starting Point** directory, the **Application name** box is already filled in.
3. From the **Execute permissions** list box, click the appropriate process option.
4. Click **OK**. The Web server finishes processing any current requests for the application before creating a separate process. At the next request for the application, the application will run in the appropriate memory space.

| **Note** |
| --- |
| Server-side include (SSI) and Internet Database Connector (IDC) applications cannot be run in a memory space separate from the Web server. |

**Related Information**

- For more information about creating applications, see Creating Applications in IIS 6.0.

# Obtaining and Backing Up SSL Certificates

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Secure Sockets Layer (SSL) certificates contain information used in establishing identities over a network, a process called authentication. Similar to conventional forms of identification, certificates enable Web servers and users to authenticate each other before establishing a connection.

*Server certificates* contain information about the server that allows the client to positively identify the server before sharing sensitive information. *Client certificates* contain personal information about the clients requesting access to your site that allow you to positively identify them before allowing them access to the site.

This topic is limited to obtaining, installing and backing up server certificates. For information about obtaining client certificates, see Obtaining Client Certificates in IIS 6.0.

There are two ways to obtain a server certificate. You can issue your own certificate, or you can obtain a certificate from a certification authority.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the runas command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To issue your own server certificate**

1. Use Microsoft Certificate Services 2.0 to create a customizable service for issuing and managing certificates. You can create server certificates for the Internet or for corporate intranets, giving your organization complete control over certificate management policies. For more information, see Microsoft Certificate Services Help.

   -or-

   Use the Web Server Certificate Wizard to request and install your server certificate.

**To obtain a server certificate from a certification authority**

1. Find a certification authority that provides services that meet your business needs and then request a server certificate.

   -or-

   Use the Web Server Certificate Wizard to create a certificate request, which you can send to the certification authority.

2. After the certificate has been processed and returned to you, use the Web Server Certificate Wizard to install the certificate.

It is important to safeguard the certificate and key pair; always back them up to a disk and keep the disk in a secure place.

**To create a backup copy of your server certificate and private key**

1. Locate the correct certificate store. This is typically the Local Computer store in Certificate Manager.
2. If you do not have Certificate Manager installed in Microsoft Management Console (MMC), you need to install it.
3. Right-click the certificate in the Personal store, point to **All Tasks**, and click **Export**.
4. Select **Yes, export the private key**.
5. Follow the wizard default settings, and enter a password for the certificate backup file when prompted.
6. Do not select **Delete the private key if export is successful**, because this will disable your current server certificate.
7. Complete the wizard to export a backup copy of your server certificate.

If you already have Certificate Manager installed in MMC, it points to the correct Local Computer certificate store.

**To add Certificate Manager to MMC**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **mmc**, and then click **OK**. The **Microsoft Management Console** appears.
3. In the **File** menu, click **Add/Remove Snap-in**.
4. On the **Standalone** tab, click **Add**.
5. From the **Available Standalone Snap-ins** list box, click **Certificates**, and click **Add**.
6. Click the **Computer account** option, and click **Next**.
7. Click the **Local computer (the computer this console is running on)** option, and click **Finish**.
8. Click **Close**, and then click **OK**.

**Related Information**

- For more information about obtaining a certificate, see Obtaining and Installing Server Certificates.

# Backing Up and Restoring the Metabase in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS administrators can create backup files using IIS Manager or a programmatic administration script. The backup files are copies of the metabase configuration file (MetaBase.xml) and the matching metabase schema file (MBSchema.xml). Using the metabase configuration backup and restore feature, the metabase can be restored from the backup files.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To create a portable backup (password required)**

1. In IIS Manager, right-click the local computer, point to **All Tasks**, and click **Backup/Restore Configuration**.
2. Click **Create Backup**.
3. In the **Configuration backup name** box, type a name for the backup file.
4. Select the **Encrypt backup using password** check box, type a password into the **Password** box, and then type the same password in the **Confirm password** box.
5. Click **OK**, and then click **Close**.

**To create a non-portable backup (password not required)**

1. In IIS Manager, right-click the local computer, point to **All Tasks**, and click **Backup/Restore Configuration**.
2. Click **Create Backup**.
3. In the **Configuration backup name** box, type a name for the backup file.
4. Click **OK**, and click **Close**.

**To restore the metabase backup**

1. In IIS Manager, right-click the local computer, point to **All Tasks**, and click **Backup/Restore Configuration**.
2. In the **Backups** list box, click the version of the **Automatic Backup** file that you want to restore, and click **Restore**. If prompted for a password, type the password you chose to secure the backup.
3. When a confirmation message appears, click **Yes**.
4. Click **OK**, and then click **Close**.

For more information about backing up and restoring the metabase, see Working with the Metabase in this reference, and Backing Up and Restoring the Metabase in the IIS 6.0 Operations Guide, which is accessible from IIS Manager.

**Related Information**

- Fore information about metabase reliability, see Backing Up and Restoring the Metabase.
- For more information about command-line administration scripts, see Using Command-Line Administration Scripts.

# Redirecting Web Sites in IIS 6.0

Updated: June 29, 2009

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When a browser requests a page or program on your Web site, the Web server locates the page identified by the URL and returns it to the browser. When you move a page on your Web site, you can't always correct all of the links that refer to the old URL of the page. To make sure that browsers can find the page at the new URL, you can instruct the Web server to *redirect* the browser to the new URL.

You can redirect requests for files in one directory to a different directory, to a different Web site, or to another file in a different directory. When the browser requests the file at the original URL, the Web server instructs the browser to request the page by using the new URL.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To redirect requests to another Web site or directory**

1. In IIS Manager, expand the local computer, right-click the Web site or directory you want to redirect, and click **Properties**.
2. Click the **Home Directory**, **Virtual Directory**, or **Directory** tab.
3. Under **The content for this source should come from**, click **A redirection to a URL**.
4. In the **Redirect to** box, type the URL of the destination directory or Web site. For example, to redirect all requests for files in the Catalog directory to the NewCatalog directory, type **/NewCatalog**.

**To redirect all requests to a single file**

1. In IIS Manager, expand the local computer, right-click the Web site or directory you want to redirect, and click **Properties**.
2. Click the **Home Directory**, **Virtual Directory**, or **Directory** tab.
3. Under **The content for this source should come from**, click **A redirection to a URL**.
4. In the **Redirect to** box, type the URL of the destination file.
5. Select the **The exact URL entered above** check box to prevent the Web server from appending the original file name to the destination URL.

You can use wildcards and redirect variables in the destination URL to precisely control how the original URL is translated into the destination URL.

You can also use the redirect method to redirect all requests for files in a particular directory to a program. Generally, you should pass any parameters from the original URL to the program, which you can do by using redirect variables.

**To redirect requests to a program**

1. In IIS Manager, expand the local computer, right-click the Web site or directory you want to redirect, and click **Properties**.
2. Click the **Home Directory**, **Virtual Directory**, or **Directory** tab.
3. Under **The content for this source should come from**, click **A redirection to a URL**.

   In the Redirect to box, type the URL of the program, including any redirect variables needed to pass parameters to the program. For example, to redirect all requests for scripts in a Scripts directory to a logging program that records the requested URL and any parameters passed with the URL, type **/Scripts/Logger.exe?URL=***$V***+PARAMS=***$P*. *$V* and *$P* are redirect variables.

4. Select the **The exact URL entered above** check box to prevent the Web server from appending the original file name to the destination URL.

**Related Information**

- For more information about redirect variables, see Redirect Reference.

- For information about how to use the URL Rewrite module to configure URL redirection in IIS 7, see Using the URL Rewrite Module.

# Hosting Multiple Web Sites

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

To create and host multiple Web sites, you must first ensure that each site has a unique identification. To accomplish this, you will need to either obtain multiple IP addresses or assign multiple host header names to a single IP address. Host header names are the friendly names for Web sites, such as www.microsoft.com.

Obtaining and maintaining multiple IP addresses is usually a task reserved for large corporations and Internet service providers (ISPs), while assigning multiple host header names is a fairly simple procedure accomplished through IIS Manager. Your computer or network must be using a name resolution system (typically DNS) in order to use multiple host header names.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To assign a host header name**

1. In IIS Manager, double-click the local computer, right-click the **Web Sites** folder, right-click the Web site, and click **Properties**.
2. On the **Web Site** tab, click **Advanced**.
3. Click **Add**.
4. In the appropriate boxes, type an IP address, TCP port, and host header value for your Web site.

   You can have multiple server certificates, multiple IP addresses, and multiple SSL ports per server.

**Note**

Although Windows Server 2003 added DNS support for UTF-8 characters, IIS 6.0 does not support Unicode characters in host headers. If you use the Web Site Creation Wizard to create a Web site and try to give the site a host header that contains Unicode characters, you will receive an error indicating that you must use only standard characters. If you use **adsutil.vbs** to configure the ServerBindings Metabase Property to use a host header containing Unicode characters, the change will be made in the metabase, but you will not be able to access the Web site.

**Related Information**

- For information about hosting multiple Web sites with multiple IP addresses, see Creating Multiple Sites Using Multiple IP Addresses.
- For more information about using host header names, see Hosting Multiple Web Sites on a Single Server.
- For more information about name resolution, see Domain Name Resolution.

# Assigning Resources to Applications in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

There are several ways to assign, or limit, the amount of resources an application can use. You can use application property sheets to control performance, cache, and process options of individual applications, or you can use *bandwidth throttling* to limit resources for an entire site or application pool. A third alternative is to control access to your application through the NTFS file system and Web server security features.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To assign resources using property sheets**

1. In IIS Manager, expand the local computer, right-click the Web site or root directory of an application, and click **Properties**.
2. Click the **Home Directory**, **Virtual Directory**, or **Directory** tab.
3. In the **Application settings** section, click **Configuration**.
4. On the **Mappings** and **Options** tabs, select the appropriate check boxes to enable or disable caching, buffering, and session states.

**To globally assign resources using bandwidth throttling**

1. In IIS Manager, expand the local computer, right-click the **Web Sites** folder, and then click **Properties**.
2. Click the **Performance** tab.
3. Under **Bandwidth** throttling, select **Limit the total network bandwidth available for all Web sites on this server** check box.
4. In the **Maximum bandwidth** box, click the up and down arrows or type the maximum number of kilobytes per second you want each site contained in the directory to use.
5. Under **Web site connections**, select either **Unlimited** or **Connections limited to**:. If you select **Connections limited to**:, click the up and down arrows in the box or type the maximum number of kilobytes per second you want each site contained in the directory to use.

**To assign resources using bandwidth throttling to an individual Web site**

1. In IIS Manager, expand the local computer, expand the **Web Sites** folder, right-click the Web site to which you want to assign resources, and click **Properties**.
2. Click the **Performance** tab.
3. Under **Bandwidth throttling**, select **Limit the network bandwidth available to this Web site** check box.
4. In the **Maximum bandwidth** box click the up and down arrows or type the maximum number of kilobytes per second you want each site contained in the directory to use.
5. Under **Web site connections**, select either **Unlimited** or **Connections limited to:**. If you select Connections limited to:, click the up and down arrows in the box or type the maximum number of Web site connections.

**Related Information**

- For more information about configuring servers for applications, see About Configuring Servers for Applications.
- For more information about bandwidth throttling, see Throttling Bandwidth.
- For more information about application configurations, see Configuring Applications in IIS 6.0.
- For information about using the NTFS file system and Web server security features, see Controlling Access to Applications in IIS 6.0.

# Controlling Access to Applications in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can control which users and computers are allowed access to your Web server and its resources. You can use both the NTFS file system and Web server security features to assign users specific access rights to directories and files. You can also use IP address restrictions to limit access by specific computers.

- Best Practices for Securing Files with NTFS Permissions: With the NTFS file system, you can limit access to your Web server's files and directories. You can configure the file and directory permissions that set the access level assigned to a particular user account or user group. For example, you can configure your Web server to enable a specific user to view and execute a file, while excluding all other users from accessing that file.

- Securing Sites with Web Site Permissions: Web permissions, unlike NTFS permissions, apply to all users accessing your Web sites. NTFS permissions apply only to a specific user or group of users with a valid Windows account. NTFS controls access to physical directories on your server, whereas Web permissions control access to virtual directories on your Web site.

- Securing Sites with IP Address Restrictions: With IP address restrictions, you can configure your Web server to assign or deny specific computers, groups of computers, or domains access to Web sites, directories, or files. For example, if your intranet server is connected to the Internet, you can prevent Internet users from accessing your Web server by assigning access only to members of your intranet, and explicitly denying access to outside users.

# Enabling ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

**Important**

To help minimize the attack surface of the server, IIS 6.0 is not installed on Windows Server 2003 by default. When you first install IIS 6.0, it is locked down -- which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable these features, IIS returns a 404 error. You can enable these features through the Web Service Extensions node in IIS Manager. For more information, see Enabling Web Service Extensions. For more information about how to troubleshoot 404 errors and other issues, see Troubleshooting in IIS 6.0.

Microsoft® ASP.NET is a unified Web development platform that provides the services necessary for developers to build enterprise-class Web applications. While ASP.NET is largely syntax compatible with ASP, it also provides a new programming model and infrastructure for more secure, scalable, and stable applications. You can feel free to augment your existing ASP applications by incrementally adding ASP.NET functionality to them.

ASP.NET is a compiled, .NET Framework-based environment. You can write applications in any language that is compatible with the .NET Framework, including Microsoft Visual Basic® .NET, Microsoft Visual C#®, and Microsoft JScript® .NET. In addition, the entire Microsoft .NET Framework is available to any ASP.NET application. Developers can easily access the benefits of these technologies, such as the managed common language runtime (CLR) environment, type safety, and inheritance.

**Note**

If you use the Configure Your Server wizard to install IIS 6.0, ASP.NET is enabled when the wizard runs. If you use **Add or Remove Programs** in Control Panel to install IIS 6.0, you must ensure that you check **ASP.NET** in the **Subcomponents of Application Server** list to install ASP.NET with IIS 6.0. Then, you must enable ASP.NET Web service extensions so your ASP.NET applications will run correctly.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To enable ASP.NET by using IIS Manager**

1. In IIS Manager, expand the local computer, and then click **Web Service Extensions**.
2. In the details pane, click **ASP.NET**, and then click **Allow**.

**Note**

If your applications require ISAPI, CGI, ASP, WebDAV, or other extensions to operate, you will need to enable those extensions as well.

**Related Information**

- For information about enabling Web service extensions, see Enabling Web Service Extensions.
- For an introduction to ASP concepts, see About ASP.
- For information about developing ASP.NET applications, see the Web Application Guide.

# Enabling ASP Pages in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Microsoft Active Server Pages (ASP) is a server-side scripting environment that you can use to create dynamic and interactive Web pages, and build powerful Web applications. When the server receives a request for an ASP file, it processes server-side script code contained in the file to build the HTML Web page that is sent to the browser. In addition to server-side script code, ASP files can contain HTML (including related client-side scripts), as well as calls to Component Object Model (COM) components that perform a variety of tasks, such as connecting to a database or processing business logic.

**Important**

To help minimize the attack surface of the server, IIS 6.0 is not installed on Windows Server 2003 by default. When you first install IIS 6.0, it is locked down -- which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable these features, IIS returns a 404 error. You can enable these features through the Web Service Extensions node in IIS Manager. For more information, see Enabling Web Service Extensions. For more information about how to troubleshoot 404 errors and other issues, see Troubleshooting in IIS 6.0.

**Procedures**

**To enable ASP pages**

1. In IIS Manager, expand the local computer, and then click **Web Service Extensions**.
2. In the details pane, click **Active Server Pages**, and then click **Allow**.

**Note**

If your ASP pages require ISAPI, CGI, Microsoft ASP.NET, WebDAV, or other extensions to operate, you will need to enable those extensions as well.

**Related Information**

- For more information about ASP pages, see Enabling ASP Pages.
- For an introduction to ASP concepts, see About ASP.
- For information about creating ASP pages and developing Web applications, see the Web Application Guide.

# Saving Configurations

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

After you have your site and application up and running the way you want, you can save all or part of the configurations for a backup copy, or for import and export to other sites or computers.

IIS automatically makes a backup copy of the metabase configuration and schema files each time the metabase changes. Administrators can also create backup files on demand, or create backup copies of individual site or application configurations and then export and import them to and from other sites or computers.

Backup files contain only configuration data; they do not include your content (.asp files, .htm files, .dll files, etc.).

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To save a metabase configuration**

1. In IIS Manager, right-click the **local computer**, point to **All Tasks**, and then click **Backup/Restore Configuration**.
2. Click **Create Backup**.
3. In the **Configuration backup name** box, type a name for the backup file.
4. To restore your backup files to a different computer, provide a password that will be used as the encryption key by doing the following:
   - Select the **Encrypt backup using password** check box, type a "strong password" in the **Password** box, and then type the same password in the **Confirm password** box.
5. Click **OK**, and then click **Close**.

**To restore a metabase configuration**

1. In IIS Manager, right-click the **local computer**, point to **All Tasks**, and then click **Backup/Restore Configuration**.
2. From the **Backups** list box, click a previous backup version, and click **Restore**.
3. When a confirmation message appears, click **Yes**.
4. Click **OK**, and then click **Close**.

**To save a site or application configuration**

1. In IIS Manager, right-click the site or application you want to back up, point to **All Tasks**, and click **Save Configuration to a File**.
2. In the **File name** box, type a file name.
3. In the **Path** box, type or browse to the location where you want to save the file.
4. Click **OK**.

**Related Information**

- For information about saving configurations using command-line tools, see Using Command-Line Administration Scripts.

- For information about importing and exporting site and application configurations, see Metabase Import and Export in IIS 6.0.

- For information about strong passwords, see "Strong passwords" in Help and Support Center for Windows Server 2003.

# Starting and Stopping Services

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You might need to restart IIS before certain configuration changes take effect or when applications become unavailable. You can restart IIS using the **Restart IIS** command in IIS Manager or by using the IISReset command-line utility. Both methods allow you to stop, start, and restart IIS Internet services, as well as reboot your computer.

Restarting or stopping IIS, or rebooting your Web server, is a severe action. When you restart the Internet service, all sessions connected to your Web server (including Internet, FTP, SMTP, and NNTP) are dropped. Any data held in Web applications is lost. All Internet sites are unavailable until Internet services are restarted. For this reason, you should avoid restarting, stopping, or rebooting your server if at all possible. For a list of features designed to improve IIS reliability and remedy the need to restart IIS, see Restarting IIS.

If the **IISReset** command-line utility is disabled, then the command-line or IIS Manager calls that require IISReset.exe will fail and return an error stating that **IISReset** is disabled. Actions that fail include the **Restart IIS** command in IIS Manager and Service Control Manager (SCM) recovery configuration actions that use the **IISReset** command-line utility (for example, the default IIS Admin SCM recovery path). However, SCM recovery actions that do not use the **IISReset** command-line utility continue to function (for example, the default World Wide Web Publishing Service SCM recovery path that restarts the WWW service).

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To restart IIS services**

1. In IIS Manager, right-click the local computer, point to **All Tasks**, then click **Restart IIS**.
2. In the **What do you want IIS to do** drop-down list, click **Restart Internet Services on** *computer name*. You can also choose to reboot the computer, stop the Internet service, or start the Internet service.
3. IIS attempts to stop all services before restarting.

**To start, stop, or pause individual sites**

- In IIS Manager, right-click the site you want to start, stop, or pause; and click **Start**, **Stop**, or **Pause**.

**To restart IIS by using the IISReset command-line utility**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd**, and then click **OK**.
3. At the command prompt, type the following:

   **Iisreset /noforce** *ComputerName*

   If you are logged on locally, the *ComputerName* parameter is not required. If you are remotely administering a server running IIS, the *ComputerName* parameter is the NetBIOS name of the computer on which you want to restart IIS.

   | **Important** |
   | --- |
   | Use the */noforce* parameter to help prevent data loss in case the IIS services cannot be stopped within the one minute time-out period. If you are certain that it is safe to force IIS to restart, you can omit the */noforce* parameter. However, be aware that you could lose data if you do not include this parameter. |

4. IIS attempts to stop all services before restarting. The **IISReset** command-line utility waits up to one minute for all

services to stop if you do not include the */noforce* parameter. If the services cannot be stopped within one minute, all IIS services are terminated, and IIS restarts.

The **iisreset** command provides several additional parameters. For example, you can adjust the time-out value by using the **iisreset/timeout** command. For more information about the parameters that are available with the **IISReset** command-line utility, open a command-prompt window, and type **iisreset /?** at the command prompt.

For more information about starting and stopping services or using the **IISReset** command-line utility to restart IIS, see Restarting IIS in the IIS 6.0 Operations Guide, which is accessible from IIS Manager, and also see IIS 6.0 Administration Scripts, Tips, and Tricks in this reference.

**Related Information**

- For more information about starting and stopping services, see Restarting IIS.
- For information about using command-line administration, see Using Command-Line Administration Scripts.

# Configuring Recycling in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| This feature of IIS 6.0 is available only when running in worker process isolation mode. |

In worker process isolation mode, IIS can be configured to periodically restart worker processes assigned to an application pool, allowing you to recycle faulty Web applications. Recycling keeps problematic applications running smoothly, especially when it is not feasible to modify the application code. This ensures that those application pools remain healthy, and that system resources can be recovered.

You can configure worker processes to restart based on elapsed time, number of requests served, scheduled times, or memory usage; or you can configure them to start on demand.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To configure a worker process to be recycled after a set elapsed time**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and click **Properties**.
2. On the **Recycling** tab, select the **Recycle worker processes (in minutes)** check box.
3. Click the up or down arrow to set the number of minutes you want to elapse before the worker process is recycled.
4. Click **OK**.

**To configure a worker process to be recycled after a set number of processing requests**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and click **Properties**.
2. On the **Recycling** tab, select the **Recycle worker process (in requests)** check box.
3. Click the up or down arrow to set the number of requests to be processed before the worker process is recycled.
4. Click **OK**.

**To configure a worker process to be recycled at scheduled times**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and click **Properties**.
2. On the **Recycling** tab, select the **Recycle worker processes at the following times** check box.
3. Click **Add** to add a time to the list, **Remove** to delete a time from the list, or **Edit** to change an existing time at which the worker process will be recycled.
4. Click **OK**.

| **Note** |
| --- |
| When recycling is set to occur at scheduled times, it can occur off-schedule if the system time is altered. To avoid unintended changes in scheduled recycling times, recycle the scheduled worker processes right after the system time is changed. |

**To configure a worker process to be recycled after consuming a set amount of memory**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and click **Properties**.
2. On the **Recycling** tab, under **Memory recycling**, select the **Maximum virtual memory (in megabytes)** or **Maximum used memory (in megabytes)** check box.
3. Click the up or down arrow to set memory limits.
4. Click **OK**.

**Related Information**

- For more information about recycling worker processes, see Recycling Worker Processes with IIS 6.0.
- For information about worker process isolation mode, see Worker Process Isolation Mode in IIS 6.0.

# Administering Servers from the Command Line in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Each system on your computer comes with a graphical user interface (GUI), such as IIS Manager, to configure and manage your settings. However, if administrators manage systems frequently, or access large amounts of data on multiple servers, then using each GUI is time consuming. It may be faster to use command-line scripts that can manage single or multiple systems programmatically.

IIS provides powerful scripting and programming tools that you can use to access and configure settings from within a command-line script or compiled application. You can use these tools to create, delete, start, stop, pause, and list various sites and applications, and to copy, import, and export configurations.

You can use command-line scripts for the following:

- Managing Web Sites Using Scripts: Describes how to create, delete, start, stop, pause, and list Web Sites on a local or remote computer.
- Managing FTP Sites Using Scripts: Describes how to create, delete, start, stop, pause, and list FTP Sites on a local or remote computer.
- Managing Web Virtual Directories Using Scripts: Describes how to create, delete, and list Web virtual directories on a local or remote computer.
- Managing FTP Virtual Directories Using Scripts: Describes how to create, delete, and list FTP virtual directories on a local or remote computer.
- Managing IIS Configurations Using Scripts: Describes how to back up, restore, delete, list, copy, import, and export IIS configurations.
- Managing Applications and Web Service Extensions Using Scripts: Describes how to enable and list applications; add and remove application dependencies; enable, disable, and list Web service extensions; and add, remove, enable, disable, and list individual files.

# Administering Servers Remotely in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can administer your server remotely by running IIS on an intranet or the Internet. You can use the following tools for this purpose:

- IIS Manager: You can use IIS Manager on your server to remotely connect to and administer an intranet server running IIS 5.0, IIS 5.1, or IIS 6.0 (IIS 3.0 and IIS 4.0 are not supported).

- Terminal Services: Terminal Services does not require you to install IIS Manager on the remote client computer because, once connected to the server running IIS, you use IIS Manager on the Web server as if you are logged on to the server locally.

- Remote Administration (HTML) Tool: You can use the Remote Administration (HTML) tool to administer your IIS Web server from any Web browser on your intranet. This version of the Remote Administration (HTML) tool is supported only on servers running Windows Server 2003 with IIS 6.0.

**Note**

If you install the Remote Administration (HTML) Tool for IIS 6.0 on a server that has been upgraded to Windows Server 2003 from Microsoft Windows NT 4.0, you may receive an error when you try to view the administrative Web site. This error occurs because, by default, buffering is set to **False** in IIS 4.0. However, in IIS 6.0, buffering is set to **True** by default, and this setting is not changed during upgrade. To view the administrative Web site in IIS 6.0, you must enable buffering.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To administer your intranet server remotely by using IIS Manager**

1. Start IIS Manager on any computer on your network that is running a member of the Windows Server 2003 family.

2. To connect to a remote computer running IIS, right-click the local computer, and then click **Connect**.

3. In the **Connect to Computer**dialog box, in the **Computer name** box, type the name of the computer to which you want to connect, or click **Browse** to browse to the computer, and then click **OK**.

**Note**

If you do not have TCP/IP and a name resolution server, such as Windows Internet Name Service (WINS) installed, you might not be able to connect to an IIS computer using the computer name. As an alternative, you can also use the IP address of the IIS computer, or you can add the host name and IP address to the local hosts file on the computer, which is located at %systemdrive%\Windows\system32\drivers\etc\hosts. For more information, see "TCP/IP" in Help and Support Center for Windows Server 2003.

**To administer your server remotely using Terminal Services**

1. Install the Terminal Services client on the computer you are using to connect.

2. While the remote computer is running, start Terminal Services and identify the name of the remote computer.

3. From the Terminal Services window, administer IIS as you would locally. You can start IIS Manager on any computer on

your network that is running Windows, or you can open a Web-based server-management appliance. You can also run scripts from the Terminal Services window.

**To enable the Remote Administration (HTTP) tool through Control Panel**

1. In **Control Panel**, click **Add or Remove Programs**.
2. In the **Add or Remove Programs** dialog box, click **Add/Remove Windows Components**.
3. In the **Windows Components Wizard** dialog box, in **Components**, click **Application Server**, and then click **Details**.
4. In the **Application Server** dialog box, in **Subcomponents of Application Server**, click **Internet Information Services (IIS)**, and then click **Details**.
5. In the **Internet Information Services (IIS)** dialog box, in**Subcomponents of Internet Information Services (IIS)**, click **World Wide Web Service**, and then click **Details**.
6. In the **World Wide Web Service** dialog box, in **Subcomponents of World Wide Web Service**, select the **Remote Administration (HTML)** check box, and then click **OK**.
7. Click **OK** two more times, and then, in the **Windows Components Wizard** dialog box, click **Next**.
8. After setup is complete, click **Finish** to close the wizard.

**To enable buffering on the administrative Web site (for upgrades from IIS 4.0 to IIS 6.0 only)**

1. In IIS Manager, double-click *servername* (local computer).
2. Double-click **Web Sites**.
3. Right-click the Administration Web site, and then click **Properties**.
4. Click **Home Directory**, click **Configuration**, and then click **Options**.
5. Check the **Enable buffering** check box, and then click **OK** twice.

**To view the Remote Administration (HTML) tool from IIS Manager**

- Expand the local computer, expand the **Web Sites** folder, right-click the **Administration** Web site, and click **Browse**.

**To administer an IIS Web server with the Remote Administration (HTML) tool**

- Open your intranet site from a Web browser and type the following in the address bar: **https://***hostname***:8098**

  Replace *hostname* with the name of the computer that you want to connect to and administer.

For more information about how to manage servers remotely by using the Remote Administration (HTML) tool, see HOW TO: Remotely Administer Internet Information Services in Windows Server 2003.

# Enabling Network File System Support

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If IIS must access files on a UNIX or Linux system, file name case sensitivity can be an issue unless Network File System (NFS) support is enabled in IIS.

Unix and Linux both support mixed-case file names, and IIS fully supports requesting static files in a case-sensitive manner. An issue arises, however, when IIS makes a subsequent request for a file from its static file cache. Because all file names are converted to uppercase letters in the IIS cache, any request after the first request from the IIS static file cache might fail or return the wrong file.

The solution to this issue is to disable the IIS static file cache so that all file requests are issued fresh, thereby retaining correct file name case. The static file cache can be disabled for individual virtual directories on Web sites, or globally for all of IIS.

| **Note** |
| --- |
| Changing this setting has no effect on how ASP files and templates are cached. |

**Procedures**

**To disable the static file cache for a particular Web site virtual directory**

- Edit the metabase and set the **MD_VR_NO_CACHE** property to 1. For example:

  `LM/W3SVC/`*n*`/ROOT/`*vdir*`MD_VR_NO_CACHE=1`

  If you subsequently want to enable the static file cache, set this property to 0.

**To disable the static file cache for all of IIS**

- Edit the registry and add the binary value **DisableStaticFileCache=1** to the HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\InetInfo\Parameters key.

  If you subsequently want to enable the static file cache, set this value to 0.

# Site Setup

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This section describes how to complete a first-time basic setup of a Web server, FTP server, SMTP (e-mail) server, and NNTP (news) server. Additionally, publishing information to your Web and FTP sites is discussed.

Internet Information Services (IIS) makes no distinction whether the site you create is an internal-only site (intranet) or an Internet site. Setup, configuration, and administration procedures are the same for both kinds of sites. Differences exist only in the specific configuration information you supply to IIS.

When you install a member of the Microsoft Windows Server™ 2003 family, IIS creates a minimal configuration consisting of a default Web site in a highly secure mode limited to static content. Other IIS services and options, such as FTP, SMTP, and NNTP are not installed by default. This section also describes how to install these services.

**In This Section**

This section includes the following information:

- Web Site Setup: Describes the basics of managing a Web site's infrastructure, from setting a site home directory and default Web Page, to redirecting requests and dynamically altering Web pages.
- FTP Site Setup: Describes installation of the FTP service, and changing default FTP settings globally and for specific FTP sites.
- SMTP Server Setup: Describes installation of the SMTP service and the service's capabilities.
- NNTP Server Setup: Describes installation of the NNTP service and how hosting a news server can be an effective tool for managing discussions.
- Web Authoring with WebDAV: Describes the features of WebDAV and how to set up a WebDAV publishing directory on an IIS server.

# Web Site Setup

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Whether your site is on an intranet or the Internet, the principles of providing content are the same. You place your Web files in directories on your server so that users can establish an HTTP connection and view your files with a Web browser. But beyond simply storing files on your server, you must manage how your site is deployed and how your site evolves. Today, an engaging Web site is seldom a static collection of pages. Most successful server administrators are kept busy accommodating ever changing Web content.

This section describes the basics of managing a Web site's infrastructure, from redirecting requests to dynamically altering Web pages.

This section includes the following information:

- Creating a Web Site from a Template: Describes how to create a new Web site from a template file.
- Setting Home Directories: Describes how to set or change the home directory of a Web site using IIS Manager or a command-line administration script.
- Setting Up Default Documents: Describes the purpose of a default document and where it should be placed, as well as file naming restrictions.
- Adding Footers to Web Pages: Describes how to automatically include HTML code in the bottom of Web pages.
- Using Virtual Directories: Describes the concept of virtual directories and how to use them to keep published data compartmentalized on the server while remaining transparent to the user.
- Domain Name Resolution: Describes the concept of name resolution, and how to register a domain name for your site.
- Using FrontPage Server Extensions to Extend Web Sites: Describes the benefits of using FrontPage® Server Extensions from Microsoft for Web site management, and explains how to set up the extensions.
- Hosting Multiple Web Sites on a Single Server: Describes how to effectively consolidate Web sites by hosting them on one server.

# Creating a Web Site from a Template

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you have a standard Web site configuration that you use or plan to use frequently, you can use IIS Manager to create a Web site template. To do this, export the configuration of the site to a file, and then use that file to create new sites. The exported configuration is stored as a metabase XML configuration file; it does not contain content. After you export the configuration file, you can import that file into a different directory on the same Web server or to a different Web server.

You can also export and import sites and application pools as configuration files to quickly migrate sites and application pools between servers. This feature allows you to import Web applications if the developer stored the application in a configuration file.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To create a Web site template file**

1. In IIS Manager, double-click the local computer, right-click the site or application that you want to back up, point to **All Tasks**, and then click **Save Configuration to a File**.
2. In the **Save Configuration to a File** dialog box, in the **File name** box, type a file name.
3. In the **Path** box, type the full path to the configuration file, or click **Browse** to browse to the location where you want to save the file, and then click **OK**.

**To create a new site from a template file**

1. In IIS Manager, double-click the local computer, right-click the **Web Sites** folder, point to **New**, and then click **Web Site (from file)**.
2. In the **Import Configuration** dialog box, in the **File** box, type the full path to the configuration file, or click **Browse** to browse for the file.
3. Click **Read File**.

   The **Select a configuration to import box** is populated.
4. In **Select a configuration to import**, click the configuration that you want to import, and then click **OK**.

# Setting Home Directories

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Each Web site must have a home directory. The default Web site home directory is *LocalDrive*:\Inetpub\Wwwroot. You can change a Web site home directory using IIS Manager or by editing the MetaBase.xml file directly. Both methods are described in this topic.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To change the home directory of a Web site using IIS Manager**

1. In IIS Manager, expand the local computer, expand the **Web Sites** directory, right-click the Web site you wish to change, and click **Stop**.
2. Use Windows Explorer, to rename the *LocalDrive*:\Inetpub\Wwwroot directory to the name of your choice. Alternatively, you can copy the entire \Wwwroot directory tree to a new location.
3. In IIS Manager, right-click your Web site, and click **Properties**.
4. Click the **Home Directory** tab, and under **The content for this resource should come from**, click **A directory located on this computer**, **A share located on another computer**, or **A redirection to a URL**, depending on where your home directory is located.
5. In the **Local path** box, type the path name, share name, or URL of your directory.

   **Note**

   If you select a directory on a network share, you might need to enter a user name and password to access the resource. IUSR_*computername* is the default account used if another account is not specified. If you use an account with administration credentials on the server, clients can gain access to server operations. This seriously jeopardizes the security of your network. For more information about security user rights see, "Security Best Practices" in Help and Support Center for Windows Server 2003.

6. In IIS Manager, expand the **Web Sites** folder, right-click the Web site you just changed, and click **Start**.

**To change the home directory of a Web site by editing the MetaBase.xml file**

1. In IIS Manager, expand the **Web Sites** folder, right-click the Web site you wish to change, and click **Stop**.
2. Use Windows Explorer to rename the \Wwwroot directory to the name of your choice. Alternatively, you can copy the entire \Wwwroot directory tree to a new location and then rename the directory.
3. From the *systemroot*\System32\Inetsrv directory, open the MetaBase.xml file in a text editor.
4. To change the Web home directory, search for "/W3svc/*1*/root" and change the Path= value to the new location of the Web home directory. Substitute the value *1* with the value corresponding to the Web site to change.
5. In IIS Manager, expand the **Web Sites** folder, right-click the Web site you've just changed, and click **Start**.

**Related Information**

- For more information about the structure of the IIS metabase, see Metabase Structure in IIS 6.0.

# Setting Up Default Documents

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can establish a default document for client requests to a Web site that does not specify a document name. Default documents can be a directory's home page or an index page. Before enabling the default document in IIS Manager, you must create the default document and place it in either the root directory or a virtual directory on the appropriate Web site.

You cannot use commas in a default document name (for example, my,file.html). Commas are used only to delimit multiple default documents in the metabase. If you include a comma in the name of a default document, IIS uses the comma to notate two default documents.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To set up or change the default document**

1. In IIS Manager, double-click the local computer, right-click the **Web Sites** folder or an individual Web site folder, and then click **Properties**.

   **Note**

   Configuration settings made at the Web Sites level are inherited by all of the Web sites on the server. You can override inheritance by configuring the individual site or site element.

2. Click the **Documents** tab.
3. Select the **Enable default content page** check box.
4. Click **Add** to add a new default document to the list.
5. Click the document you want to remove from the list and click **Remove**.
6. Click a document from the list and click **Move Up** or **Move down** to change the order in which default documents are served to client requests.
7. Click **OK**.

# Adding Footers to Web Pages

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure the Web server to automatically insert an HTML-formatted file to the bottom of every Web page sent out by your Web server (appending footers or scripts to ASP pages is not supported). For example, your file can contain HTML formatting instructions to add a simple text message and logo image to your Web pages. Once enabled, IIS automatically appends the footer file to the designated Web page or file each time the Web page or file is accessed.

| **Note** |
| --- |
| Document footers can reduce Web server performance, especially if a Web page is frequently accessed. |

A footer file should be not be a complete HTML document. It should contain only those HTML tags necessary for formatting the appearance of footer content. For example, a footer file that adds your organization's name to the bottom of every page should consist of text and the HTML tags necessary for formatting the font and color.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

### To add a footer to every Web page

1. Create an HTML footer file and save it on your Web server's hard disk.
2. In IIS Manager, expand the local computer, expand the **Web Sites** folder, right-click a Web site, directory, or file, and click **Properties**.
3. Click the **Documents** tab, and select the **Enable document footer** check box.
4. In the box below **Enable document footer**, type either the full local path to the footer file or click **Browse** to navigate to it.
5. Click **OK**.

# Using Virtual Directories

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

A virtual directory is a friendly name, or *alias*, either for a physical directory on your server hard drive that does not reside in the home directory, or for the home directory on another computer. Because an alias is usually shorter than the path of the physical directory, it is more convenient for users to type. The use of aliases is also secure because users do not know where your files are physically located on the server and therefore cannot use that information to modify your files. Aliases also make it easier for you to move directories in your site. Rather than changing the URL for the directory, you change the mapping between the alias and the physical location of the directory.

If your Web site contains files that are located in a directory other than the home directory, or on other computers, you must create virtual directories to include those files in your Web site. To use a directory on another computer, you must specify the directory's Universal Naming Convention (UNC) name, and provide a user name and password for access rights.

If you want to publish from any directory not contained within your home directory, you must create a virtual directory. For example, suppose you are setting up a Web site for your marketing team on your company's intranet. The following table shows the mapping between the physical location of the files and the URL that accesses the files.

| **Physical Location** | **Alias** | **URL** |
|---|---|---|
| C:\Inetpub\wwwroot | *home directory* (none) | http://SampleWebSite |
| \\Server2\SalesData | Customers | http://SampleWebSite/Customers |
| D:\Inetpub\wwwroot\Quotes | None | http://SampleWebSite/Quotes |
| D:\Inetpub\wwwroot\OrderStatus | None | http://SampleWebSite/OrderStatus |
| D:\Marketing\PublicRel | PR | http://SampleWebSite/PR |

Both virtual directories and physical directories (directories without an alias) appear in IIS Manager. A virtual directory is indicated by a gear icon. The following illustration shows the Web site example described above, where /Customers and /PR are virtual directories.

For a simple Web site, you might not need to add virtual directories. You can simply place all of your files in the site's home directory. If you have a complex site, or want to specify different URLs for different parts of your site, you can add virtual directories as needed. To make a virtual directory accessible from multiple sites, you must add the virtual directory to each site.

There are three ways to create or delete a virtual directory:

- Using IIS Manager; either using the Virtual Directory Creation Wizard or by importing a configuration file.

- Using Windows Explorer (this method requires that your hard drive is formatted with the NTFS file system).
- Using the lisvdir.vbs administration script.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To create a virtual directory using the Virtual Directory Creation Wizard**

1. In IIS Manager, double-click the local computer, double-click the Web site or FTP site to which you want to add a virtual directory, right-click the Web Site or folder within which you want to create the virtual directory, point to **New**, and then click **Virtual Directory**.
2. Click **Next**.
3. In the **Alias** box, type a name for the virtual directory, and then click **Next**. The alias is the name that the user types, and it should be short and easy to type.
4. In the **Directory** box, type or browse to the physical directory in which the virtual directory resides, and then click **Next**.
5. In the **Access Permissions** dialog box, set the access permissions appropriate to your needs.
6. Click **Next**, and then click **Finish**.

**To create a virtual directory by importing a configuration file**

1. In IIS Manager, double-click the Web site or FTP site to which you want to add a virtual directory, right-click the Web Site or folder within which you want to create the virtual directory, point to **New**, then click **Virtual Directory (from file)**.
2. Click **Next**.
3. In the **Import configuration** box, click **Browse** and navigate to the file containing the virtual directory configuration to import.
4. Click **Read File**, click the virtual directory configuration to import, and then click **OK**.

| **Note** |
| --- |
| The following method is available only if your server's hard disk is formatted with the NTFS file system. |

**To create a virtual directory using Windows Explorer**

1. In Windows Explorer, browse to the folder where to want to create a virtual directory for your site, right-click the directory, and click **Sharing and Security**.
2. Click the **Web Sharing** tab, and in the **Share on** list box, click the site for which you are creating a virtual directory, and click **Share this folder**.
3. In the **Alias** box, type an alias name for this virtual directory.
4. Set the **Access permissions** and **Applications permissions** by clicking the appropriate settings.
5. Click **OK**, and then click **OK** again. You can verify that the virtual directory was created by starting IIS Manager and double-clicking the Web site.

| **Important** |
| --- |

| |
|---|
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas/profile /User:***MyComputer\Administrator***cmd** to open a command window with administrator rights and then type **cscript.exe** ScriptName (include the script's full path and any parameters). |

**To create a virtual directory using the Iisvdir.vbs administration script**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cscript iisvdir.vbs /create** "*SampleWebSite*" *VirtualDirectoryName x:\path*. Substitute your Web site name, virtual directory name, and path to the physical directory as appropriate.
3. Click **OK**.

| **Note** |
|---|
| Deleting a virtual directory does not delete the corresponding physical directory or files. |

**To delete a virtual directory using IIS Manager**

1. In IIS Manager, expand the site containing the virtual directory you want to delete, right-click the virtual directory, click **Delete**, and then click **Yes**.

**To delete a virtual directory using Windows Explorer**

1. In Windows Explorer, browse to the folder containing the virtual directory you want to delete, right-click the directory, and click **Sharing and Security**.
2. Click the **Web Sharing** tab, click **Remove**, and then click **Yes**.
3. Click **OK**. You can verify that the virtual directory was deleted by starting IIS Manager and double-clicking the Web site.

| **Note** |
|---|
| The following method does not work for root virtual directories. |

**To delete a virtual directory using the Iisvdir.vbs administration script**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cscript iisvdir.vbs /delete** "*SampleWebSite*" *VirtualDirectoryName*. Substitute your Web site name and virtual directory name as appropriate.

**Related Information**

- For detailed information about the Iisvdir.vbs command-line administration script, search for "Iisvdir.vbs" in Help and Support Center for Windows Server 2003.
- For information about Security for virtual directories, see Securing Virtual Directories and "Access control" in Help and Support Center for Windows Server 2003.

# Domain Name Resolution

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In order for users to reach your site on an intranet or the Internet, you must have a unique IP address that identifies your computer on the network. This address takes the form of a string of four numbers separated by periods (for example, 192.168.1.42). Because a numeric address is difficult for people to remember, text names, or domain names, are used (for example, www.example.com). Before a user can type a domain name into a Web browser and access a Web page, the name has to be assigned to a corresponding IP address. The process of translating a domain name to an IP address is called name resolution.

**Procedures**

**To make your site available from the Internet**

1. Establish a connection to the Internet. Lease a line from an Internet Service Provider (ISP) or a telephone company. Your provider installs a cable at your site that is plugged into the network adapter card in your computer. Usually a router is also installed between your computer and the ISP. When shopping for a provider, be sure to ask what type of connection is provided and whether the provider guarantees a minimum bandwidth. Also, check on the type of security offered.

2. Obtain an IP address. Your ISP gives you an IP address, an Internet gateway (default gateway), and a subnet mask.

3. Verify your computer's network identity. To verify your IP address, at the command prompt, type **ipconfig**, and then press ENTER. Your current IP address, subnet mask, and default gateway are displayed.

   To verify your computer's name, right-click the **My Computer** icon on your desktop, and click **Properties**. The **Network Identification** tab shows your computer name.

4. Register a domain name. Many ISPs can register your domain name for you, or you can register it yourself. There are domain name registrars located around the world, available for the registration of domain names under many top-level domains (such as .com, .net, .org, as well as country/region code domains such as .us for the United States and .uk for the United Kingdom). These registrars charge a yearly fee to register and maintain your domain name. This fee varies from registrar to registrar, as do the services available. Your domain may be hosted by your ISP, the registrar you choose, or advanced users may choose to host it themselves.

**Related Information**

- For more information about name resolution, search for "dns" or "name resolution" in Windows Help.
- For information about assigning identification information to Web sites; see Naming Web Sites.
- For information about adding Web sites, see Hosting Multiple Web Sites on a Single Server.
- For information about obtaining a domain name, see the Accredited Registrar Directory at the InterNIC Web site.

# Using FrontPage Server Extensions to Extend Web Sites

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

FrontPage Server Extensions from Microsoft provides Web-based and command-line administration for extending virtual servers. Extending virtual servers by using FrontPage Server Extensions enables the site owner to author the site in FrontPage and delegate site ownership and administration credentials.

FrontPage 2002 Server Extensions from Microsoft is an update of FrontPage 2000 Server Extensions, and includes new security features, such as roles and rights, and new features for monitoring server health and Web site usage.

If you build and maintain Web sites for customers and coordinate these efforts with multiple authors, and then the features included in FrontPage 2002 Server Extensions can help you accomplish the following tasks:

- Manage Web sites either on the local server or remotely, by using HTML Administration pages or a quick command-line interface.
- Secure Web sites and grant authoring, browsing, site management, or other user rights to authorized users.
- Analyze site usage to learn who is viewing the site and how often.
- Track errors on the server to help prevent site or server crashes.
- Upgrade FrontPage Web site management functionality with features such as forms, search tools, and usage analysis.

*Extending* a Web site means enabling FrontPage Server Extensions features which improve the management of content development and security of your site. Extending a Web site adds another level of security to the site, and after a Web site is extended, a FrontPage client can open the site and author it in FrontPage. A site that is not extended cannot be opened or authored in FrontPage.

| ⚠**Caution** |
| --- |
| Sites or virtual directories that are configured to use Active Directory isolation or FTP load balancing should not be mapped to physical directories that are used for Web sites that use FrontPage Server Extensions. Doing so could enable users to view any files in that folder structure over the network. |

**Extending Web Sites**

Before you can extend Web sites by using FrontPage Server Extensions, you must create a virtual server for every Web site that you plan to extend. A virtual server differs from a virtual directory. A virtual server, in technical terms, is a virtual machine that resides on an HTTP server but appears to the user as a separate HTTP server. Several virtual servers can reside on one computer, each running its own programs and each with individualized access to input and peripheral devices. Each virtual server has its own domain name and IP address and appears, to the user, to be an individual Web site. Some Internet service providers use virtual servers for clients who want to use their own domain names.

By default, IIS provides a working virtual server named **Default Web Site**. This virtual server points to the content directory *systemdrive*\Inetpub\Wwroot. To create a new virtual server, you must create a content directory.

FrontPage Server Extensions does not support Unicode content directory names or WebDAV. In addition, to remotely administer a Web site that uses SharePoint™ Team Services (STS) from Microsoft, you must assign the _vti_bin virtual directory of new FrontPage Server Extensions virtual servers to the MSSharePointPool application pool. Do not change the MSSharePointPool application pool configuration.

If you have an STS Web site, the following types of pages do not work without excluding the virtual directory that contains the pages from the STS ISAPI filter:

- ASP pages
- ASP.NET pages

- PHP pages
- PerlScript pages

**Procedures**

**To enable these types of pages to work on your STS Web site, do the following**

1. In the **Central Administration** Web site for STS, choose to **Manage** your virtual directory or Web site.
2. Under **Defined Managed Paths**, type the path to the virtual directory that contains your excluded pages (such as <code>\MyASPPages</code>) and select **Exclude**.

Virtual servers should not be nested because virtual servers nested within each other are not visible to FrontPage Server Extensions. For example, if you must create two virtual servers, the first content directory could be located in **systemroot**\Inetpub*Test*; and the second content directory could be located in **systemroot**\Inetpub*Test2*. If the *Test2* directory were located in the *Test* directory, all the permissions in *Test2* would be overwritten by *Test*.

| **Important** |
| --- |
| Never change permissions or Access Control Lists (ACLs) at the content directory level. To maintain a secure environment, always make permissions changes and other security-related changes by using the **FrontPage 2002 Server Administration** tool. |

After creating a virtual server, create the corresponding Web site in IIS.

After creating the Web site in IIS, you are ready to extend the site. Note that a site created in FrontPage and added to IIS is already extended.

Before starting the procedure of extending the Web site, check to make sure you have enabled the FrontPage Server Extensions .dll files. The following .dll files must be installed on your machine before you can extend Web pages.

- *systemdrive*\Program Files\Common Files\Microsoft Shared\Web Server Extensions\50\Isapi_vti_adm**Fpadmdll.dll**
- *systemdrive*\Program Files\Common Files\Microsoft Shared\Web Server Extensions\50\Isapi**Shtml.dll**
- *systemdrive*\Program Files\Common Files\Microsoft Shared\Web Server Extensions\50\Isapi_vti_adm**Admin.dll**
- *systemdrive*\Program Files\Common Files\Microsoft Shared\Web Server Extensions\50\Isapi_vti_aut**Author.dll**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To extend a site using the FrontPage 2002 Server Administration tool**

1. From the **Start** menu, point to **All Programs**, point to **Administrative Tools**, and click **Microsoft SharePoint Administrator**. If IIS returns a 404 error, "The page cannot be found," check to make sure that the FrontPage 2002 Server Extensions optional component is enabled in the **Windows Components Wizard** in the **Add or Remove Programs** item of the Control Panel.
2. On the **FrontPage 2002 Server Administration** site, check to see that the virtual server and corresponding Web site that you created earlier are listed in the **Virtual Servers** section.
3. To extend the Web site, click the **Extend** link next to the virtual server name.
4. Click **Submit**. The **FrontPage 2002 Server Administration** tool adds FrontPage Server Extensions template directories to the content directory of your virtual server, and other files that contain metadata.

**Related Information**

- For more information about FrontPage Server Extensions 2002, see the Microsoft FrontPage Server Extensions Overview on MSDN.
- For more information about how to extend and administering sites by using FrontPage Server Extensions 2002, see the SharePoint Team Services on TechNet.
- For more information about how to administer FrontPage Server Extensions programmatically, see the FrontPageWeb Metabase Property.
- For more information about programmatically extending and administering sites that use FrontPage Server Extensions 2002, see the SharePoint Team Services SDK on MSDN.

# Hosting Multiple Web Sites on a Single Server

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS supports multiple Web sites on a single server. For example, rather than using three different servers to host three different Web sites, you can install all three Web sites on the same server. Consolidating Web sites saves hardware resources, conserves space, and reduces energy costs.

To ensure that user requests reach the correct Web site, you must configure a unique identity for each site on the server. To do so, you must distinguish each Web site with at least one of three unique identifiers: a host header name, an IP address, or a unique TCP port number.

Web sites hosted on the same server can be distinguished using the following unique identifiers.

- Host header name
- IP address
- TCP port number

Using host header names to uniquely identify sites on a server is recommended for most situations.

This section includes the following information:

- Creating Multiple Sites Using Multiple IP Addresses: Describes how to use unique IP addresses to to distinguish multiple sites.
- Creating Multiple Sites Using Host Header Names: Describes how to use host headers to distinguish multiple sites.
- Creating Multiple Sites Using Ports: Describes how to use nonstandard TCP port numbers to distinguish multiple sites.

# Creating Multiple Sites Using Multiple IP Addresses

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Some server configurations require the use of unique IP addresses to distinguish multiple Web sites on the same server.

IIS enables you to configure Web sites to listen on all available IP addresses, or on an individual IP address. If you use multiple IP addresses to distinguish between different sites on the same server, you must configure IIS to assign each site a unique IP address.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To add a Web site using a unique IP address identifier using the Web Site Creation Wizard**

1. In IIS Manager, expand the local computer, right-click the **Web Sites** directory, point to **New**, and then click **Web Site**.
2. Click **Next**.
3. In the **Description** box, type the name you have selected for the Web site, and click **Next**.
4. In the **Enter the IP address to use for this Web site** box, click the unique IP address reserved for this site.
5. In the **TCP port this Web site should use** box, type the port number used by all sites on the server. This should typically be left at the default of 80.
6. If SSL encryption is enabled on the server, type the SSL port number, and then click **Next**. If SSL encryption is not enabled on the server, the **SSL port** box does not appear.
7. In the **Path** box, type or browse to the path of your Web site home directory.
8. To create a secured or private Web site, clear the **Allow anonymous access to this Web site** check box, and then click **Next**. (Web sites are configured for anonymous access by default.)
9. In the **Web Site Access Permissions** box, set the permissions for the home directory.
10. Click **Next**, and then click **Finish**.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any known parameters). |

**To add a Web site using a unique IP address identifier with the Iisweb.vbs command-line script**

1. If the new Web site will be in a new directory, create the new directory.
2. From the **Start** menu, click **Run**.
3. In the **Open** box, type **cmd**, and then click **OK**.
4. At the command prompt, switch to the *systemroot*\system32 directory.
5. Type the following at the command prompt and then press ENTER:

**cscript iisweb.vbs /create** *Home Directory*

*Site Description* **" /i** *Unique IP Address* **/b** *Port*

| **Note** |
| --- |
| The Iisweb.vbs script supports many more options for creating a Web site. To see the options available, see Creating Web Sites Using Iisweb.vbs. |

**Related Information**

- For detailed information about the different methods of hosting multiple Web sites on a single server, see Hosting Multiple Web Sites on a Single Server.
- For information about Web site names, see Domain Name Resolution.

# Creating Multiple Sites Using Host Header Names

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Every Web site has a descriptive name, and can support one or more host header names. Organizations that host multiple Web sites on a single server often use host headers because this method enables them to create multiple Web site identities without using a unique IP address for each site.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To add a Web site using a host header identifier using the Web Site Creation Wizard**

1. In IIS Manager, expand the local computer, right-click the **Web Sites** directory, point to **New**, and then click **Web Site**.
2. Click **Next**.
3. In the **Description** box, type the name you have selected for the Web site, and then click **Next**.
4. In the **Enter the IP address to use for this Web site** box, click the IP address used by all sites on the server.
5. In the **TCP port this Web site should use** box, type the port number used by all sites on the server.
6. In the **Host Header for this Web site (Default:None)** box, type the host header name to identify the Web site. The host header name must contain the full name of the site, for example, www.microsoft.com.
7. If SSL encryption is not enabled on the server, the **SSL port** box does not appear. If SSL encryption is enabled on the server, type the SSL port number, and then click **Next**. Note that you cannot use host headers with SSL encryption.
8. In the **Path** box, type or browse to the path of your Web site home directory.
9. To create a secured or private Web site, clear the **Allow anonymous access to this Web site** check box, and click **Next**. (Web sites are configured for anonymous access by default.)
10. In the **Web Site Access Permissions** box, set the permissions for the home directory.
11. Click **Next**, and then click **Finish**.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any known parameters). |

**To add a Web site using a host header identifier using the Iisweb.vbs command-line administration script**

1. If the new Web site will be in a new directory, create the new directory.
2. From the **Start** menu, click **Run**.
3. In the **Open** box, type **cmd**, and then click **OK**.
4. At the command prompt, switch to the *systemroot*\system32 directory.
5. Type the following at the command prompt and then press ENTER:

**cscript iisweb.vbs /create** *HomeDirectory SiteDescription* **" /d** *Host Header* **/i** *IP Address* **/b** *Port*

| **Note** |
| --- |
| The Iisweb.vbs script supports many more options for creating a Web site. To see the options available, see Creating Web Sites Using Iisweb.vbs. |

**Related Information**

- For detailed information about the different methods of hosting multiple Web sites on a single server, see Hosting Multiple Web Sites on a Single Server.
- For information about Web site names, see Domain Name Resolution.

# Creating Multiple Sites Using Ports

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Although not recommended for production servers, you can use nonstandard TCP port numbers to create unique Web site identifiers for site development and testing purposes. You can do this by creating a Web site identity that consists of a TCP/IP address or host header name, appended with a nonstandard TCP port number. Because TCP/IP endpoints are defined by a combination of IP address (or the corresponding name) and port number, configuring a Web site with a nonstandard port number creates a unique endpoint, or identity, for the site.

If you use a nonstandard TCP port number to identify a Web site, users must know the nonstandard TCP port number assigned to the Web site, and append the port number to the Web site's name or IP address in their Web browser address bar.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To add a Web site using a unique port identifier using the Web Site Creation Wizard**

1. In IIS Manager, expand the local computer, right-click the **Web Sites** directory, point to **New**, and then click **Web Site**.
2. In the Web Site Creation Wizard, click **Next**.
3. In the **Description** box, type the name that you have selected for the Web site, and then click **Next**.
4. In the **Enter the IP address to use for this Web site** box, click the IP address used for all sites on this server.
5. In the **TCP port this Web site should use** box, type the unique port number reserved for this site.
6. Optional: In the **Host Header for this Web site (Default:None)** box, type the host header name to identify the Web site. The host header name must containing the full name of the site, for example, www.microsoft.com.
7. If SSL encryption is enabled on the server, type the SSL port number, and then click **Next**. If SSL encryption is not enabled on the server, the **SSL port** box does not appear.
8. In the **Path** box, type or browse to the path of your Web site home directory.
9. To create a secured or private Web site, clear the **Allow anonymous access to this Web site** check box, and click Next. (Web sites are configured for anonymous access by default.)
10. In the **Web Site Access Permissions** box, set the permissions for the home directory.
11. Click **Next**, and then click **Finish**.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any known parameters). |

**To add a Web site using a unique port identifier with the Iisweb.vbs command-line script**

1. If the new Web site will be in a new directory, create the new directory.
2. From the **Start** menu, click **Run**.

3. In the **Open** box, type **cmd**, and then click **OK**.
4. At the command prompt, switch to the *systemroot*\system32 directory.
5. Type the following at the command prompt and then press ENTER:

   **cscript iisweb.vbs /create** *Home Directory*

   *Site Description* **" /i** *IP Address* **/b** *Unique Port*

| **Note** |
| --- |
| The Iisweb.vbs script supports many more options for creating a Web site. To see the options available, see Creating Web Sites Using Iisweb.vbs. |

**Related Information**

- For detailed information about the different methods of hosting multiple Web sites on a single server, see Hosting Multiple Web Sites on a Single Server.
- For information about port filtering, see TCP/IP Port Filtering.

# FTP Site Setup

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

IIS includes the File Transfer Protocol (FTP) service for publishing and managing files. This version of IIS includes Isolating FTP Users to help administrators (particularly Internet hosting providers) efficiently secure and commercialize FTP services for their customers.

The FTP service is not installed by default. To set up an FTP site, you must first install the FTP service through the Control Panel. Installing the FTP service creates a default FTP site, which you can then customize to your needs using IIS Manager.

**Procedures**
**To install the FTP service**

1. From the **Start** menu, click **Control Panel**, double-click **Add or Remove Programs**, and then click **Add/Remove Windows Components**.
2. From the **Components** list, click **Application Server**, and then click **Details**.
3. From the **Subcomponents of Application Server** list, click **Internet Information Services (IIS)**, and then click **Details**.
4. From the **Subcomponents of Internet Information Services (IIS)** list, select the **File Transfer Protocol (FTP) Service** check box, and then click **OK**.
5. Click **Next**. You might be prompted for the Windows Server 2003 product CD or the network install path.
6. Click **Finish**.

| **Caution** |
| --- |
| Caution FTP sites or virtual directories that are configured to use Active Directory isolation or FTP load balancing should not be mapped to physical directories that are used for Web sites that use FrontPage® Server Extensions from Microsoft. Doing so can allow users to view any files in that folder structure over the network. |

When you install the FTP service, a default FTP directory is created at *LocalDrive*:\Inetpub\Ftproot.

Setting up the FTP service for the first time involves first setting global FTP settings, then settings for the default FTP site, and finally adding the content to the FTP site. IIS uses an inheritance model, which means that settings on higher levels are automatically inherited by lower levels. Settings at lower levels can be edited individually to override inherited settings from the next level up.

If you change a setting at a lower level, then later change a setting at a higher level that conflicts with the lower-level setting, you will be prompted to choose whether you want to change the lower-level setting to match the new higher-level setting.

Before setting up the FTP service, see Securing FTP Sites with IIS 6.0 for clarification on security issues associated with the FTP service.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To globally change FTP settings**

1. In IIS Manager, expand the local computer, right-click the **FTP Sites** folder, and click **Properties**.
2. Change the default settings on the property pages as needed. The changes are inherited by all FTP sites on your computer. For information about individual settings, click **Help**.

**To change settings for the default FTP site**

1. In IIS Manager, expand the local computer, expand the **FTP Sites** folder, right-click **Default FTP site**, and click **Properties**.
2. Change the default settings on the property pages to replace any inherited settings as needed. For information about individual settings, click **Help**.

**To publish content on your FTP site**

- Copy or move your content files into the default FTP publishing directory.

| **Note** |
| --- |
| If your network has a name resolution system, for example, DNS, visitors can type **ftp://** followed by your computer name in the address box of their browsers to reach your site. If your network does not have a name resolution system, visitors must type **ftp://**, followed by the numerical IP address of your computer. |

**Related Information**

- For information about administering or adding an FTP site, see FTP Site Administration.
- For conceptual information describing hosting multiple sites on one computer, see Hosting Multiple Web Sites on a Single Server.
- To add virtual directories to an FTP site, see Using Virtual Directories with FTP Sites.
- To customize the appearance of your FTP site, see Setting FTP Messages and Directory Output Style.
- For information about isolating FTP users and the additional security it can provide, see Isolating FTP Users.

# SMTP Server Setup

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The Simple Mail Transfer Protocol (SMTP) service provided by IIS is a simple component for delivering outgoing e-mail messages. Delivery of a message is initiated by transferring the message to a designated SMTP server. Based on the domain name of the recipient e-mail address, the SMTP server initiates communications with a Domain Name System (DNS) server, which looks up and then returns the host name of the destination SMTP server for that domain.

Next, the originating SMTP server communicates with the destination SMTP server directly through Transmission Control Protocol/Internet Protocol (TCP/IP) on port 25. If the user name of the recipient e-mail address matches one of the authorized user accounts on the destination server, the original e-mail message is transferred to that server, waiting for the recipient to pick up the message through a client program.

In the case where the originating SMTP server cannot communicate directly with the destination server, the SMTP service can transfer messages through one or more intermediate relay SMTP servers. A relay server receives the original message and then delivers it to the destination server, or redirects it to another relay server. This process is repeated until the message is delivered or a designated timeout period passes.

The SMTP service is not installed by default. You must install the SMTP service using the Control Panel. Installing the SMTP service creates a default SMTP configuration which you can then customize to your needs using IIS Manager.

Many articles about deploying and configuring the SMTP service are available by searching for "smtp" on the Microsoft Developer Network (MSDN) Web site.

**Procedures**

**To install the SMTP service**

1. From the **Start** menu, click **Control Panel**.
2. Double-click **Add or Remove Programs**.
3. From the left pane, click **Add/Remove Windows Components**.
4. From the **Components** list, click **Application Server**, and then click **Details**.
5. From the **Subcomponents of Application Server** list, click **Internet Information Services (IIS)**, and then click **Details**.
6. From the **Subcomponents of Internet Information Services (IIS)** list, select the **SMTP Service** check box.
7. Click **OK**.
8. Click **Next**. You might be prompted for the Windows Server 2003 family CD or the network install path.
9. Click **Finish**.

When you install the SMTP service, a default SMTP server configuration is created with a message store in *LocalDrive*:\Inetpub\Mailroot.

When setting up the SMTP service for the first time, you can configure global settings for a SMTP virtual server, as well as settings for individual components of the virtual server.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To configure global SMTP settings**

1. In IIS Manager, expand the local computer, right-click **Default SMTP Virtual Server**, and click **Properties**.

2. Change the default settings on the property pages as needed. For information about individual settings, click **Help**.

**To configure SMTP virtual server components settings**

1. In IIS Manager, expand the local computer, expand **Default SMTP Virtual Server**, right-click the component you want to configure, and click **Properties**.

2. Change the default settings on the property pages as needed. For information about individual settings, click **Help**.

**Related Information**

# NNTP Server Setup

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Using a mail-based mechanism for hosting discussions of interest to a variety of people can become inefficient as the number of discussion participants grows. Sending a separate copy of the message to each of the interested parties consumes large quantities of bandwidth, CPU resources, and disk space among the many recipients and mail servers hosting them.

Significant resources can be saved if popular messages are hosted in a single database. This single database is known as a news server and the messages on such a server are called news items or articles. Using the Network News Transfer Protocol (NNTP) service, you can create your own news server to host discussions. NNTP is the protocol for the distribution, inquiry, posting, and retrieval of news items between a news server and client.

Access to the news server can be open to everyone, or it can require user authentication. The NNTP service allows fine tuning of security policies and is capable of handling a large number of virtual domains and independent server instances on a single computer.

The NNTP service is not installed by default. You must install the NNTP service using the Control Panel. Installing the NNTP service creates a default NNTP configuration, which you can then customize to your needs using IIS Manager.

Many articles about deploying and configuring the NNTP service are available by searching for "nntp" on the Microsoft Developer Network (MSDN) Web site.

**Procedures**

**To install the NNTP service**

1. From the **Start** menu, click **Control Panel**.
2. Double-click **Add or Remove Programs**.
3. From the left pane, click **Add/Remove Windows Components**.
4. From the **Components** list, click **Application Server**, and then click **Details**.
5. From the **Subcomponents of Application Server** list, click **Internet Information Services (IIS)**, and then click **Details**.
6. From the **Subcomponents of Internet Information Services (IIS)** list, select the **NNTP Service** check box.
7. Click **OK**.
8. Click **Next**. You might be prompted for the Windows Server 2003 family CD or the network install path.
9. Click **Finish**.

When you install the NNTP service, a default NNTP virtual server configuration is created with a message store in *LocalDrive*:\Inetpub\Nntpfile\Root.

When setting up the NNTP service for the first time, you can configure global settings for an NNTP virtual server, as well as settings for individual components of the virtual server.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To configure global NNTP settings**

1. In IIS Manager, expand the local computer, right-click **Default NNTP Virtual Server**, and click **Properties**.
2. Change the default settings on the property pages as needed. For information about individual settings, click **Help**.

**To configure NNTP virtual server component settings**

1. In IIS Manager, expand the local computer, expand **Default NNTP Virtual Server**, right-click the component you want to configure, and click **Properties**.
2. Change the default settings on the property pages as needed. For information about individual settings, click **Help**.

# Web Authoring with WebDAV

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Web Distributed Authoring and Versioning (WebDAV) extends the HTTP/1.1 protocol to allow clients to publish, lock, and manage resources on the Web. This section describes how to set up a WebDAV publishing directory on an IIS server, and how clients can connect to the server to edit and manipulate files.

| **Note** |
| --- |
| WebDAV is an optional component of IIS 6.0 and is not installed by default. See Installing IIS for information about installing WebDAV. After WebDAV is installed, it can be enabled through the Web Services Extensions node in IIS Manager. |

This section includes the following information:

- About WebDAV: Describes how WebDAV can create directories from which remote users can publish and manipulate files.
- Creating Publishing Directories: Describes how to set up a WebDAV publishing directory.
- Managing WebDAV Security: Provides tips on how to optimize IIS and Windows Server 2003 family security to secure your WebDAV site.
- Searching WebDAV Directories: Describes how to configure a WebDAV directory so that users can search it for content and document properties.
- WebDAV Redirector_IIS_SP1_Ops: Describes how WebDAV Redirector treats files on the Web like they were a mapped network drive.

| **Note** |
| --- |
| WebDAV publishing is an implementation of the HTTP 1.1 protocol as specified in RFC 2518, and it is supported in IIS versions 5.0, 5.1, and 6.0. |

**Related Information**

- For more information about file and directory security, see "Encrypting File System" (EFS) in Help and Support Center for Windows Server 2003. EFS is a new feature in Windows Server 2003, Standard Edition. Also, see Securing Files with NTFS Permissions.
- For information about HTTP Extensions for WebDAV Distributed Authoring, see RFC 2518 at the Internet Engineering Task Force Web site.

# About WebDAV

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Web Distributed Authoring and Versioning (WebDAV) extends the HTTP/1.1 protocol to allow clients to publish, lock, and manage resources on the Web.

Integrated into IIS, WebDAV allows clients to do the following:

- Manipulate resources in a WebDAV publishing directory on your server. For example, users who have been assigned the correct rights can copy and move files around in a WebDAV directory.
- Modify properties associated with certain resources. For example, a user can write to and retrieve a file's property information.
- Lock and unlock resources so that multiple users can read a file concurrently. However, only one person can modify the file at a time.
- Search the content and properties of files in a WebDAV directory.

Setting up a WebDAV publishing directory on your server is as straightforward as setting up a virtual directory through IIS Manager. After you have set up your publishing directory, users who have been assigned the correct rights can publish documents to the server and manipulate files in the directory. Before you can set up a WebDAV directory, you must install Windows XP Professional or a member of the Windows Server 2003 family.

**Important**

To help minimize the attack surface of the server, IIS 6.0 is not installed on Windows Server 2003 by default. When you first install IIS 6.0, it is locked down -- which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable these features, IIS returns a 404 error. You can enable these features through the Web Service Extensions node in IIS Manager. For more information about how to troubleshoot 404 errors and other issues, see Troubleshooting in IIS 6.0.

**WebDAV Clients**

You can access and publish to a WebDAV directory through one of the following Microsoft products or through any other client that supports the industry standard WebDAV protocol. For the specific procedure on how to access and publish through these Microsoft products, consult the specific product's Help.

- Windows clients (Windows 2000 and Windows XP): Connect to a WebDAV directory by adding the directory to the list of Network Places and display the contents as if it were part of the same file system on your local computer. Once connected, you can drag and drop files, retrieve and modify file properties, and complete many other file-system tasks. You can also connect using the command-line client (known as WebDAV Redirector). This client allows you to use existing applications across the Web and share files through firewalls and proxy servers.
- Internet Explorer (versions 5.0 and 6.0): Connect to a WebDAV directory by opening the target directory as a Web folder and complete the same file-system tasks as Windows clients.
- Microsoft Office products (Office 2000 and Office XP): Create, publish, edit, and save documents directly into a WebDAV directory through any application in Office 2000 or Office XP.

**Note**

Even if users connect from behind a firewall, they can still publish on a WebDAV directory if they have the correct permissions and if the firewall is configured to allow publishing.

When enabling WebDAV publishing on your intranet, ensure that all WebDAV clients are running the WebClient service.

**Procedures**

**To check the status, or to enable the WebClient service on a WebDAV client machine**

1. From the **Start** menu, point to **Administrative Tools**, and click **Computer Management**.
2. In the details pane, double-click **Services and Applications**.
3. Double-click **Services**.
4. Scroll down, right-click **WebClient**, and click **Properties**.
5. In the Startup type list box, click **Automatic**.
6. Click **Apply**.
7. In the **Service status** section, click **Start**.
8. Click **OK**.

**Searching in WebDAV**

Once connected to a WebDAV directory, you can quickly search the files on that directory for content as well as properties. For example, you can search for all files that contain the word *table* or for all files written by *Fred*.

**Integrated Security**

WebDAV is integrated with the Windows Server 2003 family and IIS, which means WebDAV takes advantage of the security features offered by the platform and the Web server, including permissions control and discretionary access control lists (DACLs) in the NTFS file system. For information about IIS security, see Security in IIS 6.0.

Clients with proper user rights can write to a WebDAV directory, so it is vital that you control who accesses your directory. IIS has reinforced Integrated Windows Authentication by building in support for the Kerberos V5 security protocol. (Note that Integrated Windows authentication and Kerberos V5 are not the same thing. Integrated Windows authentication now supports Kerberos V5.) By selecting Integrated Windows authentication, you can make sure that only clients with the correct user rights can access and write to the WebDAV directory on your intranet. For information about how the Kerberos V5 protocol works, see "Kerberos V5 protocol" in Windows Server 2003 family Help.

In addition, IIS supports Digest authentication and Advanced Digest authentication. Created for Windows domain servers, Digest and Advanced Digest authentication offer tighter security for passwords and for transmitting information across the Internet. For information about Digest authentication, see Digest Authentication in IIS 6.0. For information about Advanced Digest authentication, see Advanced Digest Authentication in IIS 6.0.

**Related Information**

- For more information about file and directory security, see "Encrypting File System" in Help and Support Center for Windows 2003. EFS is a new feature in Windows Server 2003 family.

# Creating Publishing Directories

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Before setting up your WebDAV publishing directory, ensure that your publishing directory resides in an NTFS partition and be sure the WebDAV extension is enabled in IIS Manager.

WebDAV publishing and file management requires the following permissions on the *NTFS directory*:

- **Read**: Enables users to read the contents of a file.
- **Read and Execute**: Enables user to read a file and run scripts or Common Gateway Interfaces (CGIs).
- **List**: Enables users to view the contents of the directory.
- **Write**: Enables users to access and change the source of a script and to publish files.
- **Modify**: Enables users to rename or delete a directory or file.

| **Note** |
| --- |
| Assigning Write access does not give clients the ability to modify Active Server Pages (ASP) or any other script-mapped files. To allow these files to be modified, you must assign Write permission and Script source access after creating the virtual directory. For information about setting these permissions, see Securing Sites with Web Site Permissions. |

WebDAV publishing and file management requires the following permissions on the *IIS virtual directory*:

- **Read**: Enables users to read the contents of a file.
- **Directory Browsing**: Enables users to view the contents of the directory.
- **Write**: Enables users to access and change the source of a script and to publish files.
- **Indexing** (optional): Enables users to search a directory.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set up a publishing directory**

1. Create a directory on your Web server and set the desired NTFS permissions. You can create this directory anywhere on your Web server.
2. In IIS Manager, create a virtual directory and set the desired virtual directory permissions. For instructions, see Using Virtual Directories.
3. Type **WebDAV** as the alias for this virtual directory, and link it to the physical directory you created in Step 1.

After you finish setting up a WebDAV virtual directory, you can allow clients to publish to it. For information about how users can connect to the directory through any of the Microsoft WebDAV clients, see About WebDAV.

**Related Information**

- For more information about NTFS and IIS user rights, see Access Control with IIS 6.0.

# Managing WebDAV Security

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This topic provides a brief overview of recommended security practices for remote publishing. It briefly describes how to protect your server and content by authenticating client connections to your server and by controlling access to content on your server. Included in this topic are descriptions of the following:

- Authenticating Clients
- Controlling Access

| **Note** |
| --- |
| For security reasons and to to enable DAV custom properties, ensure that your publishing directory resides on an NTFS partition. To learn more about NTFS partitions, see Windows Server 2003 family Help. |

**Authenticating Clients**

The best way to configure a WebDAV directory depends on the kind of publishing that you want to do. When you create a virtual directory through IIS, Anonymous and Integrated Windows authentication are both turned on. Although this default configuration works well for clients connecting to your server, reading content on a Web page, and running scripts, it does not work well with clients publishing to a directory and manipulating files in that directory.

IIS offers the following authentication methods:

- Kerberos is the primary security protocol for authentication within a domain. Kerberos is the best option for WebDAV client authentication and file security.
- Anonymous authentication grants anyone access to the directory. You should turn off anonymous access to your WebDAV directory. Without controlling who has access, your directory could be attacked by unknown clients.
- Basic authentication sends passwords over the connection in clear text. Clear text passwords can be intercepted and read. Turn on Basic authentication only if you encrypt passwords by using Secure Sockets Layer.
- Digest authentication is a good choice for publishing information on a server that is accessed over the Internet and through firewalls because the passwords are sent over the network as an MD5 hash. However, passwords are stored as plain text in Active Directory.
- Advanced Digest authentication is an improvement over Digest authentication because in addition to sending passwords over the network as an MD5 hash, the passwords are also stored in Active Directory as an MD5 hash rather than plaintext. This makes Advanced Digest the best choice for publishing information on a server that is accessed over the Internet and through firewalls.
- Integrated Windows authentication works best when you are setting up a WebDAV directory on an intranet.
- .NET Passport authentication uses cookies to validate user credentials.

**Controlling Access**

This section describes how you can control access to your WebDAV directory by coordinating IIS and Windows Server 2003 permissions, and how you can protect your script files.

**Configuring Web Permissions**

The following are various ways to configure Web permissions based on the purpose of the material you are publishing:

- Read, Write, and directory browsing enabled: Turning on these permissions allows clients to see a list of resources, modify them (except for those resources without Write permission), publish their own resources, and manipulate files.

- Write enabled; and Read and directory browsing disabled: If you want clients to publish private information on the directory, but do not want others to see what has been published, set Write permission and do not set Read or directory browsing permission. This configuration works well if clients are submitting ballots or performance reviews.

- Read and Write enabled; and directory browsing disabled: Set this configuration if you want to rely on obscuring file names as a security method. However, be aware that security by obscurity is a low-level security precaution because an attacker could guess file names by trial and error.

- Index this resource enabled: Be sure to enable Indexing Service if you plan to let clients search directory resources.

**Controlling Access with DACLs**

WebDAV takes advantage of the security features offered by the platform and the Web server, including permissions control and discretionary access control lists (DACLs) in the NTFS file system. When setting up a WebDAV publishing directory on an NTFS file system drive, make sure the **Everyone** group has Read permission only. Then assign Write permission to specific individuals or groups.

**Protecting Script Code**

If you have script files in your publishing directory that you do not want to expose to clients, you can deny access to these files by verifying that **Script source access permission** is not assigned. Executable files are treated as static HTML files unless **Scripts and Executables** is enabled for the directory.

To prevent .exe files from being downloaded and viewed as HTML files, but to allow .exe files to run, on the **Virtual Directory** property sheet of the publishing directory, change the Execute Permissions to **Scripts and Executables**.

This level of permission makes all executable files subject to the **Script source access** setting. When **Script source access** is selected, clients with Read permission can see all executables; and clients with Write permission can edit them, as well as run them.

With the following permissions, clients can write to an executable file that does not appear in the Application Mapping:

- Write permission is assigned.

- Execute Permissions is set to **Scripts only**.

With the following permissions, clients can write to any executable file, regardless of whether it appears in the Application Mapping:

- **Script source access** is assigned.

- Execute Permissions is set to **Scripts and Executables**.

**Related Information**

- For more information about Web permissions, see Securing Sites with Web Site Permissions.

- For more information about Kerberos authentication, see Help and Support Center for Windows Server 2003.

# Searching WebDAV Directories

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

After you create a WebDAV publishing directory, you may want to allow users to search for content and file properties.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set up your publishing directory for searching**

1. If you want to let clients search for resource properties, make sure the directory is on a drive formatted with the NTFS file system. If you put the directory on a drive formatted with the file allocation table (FAT) file system, clients can search for resource content but cannot search for resource properties.
2. Right-click the **My Computer** icon on your server's desktop, and then click **Manage**.
3. In the navigation pane of the Computer Management console, expand the Services and Applications node, and then select **Services**.
4. In the details pane, right-click **Indexing Service**, and then select **Properties**.
5. On the **General** tab of the Indexing Service Properties window, set the **Startup type** to **Automatic**, and then click the **Start** button.
6. After the Indexing Service starts, click **OK**, and then close the Computer Management Window.
7. In IIS Manager, expand the local machine, right-click your WebDAV directory, and click **Properties**.
8. Click the **Virtual Directory** tab and make sure **Index this resource** and **Read** access options are selected. If **Index this resource** is not selected, Indexing Service will not create a catalog for that directory, and no one will be able to search it. If **Read** access has not been selected, a client can search the directory, but will not be able to see the results of the search.

**Related Information**

- For information about how to enable the Indexing Service in the Windows Component Wizard, see Installing IIS.
- For details about setting IIS permissions for a virtual directory, see Securing Sites with Web Site Permissions.

# WebDAV Redirector_IIS_SP1_Ops

Updated: August 22, 2005

Applies To: Windows Server 2003 R2, Windows Server 2003 with SP1

WebDAV Redirector is a remote file system over the WebDAV protocol that allows Windows XP client machines to connect to your WebDAV publishing directory through the command line. Once connected, all existing Win32 applications (without any modification) can create, modify, and save files on Web shares (IIS virtual directories). The WebDAV Redirector enables you to manipulate files on the Web as though the files exist on a mapped network drive.

Your WebDAV Web site (the site that contains the virtual directory mapped to your WebDAV publishing directory) must be set up exclusively as a WebDAV site. Therefore, you must delete all FrontPage custom headers. If your WebDAV Web site is set up as both a DAV and FrontPage site, IIS defaults to the FrontPage custom header and blocks DAV command-line connections.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To enable WebDAV Redirector on your Web server**

1. In IIS Manager, expand the local computer, right-click your WebDAV Web site (the site that contains the virtual directory mapped to your WebDAV publishing directory) and click **Properties**.
2. Click the **HTTP Headers** tab.
3. Remove any headers listed in the **Custom HTTP headers** list box.
4. Click **Apply**.
5. Click **OK**.

After you have set up your WebDAV Publishing Directory, you can connect to that directory through the command prompt using Windows XP clients. Once connected, all existing Win32 applications (without any modification) can create, modify, and save files on Web shares (IIS virtual directories).

# Server Administration Guide

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This section describes how to administer your server and Web sites by using the many tools and features developed in Internet Information Services (IIS) 6.0 to improve server management, performance, reliability, and security. This section also includes conceptual information regarding some of the key changes to the IIS architecture and to the metabase.

| **Important** |
| --- |
| To help minimize the attack surface of the server, IIS 6.0 is not installed on Windows Server 2003 by default. When you first install IIS 6.0, it is locked down -- which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable these features, IIS returns a 404 error. You can enable these features through the Web Service Extensions node in IIS Manager. For more information about how to troubleshoot 404 errors and other issues, see Troubleshooting. |

**In This Section**

This section includes the following information:

- IIS Metabase: Describes the IIS 6.0 Extensible Markup Language (XML) metabase, a hierarchical repository for most IIS configuration values.
- Web Site Administration: Describes how to manage Web site infrastructure, including how to manage multiple Web sites, redirect requests, and restart IIS.
- FTP Site Administration: Describes how to manage File Transfer Protocol (FTP) site infrastructure, including multiple FTP sites, data transmission, and user isolation.
- NNTP Administration: Describes how to manage Network News Transfer Protocol (NNTP) site infrastructure, including restricting access to newsgroups, configuring expiration policies, and NNTP security.
- SMTP Administration: Describes how to manage Simple Mail Transfer Protocol (SMTP) site infrastructure, including setting connections, protocol logging, and SMTP security.
- Configuring Applications: Describes how to configure IIS Manager so that various applications -- including Microsoft® Active Server Pages (ASP), Internet Service API (ISAPI), and Common Gateway Interfaces (CGI) -- run on your IIS server.
- Configuring Servers for Applications: Describes how to enable IIS to run in either IIS 5.0 application isolation mode or worker process isolation mode. Also describes how to enable dynamic content in IIS 6.0.
- Using Command-Line Administration Scripts: Describes how to use scripts to perform server administration tasks.
- Administering IIS Programmatically: Introduces the three programmatic interfaces that are supported by IIS 6.0.

# IIS Metabase

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The metabase is a repository for most Internet Information Services (IIS) configuration values. The metabase is a plaintext XML file and can be edited manually or programmatically. The metabase is also extensible in a highly efficient manner. As your IIS deployment grows, so does the metabase; however, by using an inheritance model, explicit declarations of duplicate values is avoided, reducing overhead when configuration values need to be read from the metabase.

This section includes the following information:

- Enabling Edit-While-Running in IIS 6.0: Explains how to enable metabase edit-while-running by using IIS Manager and the command line.
- Backing Up and Restoring the Metabase in IIS 6.0: Discusses backing up and restoring the metabase.
- Metabase Import and Export in IIS 6.0: Describes site cloning, application cloning, and creating a metabase template to import from other servers running IIS.
- Metabase Auditing: Describes enabling and disabling the feature that audits changes to IIS metabase settings.

Working with the Metabase

# Enabling Edit-While-Running in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Enabling metabase edit-while-running requires that the metabase history feature is enabled and set to a value of at least **10**. The second procedure below requires IIS to be restarted. Restarting IIS stops all sites for a short time. To enable direct metabase edit without interruption of service, use the first procedure below.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To enable metabase edit-while-running using IIS Manager**

1. In IIS Manager, right-click the local computer, and then click **Properties**.
2. Select the **Enable Direct Metabase Edit** check box.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any known parameters). |

**To enable metabase edit-while-running from the command line**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd**, and click **OK**.
3. At the command prompt, type **iisreset /stop**, and press ENTER. Leave the command window open.

Open the MetaBase.xml file with a plain text editor. By default, the MetaBase.xml file is located in the systemroot\system32\inetsrv directory.

| **Important** |
| --- |
| All text within MetaBase.xml is case sensitive. |

1. In the IIsComputer node, change the value of the **EnableEditWhileRunning** property from **0** (**FALSE**) to **1** (**TRUE**). The change should look as follows:

```
<IIsComputer Location ="/LM"

EnableEditWhileRunning="1"

EnableHistory="1"

MaxBandwidth="4294967295"

MaxHistoryFiles="10">
```

2. Save changes to the MetaBase.xml file.

3. At the command prompt, type **iisreset /start**, and press ENTER.

**Related Information**

- For information about enabling metabase history, see Configuring the Metabase History Feature in IIS 6.0.
- For more information about the **EnableEditWhileRunning** property, see EnableEditWhileRunning Metabase Property.
- For information about restarting IIS, see Restarting IIS.

# Backing Up and Restoring the IIS Metabase

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS administrators can create backup files using IIS Manager or a programmatic administration script. The backup files are copies of the metabase configuration file (MetaBase.xml) and the matching metabase schema file (MBSchema.xml). Using the metabase configuration backup and restore feature, the metabase can be restored from the backup files.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To create a portable backup (password required)**

1. In IIS Manager, right-click the local computer, point to **All Tasks**, and click **Backup/Restore Configuration**.
2. Click **Create Backup**.
3. In the **Configuration backup name** box, type a name for the backup file.
4. Select the **Encrypt backup using password** check box, type a password into the **Password** box, and then type the same password in the **Confirm password** box.
5. Click **OK**, and then click **Close**.

**To create a non-portable backup (password not required)**

1. In IIS Manager, right-click the local computer, point to **All Tasks**, and click **Backup/Restore Configuration**.
2. Click **Create Backup**.
3. In the **Configuration backup name** box, type a name for the backup file.
4. Click **OK**, and click **Close**.

**To restore the metabase backup**

1. In IIS Manager, right-click the local computer, point to **All Tasks**, and click **Backup/Restore Configuration**.
2. In the **Backups** list box, click the version of the **Automatic Backup** file that you want to restore, and click **Restore**. If prompted for a password, type the password you chose to secure the backup.

**Related Information**

- For information about metabase reliability, see Backing Up and Restoring the Metabase in IIS 6.0
- For more information about command-line administration scripts, see Using Command-Line Administration Scripts.

# Configuring the Metabase History Feature in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

By default, the metabase history feature is enabled and the number of history file pairs (MetaBase.xml and MBSchema.xml) that are saved within the history folder is defined by the default value of the MaxHistoryFiles Metabase Property. If the EnableHistory Metabase Property is not written in the MetaBase.xml file, then IIS interprets the absence of the property to mean that the history feature is enabled and the MaxHistoryFiles Metabase Property is set to the default value. For information about the default values of properties, see the Metabase Property Reference.

**Procedures**

**The procedure title**

1. Open the MetaBase.xml file by using a text editor (MetaBase.xml is located in the systemroot\system32\inetsrv directory), and then navigate to the /LM level.
2. If the EnableHistory Metabase Property and MaxHistoryFiles Metabase Propertyare not in the metabase, add them at the /LM level.
3. Set the value of the **EnableHistory** property to **0** (zero).
4. Save the MetaBase.xml file.

**To enable the metabase history feature**

1. Open the MetaBase.xml file by using a text editor (MetaBase.xml is located in the systemroot\system32\inetsrv directory), and then navigate to the /LM level.
2. Set the value of the EnableHistory Metabase Property property to **1** or remove the **EnableHistory** property from MetaBase.xml.
3. Save the MetaBase.xml file.

**To change the number of history files that are stored in the history folder**

1. Open the MetaBase.xml file by using a text editor (MetaBase.xml is located in the systemroot\system32\inetsrv directory), and then navigate to the /LM level.
2. Change the value of the MaxHistoryFiles Metabase Property.
3. Save the MetaBase.xml file.

| ⚠Caution |
| --- |
| Disabling history files can have serious consequences. Without history files, you might have to reconfigure the IIS server from an empty state. Also, you should ensure that the history files are protected by access control lists (ACLs). By default, only members of the Administrators group can view the history files. For information about configuring ACLs, see "Access control" in Help and Support Center for Windows Server 2003. |

**Related Information**

- For more information about the metabase history feature and how it is used, see The Metabase History Feature.

# Restoring the Metabase with History Files

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS periodically creates history files consisting of copies of the metabase configuration file (MetaBase.xml) and the matching metabase schema file (MBSchema.xml). Restoring the metabase from history files is similar to restoring the metabase from backup files.

Use the first procedure below to restore the metabase from a history file using IIS Manager. If you want to restore the metabase without using IIS Manager, use the second procedure below.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer***\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

**Procedures**

**To restore the metabase using IIS Manager**

1. In IIS Manager, right-click the local computer, point to **All Tasks**, and click **Backup/Restore Configuration**.
2. In the **Backups** list, click the **Automatic Backup** you want to restore, and then click **Restore**.
3. Read the message that appears and click **Yes** if you want to continue.
4. Click **OK**.

**To manually restore the metabase**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd**, and then click **OK**.
3. Stop the IIS services by typing **iisreset /stop** at the command prompt, and then press **ENTER**. The command prompt displays the following:

   ```
   Attempting stop...

   Internet services successfully stopped
   ```

   If the IIS services do not stop, and it is possible to restart the computer, type **iisreset /stop /rebootonerror**, and then press ENTER.
4. Make copies of your current metabase files. At the command prompt, type **cd %systemroot%\System32\Inetsrv**, and then press ENTER to navigate to the folder where the files are. Next, type **copy MBSchema.xml MBSchema.old**, and then press ENTER to copy the schema file. Finally, type **copy MetaBase.xml Metabase.old**, and then press ENTER to copy the metabase configuration file.
5. Locate the metabase history files. At the command prompt, type **cd %systemroot%\System32\Inetsrv\History**, and then press ENTER.
6. Select the version of history files that you want. At the command prompt, type **dir**, and then press ENTER. All of the files appear in the following format:

   ```
   <date> <time> <file size> MBSchema_<identifying number>_0000000000.xml

   <date> <time> <file size> MetaBase_<identifying number>_0000000000.xml
   ```

   When you restore the IIS metabase to a previous version, you will need matching metabase schema and configuration files. Select matching files by their identifying number.

7. Copy the chosen history schema file over the existing metabase schema. At the command prompt, type **copy /y MBSchema_<identifying number>_0000000000.xml %systemroot%\System32\Inetsrv\MBSchema.xml**, and then press ENTER. With this command, you copy the file and rename it at the same time.

8. Copy the matching history configuration file over the existing metabase configuration. At the command prompt, type **copy /y Metabase_<identifying number>_0000000000.xml %systemroot%\System32\Inetsrv\MetaBase.xml**, and then press ENTER. Again, this command copies the file and renames it at the same time.

| **Important** |
| --- |
| If you mix up the names or copy a schema and configuration file that do not match, the metabase restoration will fail when you start the IIS services. |

9. Restart IIS. At the command prompt, type **iisreset /start**, and then press ENTER. The command prompt displays the following:

```
Attempting start...

Internet services successfully started
```

If the IIS services do not restart, repeat these steps beginning at step 4, and copy a different set of history files over the current metabase files.

**Related Information**

- For more information about metabase history files, see Backing Up and Restoring the Metabase in IIS 6.0.
- For more information about metabase key names and paths, property inheritance, security, and reliability, see Metabase Structure in IIS 6.0.

# Backing Up the Metabase with Backup Files

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Using the configuration backup/restore feature, you can generate complete backup copies of the IIS metabase. You can create backup files using either IIS Manager or a command-line administration script. For information about backing up and restoring the metabase using scripts, see Backing Up IIS Configurations Using Iisback.vbs.

| **Note** |
| --- |
| The metabase is locked while the backup is in progress. |

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:** *Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

### To back up the IIS metabase

1. In IIS Manager, right-click the local computer, point to **All Tasks**, and click **Backup/Restore Configuration**.
2. Click **Create Backup** and type a name for the backup file in the **Configuration backup name** box. Note that the backup name is not case-sensitive.
3. Optional: If you want to create a secure backup (for portability between computers), select the **Encrypt backup using password** check box, type a password in the **Password** box, and then type the same password in the **Confirm password** box.
4. Click **OK**.

**Related Information**

- For information about backing up and restoring the IIS metabase using a command-line administration script, see Managing IIS Configurations Using Scripts
- For more information about backing up the metabase, see Backing Up and Restoring the Metabase in IIS 6.0.
- For more information about the initial metabase configuration backup, see Backing Up IIS Configurations Using Iisback.vbs.

# Restoring the Metabase with Backup Files

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS administrators can restore backup files using either IIS Manager or a command-line administration script. You can restore a metabase backup to the same computer on which the backup was made, or onto a different computer. For information about restoring the metabase using scripts, see Restoring IIS Configurations Using Iisback.vbs.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To restore an IIS metabase backup**

1. In IIS Manager, right-click the local computer, point to **All Tasks**, and click **Backup/Restore Configuration**.
2. In the **Backups** list, click the backup you want to restore and click **Restore**.

   | **Note** |
   | --- |
   | If you want to restore IIS to its initial configuration, restore the backup named **Initial Backup** (created automatically by IIS setup). |

3. Read the message that appears and click **Yes** if you want to continue.
4. If you are restoring a secure backup, you are prompted for the password you typed when the backup was created. Type the password and click **OK**. Note that passwords are case sensitive.
5. Click **OK**.

| **Important** |
| --- |
| Before restoring a metabase from one computer to a different computer, you must first delete the computer-specific information from the metabase file. See "Related Information" below. |

**Related Information**

- For information about backing up and restoring the IIS metabase using a command-line administration script, see Managing IIS Configurations Using Scripts.
- For more information about restoring the metabase using backup files, see Backing Up and Restoring the Metabase in IIS 6.0.
- For information about removing computer-specific information from a metabase copy, see Machine-Specific and System-Specific Information.

# Metabase Import and Export in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can copy elements of a metabase in order to clone applications or Web sites, or to produce a metabase template. These copied elements may be moved to another computer or added back to the metabase of the computer from which the elements were copied.

This section includes the following operational information:

- Exporting Metabase Elements with IIS Manager: Explains how to create export files for metabase elements using IIS Manager. Export files must be created before the import feature can be used.
- Importing Metabase Elements with IIS Manager: Explains how to import metabase element files using IIS Manager.
- Moving Sites and Applications to Another Computer in IIS 6.0: Discusses the procedure for creating a template of an import file and special considerations when importing and exporting sites and applications.

# Exporting Metabase Elements with IIS Manager

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the metabase import/export feature to create an export file, containing specifically selected elements of a metabase configuration file. This export file can later be imported into the metabase configuration file on the same computer or on another computer running a member of the Microsoft Windows Server™ 2003 family. To create an export file using a command-line script, see Exporting IIS Configurations Using Iiscnfg.vbs.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To export metabase elements**

1. In IIS Manager, double-click the **Local Computer**, right-click the application pool, Web site, FTP site, or virtual directory that you want to export, point to **All Tasks**, and then click **Save Configuration to a File**.
2. In the **File name** box, type the name that you want to give to your export file.
3. In the **Path** box, type or browse to the path for where you want the export file to be saved. For security purposes, select a folder on which you have already restricted access by setting strict Access Control with IIS 6.0 permissions. Any files created in such a folder inherit the access control list (ACL).
4. If you want to encrypt your export file for increased security, select the **Encrypt configuration using password** check box, and type a strong password in the **Password** and **Confirm password** boxes.
5. Click **OK** and verify that your export file has been created.

**Related Information**

- For more information about exporting an IIS configuration, see Exporting IIS Configurations Using Iiscnfg.vbs.
- For more information about importing an IIS configuration, see Importing IIS Configurations Using Iiscnfg.vbs.
- For more information about metabase backup and restore, see Backing Up and Restoring the Metabase in IIS 6.0.

# Importing Metabase Elements with IIS Manager

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you have created a metabase export file, you can import that file into the metabase configuration file on the same computer or another computer running a member of the Microsoft Windows Server™ 2003 family. To import a file by using a command-line script, see Importing IIS Configurations Using Iiscnfg.vbs.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To import metabase elements**

1. Before importing metabase elements from a file, make sure you have removed or changed all machine- and system-specific information. For more information, see Machine-Specific and System-Specific Information.
2. In IIS Manager, double-click the **Local Computer**; right-click the Web site, FTP site, virtual directory, or application pool node to which you want to import configuration data; point to **New**; and then, depending on the type of node to which you want to import configuration data, click **Web Site (from file)**, **FTP Site (from file)**, **Virtual Directory (from file)**, or **Application Pool (from file)**.
3. In the **File** box, type the path to your import file or click **Browse** to locate it.
4. Click **Read File**, click the object whose configuration you want to import, and then click **OK**.
5. If the element already exists in the metabase, the following message appears: This <*element*> already exists. You can choose **Create a new** <*element*> or **Replace the existing** <*element*>, and then click **OK**. Note that if you choose to replace the existing element, you lose all previous configuration settings.

**Related Information**

- For more information about exporting an IIS configuration, see Exporting IIS Configurations Using Iiscnfg.vbs.
- For more information about importing an IIS configuration, see Importing IIS Configurations Using Iiscnfg.vbs.
- For more information about metabase backup and restore, see Back Up and Restore the IIS Metabase.

# Moving Sites and Applications to Another Computer in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the metabase export feature to configure multiple computers with the same basic IIS configuration settings. The procedures below illustrate how to create complete metabase templates for porting the World Wide Web Publishing Service (WWW service), or elements of a metabase, to another computer.

The first procedure below creates a complete, system-independent copy of the metabase configuration and saves it to a file. The file can then be imported to other IIS 6.0 servers without overwriting or conflicting with settings on the target system. The second procedure below creates a template for importing elements of a configuration to another computer.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any known parameters). |

**Procedures**

**To port an entire system-independent metabase configuration to another computer**

1. Open a command prompt, and switch to the systemroot\system32 directory.
2. Type **cscript iiscnfg.vbs /export /f** *path******filename***.xml /d** *password* **/sp**, and press ENTER.
3. Copy the .xml file you created to a temporary directory on the target system.
4. On the target system, open a command prompt and switch to the systemroot\system32 directory.
5. Type **cscript iiscnfg.vbs /import /f** *path******filename***.xml /d** *password* **/sp / /dp / /children /inherited /merge**, and press ENTER.
6. Before relying upon the imported elements in a production mode, test your computers after importing metabase elements.

**To port metabase elements to another computer**

1. Configure an IIS server to the state that you want ported to other computers.
2. Export a metabase element to a file, either using IIS Manager; the Exporting IIS Configurations Using Iiscnfg.vbs that is included with IIS; a custom script using the **IIsComputer.Export** method of the Windows Management Instrumentation (WMI) provider for IIS or the **Export** method of the Active Directory Services Interfaces (ADSI) provider for IIS; or a custom application using Admin Base Objects (ABO). For more information about these methods, see Using IIS Programmatic Administration in the IIS Software Development Kit (SDK) on MSDN.

   | **Note** |
   | --- |
   | IIS Manager includes inherited settings by default. If you are not using IIS Manager, you can specify the inherit flag if you want to include all inherited settings. |

3. Clean up the export file by removing or changing all the machine- and system-specific information, and removing all other settings that you do not want applied to other computers. The cleaned-up export file becomes your import file.
4. On the new computers, create any physical folders that are needed for site and virtual directory paths, copy any content files (.asp files, ISAPIs, and so on) that need to be ported, and register any components that were copied over.
5. Import your file onto each computer to which you want to apply the settings. Make sure to use the merge flag if you do not want settings in the import file to overwrite any existing settings on the computer. Choose the inherit flag if you used it to create the export file.

6. Before relying upon the imported elements in a production mode, test your computers after importing metabase elements.

**Related Information**

- For more information about importing an IIS configuration, see Importing IIS Configurations Using Iiscnfg.vbs.
- For more information about exporting an IIS configuration, see Exporting IIS Configurations Using Iiscnfg.vbs.
- For more information about behaviors of imported or exported metabases, see Metabase Import/Export Behavior.
- For more information about metabase import and export options, see Managing IIS Configurations Using Scripts.

# Auditing the Metabase

Updated: August 22, 2005

Applies To: Windows Server 2003 R2, Windows Server 2003 with SP1

Beginning with the SP1 release, IIS 6.0 features metabase auditing to allow tracking of each change that is made to the metabase. Changes to the metabase are recorded under the IIS-metabase event source in the NT Security log as follows:

- What was changed (metabase node, property, and old and new values).
- When the change was made (date and time).
- Who made the change (domain and user name).
- Success or failure of the change attempt (HRESULT).

Metabase auditing is disabled by default. Enabling metabase auditing requires these tasks:

- Globally enable object auditing in Windows Server 2003.
- Enable metabase auditing for IIS 6.0 SP1.

**Procedures**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName***"mmc systemroot\system32\inetsrv\iis.msc"**. |

**To globally enable object auditing in Windows Server 2003**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **gpedit.msc**, and then click **OK**.
3. In the Group Policy Editor, expand **Local Computer Policy**, and then click **Computer Configuration**/**Windows Settings/Security Settings/ Local Policies/Audit Policy**.
4. Double click **Audit object access**.
5. Check both **Success** and **Failure** check boxes.
6. Click **OK**.

To globally disable object auditing, repeat steps, and then clear the **Success** and **Failure** check boxes.

**To enable or disable metabase auditing**

1. From the **Start** menu, open the command-line window.
2. Enter one of the following commands to execute the script, iiscnfg.vbs, filling in the path to the metabase location:

   **iiscnfg /enableAudit** *path*

   **iiscnfg /disableAudit** *path*

   For example, to enable metabase auditing on a Web virtual directory, “MyVdir”, type:

   **c:\%systemroot%\system32\iiscnfg.vbs /enableAudit W3SVC/1/ROOT/MyVdir**

For example, to enable metabase auditing on the entire metabase, type:**c:\%systemroot%\system32\iiscnfg.vbs /enableAudit** */ /r*

3. Press **Enter**.

**To verify that metabase auditing is working**

1. Change a metabase setting.
2. In the NT Security event log, verify that the change to the metabase is recorded under the event-source name "IIS-metabase."

For more information about metabase auditing, see Metabase Auditing.

For more information about event messages produced by metabase auditing, see Metabase Auditing Event Messages.

# Web Site Administration

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Suppose you just deployed an expensive, new Web site only to discover that a company logo was omitted from all of the site's pages. Or, imagine that you are suddenly asked to route thousands of users to alternate Web sites while technicians scramble to troubleshoot a malfunctioning computer. Such issues only begin to hint at the day-to-day challenges of successfully managing a Web site. And although effective Web site management ultimately depends on an administrator's skill, there are a number of basic tools and procedures that you can use to deal with the most common management tasks and emergencies.

**Getting Started**

To begin with, you should set up your Web sites by indicating which directories contain the documents that you want to publish. The Web server cannot publish documents that are not within these specified directories. So, the first step in deploying a Web site should be to first determine how you want your files organized. You then use IIS Manager to identify which directories are part of the site.

If you want to get started right away without having to create a special directory structure and your files are all located on the same hard disk of the computer running Internet Information Services (IIS), you can publish your documents immediately by copying your Web files into the default home directory, *LocalDrive*:\Inetpub\Wwwroot. (For an FTP site, copy your files into *LocalDrive*:\Inetpub\Ftproot.) Intranet users then can access these files with the following URL: http*://servername/filename*. To learn how to host multiple sites and organize disparate Web content, see the procedures in this section. They explain such things as how to change the default location of your files and how to add directories that are located on other hard disks or on computers across the network.

**Home Directories**

Each Web or FTP site must have one home directory. The *home directory* is the central location for your published pages. It contains a home page or index file that welcomes visitors and contains links to other pages in your site. The home directory is mapped to your site's domain name or to your server name. For example, if your site's Internet domain name is www.microsoft.com and your home directory is C:\Website\Microsoft, then browsers use the URL http://www.microsoft.com to access files in your home directory. On an intranet, if your server name is AcctServer, then browsers use the URL http://acctserver to access files in your home directory.

A default home directory is created when you install IIS, and when you create a new Web site. For instructions to change the home directory, see Setting Home Directories.

**Virtual Directories**

To publish from any directory not contained within your home directory, you must create a *virtual directory*. A virtual directory is a directory that is not contained in the home directory but appears to client browsers as though it were.

A virtual directory has an *alias*, or a name that Web browsers use to access that directory. Because an alias is usually shorter than the path name of the directory, it is more convenient for users to type. An alias is more secure because users do not know where your files are physically located on the server and cannot use that information to modify your files. Aliases make it easier for you to move directories in your site. Rather than changing the URL for the directory, you change the mapping between the alias and the physical location of the directory.

For example, suppose you are setting up a Web site for your marketing team on your company's intranet. The following table shows the mapping between the physical location of the files and the URL that accesses the files.

| Physical Location | Alias | URL |
|---|---|---|
| C:\Inetpub\Wwwroot | *home directory* (none) | http://SampleWebSite |
| \\Server2\SalesData | Customers | http://SampleWebSite/Customers |
| D:\Inetpub\Wwwroot\Quotes | None | http://SampleWebSite/Quotes |
| D:\Inetpub\Wwwroot\OrderStatus | None | http://SampleWebSite/OrderStatus |
| D:\Marketing\PublicRel | PR | http://SampleWebSite/PR |

Both virtual directories and physical directories (directories without an alias) appear in IIS Manager. A virtual directory is indicated by a wheel icon. The following illustration shows the Web site example described above, where /Customers and /PR

are virtual directories.

For a simple Web site, you might not need to add virtual directories. You can simply place all of your files in the site's home directory. If you have a complex site or want to specify different URLs for different parts of your site, you can add virtual directories as needed.

**Reroute Requests with Redirects**
When a browser requests a page on your Web site, the Web server locates the page identified by the URL and returns it to the browser. When you move a page on your Web site, you can't always correct all of the links that refer to the old URL of the page. To make sure that browsers can find the page at the new URL, you instruct the Web server to give the browser the new URL. The browser uses the new URL to request the page again. This process is called "redirecting a browser request" or "redirecting to another URL." Redirecting a request for a page is similar to using a forwarding address with a postal service. The forwarding address ensures that letters and packages addressed to your original residence are delivered to your new residence.

Redirecting a URL is useful when you are updating your Web site and want to make a portion of the site temporarily unavailable, or when you have changed the name of a virtual directory and want links to files in the original virtual directory to access the same files in the new virtual directory.

**Server-Side Includes**
Often, it can be useful to dynamically alter Web content after the content has been requested, but before it gets returned to the browser. IIS includes a feature called server-side includes that provides this functionality.

Using server-side includes (SSI), you can carry out a number of of Web site management activities from adding dynamic time stamps to running a special shell command each time a file is requested. SSI commands, called *directives*, are added to Web pages at design time. When a page is requested, the Web server parses out all the directives it finds in a Web page and then executes them. A commonly used SSI directive inserts, or *includes*, the contents of a file into a Web page. For example, if you are required to continually update a Web page advertisement, you could use SSI to include the advertisement's HTML source in the Web page. To update the advertisement, you need only modify the file containing the advertisement's HTML source. You do not have to know a scripting language to use SSI; simply follow the correct directive syntax.

**ASP and ASP .NET**
ASP is a server-side scripting environment that you can use to create dynamic and interactive Web pages, and build powerful Web applications. When the application server receives a request for an ASP file, it processes server-side script code contained in the file to build the HTML Web page that is sent to the browser. In addition to server-side script code, ASP files can contain HTML (including related client-side scripts) as well as calls to COM components that perform a variety of tasks, such as connecting to a database or processing business logic. ASP requires you to use a scripting language, such as VBScript or JScript.

ASP .NET is the next generation of the Microsoft server-side scripting environment. It provides a new programming model and infrastructure, enabling Web developers to build and deploy enterprise-class Web applications that are more secure, scalable, and stable than ever before.

# About Web Site Administration

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Suppose you just deployed an expensive, new Web site only to discover that a company logo was omitted from all of the site's pages. Or, imagine that you are suddenly asked to route thousands of users to alternate Web sites while technicians scramble to troubleshoot a malfunctioning computer. Such issues only begin to hint at the day-to-day challenges of successfully managing a Web site. And although effective Web site management ultimately depends on an administrator's skill, there are a number of basic tools and procedures that you can use to deal with the most common management tasks and emergencies.

**Getting Started**

To begin with, you should set up your Web sites by indicating which directories contain the documents that you want to publish. The Web server cannot publish documents that are not within these specified directories. So, the first step in deploying a Web site should be to first determine how you want your files organized. You then use IIS Manager to identify which directories are part of the site.

If you want to get started right away without having to create a special directory structure and your files are all located on the same hard disk of the computer running Internet Information Services (IIS), you can publish your documents immediately by copying your Web files into the default home directory, *LocalDrive*:\Inetpub\Wwwroot. (For an FTP site, copy your files into *LocalDrive*:\Inetpub\Ftproot.) Intranet users then can access these files with the following URL: http*://servername/filename*. To learn how to host multiple sites and organize disparate Web content, see the procedures in this section. They explain such things as how to change the default location of your files and how to add directories located on other hard disks or on computers across the network.

**Home Directories**

Each Web or FTP site must have one home directory. The *home directory* is the central location for your published pages. It contains a home page or index file that welcomes visitors and contains links to other pages in your site. The home directory is mapped to your site's domain name or to your server name. For example, if your site's Internet domain name is www.microsoft.com and your home directory is C:\Website\Microsoft, then browsers use the URL http://www.microsoft.com to access files in your home directory. On an intranet, if your server name is AcctServer, then browsers use the URL http://acctserver to access files in your home directory.

A default home directory is created when you install IIS, and when you create a new Web site. For instructions to change the home directory, see Setting Home Directories.

**Virtual Directories**

To publish from any directory not contained within your home directory, you must create a virtual directory. A *virtual directory* is a directory that is not contained in the home directory but appears to client browsers as though it were.

A virtual directory has an *alias*, or a name that Web browsers use to access that directory. Because an alias is usually shorter than the path name of the directory, it is more convenient for users to type. An alias is more secure because users do not know where your files are physically located on the server and cannot use that information to modify your files. Aliases make it easier for you to move directories in your site. Rather than changing the URL for the directory, you change the mapping between the alias and the physical location of the directory.

For example, suppose you are setting up a Web site for your marketing team on your company's intranet. The following table shows the mapping between the physical location of the files and the URL that accesses the files.

| Physical Location | Alias | URL |
|---|---|---|
| C:\Inetpub\Wwwroot | *home directory* (none)" | http://SampleWebSite |
| \\Server2\SalesData" | Customers | http://SampleWebSite/Customers |
| D:\Inetpub\Wwwroot\Quotes | *None* | http://SampleWebSite/Quotes |
| D:\Inetpub\Wwwroot\OrderStatus | *None* | http://SampleWebSite/OrderStatus |
| D:\Marketing\PublicRel | PR | http://SampleWebSite/PR |

Both virtual directories and physical directories (directories without an alias) appear in IIS Manager. A virtual directory is indicated by a wheel icon. The following illustration shows the Web site example described above, where /Customers and /PR

are virtual directories.

For a simple Web site, you might not need to add virtual directories. You can simply place all of your files in the site's home directory. If you have a complex site or want to specify different URLs for different parts of your site, you can add virtual directories as needed.

**Reroute Requests with Redirects**

When a browser requests a page on your Web site, the Web server locates the page identified by the URL and returns it to the browser. When you move a page on your Web site, you can't always correct all of the links that refer to the old URL of the page. To make sure that browsers can find the page at the new URL, you instruct the Web server to give the browser the new URL. The browser uses the new URL to request the page again. This process is called "redirecting a browser request" or "redirecting to another URL." Redirecting a request for a page is similar to using a forwarding address with a postal service. The forwarding address ensures that letters and packages addressed to your original residence are delivered to your new residence.

Redirecting a URL is useful when you are updating your Web site and want to make a portion of the site temporarily unavailable, or when you have changed the name of a virtual directory and want links to files in the original virtual directory to access the same files in the new virtual directory.

**Server-Side Includes**

Often, it can be useful to dynamically alter Web content after the content has been requested, but before it gets returned to the browser. IIS includes a feature called server-side includes that provides this functionality.

Using server-side includes (SSI), you can carry out a number of of Web site management activities from adding dynamic time stamps to running a special shell command each time a file is requested. SSI commands, called *directives*, are added to Web pages at design time. When a page is requested, the Web server parses out all the directives it finds in a Web page and then executes them. A commonly used SSI directive inserts, or *includes*, the contents of a file into a Web page. For example, if you are required to continually update a Web page advertisement, you could use SSI to include the advertisement's HTML source in the Web page. To update the advertisement, you need only modify the file containing the advertisement's HTML source. You do not have to know a scripting language to use SSI; simply follow the correct directive syntax.

**ASP and ASP .NET**

ASP is a server-side scripting environment that you can use to create dynamic and interactive Web pages, and build powerful Web applications. When the application server receives a request for an ASP file, it processes server-side script code contained in the file to build the HTML Web page that is sent to the browser. In addition to server-side script code, ASP files can contain HTML (including related client-side scripts) as well as calls to COM components that perform a variety of tasks, such as connecting to a database or processing business logic. ASP requires you to use a scripting language, such as VBScript or JScript.

ASP .NET is the next generation of the Microsoft server-side scripting environment. It provides a new programming model and infrastructure, enabling Web developers to build and deploy enterprise-class Web applications that are more secure, scalable, and stable than ever before.

# Naming Web Sites

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

A server running IIS can host multiple Web sites. Each Web site is said to be running on a virtual server. Each virtual Web site has a descriptive name and can support one or more host header names. Host header names make it possible to host multiple domain names on one computer.

You can have multiple server certificates, multiple IP addresses, and multiple SSL ports per server.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To name a Web site**

1. In IIS Manager, expand the local computer, right-click the Web site, and click **Properties**.
2. On the **Web Site** tab, in the **Description** box, type a descriptive name for the site, and then click **OK**.

**To assign a host header name to a Web Site**

1. Ask your system administrator to add the new site name mapping for your static IP address to your name resolution system (typically DNS).
2. In IIS Manager, right-click the Web site to which you which you want to assign a host header name, and click **Properties**.
3. On the **Web Site** tab, click **Advanced**.
4. Click **Add** to assign a host header name, IP address, and port for the Web site.
5. Click **OK** twice.

**Note**

If you attempt to create a host header for a Web site containing a Unicode character, you will receive an error indicating that you must only use standard characters. This is because the Domain Name System (DNS) standard does not recognize Unicode characters.

**Related Information**

- For more information about using host header names, see Creating Multiple Sites Using Host Header Names.

# Starting and Stopping Web Sites

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

By default, sites start automatically when your computer starts. Stopping a site does not interfere with other Internet services that are running. Pausing a site prevents the site from accepting new connections but does not affect requests that are already being processed. Starting a site resumes Internet services for the site.

You can start, stop, or pause a Web site using either IIS Manager or a command-line administration script. Both methods are detailed below.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To start, stop, or pause a Web site using IIS Manager**

- In IIS Manager, right-click the site you want to start, stop, or pause; and click **Start**, **Stop**, or **Pause**.

**Note**

If a site stops unexpectedly, IIS Manager might not correctly indicate the state of the site. In IIS, right-click the **Web Sites** folder and click **Refresh** to see the current state of all Web sites.

**Important**

You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters).

**To start, stop, or pause a Web site using a command-line administration script**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd**, and click **OK**.
3. At the command prompt, type **cscript iisweb.vbs /***action* **"***WebSiteName***"** and press ENTER. Substitute start, stop, or pause for *action*. Substitute your actual Web site name (for example "Default Web Site") for *WebSiteName*.

**Related Information**

- For information about restarting all of your Internet services, see Restarting IIS.
- To quickly establish a site that uses the default settings, see Site Setup.
- To change properties on existing Web sites, see Changing Default Web Site Settings Web site.

# Working with MIME Types

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Multipurpose Internet Mail Extensions (MIME) types instruct a Web browser or mail application how to handle files received from a server. For example, when a Web browser requests an item on a server, it also requests the MIME type of the object. Some MIME types, like graphics, can be displayed inside the browser. Others, such as word processing documents, require an external helper application to be displayed.

When IIS delivers a mail message to a mail application, or a Web page to a client Web browser, it also sends the MIME type of the data it is sending. If there is an attached or embedded file in a specific format, IIS also tells the client application the MIME type of the embedded or attached file. The client application then knows how to process or display the data being received from IIS.

IIS serves only files with known extensions registered in the MIME types list or with the operating system. IIS allows you to configure additional MIME types and change or remove MIME types. Removing a MIME type in IIS does not block access to that MIME type by other applications if it is also registered with the operating system.

IIS is preconfigured to recognize a default set of global MIME types. These MIME types are recognized by all Web sites you create in IIS. MIME types can also be defined at the Web site and directory levels, independent of one another or the types defined globally. When you view MIME types at the Web site or directory level, only the types unique to that level are displayed, not all types inherited from the next level up.

| **Note** |
| --- |
| If you apply a MIME type at the global level after modifying the same MIME type at a lower level, the global-level MIME type overrides the modified MIME type at the lower level. |

| **Note** |
| --- |
| IIS returns a 404.3 error if a client request refers to a file name extension that is not defined in the MIME types. |

**In This Section**

This section contains the following information:

- Viewing Available MIME Types: Explains how to view available MIME types by using IIS Manager and Adsutil.vbs.
- Creating Global MIME Types: Explains how to add MIME types at the global level in IIS.
- Creating MIME Types for a Web site or directory: Explains how to add MIME types at the Web site or directory level in IIS.
- Editing Global MIME Types: Explains how to edit MIME types at the global level in IIS.
- Editing MIME Types for a Web site or directory: Explains how to edit MIME types at the Web site or directory level in IIS.
- Removing Global MIME Types: Explains how to remove MIME types at the global level in IIS.
- Removing MIME Types from a Web site or directory: Explains how to remove MIME types at the Web site or directory level in IIS.

# Viewing Available MIME Types

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

To help prevent attackers from sending files that could compromise the security of your Web server, the IIS static file handler serves only the files that are explicitly listed in the list of Multipurpose Internet Mail Extensions (MIME) types. IIS is preconfigured to recognize a default set of global MIME types that are recognized by all of the Web sites that you create with IIS.

**Procedures**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To see a list of all available MIME types by using IIS Manager**

1. In IIS Manager, right-click the local computer, and then click **Properties**.
2. In **MIME types**, click **MIME Types**.

   The registered MIME types are displayed in **Registered MIME types (file extensions)**. You can add, change, or remove MIME types from the list.

**To see a list of all available MIME types by using Adsutil.vbs**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd**, and then click **OK**.
3. At the command prompt, switch to the *drive*\Inetpub\AdminScripts directory.
4. Type the following at the command prompt and then press ENTER:

   **cscript.exe adsutil.vbs enum /Mimemap**

**Related Sections**

- For more information about MIME types, see MIME Types.
- For more information about adding, editing, or removing MIME types, see Working with MIME Types.

# Creating Global MIME Types

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you have MIME types that you want all of your Web sites to recognize, you can add the new MIME types at the global level in IIS.

| **Important** |
| --- |
| You can also configure IIS to serve undefined file types by adding a wildcard character (*) MIME type. Do not use wildcard MIME-types on production servers. Doing so can result in IIS serving unrecognized files and displaying sensitive information to users. Wildcard MIME-types are intended for testing purposes or in scenarios where Internet Server API (ISAPI) filters have been developed specifically to handle these wildcard scenarios, for example, a custom authentication ISAPI. |

**Procedures**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

### To add a global MIME type

1. In IIS Manager, expand the local computer, right-click the computer on which you want to add a MIME type, and click **Properties**.
2. Click **MIME Types**.
3. Click **New**.
4. In the **Extension box**, type the file name extension.
5. In the **MIME type** box, type a valid MIME type.

   To create a MIME type for an undefined MIME type, type an asterisk (*****) in the **Extension** box, and type **application/octet-stream** in the **MIME type** box.

   To create a MIME type for a file without an extension, type a period (**.**) in the **Extension** box, and type your MIME type in the **MIME type** box.
6. Click **OK**.

# Creating MIME Types for a Web site or directory

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you have MIME types that you want a particular Web site or directory to recognize, you can add the new MIME types at the Web site or directory level in IIS.

| **Important** |
| --- |
| You can also configure IIS to serve undefined file types by adding a wildcard character (*****) MIME type. Do not use wildcard MIME-types on production servers. Doing so can result in IIS serving unrecognized files and displaying sensitive information to users. Wildcard MIME-types are intended for testing purposes or in scenarios where Internet Server API (ISAPI) filters have been developed specifically to handle these wild card scenarios, for example, a custom authentication ISAPI. |

**Procedures**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To add a MIME type to a Web site or directory**

1. In IIS Manager, right-click the Web site or Web site directory for which you want to add a MIME type, and click **Properties**.
2. Click the **HTTP Headers** tab.
3. Click **MIME Types**.
4. Click **New**.
5. In the **Extension** box, type the file name extension.
6. In the **MIME type** box, type a valid MIME type. If you define a MIME type that has already been defined at a higher level, you are prompted to select the level where the MIME type should reside.

   To create a MIME type for an undefined MIME type, type an asterisk (*****) in the **Extension** box, and type **application/octet-stream** in the **MIME type** box.

   To create a MIME type for a file without an extension, type a period (**.**) in the **Extension** box, and type your MIME type in the **MIME type** box.
7. Click **OK**.

The following illustration shows the relationship between a MIME type defined in IIS and a file type defined on a client computer.

New MIME type being defined in IIS.

Matching File Type and Application defined on client.

# Editing Global MIME Types

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you need to make changes to global MIME types, you can edit them at the global level in IIS.

**Procedures**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To edit a global MIME type**

1. In IIS Manager, expand the local computer, right-click the computer on which you want to edit a MIME type, and click **Properties**.
2. Click **MIME Types**.
3. Select the item you want to edit from the **Registered MIME types (file extensions)** list.
4. Click **Edit**.
5. Edit the information in the **Extension** and **MIME type** boxes as necessary.
6. Click **OK**.

# Editing MIME Types for a Web site or directory

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you need to make changes to MIME types recognized by a particular Web site or directory, you can edit them at the Web site or directory level in IIS.

**Procedures**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To edit a MIME type for a Web site or directory**

1. In IIS Manager, right-click the Web site or Web site directory for which you want to add a MIME type, and click **Properties**.
2. Click the **HTTP Headers** tab.
3. Click **MIME Types**.
4. Select the item you want to edit from the **Registered MIME types (file extensions)** list.
5. Click **Edit**.
6. Edit the information in the **Extension** and **MIME type** boxes as necessary.
7. Click **OK**.

# Removing Global MIME Types

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you want to globally restrict IIS from serving files with certain extensions, you can remove the related MIME types from the global list of registered MIME types in IIS Manager.

If you use IIS Manager to remove a MIME type mapping, you must also verify that the MIME type does not exist in the registry at HKEY_CLASSES_ROOT*extension*. If the MIME type also exists in the registry, you must remove it. If the MIME type continues to exist in the registry, files with that extension continue to be served. Be aware, however, that if you remove a MIME type mapping from the registry, other applications may be affected, because the registry database is shared by multiple applications.

**Procedures**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

### To remove a Global MIME type

1. In IIS Manager, expand the local computer, right-click the computer on which you want to add a MIME type, and click **Properties**.
2. Click **MIME Types**.
3. From the **Registered MIME types** list, click the MIME type you want to remove, and then click **Remove**.
4. Click **OK**.

**Related Information**

For information about the inheritance and merge behavior of MIME types, see MIME Types.

# Removing MIME Types from a Web site or directory

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you do not want to serve files with certain extensions from a Web site or directory, you can remove the related MIME types from the list of MIME types registered for that particular Web site or directory.

If you use IIS Manager to remove a MIME type mapping, you must also verify that the MIME type does not exist in the registry at HKEY_CLASSES_ROOT*extension*. If the MIME type also exists in the registry, you must remove it. If the MIME type continues to exist in the registry, files with that extension continue to be served. Be aware, however, that if you remove a MIME type mapping from the registry, other applications may be affected, because the registry database is shared by multiple applications.

**Procedures**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

### To remove a MIME type from a Web site or directory

1. In IIS Manager, right-click the Web site or Web site directory from which you want to remove a MIME type, and click **Properties**.
2. Click the **HTTP Headers** tab.
3. Click **MIME Types**.
4. From the **Registered MIME types** list, click the MIME type you want to remove, and then click **Remove**.
5. Click **OK**.

**Related Information**

For information about the inheritance and merge behavior of MIME types, see MIME Types.

# Changing Default Web Site Settings

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

During IIS installation, default values are set for the various properties assigned to Web sites. Properties can be set at the global level, affecting all Web sites on a server, on the individual site level, at the directory level, or at the file level. IIS uses an inheritance model, which means that settings on higher levels are automatically inherited by lower levels. Settings at lower levels can be edited individually to override inherited settings from the next level up.

If you change a setting at a lower level, then later change a setting at a higher level that conflicts with the lower level setting, you will be prompted to choose whether you want to change the lower-level setting to match the new higher-level setting.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set master properties for all sites assigned to a computer**

1. In IIS Manager, expand the local computer, right-click the **Web Sites** folder, and click **Properties**.
2. Click **Help** on any of the tabs for more information about those settings.

**To set properties for a single Web site**

1. In IIS Manager, right-click the Web site whose settings you want to change, and click **Properties**.
2. Click **Help** on any of the tabs for more information about those settings.

# Implementing Incremental Web Site Numbering

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In IIS 5.1 and earlier, IIS-generated Web site numbers incrementally. The first site was numbered 1, the second site numbered 2, and so on. Beginning with IIS 6.0, the default numbering scheme has changed. Upon installation of IIS 6.0, IIS generates a default Web site that is numbered 1. IIS then generates the Web site identification number, based on a hash of the site name, for any additional sites that you create.

You can retain the incremental numbering scheme of IIS 5.1 and earlier. This might be preferable if you have existing scripts, applications, or logging tools that rely on incremental site numbering.

See "Related Information" at the end of this topic for links to specific step-by-step procedures related to the general steps described.

| **Important** |
| --- |
| This topic contains information about modifying the registry. Using Registry Editor incorrectly can cause serious problems that require reinstalling the operating system. Because Registry Editor bypasses the standard safeguards that prevent you from entering settings that are conflicting or likely to degrade performance or damage your system, exercise caution when making changes to the registry. Microsoft cannot guarantee that problems resulting from the incorrect use of Registry Editor can be solved. For information about how to edit the registry, see the "Changing Keys and Values" topic in Registry Editor Help. |

**Procedures**

### Implementing Incremental Web Site Numbering on an Existing IIS 6.0 Installation

1. Enable incremental Web site numbering on your production IIS 6.0 server and on a staging IIS 6.0 server.
2. Export the entire metabase from the production server and import this metabase to the staging server.
3. Enable the metabase edit-while-running feature on the staging server, and then stop the World Wide Web Publishing service (WWW service).
4. Open the MetaBase.xml file on the staging server in Notepad or another plain text editor.
5. Find the first Web site that you want to renumber in the MetaBase.xml file. Perform a search-and-replace through the entire metabase, replacing every occurrence of the original Web site number with the incremental number that you want to assign to the site. Repeat the search-and-replace pass for all Web sites, incrementing each successive Web site number by 1.
6. Save the MetaBase.xml file and restart the WWW service.
7. Test your sites and Web applications by requesting content from each of them. If any failures occur, identify the cause and correct it. Most failures will likely result from leftover references to the original Web site number.
8. Disable edit-while-running (once debugging is complete), test the sites again for functionality, and then export the entire metabase from the staging server and import it onto the production server.
9. Restart the WWW service on your production server and then validate functionality by making a request to the home page of your main site.

| **Important** |
| --- |
| If you want to use incremental site numbering in IIS 6.0, it is best to enable incremental site numbering immediately after installing IIS 6.0, and before creating any new Web sites. This avoids the possibility of accidentally creating new Web sites with numbers out of sequence. |

### Notes

- Enabling incremental Web site numbering does not change the identification number of existing sites.

- If your server already contains Web sites that were created by using the IIS 6.0 default numbering scheme, and you enable incremental Web site numbering, the next site created will be numbered with the first unused incremental number. For example, if you enable incremental site numbering on a server with existing sites numbered 1, 2, 3, and 10, the next site number will be 4.

- When remotely administering a server running IIS 6.0 with incremental site numbering enabled, make sure that the server from which you are performing the remote administration also has incremental site numbering enabled. This is necessary because the value of the IncrementalSiteIDCreation registry entry on the system from which you are performing the administration determines how site identification numbers are generated on the IIS server being administered.

**Related Information**

- For information about the IncrementalSiteIDCreation registry entry, see Global Registry Entries.

- For information about how to enable metabase edit-while-running, see Enabling Edit-While-Running in IIS 6.0.

- For information about exporting and importing the metabase, see Exporting IIS Configurations Using Iiscnfg.vbs and Importing IIS Configurations Using Iiscnfg.vbs.

# Using Content Expiration

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you have time-sensitive information on your Web site, you can configure settings that will ensure that obsolete information isn't cached by proxies or Web browsers. You can configure Web site content to automatically expire at any time. When content expiration is enabled, the Web browser compares the current date to the expiration date to determine whether to display a cached page or request an updated page from the server. Server-side technology, such as Microsoft ASP.NET can be used to dynamically change the content served. Typically, time-sensitive information is limited to individual files, directories, or Web sites; however, you can also set content expiration for all Web sites on a computer.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set the expiration of Web site content**

1. In IIS Manager, double-click the local computer; right-click the **Web Sites** folder, an individual Web site folder, a virtual directory, or a file; and then click **Properties**.

   | **Note** |
   | --- |
   | Configuration settings made at the Web Sites level are inherited by all of the Web sites on the server. You can override inheritance by configuring the individual site or site element. |

2. Click the **HTTP Headers** tab.
3. Select the **Enable content expiration** check box.
4. Click **Expire immediately**, **Expire after**, or **Expire on**, and type the appropriate expiration information in the corresponding boxes.
5. Click **OK**.

To verify that expiration dates are working correctly, look for Not Modified messages in the HTTP response packet of your Network Monitor capture summary.

**Related Information**

- For more information about Web site settings, see Changing Default Web Site Settings.
- For information about additional ways to optimize performance, see Optimizing a Page-Load Performance Profile.

# Using Content Ratings

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure your Web server's content rating features to embed descriptive labels in HTTP headers of your Web page. Some Web browsers, such as Microsoft Internet Explorer 3.0 or later, can detect these content labels and help users to identify potentially objectionable Web content. Your Web server's default Platform for Internet Content Selection (PICS)-based rating system uses a system developed by the Internet Content Rating Association (ICRA), which rates content according to levels of violence, nudity, sexual content, and offensive language. Before setting your Web content ratings, you should complete a ICRA questionnaire to obtain the recommended content ratings for your particular Web content.

If you are running a publicly viewable Web site, it is good practice to have the content rated. Doing so does not automatically make your site unavailable to users because the users must also enable content ratings and set content thresholds on their client computer for the rating information to have any effect on their browsing experience.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set content ratings**

1. In IIS Manager, expand the local computer; right-click a Web site, directory, or file; and click **Properties**.
2. Click the **HTTP Headers** tab.
3. In the **Content rating** section, click **Edit Ratings**.
4. Click the **Ratings** tab and select the **Enable ratings for this content** check box.
5. In the **Category** list, click a ratings category. Drag or click the rating slider to set the level of potentially objectionable material for the category. Each setting displays a description of the rating level.
6. Under **E-mail address of person rating this content**, type the e-mail address of the person who rated the content.
7. Click the arrow next to the **Expire on** box and click a ratings expiration date from the calendar.
8. Click **OK**.

# Using Server-Side Include Directives

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Server-side include (SSI) directives instruct the Web server to insert various types of content into a Web page. These types of content can include the value of a server variable (sometimes called a CGI variable), the output of a shell command, a modification date and/or size of a file, or the contents of another file (when the #include statement is used). Directives can also include a string of SSI errors.

You can use SSI directives to instruct the Web server to include text, graphics, or application output into a Web page just before sending that information to the browser. You can use SSI to include, for example, a time/date stamp, a copyright notice, or a form for a customer to fill out and return. Including a file is an easy way to incorporate text or links to graphics that are repeated in many files. SSI provides special preprocessing directives that help you access information about a file or display the value of a server variable. SSI also provides a directive that you can use to insert the output from an application or a shell command into a Web page. Rather than adding the content or output to every file, you can save the content into an include file. The include files are called through a simple statement that instructs the Web server to insert the content or output into the applicable Web pages.

IIS processes SSI directives while it processes the Web page. When the Web server reaches an SSI directive, it inserts the contents of the include file, or the output of the application directly into the Web page. If the include file contains an SSI directive, that file or output is also inserted. In addition to the basic directive used to include a file, you can use SSI directives to insert information about a file (such as its size) or to run an application or a shell command.

By default, IIS is set to process server-side include files with the file name extensions .stm, .shtm, or .shtml, although you can configure other file name extensions to be processed as well. IIS also looks for and processes the #include directive in files with the .asp file name extension. Ensure that all files containing SSI directives have a defined SSI file name extension. Furthermore, SSI directives, as well as other script maps, work in any file whose file name extension is mapped to the ssinc.dll. If, for some reason, the extensions were deleted from the applications mappings list, use the procedure below to add the SSI file name extensions to the list.

Also be sure to put SSI files into a directory with Scripts or Execute access permissions. You should limit user access to this directory to avoid attacks by malicious users. For more information, see Access Control with IIS 6.0 and Setting NTFS Permissions for Directories or Files.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To enable server-side includes**

1. In IIS Manager, expand the local computer, right-click the **Web Sites** folder (to enable SSI on all Web sites) or right-click a specific Web site, and click **Properties**.
2. Click the **Home Directory** tab.
3. In the **Application settings** section, click **Configuration**.
4. On the **Mappings** tab, click **Add**.
5. In the **Add/Edit Application Extension Mapping** dialog box, enter all of the required information.
6. Click **OK**.

To disable server-side includes on your IIS Web server, you must remove SSI extensions from the application mappings list. If your Web server receives a request for a page and the SSI extension has been removed, IIS will not process the SSI directive within the page. You can disable the processing of server-side include directives on all Web sites or on a specific Web site.

**To disable server-side includes**

1. In IIS Manager, expand the local computer, right-click the **Web Sites** folder (to disable SSI on all Web sites) or right-click a specific Web site, and click **Properties**.
2. Click the **Home Directory** tab.
3. In the **Application settings** section, click **Configuration**.
4. On the **Mappings** tab, scroll down in the **Application Mappings** list, click the SSI extension you wish to disable, and then click **Remove**.
5. Click **OK**.

**Related Information**

- For information about enabling the execution of shell commands, see the SSIEnableCmdDirective section in WWW Service Registry Entries.
- For specific programmatic information about implementing server-side include directives, search for "ssi" on the Microsoft Developer Network (MSDN) Web site.

# Redirecting Requests to Files, Directories, or Programs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can redirect requests for files in one directory to a different directory, to a different Web site, or to a file in a different directory. When the browser requests the file from the original URL, the Web server instructs the browser to request the page from the redirected URL.

An advanced capability of the redirect method allows you to redirect all requests for files in a particular directory to a program. Generally speaking, you should also pass any parameters from the original URL to the program, which you can do by using redirect variables.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To redirect requests to another directory or Web site**

1. In IIS Manager, expand the local computer, right-click the Web site, virtual directory, or directory within a Web site to which you want to add a redirect, and click **Properties**.
2. Click the **Home Directory**, **Virtual Directory**, or **Directory** tab.
3. Under **The content for this resource should come from**, click **A redirection to a URL**.
4. In the **Redirect to** box, type the path to the destination directory or the URL of the Web site. For example, to redirect all requests for files in the /Catalog directory to the /NewCatalog directory on another Web site, type **http://***sitename***/NewCatalog**. The redirect must be to a fully qualified URL.
5. Set the required flags as specified below, and then click **OK**. More than one flag is allowed.
   - Select **The exact URL entered above** to indicate that the value provided for the destination is an absolute target location.
   - Select **A directory below this one** to indicate that redirection should occur only once, because the destination is in a subdirectory of the original URL. This setting also instructs IIS to redirect requests only if they are to subfolders or files of the original URL.
   - Select **A permanent redirection for this resource** to indicate that this redirection is permanent for this resource.
   - Clear **A permanent redirection for this resource** to indicate that this redirection is temporary for this resource.

**To redirect all requests to a single file**

1. In IIS Manager, right-click the Web site or directory, and click **Properties**.
2. Click the **Home Directory**, **Virtual Directory**, or **Directory** tab.
3. Under **The content for this resource should come from**, click **A redirection to a URL**.
4. In the **Redirect to** box, type the URL of the destination file. The redirect must be to a fully qualified URL.
5. Under **The client will be sent to**, select The exact URL entered above check box to prevent the Web server from appending the original file name to the destination URL.
6. Click **OK**.

You can use wildcards and redirect variables in the destination URL to precisely control how the original URL is translated into the destination URL.

**To redirect requests to a program**

1. In IIS Manager, right-click the Web site or directory, and click **Properties**.
2. Click the **Home Directory**, **Virtual Directory**, or **Directory** tab.
3. Under **The content for this resource should come from**, click **A redirection to a URL**.
4. In the **Redirect to** box, type the URL of the program, including any redirect variables needed to pass parameters to the program.

   For example, to redirect all requests for scripts in a Scripts directory to a logging program that records the requested URL and any parameters passed with the URL, type **/Scripts/Logger.exe?URL=$V+PARAMS=$P**. $V and $P are redirect variables.
5. Under **The client will be sent to**, select **The exact URL entered above** check box to prevent the Web server from appending the original file name to the destination URL.
6. Click **OK**.

**Related Information**

- For more information about writing redirection strings with variables and flags, see the Redirect Reference.

# Restarting IIS

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You might need to restart Internet Information Services (IIS) before certain configuration changes take effect or when applications become unavailable. Restarting IIS is the same as first stopping IIS, and then starting it again, except it is accomplished with a single command. There are two ways to restart IIS:

- Using IIS Manager.
- Using the **IISReset** command-line utility.

Both methods allow you to stop, start, and restart IIS Internet services. The **Restart IIS** command in IIS Manager and the **IISReset** command-line utility do not restart the HTTP protocol stack (HTTP.sys) or Internet services outside of IIS. In previous versions of IIS, restarting IIS using the **IISReset** command-line utility was a common practice for recovering from an unresponsive application.

Restarting or stopping IIS, or rebooting your Web server, is a severe action. When you restart the Internet service, all sessions connected to your Web server (including Internet, FTP, SMTP, and NNTP) are dropped. Any data held in Web applications is lost. All Internet sites are unavailable until Internet services are restarted. For this reason, you should avoid restarting, stopping, or rebooting your server if at all possible. IIS 6.0 includes application pool recycling and several other features that provide alternatives to restarting IIS. For a list of features designed to improve IIS reliability and remedy the need to restart IIS, see "Alternatives to Restarting IIS" in this topic.

| **Note** |
| --- |
| Changes to the metabase can be lost when restarting IIS. To avoid losing metabase changes and to trigger history files that back up the metabase, use the SaveData method. For more information about the SaveData method, see "SaveData" in the Platform SDK on MSDN. |

With IIS 6.0, the World Wide Web Publishing Service (WWW service) lives in the service host, Svchost.exe. The FTP, NNTP, and SMTP services and the IIS metabase, known as the IIS Admin service, lives in Inetinfo.exe. If the IIS Admin service terminates abnormally, IIS restarts automatically. This feature is known as Automatic Restart. Previously, in IIS 5.0, if the IIS Admin service terminated abnormally, both the WWW service and IIS Admin service had to be restarted because they shared the same application space. In IIS 6.0, if the IIS Admin service terminates abnormally, the WWW service does not go down because the IIS Admin service and the WWW service run in separate process spaces. In this case, the WWW service acknowledges that the metabase has terminated abnormally and checks to see if the **IISReset** command-line utility is configured on the IIS Admin service. If **IISReset** is configured on the IIS Admin service, IIS waits for the IIS Admin service to start again and reconnects the WWW service.

All of the Internet services listed below, if installed, are affected when you restart IIS. Not all of the services listed below are installed by default.

| **Service** | **Description** |
| --- | --- |
| IIS Admin service | This service manages all the services of IIS other than the WWW service (FTP, NMTP, and SMTP). |
| WWW service | This service provides Web connectivity between clients and Web sites. |
| HTTP SSL service | This service provides secure Web connectivity between clients and Web sites. |
| FTP service | This service provides FTP connectivity and administration through IIS Manager. |
| SMTP service | This service transports electronic mail across the network. |
| NNTP service | This service transports network news across the network. |

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To restart IIS using IIS Manager**

1. In IIS Manager, right click the local computer, point to **All Tasks**, then click **Restart IIS**.
2. In the **What do you want IIS to do** list, click **Restart Internet Services on** *computername*.
3. IIS attempts to stop all services before restarting. IIS waits up to five minutes for all services to stop. If the services cannot be stopped within five minutes, all IIS services are terminated, and IIS restarts. In addition, clicking **End now** forces all IIS services to stop immediately, and IIS is restarted.

**Caution**

If IIS is terminated before its services have stopped normally, data loss can result. If possible, back up your IIS configuration before restarting IIS. See Backing Up and Restoring the Metabase for information about backing up your IIS configuration.

**Important**

You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:***MyComputer***\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters).

**To restart IIS using the IISReset command-line utility**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd**, and click **OK**.
3. At the command prompt, type **iisreset /noforce** *computername*, and press ENTER.

   **Note**

   The **/noforce** parameter is recommended as a safeguard against data loss in case the IIS services cannot all be stopped within the one minute timeout period. If you are certain that it is safe to force IIS to restart, you can omit the **/noforce** parameter. In addition, if you are logged on locally, the *computername* parameter is not required. If you are administering an IIS server remotely, the *computername* parameter is the NetBIOS name of the computer on which you wish to restart IIS.

4. IIS attempts to stop all services before restarting. The **IISReset** command-line utility waits up to one minute for all services to stop. If the services cannot be stopped within one minute, all IIS services are terminated, and IIS restarts.

**Note**

You can adjust the timeout value using the **iisreset /timeout** command.

The IISReset command-line utility has several options available. For more information about the options available with the **IISReset** command-line utility, open a command-prompt window, and type **iisreset /?** You can also search for "iisreset" in Windows Help.

**Automatic Restart**

Automatic Restart is enabled by default for the IIS Admin service and WWW service. If a process within either service terminates abnormally, the service restarts automatically. The WWW service restarts using the **net start** command. The IIS

Admin service restarts using the **iisreset** command. These commands are issued internally without user intervention. You can disable Automatic Restart using the following procedures.

**To disable restart of IIS Admin service**

1. From the **Start** menu, right-click **My Computer**, and click **Manage**.
2. In the console tree, expand the **Services and Applications** node, and click **Services**.
3. Right-click **IIS Admin Service**, and click **Properties**.
4. Click the **Recovery** tab, and in the **First failure**, **Second failure**, and **Subsequent failures** list boxes, click **Take No Action**.
5. Click **OK**.

The following command can only be issued on the local machine.

**To disable restart of IIS Admin service from the command line**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd**, and click **OK**.
3. At a command prompt, type **iisreset /disable**, and press ENTER. This command disables IIS and prevents all **iisreset** calls from executing.

| **Note** |
| --- |
| To re-enable the IIS Admin service, at the command prompt, type **iisreset /enable**, and press ENTER. |

**To disable restart of the WWW service**

1. From the **Start** menu, right-click **My Computer**, and click **Manage**.
2. In the console tree, expand the **Services and Applications** node, and click **Services**.
3. Right-click **World Wide Web Publishing Service**, and click **Properties**.
4. Click the **Recovery** tab, and in the **First failure**, **Second failure**, and **Subsequent failures** list boxes, click **Take No Action**.
5. Click **OK**.

**Alternatives to Restarting IIS**

If you have to restart IIS often because of a faulty application, consider debugging or rewriting the application. To ensure that your applications do not interfere with other services and cause the need to restart IIS, it is recommended that you enable the following:

- Worker Process Isolation Mode in IIS 6.0: Worker process isolation mode is the default service mode in IIS. Worker process isolation mode delivers all the benefits of IIS 6.0 new architecture: robust application pooling, automated restarts, scalability, debugging, and precise performance tuning.
- Recycling Worker Processes with IIS 6.0: In worker process isolation mode, IIS can be configured to periodically restart worker processes in an application pool, allowing you to manage precisely those worker processes that are faulty.
- Configuring Rapid-Fail Protection in IIS 6.0: Worker process isolation mode can be configured so that if a particular application pool experiences consecutive multiple failures, the application can be automatically disabled, allowing for rapid-fail protection.
- Enabling CPU Monitoring in IIS 6.0: CPU monitoring is a tool for monitoring and automatically shutting down worker processes that consume large amounts of CPU time.

**Related Information**

- For more information about improving the performance of IIS network resources using related features like bandwidth throttling, HTTP Compression, and connection limits, see Administering Network Resources.

- For more information about configuring IIS to run Web applications and how to deal with reliability issues caused by Web applications, see Configuring Servers for Applications.

- For information about starting and stopping individual Web and FTP sites, see Starting and Stopping Web Sites.

# FTP Site Administration

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

Whether your site is on an intranet or the Internet, the principles of providing a place to upload and download files using FTP are the same. You place your files in directories on your FTP server so that users can establish an FTP connection and transfer files with an FTP client or FTP-enabled Web browser. But beyond simply storing files on your server, you must manage how your site is deployed, and more importantly, how your site evolves. This section presents the basics of managing the infrastructure of an FTP site, from securing your site to hosting multiple sites.

This version of Internet Information Services (IIS) includes Isolating FTP Users to help administrators, and particularly Internet hosting providers, efficiently secure and commercialize the FTP services for their customers.

The FTP service is not installed by default on the operating systems in the Microsoft Windows Server™ 2003 family. To install the FTP service, see FTP Site Setup.

This section includes the following information:

- Changing FTP Site Home Directories: Describes the concept of a home directory and methods for changing the home directory of an FTP site.
- Naming FTP Sites: Describes assigning a descriptive name to an FTP site.
- Setting FTP Messages and Directory Output Style: Describes the message and directory output options.
- Using Virtual Directories with FTP Sites: Describes the concept of a virtual directory and methods for creating and removing a virtual directory.
- Stopping and Starting FTP Sites: Describes why you would need to stop and restart your FTP sites and how to perform these actions.
- Changing Default FTP Site Settings: Describes how to change default settings globally or on an individual site.
- Creating Multiple FTP Sites: Describes how to use IP addresses or port numbers to differentiate multiple FTP sites.
- Adding FTP Sites to Your Server: Describes the process of adding a new FTP site to a server running IIS.
- Redirecting FTP Requests to Directories or Network Shares: Describes forwarding file requests to a different directory or network share.
- Modes and Data Transmission: Describes the different FTP connection and data transfer modes supported by IIS.
- Server-to-Server FTP Transfer: Describes how to configure IIS for server-to-server FTP transfer by changing the EnablePortAttack registry key. The topic also suggests using Web Distributed Authoring and Versioning (WebDAV) publishing as a file transfer alternative.
- Restarting FTP Uploads and Downloads: Describes the FTP **rest** command, which addresses the problem of losing a network connection while downloading a file.
- Securing FTP Sites: Describes some of the misconceptions about FTP security and how to establish a secure FTP site.
- Isolating FTP Users: Describes the concept of FTP user isolation and which type of isolation to use to restrict users to their own directories.

# Adding FTP Sites to Your Server

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

IIS enables you to create multiple FTP sites on a single server. To add a site to a server, you must prepare the server and associated network services, and create a unique identity for the site.

**Preparing to Add an FTP Site**

Adding an FTP site to a server that is already hosting an FTP site requires some preparation.

- Multiple FTP sites can use the same IP address. If you use a unique IP address to identify a new FTP site, however, you must obtain a static IP address from your organization or Internet service provider (ISP) and configure the TCP/IP settings on the server.

- Standard FTP services use TCP port 21 by default, and it is generally not recommended to use any other port for FTP services. However, if you use a nonstandard TCP port number to identify a new FTP site for special situations (typically used on private Web sites for development and testing purposes), select a TCP port number above 1023 so it does not conflict with well-known port numbers assigned by the Internet Assigned Numbers Authority.

- Use Windows Explorer to create a home directory for the FTP site content. Create subdirectories to store other content as needed. To organize home directories for multiple FTP sites on the same server, you can create a top-level directory for storing all home directories, and then create subdirectories for each site. You can create a home directory on the local server, or as a uniform naming convention (UNC) path on a network share. You can also create virtual directories that map to the physical directories.

**Adding an FTP Site**

IIS provides the following two methods for adding a new FTP site:

- IIS Manager.

- The Iisftp.vbs command-line administration script.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To add an FTP site through IIS Manager**

1. In IIS Manager, double-click the local computer, right-click the **FTP Sites** folder or a specific FTP site folder, point to **New**, and then click **FTP Site**.

2. In the FTP Site Creation Wizard, click **Next**.

3. In the **Description** box, type the name that you have selected for the FTP site, and then click **Next**.

4. Under **Enter the IP address to use for this FTP site**, click **All Unassigned** to allow FTP to respond to all unassigned IP addresses on the server, or click a specific IP address for the site.

   **Note**

In the FTP Site Creation Wizard, **All Unassigned** refers to IP addresses that are assigned to a computer but not assigned to a specific site. The default FTP site uses all of the IP addresses that are not assigned to other sites. Only one site can be set to use unassigned IP addresses for a given port number. For more information about how sites are identified, see Creating Multiple FTP Sites.

5. The TCP port is assigned to port 21 by default. To use a nonstandard port number to create a unique identity for a private FTP site, under **Type the TCP port for this FTP site**, type a new port number above 1023, and then click **Next**.
6. Click the appropriate user isolation method for this site, and then click **Next**.
7. In the **Path** box, type or browse to the path of your FTP site home directory, and then click **Next**.
8. Select **Read** permissions, or select **Read** and **Write** permissions for the site.
9. Click **Next**, and then click **Finish** to close the FTP Site Creation Wizard.

**Important**

You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:***MyComputer***\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters).

**To add an FTP site by using the Iisftp.vbs command-line administration script**

1. If the new FTP site will be in a new directory, create the new directory.
2. From the **Start** menu, click **Run**.
3. In the **Open** box, type **cmd**, and then click **OK**.
4. At the command prompt, switch to the **systemroot**\System32 directory.
5. Type the following, and then press ENTER:

   **cscript iisftp.vbs /create** *HomeDirectory* **"** *SiteDescription* **"** *IPAddress* **/b** *PortNumber*

   For example, the following command creates and starts an FTP site called MyFTPSite on port 21, which is at IP address 123.456.789 with C:\Inetpub\Ftproot\NewDirectory as its home directory:

   **cscript iisftp.vbs /create c:\inetpub\ftproot\newdirectory "myftpsite" /i 123.456.789 /b 21**.

**Note**

The Iisftp.vbs script supports many more options for creating an FTP site. To see the options available, search for "iisftp.vbs" in Help and Support Center for Windows Server 2003.

# Naming FTP Sites

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

A server running IIS can host multiple FTP sites. Each site runs on a virtual server, and each FTP site has a descriptive name.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To name an FTP site**

1. In IIS Manager, expand the **FTP Sites** folder, right-click the FTP site you want to name, and click **Properties**.
2. On the **FTP Site** tab, in the **Description** box, type a descriptive name for the site.
3. Click **OK**.

**Related Information**

- For information about installing the FTP service, see FTP Site Setup.
- For instructions about how to add new FTP sites, see Adding FTP Sites to Your Server.

# Using Virtual Directories with FTP Sites

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

Overview and procedures for creating and deleting virtual directories for FTP sites using IIS Manager and command-line scripts.

A virtual directory is a friendly name, or alias, either for a physical directory on your server hard disk that does not usually reside under the FTP site's home directory. The use of aliases is secure because users do not know where your files are physically located on the server relative to the FTP site's home directory, and therefore cannot use that information to attempt to modify your files. Aliases also make it easier for you to move directories in your site. Rather than changing the URL for the directory, you need only change the mapping between the alias and the physical location of the directory.

Another advantage of aliases is that you can publish content in multiple directories, to be accessed by all users, and control read/write permissions for each virtual directory separately. Even with User Isolation enabled, you can share public content by creating a virtual directory with access permission for all users.

If your FTP site contains files that are located in a directory other than the home directory, or on other computers, you must create virtual directories to include those files in your FTP site. To create a virtual directory that points to a physical directory on another computer, you must specify the full UNC path to the directory, and provide a user name and password for user rights.

If you want to publish from any directory not contained within your home directory, you must create a virtual directory. For example, suppose you are setting up a FTP site for your marketing team on your company's intranet. The following table shows an example of how you might construct the mapping between the physical location of the files and the URL that accesses the files.

| URL | Physical Location | Alias |
|---|---|---|
| ftp://SampleFTPSite | C:\Inetpub\Ftproot | home directory |
| ftp://SampleFTPSite/PR | C:\Marketing\PublicRel | PR |
| ftp://SampleFTPSite/PR/OldPR | C:\Documents\Old | OldPR |
| ftp://SampleFTPSite/PRPublic | C:\Documents\Public | PRPublic |
| ftp://SampleWebSite/Customers | //Server2/SalesData | Customers |

Both virtual directories and physical directories (directories without an alias) appear in IIS Manager. A modified folder icon indicates a virtual directory. The following illustration shows the FTP site example described above, where Customers, PR, and PRPublic are virtual directories.

You can also define nested virtual directories. For example, within the PR virtual directory, you can create another virtual directory, for example, named Oldpr. The content in Oldpr is accessible using the URL ftp://SampleFTPSite/PR/Oldpr.

**Note**

The FTP server does not include the names of any virtual directories when the content of the current working directory is requested by a client application. Physical directories, however, are listed.

**Important**

Access to the content of a virtual directory depends on the current working directory. For example, if a user is connected to the root directory of SampleFTPSite, assuming that the user has the necessary permissions, the user can change the working directory to the following paths: /PRPublic, /PR, /PR/Oldpr, and /Customers only if the user knows the site structure. For example, if the current working directory is /PRPublic, the user will receive an error message when attempting to change the working directory to /PR by typing the command **cwd /PR**, but will successfully change the working directory to /PR by typing the command **cwd ./PR**.

Also, a user can use a combination of physical directory names and virtual directory names to change the working directory. For example, assume that under the physical path to which the PR virtual directory is mapped, there is a physical folder named Test, and the current working directory is the root of SampleFTPSite. The user can change the working directory to the physical Test folder using the command **cwd PR/Test**.

For a basic FTP site, you can place all of your files in the site's home directory, and most likely do not need to add virtual directories. If you have a complex site, or want to specify different URLs for different parts of your site, you can add virtual directories as needed. To make a virtual directory accessible from multiple sites, you must add the virtual directory to each site.

There are two ways to create or delete a virtual directory:

- Using IIS Manager.
- Using the iisftpdr.vbs administration script.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To create a virtual directory using IIS Manager**

1. In IIS Manager, expand the local computer, expand the **FTP Sites** folder, expand the FTP site to which you want to add a virtual directory, right-click the site or folder within which you wish to create the virtual directory, point to **New**, and then click **Virtual Directory**.
2. Click **Next**.
3. In the **Alias** box, type a name for the virtual directory, and click **Next**. This is the name the user types, and should be short and easy to type.
4. In the **Directory** box, type or browse to the physical directory in which the virtual directory resides, and click **Next**.
5. Under **Allow the following permissions**, select the check boxes next to the access permissions appropriate to your needs, and click **Next**.
6. Click **Finish**. The virtual directory is created below the currently selected folder level.

**Important**

You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer***\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe***ScriptName* (include the script's full path and any parameters).

**To create a virtual directory using the Iisftpdr.vbs administration script**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd**, and click **OK**.
3. At the command prompt, type **cscript iisftpdr.vbs /create** *SampleFTPSite VirtualDirectoryName x*:****_path_, and press ENTER. Substitute your FTP site name, virtual directory name, and path to the physical directory as appropriate.

| **Note** |
| --- |
| Deleting a virtual directory does not delete the corresponding physical directory or files. |

**To delete a virtual directory using IIS Manager**

- In IIS Manager, expand the FTP site containing the virtual directory you want to delete, right-click the virtual directory, click **Delete**, and then click **Yes**.

| **Note** |
| --- |
| The below method does not work for root virtual directories. |

**To delete a virtual directory using the Iisftpdr.vbs administration script**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd**, and click **OK**.
3. At the command prompt, type **cscript iisftpdr.vbs /delete** *SampleFTPSite VirtualDirectoryName*, and press ENTER. Substitute Your FTP site name and virtual directory name as appropriate.

**Related Information**

- For information about installing the FTP service, see FTP Site Setup.
- For information about Security for virtual directories, see Securing Virtual Directories, and see Access Control with IIS 6.0.

# Changing Default FTP Site Settings

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

During installation of IIS, default values are set for the various properties assigned to FTP sites. Properties can be set at the global level, affecting all FTP sites on a server; on the individual site level; or at the directory or file level. IIS uses an inheritance model, which means that settings at higher levels are automatically inherited by lower levels. Settings at lower levels can be edited individually to override inherited settings from the next level up.

If you change a setting at a lower level, then later change a setting at a higher level that conflicts with the lower level setting, you are prompted to choose whether you want to change the lower-level setting to the new higher-level setting.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To globally set properties for all FTP sites**

1. In IIS Manager, expand the local computer, right-click the **FTP Sites** folder, and click **Properties**.
2. Click **Help** on any of the tabs for more information about those settings.

**To set properties for a single FTP site**

1. In IIS Manager, expand the **FTP Sites** folder, right-click the FTP site whose settings you want to change, and click **Properties**.
2. Click **Help** on any of the tabs for more information about those settings.

**Related Information**

- For information about installing the FTP service, see FTP Site Setup.

# Creating Multiple FTP Sites

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

You can create multiple FTP sites using multiple IP addresses and multiple ports. While creating multiple sites with multiple IP addresses is a common and recommended practice, it can be more complicated because, by default, clients call port 21 when using the FTP protocol. Therefore, if you create multiple FTP sites using multiple ports, you need to inform users of the new port number so their FTP clients can locate and connect to the port.

If you create a new site using the same port as an existing site with the same IP address, the new site will not start. The general rule is that you can have multiple sites using the same IP and port, but only one site from this group can run at a time. If you try to start another site from this group, you receive an error message.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To create multiple FTP sites using multiple IP addresses**

1. In IIS Manager, expand the local computer, right-click the **FTP Sites** folder, point to **New**, and click **FTP Site**.
2. Click **Next**.
3. In the **Description** box, type a description of your FTP site, and then click **Next**.
4. Under **Enter the IP address to use this FTP site**, type a new IP address, and leave the TCP port setting at **21**.
5. Complete the rest of the **FTP Site Creation Wizard**.

**To create multiple FTP sites using multiple ports**

1. In IIS Manager, expand the local computer, right-click the **FTP Sites** folder, point to **New**, and click **FTP Site**.
2. Click **Next**.
3. In the **Description** box, type a description of your FTP site, and then click **Next**.
4. Under **Enter the IP address to use for this FTP site**, type your Web server's IP address.
5. Under **Type the TCP port for this FTP site**, change the TCP port from the default setting of 21 to an unallocated port number. If you are uncertain which port numbers are already allocated, choose a high number, for example a number between 5000 and 5999.
6. Complete the rest of the **FTP Site Creation Wizard**.

**Related Information**

- For information about installing the FTP service, see FTP Site Setup.

# Stopping and Starting FTP Sites

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

The need to stop and restart an FTP site typically indicates a problem with the site. If your FTP site is slow, unresponsive, or is not running properly in some other way, stopping and then restarting the site can resolve a temporary problem with the software.

By default, FTP sites start automatically when your computer restarts. Starting a site restarts or resumes a specific site, or the FTP service if it was not previously running, which might immediately fix problems. Stopping a site disables the specific FTP site, disconnecting all client connections to the site. Stopping the FTP service stops all FTP sites and unloads the FTP service. Pausing a site prevents the FTP service from accepting new connections but does not affect requests that are already being processed.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To start, stop, or pause an FTP site**

- In IIS Manager, expand the local computer, expand the **FTP Sites** folder, right-click the site you want to start, stop, or pause, and click **Start**, **Stop**, or **Pause**.

If a site stops unexpectedly, IIS Manager might not correctly indicate the state of the site. In IIS Manager, right-click the **FTP Sites** folder and click **Refresh** to see the current state of all FTP sites.

**Related Information**

- For information about installing the FTP service, see FTP Site Setup.
- For information about restarting all of your Internet services,see Restarting IIS.
- To change properties on existing FTP sites, see Changing Default FTP Site Settings.

# Setting FTP Messages and Directory Output Style

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

By default, the IIS FTP service sends a banner message that identifies the FTP service, and the fact that FTP runs in IIS, to the client. The message can be a greeting that welcomes users to the FTP site when they log on, an exit message (see note) that users see when they log off, a message that informs users when the maximum number of connections has been reached, or a banner message. Also, you can send the client informational messages about your FTP sites. The message can be a greeting, an exit message, or information about connection status. These messages are blank by default.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer***\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

**Procedures**

**To suppress the default FTP banner for all FTP sites on a computer**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd** and click **OK**.
3. At the prompt, type the following command and then press ENTER:

   **Cscript.exe adsutil.vbs SET MSFTPSVC/SuppressDefaultFTPBanner true**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To globally set messages on all FTP sites**

1. In IIS Manager, expand the local computer, right-click the **FTP Sites** folder, and then click **Properties**.
2. Click the **Messages** tab.
3. Type messages in any of, or all of, the **Banner**, **Welcome**, **Exit**, and **Maximum connections** boxes. These messages will appear on all FTP sites.
4. Click **Apply**, and then click **OK**.

**To set messages on a specific FTP site**

1. In IIS Manager, right-click the FTP site for which you want to change messages, and then click **Properties**.
2. Click the **Messages** tab.
3. Type messages in any of, or all of, the **Banner**, **Welcome**, **Exit**, and **Maximum connections** boxes. Messages set at the individual FTP site level override messages set at the global level.
4. Click **Apply**, and then click **OK**.

**Setting the Directory Output Style**

You can set the directory output style of all FTP sites, or an individual FTP site to be in either MS-DOS® or UNIX format. The directory output style defines the format that is used when an FTP client sends a **/list** command. The default directory output

style is MS-DOS format.

| Note |
| --- |
| Although the exit message box can contain up to 30,000 characters, the FTP exit message size is limited to 1024 characters, including the reply code, blank, carriage return, and null. To prevent the exit message from being truncated, limit the length of the exit message to 1017 characters. |

The UNIX directory listing style displays the year in a four-digit format when the year in the date of the file is different from the year in the date of the FTP server. No year is returned in cases where the year in the date of the file is the same as the year in the date of the FTP server.

**To set the global FTP directory output style**

1. In IIS Manager, right-click the **FTP Sites** folder, and then click **Properties**.
2. Click the **Home Directory** tab.
3. Under **Directory listing** style, click **UNIX** or **MS-DOS®**.
4. Click **Apply**, and then click **OK**.

**To set the FTP directory output style for an individual FTP site**

1. In IIS Manager, expand the **FTP Sites** folder, right-click the FTP site for which you want to change the directory listing style, and then click **Properties**.
2. Click the **Home Directory** tab.
3. Under **Directory listing style**, click **UNIX or MS-DOS®**. The output style set at the individual FTP site level overrides the output style set at the global level.
4. Click **Apply**, and then click **OK**.

| Note |
| --- |
| The MS-DOS directory listing style displays the year in a two-digit format by default. You can change this setting to display the year in a four-digit format. |

**Related Information**

- For information about installing the FTP service, see FTP Site Setup.

# Changing FTP Site Home Directories

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

Each FTP site on a computer must have its own home directory. The default home directory for the default FTP site is *LocalDrive*:\Inetpub\Ftproot.

There are two ways to change the home directory of an FTP site:

- Use IIS Manager
- Edit the MetaBase.xml file directly.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To change the home directory of an FTP site using IIS Manager**

1. In IIS Manager, expand the local computer, expand the **FTP Sites** folder, right-click the FTP site whose home directory you want to change, and click **Stop**.
2. Right-click the FTP site again, and click **Properties**.
3. Click the **Home Directory** tab.
4. Under **The content for this resource should come from**, click the location of your home directory.

   **Note**

   If you select a directory on a network share, you might need to enter a user name and password to access the resource. IUSR_computername is the default account used if another account is not specified. If you use an account with administrative credentials on the server, clients can gain access to server operations. This seriously jeopardizes the security of your network. For more information about security see, Security Best Practices in Windows Help.

5. Click **Apply**, and then click **OK**.
6. Right-click the FTP site you've just changed, and click **Start**.
7. Optional: Move or copy the content for the FTP site from the original home directory to the new home directory.

**To change the home directory of an FTP site by editing the MetaBase.xml file**

1. In IIS Manager, right-click the local computer, point to **All Tasks**, and click Select **Restart IIS...**.
2. In the **Stop/Start/Reset** dialog box, click **Stop Internet Services**, and click **OK**.
3. Expand the **FTP Sites** folder, right-click the FTP site you want to change, and click **Stop**.
4. In Windows Explorer, from the *localdrive*\System32\Inetsrv folder, open the MetaBase.xml file in a text editor.
5. To change the FTP home directory, search for "/msftpsvc/*1*/root" and change the **Path=** value to the new location of the FTP home directory. Substitute the value *1* with the value corrresponding to the FTP site you want to change.
6. In IIS Manager, right-click the local computer, point to **All Tasks**, and click **Select Restart IIS...**.

7. In the **Stop/Start/Reset** dialog box, click **Start Internet Services**, and click **OK**.
8. Optional: Move or copy the content for the FTP site from the original home directory to the new home directory.

**Related Information**

- For information about installing the FTP service, see FTP Site Setup.

# Securing FTP Sites with IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

FTP is commonly misunderstood as a secure means for transferring data, because the FTP server can be configured to require a valid user name and password combination prior to granting access. Be aware that neither the credentials specified at logon nor the data itself is encrypted or encoded in any way. All credentials are sent across the network in plaintext. In other words, all FTP data can be easily intercepted and analyzed by any station on any network between the FTP client and FTP server. The risk of plaintext credentials is that someone other than the intended users could log on to FTP and download the files you have placed there. If you intend to place sensitive data on your FTP site or if secure communication between clients and your FTP server are important, consider using FTP over an encrypted channel such as a Virtual Private Network secured with Point-to-Point Tunneling Protocol or Secure Internet Protocol (IPSec). You should also consider using WebDAV, which utilizes Secure Sockets Layer (SSL).

| **Caution** |
| --- |
| FTP sites or virtual directories that are configured to use Active Directory isolation or FTP load balancing should not be mapped to physical directories that are used for Web sites that use FrontPage® Server Extensions from Microsoft. Doing so can allow users to view any files in that folder structure over the network. |

- For information about installing the FTP service, see FTP Site Setup.
- To learn how to set up a private network over the Internet using Point-to-Point Tunneling Protocol (PPTP) or how to set up secure IP communications with a Virtual Private Network (VPN) and IPSec, see "PPTP", "VPN", and "IPSec" in Help and Support Center for Windows Server 2003.

# Isolating FTP Users

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

FTP user isolation is a solution for Internet service providers (ISPs) and application service providers who want to offer their customers individual FTP directories for uploading files and Web content. FTP user isolation prevents users from viewing or overwriting other users' Web content by restricting users to their own directories. Users cannot navigate higher up the directory tree because the top-level directory appears as the root of the FTP service. Within their specific site, users have the ability to create, modify, and delete files and folders.

FTP user isolation is a site property, not a server property. It can be turned on or off for each FTP site.

FTP user isolation supports the following three isolation modes, each of which enables different levels of isolation and authentication:

- Do not isolate users: This mode does not enable FTP user isolation. It is designed to work similarly to earlier versions of IIS.
- Isolate users: This mode authenticates users against local or domain accounts before they can access the home directory that matches their user name.
- Isolate users using Active Directory: This mode authenticates user credentials against a corresponding Active Directory container, rather than searching the entire Active Directory, which requires large amounts of processing time.

| **Note** |
| --- |
| This mode requires an Active Directory server running on an operating system in the Windows Server 2003 family. A Windows 2000 Active Directory can also be used but requires manual extension of the User Object schema. To learn more about setting up an Active Directory server, see Help and Support Center for Windows Server 2003. |

**In this section:**

- Creating a New FTP Site with Isolate Users Mode: Describes how to create a new FTP site with **Isolate users** mode.
- Converting an Existing FTP Site to Isolate Users Mode: Describes how to convert an existing FTP site to **Isolate users** mode.
- Creating a New FTP Site with Isolate Users Using Active Directory Mode: Describes how to create a new FTP site with **Isolate users using Active Directory** mode.
- Enabling Anonymous Access for an FTP Site Configured with Isolate Users Using Active Directory Mode: Describes how to enable anonymous access for an FTP site configured with **Isolate users using Active Directory** mode.
- Converting an Existing FTP Site to Isolate Users Using Active Directory Mode: Describes how to prepare and convert an existing FTP site to **Isolate users using Active Directory** mode.

**Related Information**

- For more information about FTP user isolation modes, see Hosting Multiple FTP Sites with FTP User Isolation.
- For information about installing the FTP service, see FTP Site Setup.

# Creating a New FTP Site with Isolate Users Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

**Isolate users** mode authenticates users against local or domain accounts before they can access the home directory that matches their user name. All user home directories are in a directory structure under a single FTP root directory where each user is placed and restricted to their home directory. Users are not permitted to navigate out of their home directory. If users need access to dedicated shared folders, you can also establish a virtual root. This mode does not authenticate against Active Directory directory service.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To create a new FTP site with Isolate users mode**

1. In IIS Manager, click the local computer, right-click the **FTP Sites** folder, point to **New**, and then click **FTP Site**.
2. In **Welcome to the FTP Site Creation Wizard**, click **Next**.
3. In **FTP Site Description**, type a description for the FTP site, and then click **Next**.
4. In **IP Address and Port Settings**, type an IP address and port number, and then click **Next**.
5. In **FTP User Isolation**, click **Isolate users**, and then click **Next**.
6. In **FTP Site Home Directory**, type or browse to the FTP site home directory, and then click **Next**.
7. Enable the Read and Write permissions as appropriate, and then click **Next**, and click **Finish**.

| **Important** |
| --- |
| Adhere to the following convention when creating each user's FTP site directories: |

- If anonymous access is allowed, create the subdirectories **LocalUser** and **LocalUser\Public**under the FTP site home directory.
- If users of the local computer log on with their individual account user names (rather than as anonymous users), create the subdirectory **LocalUser**and a separate directory **LocalUser***UserName* under the FTP site home directory for each user allowed to connect to the FTP site.
- If users of different domains log on with their explicit *Domain**UserName* credentials, create a subdirectory for each domain (by using the name of the domain) under the FTP site root directory. Under each domain directory, create a directory for each user. For example, to support access by user Contoso\user1, create the Contoso and Contoso\user1 directories.

**Related Information**

# Converting an Existing FTP Site to Isolate Users Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

You can convert an existing FTP site to **Isolate users** mode after you upgrade to Windows Server 2003.

**To convert an existing FTP site to Isolate users mode**

1. In IIS Manager, click the local computer, double-click the **FTP Sites** folder, right-click the FTP site that you want to convert, and then click **Stop**.

| **Important** |
| --- |
| You must stop the FTP service because you need to move user directories to new locations. |

2. If users log on to the FTP site with local machine accounts or if you allow anonymous access to the FTP site, complete the following steps:
   a. Under the FTP home directory, create a subdirectory named **LocalUser**.
   b. If you allow anonymous access to the site, create a subdirectory under **LocalUser** named **Public**. This will be the home directory for anonymous users.
   c. Move the content for the anonymous user from the existing location to the new **Public** subdirectory.
   d. For each FTP user with a local computer account, create a subdirectory under **LocalUser** with the user account name. Move content from existing user directories to these new directories.
3. If domain users access the site, complete all of the following steps:
   a. Create a subdirectory under the FTP home directory for each domain for which users are accessing the site. The subdirectories must be named by the domain names.
   b. For each user, create a subdirectory under the corresponding domain-named subdirectory, and move existing content into the new subdirectories.
4. To finish the conversion, do one of the following:
   - Use the FTP Site Creation Wizard to create a new FTP site, and point the site path to the FTP home directory.
   - Edit the metabase, set the **UserIsolationMode** metabase property to **1** for the site and the path in the corresponding **/Root**virtual root section to the new site home directory.

| **Important** |
| --- |
| Before you edit the metabase, verify that you have a backup copy that you can restore if a problem occurs. |

5. In IIS Manager, click the local computer, double-click the **FTP Sites** folder, right-click the converted FTP site, and then click **Start**.

**Related Information**

# Creating a New FTP Site with Isolate Users Using Active Directory Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

**Isolate users using Active Directory** mode authenticates user credentials against a corresponding Active Directory container, rather than searching the entire Active Directory, which requires large amounts of processing time.

| **Note** |
| --- |
| This mode requires an Active Directory server running on an operating system in the Windows Server 2003 family. A Windows 2000 Active Directory can also be used but requires manual extension of the User Object schema. To learn more about setting up an Active Directory server, see Help and Support Center for Windows Server 2003. |

Specific FTP server instances can be dedicated to each customer to ensure data integrity and isolation. When a user's object is located within the Active Directory container, the **msIIS-FTPRoot** and **msIIS-FTPDir** properties are extracted to provide the full path to the user's home directory. If the FTP service can successfully access the path, the user is placed within the home directory, which represents the FTP root location. The user sees only their FTP root location and is, therefore, restricted from navigating higher up the directory tree. The user is denied access if either the **msIIS-FTPRoot** or **msIIS-FTPDir** property do not exist, or, if these two together do not form a valid and accessible path.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas/user:***Administrative_AccountName***"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To create FTP sites with Isolate users using Active Directory mode**

1. In IIS Manager, click the local computer, right-click the FTP Sites folder, point to New, and click FTP Site.
2. In the **Welcome to the FTP Site Creation Wizard**, click **Next**.
3. In **FTP Site Description**, type a description for the FTP site, and then click **Next**.
4. In **IP Address and Port Settings**, type an IP address and port, and then click **Next**.
5. In **FTP User Isolation**, click **Isolate users using Active Directory**, and then click **Next**.
6. In the **User name** text box, type the user name, using the *Domain\User* format, or browse to the user name. Choose a user with minimal domain privileges. This user name is used to access Active Directory and read the home directory properties.
7. In the **Password** text box, type the password of the user.
8. In the **Enter the default Active Directory domain** text box, type or browse to the default domain name.

   | **Note** |
   | --- |
   | This domain name is used for the users who do not specify their user domain when they log on. In other words, a user connecting with the user name Domain1\User1 is authenticated against Domain1, while a user connecting as User2 is authenticated against the default logon domain. If a default domain is not named and a user does not specify a domain name, access is denied for all but anonymous users. Type the base domain name only, not the fully qualified name. For example, type **MyDomain**, not **MyDomain.dept.microsoft.com**. |

9. Click **Next**. You are prompted to re-enter the password for the user entered in the previous steps.
10. Enable the Read and Write permissions as appropriate, and then click **Next**, and click **Finish**.

**Related Information**

# Enabling Anonymous Access for an FTP Site Configured with Isolate Users Using Active Directory Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

By default, anonymous access is disabled to sites created in **Isolate users using Active Directory** mode.

**To enable anonymous access for the FTP site configured with Isolate users using Active Directory mode**

- Configure the metabase properties as shown in the following example. You can do so by using the adsutil.vbs SET command-line tool.
    - **adsutil set /msftpsvc/6634/AllowAnonymous TRUE**
    - **adsutil set /msftpsvc/6634/AnonymousOnly FALSE**
    - **adsutil set /msftpsvc/6634/AnonymousUserName MyDomain\LowPrivUser**
    - **adsutil set /msftpsvc/6634/AnonymousUserPass PaSsWoRd**

| **Note** |
| --- |
| When a site is created with Isolate Users Using Active Directory mode, the **Path** property of the root FTP virtual directory (which, for the other isolation modes identifies the home directory) is set empty. Also, the **AccessFlags** property of the root FTP virtual directory contains the **AccessNoPhysicalDir** flag. Do not alter these two values. If you change or remove them, further access to the site is not allowed. |

**Related Information**

- For more information about FTP user isolation, see Hosting Multiple FTP Sites with FTP User Isolation.
- For more information about using adsutil.vbs, see Using the Adsutil.vbs Administration Script.

# Converting an Existing FTP Site to Isolate Users Using Active Directory Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

You can convert an existing FTP site to **Isolate users using Active Directory** mode after you upgrade to Windows Server 2003. Before you convert an existing FTP site to the **Isolate users using Active Directory** mode, complete the following procedure.

**To prepare to convert an existing FTP site to Isolate users using Active Directory mode**

1. Plan user distribution over your network file server resources.
2. Create server shares and user directories for all users that have access to FTP.
3. Make sure to create a directory for anonymous access (if you want to enable anonymous user connections).
4. For each user, set the **msIIS-FTPRoot** and **msIIS-FTPDir** properties in Active Directory to point to the new home directory using Iisftp.vbs, by typing the following at the command line:

   **Iisftp.vbs /SetADProp** *UserName* **FTPRoot** *Server* **** *Share*

   **Iisftp.vbs /SetADProp** *UserName* **FTPDir** *Directory*

   For complete Iisftp.vbs syntax, type **Iisftp.vbs /SetADProp /?**at the command prompt.

You can complete the conversion by using the FTP Site Creation Wizard (recommended), or by following the procedure below to configure the metabase.

**To convert an existing FTP site to Isolate users using Active Directory mode**

1. In IIS Manager, click the **local computer**, double-click the **FTP Sites** folder, right-click the FTP site that you want to convert, and then click **Stop**.
2. Move existing user content into the new directories.
3. Edit the metabase directory or use adsutil.vbs to configure the following metabase properties:

   - **UserIsolationMode**: Set to **2**.
   - **ADConnectionUserName**: Set to a user that has permission to read Active Directory properties. Use *Domain**UserName*format.
   - **ADConnectionPassword**: Set to the password for the user in **ADConnectionUserName**.
   - **DefaultLogonDomain**: Set to the default domain name.
   - For the site root virtual directory: Set the **Path** property to an empty string, and add the value **AccessNoPhysicalDir**to the **AccessFlags**property, using the **|** operator; for example: **AccessFlags=AccessRead|AccessNoPhysicalDir**.
   - **AllowAnonymous**, **AnonymousUserName**, and **AnonymousPassword**: See To enable anonymous access for the Isolate Users Using Active Directory FTP site earlier in this topic for information about how to set these properties.

   | **Important** |
   | --- |
   | Before you edit the metabase, verify that you have a backup copy that you can restore if a problem occurs. |

4. In IIS Manager, click the **local computer**, double-click the **FTP Sites** folder, right-click the converted FTP site, and then

click **Start**.

**Related Information**

# Modes and Data Transmission

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

When using FTP, there are two things to consider. The first is the connection mode, which can be either passive or active; and the second is the data transfer mode, which can be stream, block, or compressed.

The IIS-based FTP service supports both active and passive mode connections, depending on the method that is specified by the client. IIS does not support disabling either active or passive connection modes.

The default data transfer mode for IIS-based FTP is stream. IIS does not currently support block or compressed data transfer mode.

Unlike HTTP and other protocols used on the Internet, the FTP protocol uses a minimum of two connections during a session: a half-duplex connection for control, and a full-duplex connection for data transfer. By default, TCP port 21 is used on the server for the control connection, but the data connection is determined by the method that the client uses to connect to the server, as detailed below.

- *Active-mode FTP connections* are sometimes referred to as "client-managed" because the client sends a **port** command to the server, over the control connection. The command requests the server to establish a data connection from TCP port 20 on the server to the client, using the TCP port that is specified by the **port** command.

- *Passive-mode FTP connections* are sometimes referred to as "server-managed", because after the client issues a **pasv** command, the server responds with one of its transient ports used as the server-side port of the data connection. After a data connection command is issued by the client, the server connects to the client using the port immediately above the client-side port of the control connection.

**Data Transfer and Firewalls**

The most common problem encountered with FTP over the Internet involves data transfers through a proxy server, a firewall, or a Network Address Translation (NAT) device. In most cases these network security devices allow the control connection to be established over TCP port 21 (that is, the user can successfully log on to the FTP server), but when the user attempts a data transfer such as DIR, LS, GET, or PUT, the FTP client appears to stop responding because the network security device is blocking the data connection port that is specified by the client. If the network security device supports logging, you can verify port blocking by reviewing the deny/reject logs on the network security device.

The following table includes FTP clients provided by Microsoft, and the connection mode supported by each client.

| FTP Client | Transfer Mode |
|---|---|
| Command line | Active |
| Internet Explorer 5.1 and earlier | Passive |
| Internet Explorer 5.5 and later | Active and Passive |
| FrontPage 1.1 to FrontPage 2002 | Active |

- For information about installing the FTP service, see FTP Site Setup.

- For more information about FTP data transmission, refer to the FTP protocol specification at the World Wide Web Consortium Web site.

- For information about setting the port range used for passive-mode FTP connections, see the PassivePortRange Metabase Property.

# Restarting FTP Uploads and Downloads

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

If your connection closes unexpectedly while uploading or downloading a file using FTP, it might not be necessary to transfer the entire file again, because the IIS -based FTP service supports restarting failed FTP uploads and downloads. If your FTP client software supports FTP restart, you can reestablish the FTP connection and restart the file transfer; and the file transfer will automatically pick up where it left off.

The command-line FTP client included with Microsoft Windows does not support restarting downloads. You must use a third-party command-line FTP client for that functionality. If you are using a command-line FTP client, uploads can be resumed by using the **append** command to add data to an existing file. Downloads can be restarted by first issuing a **rest** command with the desired offset, and then issuing the **retr** command.

| **Note** |
| --- |
| The IIS implementation of FTP restart is limited to an offset of less than four gigabytes. |

- For information about installing the FTP service, see FTP Site Setup.
- For information about the commands supported by the Microsoft Windows command-line FTP client, see the Microsoft Developer Network (MSDN) Web site.
- For the official FTP specification with the entire FTP command set, see the World Wide Web Consortium Web site.

# Server-to-Server FTP Transfer

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

You can configure IIS to allow server-to-server FTP transfers by changing the EnableDataConnTo3rdIP and EnablePasvConnFrom3rdIP keys in the system registry. By default, the EnablePasvConnFrom3rdIP registry key is disabled to prevent malicious attacks against the FTP service. Although details for configuring server-to-server transfers are listed below, Microsoft does not recommend enabling the EnablePasvConnFrom3rdIP registry key on IIS-based FTP servers connected to the Internet.

| **Important** |
| --- |
| Using Registry Editor incorrectly can cause serious problems that require reinstalling the operating system. Because Registry Editor bypasses the standard safeguards that prevent you from entering settings that are conflicting or likely to degrade performance or damage your system, exercise caution when making changes to the registry. Microsoft cannot guarantee that problems resulting from the incorrect use of Registry Editor can be solved. For information about how to edit the registry, see the "Changing Keys and Values" topic in Registry Editor Help. |

The procedure below lists the steps required to transfer a binary file (called MyFile.xls) from Server1 (IP Address: 192.168.0.10) to Server2 (IP Address: 192.168.1.20) using the command-line FTP client on Workstation1. You must have Write permissions granted on Server2 for this example to work. You must also have two computers running the IIS-based FTP service.

The server that initiates the data channel (Server1 in this

example) must have the following value set in the registry:

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\MSFTPSVC\Parameters\EnableDataConnTo3rdIP=1

Server2 must have the following value set in the registry:

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\MSFTPSVC\Parameters\EnablePasvConnFrom3rdIP=1

In normal client/server FTP transfers, the user is only responsible for entering "friendly" commands to the server; the client responds automatically. When a server-to-server FTP transfers is performed, another server is the client. Therefore, the user is responsible for sending all FTP commands to both servers (in RFC959 format, preceded by the "literal" keyword).

**Procedures**
**To transfer a binary file between FTP servers**

1. Connect to Server1 using a command-line FTP client. (This connection will be referred to as Client1).
2. Connect to Server2 using a command-line FTP client. (This connection will be referred to as Client2).
3. Issue the following command in Client2: **literal pasv**.

   The computer responds with: 227 Entering Passive Mode (192,168,1,20,15,61).

   Note that 15,61 represents the low and high order bytes of the port number (port 3901 in this case), which is randomly assigned with each FTP connection. As a result, the last two numbers of this string will be different.
4. Issue the following command in Client1: **literal port 192,168,1,20,15,61**.

   The computer responds with: 200 Port Command Successful.

   Use the IP and port string returned in step 3.
5. Issue the following command in both Client1 and Client2: **literal type i**.

   The computer responds with: 200.
6. Type **set to I**.
7. Issue the following command in Client1: **literal retr myfile.bin**.

The computer responds with: 125 Data Connection already open; Transfer Starting.

8. Issue the following command in Client2: **literal stor myfile.bin**.

   The computer responds with: Opening BINARY mode data connection for myfile.bin.

9. Continue issuing the **literal stat** command on Client2 until it returns a 211 response indicating "No data connection is listed".

   This 211 response message is several lines long and indicates that the transfer is no longer in progress.

10. To transfer files from Server2 to Server1, issue the **literal retr** command from Client1 and the **literal stor** command from Client2.

**File Transfer Alternatives**

If you are concerned about FTP security, or if a network security device like a firewall prevents server-to-server data transmission, consider using a file transfer alternative like Web authoring with WebDAV. WebDAV is the recognized standard for HTTP file transfers.

**Related Information**

- For information about **port**, **pasv**, **stor**, **retr**, **stat**, and other literal FTP commands, see the World Wide Web Consortium Web site.

# Redirecting FTP Requests to Directories or Network Shares

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

You can redirect requests for files in one directory to a different directory or to a network share. When an FTP client requests the file from the original URL, the FTP server instructs the client to request the file from the redirected resource. Redirection is useful when users have grown accustomed to using a particular URL to access certain files.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the runas command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To redirect requests to another directory or network share**

1. In IIS Manager, expand the **FTP Sites** folder, right-click the FTP site or directory within an FTP site to which you want to add a redirect, and click **Properties**.
2. Click the **Home Directory**, **Virtual Directory**, or **Directory** tab.
3. Under **The content for this resource should come from**, click the location from which the files should be served.
4. In the **Local path** box, type or browse to the path from which you want the files served.
5. Click **OK**.

**Making an FTP virtual directory visible to users**

You can configure your FTP site so that a user browsing the site sees a directory entry for a virtual directory. While the directory entry the user sees is a physical directory, when the user navigates into the physical directory, the contents listed are actually of a virtual directory you have specified. This is possible because IIS lists virtual paths before listing physical paths. This makes it appear to the user that they are seeing the contents of a physical directory, when in fact they are seeing the content in a virtual directory.

**To make an FTP virtual directory visible to users**

1. Create a physical directory in the user's home FTP directory. For example, if your FTP site is configured for user isolation, the user's home directory will either be LocalUser\Public (for anonymous users), or LocalUser*username* (for authenticated users).
2. In IIS Manager, expand the local computer, expand the **FTP Sites** folder, expand the FTP site to which you want to add a virtual directory, right-click the site or folder within which you wish to create the virtual directory, point to **New**, and then click **Virtual Directory**.
3. Click **Next**.
4. In the **Alias** box, type the name for the virtual directory and click **Next**.

   | **Important** |
   | --- |
   | The alias must exactly match the name of the directory you created in step 1. |

5. In the **Directory** box, type the path to, or browse to the physical directory where the content for this virtual directory resides, and click **Next**.
6. Under **Allow the following permissions**, select the check boxes next to the access permissions appropriate to your needs, and click **Next**.

7. Click **Finish**. The virtual directory is created within the FTP site.

   When a user browses the FTP site, the physical directory you created in step 1 is displayed in the folder listing. When the user then navigates to the physical directory, however, the content of the redirected virtual directory is actually displayed

| **Note** |
| --- |
| You can also use this procedure with nested virtual directories. |

**Related Information**

- For information about how to set up a user's home FTP directory using user isolation, see Isolating FTP Users.
- For information about installing the FTP service, see FTP Site Setup.

# NNTP Administration

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Newsgroups make it easy for users in your organization to engage in discussions on various topics with each other and with users outside of the organization. Whether enabling a departmental newsgroup or providing a full feed of Internet newsgroups, the principals of setting up a news server are the same.

This section includes the following information:

- Creating NNTP Virtual Servers: Describes multiple-server strategies and how to create virtual Network News Transfer Protocol (NNTP) servers.
- Creating Virtual Directories in IIS 6.0: Describes how to create and modify virtual directories.
- Configuring NNTP Virtual Servers: Introduces the settings options for NNTP virtual servers.
- Starting, Stopping, or Pausing NNTP Virtual Servers: Describes how to start, stop, and pause NNTP virtual servers and the difference between managing servers and services.
- Starting, Stopping, or Pausing the NNTP Service: Describes how to start, stop, and pause NNTP services and how it differs from managing virtual servers.
- NNTP Security: Introduces NNTP security concepts.
- Managing Newsgroups: Introduces concepts in managing newsgroups including how to create, moderate, edit, delete, and configure them.
- Configuring Expiration Policies: Describes how to set and modify newsgroup expiration policies.

# Creating NNTP Virtual Servers

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can create as many NNTP virtual servers as you need. Each virtual server should have a unique IP address/TCP port combination. Although it is possible to have multiple NNTP virtual servers on a single IP address by using a different TCP port for each one, this configuration is not recommended because the client software must then be specially configured to use the nonstandard TCP port.

When you create an NNTP virtual server, you are prompted to enter two directory paths: a path for internal files and a path for newsgroup files. If possible, put these two paths on different disk partitions because the internal files can be corrupted if the disk partition runs out of disk space. Keeping them on a separate disk partition reduces the chance that the disk partition can run out of disk space.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To create a new NNTP virtual server**

1. In IIS Manager, expand the local computer, and then right-click an existing NNTP virtual server, point to **New**, and click **Virtual Server**.
2. Follow the instructions of the New NNTP Virtual Server Wizard. Be sure to select an IP address that is not being used by another NNTP virtual server.
3. The new NNTP virtual server will start automatically. However, if you have assigned it an IP address/TCP port combination that is already in use, it won't start. You must reconfigure the IP address/TCP port combination to one that is unique.
4. Configure the new NNTP virtual server.

**Related Information**

- For information about creating virtual directories, see Creating Virtual Directories in IIS 6.0.

# Creating Virtual Directories with IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can create as many virtual directories as you want. Create virtual directories that match the structure of your newsgroup hierarchy.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To create a virtual directory**

1. In IIS Manager, expand the local computer, and then expand the NNTP virtual server that you want.
2. Right-click **Virtual Directories**, point to **New**, and then click **Virtual Directory**.
3. Follow the New NNTP Virtual Directory Wizard. Create a newsgroup subtree for this virtual directory.
4. Select either **File System** (a local location) or **Remote** as a storage location for the news content. This location can be configured later if necessary by clicking **Contents** in the **Virtual Directory** box.
5. If you selected **File System**, type a path to the local folder, or click **Browse** to select a folder. If you selected **Remote**, type a path to the remote location, or click **Browse** to select a remote folder. For a remote location, you must also provide a user name and password that Microsoft NNTP Service can use to log on to that remote computer. Type a name or click **Browse** to search for one. Click **Check** to ensure that the user name/password combination you plan to use is valid.

| **Note** |
| --- |
| If you store content in a remote location, the remote computer must be configured with at least read/write permissions for the user name you provide. Make sure that the remote location is secure and that it is maintained by trusted administrators. |

**To modify a virtual directory**

1. In IIS Manager, expand the local computer, and then expand the NNTP virtual server that you want.
2. Right-click the virtual directory that you want to modify, and then click **Properties**.
3. Change the options in the virtual directory's **Properties** box as needed.

**Related Information**

- For information about creating an NNTP virtual server, see Creating NNTP Virtual Servers.

# Configuring NNTP Virtual Servers

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

For each Network News Transfer Protocol (NNTP) virtual server you can configure security, create newsgroups, set newsgroup limits, and so on. Most configuration options are assigned default values when a new NNTP virtual server is created.

Each NNTP virtual server is listed separately in IIS Manager. Each one has its own properties, expiration policies, and virtual directories. Be sure to select the correct NNTP virtual server before changing properties. To open the properties dialog box for an NNTP virtual server, right-click the NNTP virtual server, and then click **Properties**.

Besides creating newsgroups for the new NNTP virtual server, you must specify the following virtual server settings:

| Tab | Settings |
|---|---|
| Access | Configure client access to the NNTP virtual server and to establish transmission security. |
| General | Specify IP address, connection limits, path header, and logging settings. |
| Security | Add Windows user accounts and groups to the list of NNTP virtual server operators. |
| Settings | Configure a maximum limit for the size of news articles and news feeds, and specify the SMTP server to which moderated messages are sent. |

This section includes the following information:

- NNTP Access Tab: Describes the options that are available on the **Access** tab.
- NNTP General Tab: Describes the options that are available on the **General** tab.
- NNTP Security Tab: Describes the options that are available on the **Security** tab.
- NNTP Settings Tab: Describes the options that are available on the **Settings** tab.

# NNTP Access Tab

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use the **Access** tab to restrict access to individual newsgroups or sets of newsgroups on the basis of the user name, or to restrict access to all newsgroups on the basis of the client computer IP address.

The **Access** tab contains the following options:

| Option | Description |
|---|---|
| Access control | Authentication options. You can choose one or more options. To view the options, click **Authentication**. |
| Allow anonymous | Unrestricted user access to newsgroups that do not have permissions set on their directories. User names and passwords are not required. |
| Anonymous | Opens the **Anonymous Account** dialog box, which allows you to select a Windows account that will be used when someone logs on anonymously. |
| Username | The user name of the Windows user account used by all anonymous connections. This account defines the privileges of anonymous users. To select an account already defined on this computer, click **Browse**. |
| Password | The password for the anonymous user account. |
| Enable automatic password synchronization | The automatic update of the password in the NNTP service when the password in the computer running a member of the Windows Server 2003 family is changed. |
| Basic authentication | Authentication that requires the user to provide a valid Windows user name and password that are authorized for access to that directory. The user name and password are sent as unencrypted clear text across the network. Permissions are set on the directory. |
| Integrated Windows Authentication | Authentication that encrypts the user name and password and then sends them to the NNTP service. The user name and password must be authorized for access to the requested newsgroup directory. Microsoft Outlook Express supports this protocol. Permissions are set on the directory. |
| Enable SSL client authentication | Enables secure client authentication using Secure Sockets Layer (SSL) encryption and certificates. A server SSL certificate is required. |
| Require SSL client authentication | Requires clients to provide an encrypted user name and password using SSL. |
| Enable client certificate mapping to Windows user accounts | Uses the Windows account mapped to the SSL client certificate to authenticate the user. Click **Client Mappings** to enter certificates and Windows account names. |
| Secure communication | Click **Certificate** to start the Web Server Certificate Wizard. |
| Connection control | The specific IP addresses that are allowed or not allowed access to this Network News Transfer Protocol (NNTP) virtual server. By default, all IP addresses are granted access. To view the options, click **Connection**. |

| | |
|---|---|
| All except the list below | Allows access to this NNTP virtual server to all IP addresses except for those listed. |
| Only the list below | Denies access to this NNTP virtual server to all IP addresses except for those listed. |
| Add | Click this button to open the **Computer** window where you can add computers or domains to the list. |
| IP address | The IP address for a single computer that is being added. Click **DNS Lookup** to find the IP address associated with the DNS name of the computer. |
| Subnet address | The base IP address for a group of computers that is being added. A subnet mask is required. |
| Subnet mask | The subnet mask that specifies the range of IP addresses for a group of computers that is being added. |
| Name | The domain name of a group of IP addresses that is being added. |

**Related Information**

- For information about NNTP security, see NNTP Security.
- For additional information about the **Access** tab, see Restricting Access to Newsgroups.

# NNTP General Tab

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use the **General** tab to specify how clients connect to the NNTP service.

The **General** tab contains the following options:

| "Option" | "Description" |
|---|---|
| IP address | The IP address of the Network News Transfer Protocol (NNTP) virtual server. |
| Advanced | Opens the **Advanced** dialog box where you can enable multiple IP addresses for the NNTP virtual server and configure TCP and Secure Sockets Layer (SSL) port numbers. |
| TCP port | The TCP port used by clients to connect to the NNTP service. You can enter any unique TCP port number. The default is port119. |
| SSL port | The TCP port used by clients to connect to the NNTP service using SSL. You can enter any unique TCP port number. The default is port 563. |
| Limit number of connections to | When the check box is selected, this option limits the number of simultaneous client connections to the NNTP virtual server. The default is 5,000 connections. |
| Connection time out (minutes) | The number of minutes before an inactive client is disconnected. The default is 10 minutes. |
| Path header | The string used for the Path line in each news posting. The **Path header** displays the path a news message takes to reach its destination. When a message is forwarded from a news server, a descriptive string is added to the message in the Path line. Any punctuation character except the period (.) can separate the Path header. For information about how NNTP Path statements are generated, see Request for Comments (RFC) 1036.<br><br>The default value is the Domain Name System (DNS) name of the NNTP virtual server. You do not need to change the default value. |
| Enable logging | Enables logging to track users of the NNTP virtual server. The default log file directory is **systemroot**\System32\LogFiles\Nntpsvc1. To enable logging, you must also select the **Log access** check box in the **Virtual Directory** dialog box.<br><br>**Note**<br>Auditing server activity with log files is a good way to detect if unauthorized external users are attempting to access your virtual server or if internal users are trying to access resources that they do not have permissions to access. For more information about auditing and using Event Viewer, see Windows Server 2003 family Help. |
| Active log format | The transaction log format. To specify log properties, click **Properties**. |

# NNTP Security Tab

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use the **Security** tab to specify the operators who are allowed access to the NNTP virtual server.

The **Security** tab contains the following options:

| Option | Description |
|---|---|
| Operators | The operators or groups of operators that are authorized to access this NNTP virtual server. The default value is the Administrators group for the computer. |
| Add | Opens the **Select Users or Groups** dialog box where you can select new operators. |
| Remove | Removes the selected operator. |
| Object Types (in the **Select Users or Groups** dialog box) | Objects from which to select operators. |
| Locations (in the **Select Users or Groups** dialog box) | The available locations in the selected domain. |
| Enter the object names to select (in the **Select Users or Groups** dialog box) | Provides a space to type the object names that you want to find. |

**Related Information**

- For information about NNTP security, see NNTP Security.
- For information about restricting operator access, see Restricting Operator Access.

# NNTP Settings Tab

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use the **Settings** tab to set limits on posting articles, to enable control messages, and to enable moderated newsgroups.

The **Settings** tab contains the following options:

| Option | Description |
|---|---|
| Allow client posting | When selected, this option allows clients to post articles to newsgroups on this NNTP virtual server. |
| Limit post size (KB) | Specifies, in kilobytes, the largest single article that a user can post. To have no limit, clear the check box. |
| Limit connection size (MB) | Specifies, in megabytes, the maximum amount of data that a user can post to a newsgroup during a connection. To have no limit, clear the check box. |
| Allow feed posting | When selected, this option allows clients to post articles to newsfeeds on this NNTP virtual server. |
| Limit post size (KB) | Specifies, in kilobytes, the largest single article that a user can post to a newsfeed. To have no limit, clear the check box. |
| Limit connection size (MB) | Specifies, in megabytes, the maximum amount of data that a user can post to a newsfeed during a connection. To have no limit, clear the check box. |
| Allow servers to pull news articles from this server | Allows other NNTP servers to use pull feeds to get more than one article at a time from this server. |
| Allow control messages | Allows clients and servers to send control messages that create and remove newsgroups and delete individual articles. |
| SMTP server for moderated groups | The DNS name of the SMTP mail server that sends articles to the moderators of newsgroups or specifies the directory path where these articles are placed. The directory must be a local directory. |
| Default moderator domain | The default domain for moderated newsgroups. The domain must be a qualified domain name. Articles posted to moderated news groups that have no specified moderator are sent to *news_group_name@default_moderator_domain*, where *news_group_name* is the name of the newsgroup to which the article is sent and *default_moderator_domain* is the value that you specify for this option. |
| Administrator e-mail account | An e-mail address for receiving the non-delivery reports (NDRs) of moderated newsgroup articles that cannot be delivered to the specified moderator. To enable sending NDRs, create a new DWORDvalue named MailFromHeader with a value of 1in the following registry key:<br>HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet \Services\NntpSvc\Parameters\ |

# Starting, Stopping, or Pausing NNTP Virtual Servers

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use IIS Manager in the Microsoft Management Console (MMC) to start, stop, and pause the default NNTP virtual server and any other virtual servers that you have created.

You can also start, stop, and pause the NNTP service. However, stopping the service stops all of the NNTP virtual servers that are running on your computer. When the NNTP service is stopped, you cannot use MMC to perform administrative functions on any NNTP virtual server.

It is important to make sure that only trusted and qualified administrators in your organization have the necessary permissions to start or stop an NNTP virtual server. For more information, see Restricting Operator Access.

When an NNTP virtual server is started, it accepts new connections from users. When you stop an NNTP virtual server, it disconnects current users and does not accept new connections. When you pause an NNTP virtual server, it does not accept new connections but continues to service existing connections. If you want to stop an NNTP virtual server but not disconnect users currently connected to the virtual server, you can also choose to shut down gracefully.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To start, stop, or pause an NNTP virtual server**

1. In IIS Manager, expand the local computer, and then click the NNTP virtual server that you want.
2. On the **Action** menu, click **Start**, **Stop**, or **Pause**.

**To shut down an NNTP virtual server gracefully**

1. Pause the virtual server to prevent new connections.
2. To check for current users, use IIS Manager. Click **Current Sessions**. All current users are listed.
3. If you want to block current users from posting new articles, click the NNTP Settings Tab, and then clear the **Allow client posting** check box.
4. Stop the NNTP virtual server after all of the current users have disconnected.

**Related Information**

- For information about starting, stopping, or pausing the NNTP service, see Starting, Stopping, or Pausing the NNTP Service.

# Starting, Stopping, or Pausing the NNTP Service

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The NNTP service runs as a service on computers running a member of the Windows Server 2003 family. There can be multiple NNTP virtual servers on a computer, but only one instance of the NNTP service.

It is important to make sure that only trusted and qualified administrators in your organization have the necessary permissions to start or stop the NNTP service. For more information, see Restricting Operator Access.

You can start, stop, or pause each virtual server independently of one another while the NNTP service is running. It is important to remember, however, that pausing or stopping the entire NNTP service will affect all of the NNTP virtual servers. When the service is stopped, you cannot use Microsoft Management Console (MMC) to perform administrative functions on any NNTP virtual server.

The one exception is that, in MMC only, you can start a virtual server while the NNTP service is stopped. Starting an NNTP virtual server will also restart the entire the NNTP service. This, in turn, will start all other NNTP virtual servers that had been running when the NNTP service was originally stopped.

When you start the NNTP service, it accepts new connections from users. When you stop the NNTP service, it disconnects current users and does not accept new connections. When you pause the NNTP service, every running NNTP virtual server stops accepting new connections but continues to service existing connections. If you want to stop the NNTP service but not disconnect users currently connected to each of the virtual servers, you can also choose to shut down gracefully.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To start, stop, or pause the NNTP service**

1. From the **Start** menu, point to **Administrative Tools**, and then click **Component Services**.
2. In the **Component Services** box, click **Services (Local)**.
3. In the details pane, right-click **Network News Transfer Protocol (NNTP)**, and then click **Start**, **Stop**, or **Pause**.

**Note**

When you restart the NNTP service, all NNTP virtual servers that were running when you shut down the service will automatically restart. However, an NNTP virtual server that was already stopped when the service was shut down will remain stopped, even after the NNTP service is restarted.

**To shut down the NNTP service gracefully**

1. Follow the previous procedure to pause the NNTP service. This option prevents new connections.
2. Check for current users on each of your NNTP virtual servers. In IIS Manager, expand each NNTP virtual server and click **Current Sessions**. All current users are listed.
3. If you want to block current users from posting new articles, click the NNTP Settings Tab, and then clear the **Allow client posting** check box.
4. Stop each NNTP virtual server after all of the current users have disconnected.
5. After all of the current users have disconnected from each virtual server, stop the NNTP service.

**Related Information**

- For information about starting, stopping, or pausing NNTP virtual servers, see Starting, Stopping, or Pausing NNTP

Virtual Servers.

# NNTP Security

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

By default, any user who can connect to the Network News Transfer Protocol (NNTP) service can view all newsgroups. These users connect anonymously, which means that they do not have to supply a user name or password. The Setup program creates a different Windows user account that is used by all anonymous users.

You can configure security to control who has access to specific newsgroups and who can operate the NNTP service. You can also restrict access on the basis of the client computer IP address. If users connect to the NNTP service over a public network, you can encrypt that connection by using the Secure Sockets Layer (SSL) protocol so that others cannot intercept the articles being sent and received.

Security is based on Windows user accounts and directory permissions. User access to newsgroups is restricted on the basis of user name and password.

This section includes the following information:

- Restricting Access to Newsgroups: Describes how to restrict newsgroup access and set authentication methods.
- Limiting Access by IP Address: Describes how to restrict access to the NNTP service by the IP address of the client computer.
- Restricting Operator Access: Describes how to add and remove NNTP operator privileges.
- Securing Connections with SSL: Describes Secure Sockets Layer (SSL) concepts and how to implement them.

# Restricting Access to Newsgroups

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can control access to individual newsgroups or sets of newsgroups by setting permissions for the directories that contain those newsgroups. You can set permissions for an individual directory or for a set of directories. You can also limit access to all newsgroups according to the IP address of the client computer.

If you do not want to restrict access to a newsgroup, enable anonymous access and do not set any permissions for the directory that contains the newsgroup. To enable anonymous access, on the NNTP Access Tab, click the **Authentication** button under **Access control**, and then select the **Allow anonymous** check box.

**Procedures**

**To restrict access to a newsgroup**

1. Create Windows user accounts for users. It is recommended that you organize users into groups and then grant permissions by group to simplify administration. If possible, use accounts and groups that are already established in your organization.
2. Define permissions for the directory that contains the newsgroup. Be sure to give the LocalSystem account full access to all newsgroup directories so that the Network News Transfer Protocol (NNTP) service has access to newsgroup files.
3. Set the authentication method used by the NNTP service.

The NNTP service supports two methods for authentication of users:

- Basic authentication
- Integrated Windows authentication

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To set the authentication method**

1. In IIS Manager, expand the local computer, right-click the NNTP virtual server, and then click **Properties**.
2. On the **Access** tab, under **Access control**, click **Authentication**.
3. Select one or more of the following:
   - The **Allow anonymous** check box.
   - The **Basic authentication** check box.
   - The **Integrated Windows Authentication** check box.
   - The **Enable SSL client authentication** check box.

| **Important** |
| --- |
| If you are going to require only Basic authentication, it is highly recommended that you also enable SSL to prevent user names and passwords from being compromised during transmission. |

4. To require Secure Sockets Layer (SSL) authentication, select the **Require SSL client authentication** check box.
5. To associate client certificates with Windows user accounts, select the **Enable client certificate mapping to Windows user accounts** check box, and then click **Client Mappings**.

**Related Information**

- For information about limiting access by IP address, see Limiting Access by IP Address.
- For information about restricting operator access, see Restricting Operator Access.
- For information about securing connections with SSL, see Securing Connections with SSL.

# Limiting Access by IP Address

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can limit access to the NNTP service by the IP address of the client computer. By default, all IP addresses have access to the NNTP service.

You can either allow or deny access to a specific list of IP addresses. IP addresses can be specified individually or as a group by using a subnet mask. You can also specify IP addresses by using a domain name, but doing so adds the overhead of a DNS lookup for each connection.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To limit access by IP address**

1. In IIS Manager, expand the local computer, right-click the NNTP virtual server, and then click **Properties**.
2. On the **Access** tab, under **Connection control**, click **Connection**.
3. In the **Connection** box, click **All except the list below** to deny access to a list of IP addresses, or click **Only the list below** to allow access to a list of IP addresses.
4. In the **Connection** box, click **Add** for each IP address you want to grant or deny access to the NNTP virtual server.
5. In the **Computer** box, click one of the following options: **Single Computer**, **Group of computers**, or **Domain**. Then proceed as follows:
   - For the **Single Computer** option: In **IP address**, type the IP address of the computer. (If you don't know the IP address, click **DNS Lookup**.)
   - For the **Group of computers** option: In **Subnet address**, type the IP address. Then, in **Subnet mask**, type the subnet mask for the group of computers.
   - For the **Domain** option: In **Name**, type the domain name of the computer.
6. Click **OK**.

**Related Information**

- For information about restricting operator access, see Restricting Operator Access.
- For information about securing connections with SSL, see Securing Connections with SSL.

# Restricting Operator Access

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Operators of the NNTP service must be assigned operator user rights. By default, everyone in the Administrators group on computers running a member of the Windows Server 2003 family is assigned operator user rights.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

### To add an operator

1. In IIS Manager, expand the local computer, right-click the NNTP virtual server, and then click **Properties**.
2. On the **Security** tab, click **Add**.
3. In the **Select Users or Groups** box, click **Locations**, and then click the domain of the operator you want to add.
4. In the **Select Users or Groups** box, click **Object Types**, click the operator or group, and then click **OK**.
5. In the **Select Users or Groups** box, type the object name to select, or click **Advanced** to search for a particular object.
6. After you make all of your selections, click **OK**.

### To remove an operator

1. In IIS Manager, expand the local computer, right-click the NNTP virtual server, and then click **Properties**.
2. On the **Security** tab, in the **Operators** list, click the operator that you want to remove.
3. On the **Security** tab, click **Remove**, and then click **OK**.

**Related Information**

- For information about limiting access by IP address, see Limiting Access by IP Address.
- For information about securing connections with SSL, see Securing Connections with SSL.

# Securing Connections with SSL

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Secure Sockets Layer (SSL) provides a secure, encrypted connection between the NNTP service and the client computer. SSL can protect your private information when users connect across a public network such as the Internet.

SSL support requires an SSL certificate, and this certificate has to be installed on a computer running a member of the Windows Server 2003 family. SSL must also be supported by the client software. Microsoft Outlook Express supports SSL.

If a server certificate is installed, the NNTP service uses SSL whenever a client requests it. You can optionally require SSL for all newsgroups or for newsgroups located in a virtual directory. You can also use SSL authentication of clients.

**Procedures**

**To enable SSL**

- Obtain and install an SSL server certificate.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To require an SSL connection for access to newsgroups**

1. In IIS Manager, expand the local computer, expand the NNTP virtual server, and then click **Virtual Directories**.
2. In the details pane, right-click the virtual directory that you want to modify, and then click **Properties**.
3. On the **General** tab, click **Secure**.
4. In the **Security** box, select the **Require secure channel** check box.

**To enable SSL authentication for clients**

1. In IIS Manager, expand the local computer, right-click the NNTP virtual server, and then click **Properties**.
2. On the **Access** tab, click **Authentication**.
3. In the **Authentication Methods** box, select the **Enable SSL client authentication** check box.

**Related Information**

- For information about limiting access by IP address, see Limiting Access by IP Address.

# Managing Newsgroups

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

As soon as you create your newsgroups, users can begin posting articles to them. If you want a moderator to review new articles before they are posted, define a moderated newsgroup.

You can change the properties of an existing newsgroup or delete the newsgroup if you no longer need it. You can also select options that enable the NNTP service to delete articles after a specified number of hours or when the amount of disk space used by newsgroups reaches specified limits. Finally, you can filter which newsgroups are visible to users and the number that will display whenever the **Newsgroups** node is selected under the Network News Transfer Protocol (NNTP) virtual server.

This section includes the following information:

- Creating Newsgroups in IIS 6.0: Describes how to use the New Newsgroup Wizard to create a newsgroup.
- Moderating Newsgroups in IIS 6.0: Introduces the concept of moderating newsgroups, how to enable moderating, and how to create a moderated newsgroup.
- Editing and Deleting Newsgroups: Describes how to edit the properties of an existing NNTP service newsgroup or delete a newsgroup that you no longer need.
- Defining Newsgroup Limits and Expirations: Describes how to limit the length of time articles are kept in an NNTP service newsgroup by defining expiration policies for newsgroups.
- Limiting Newsgroup Enumeration in IIS 6.0: Describes how to limit the number of newsgroups that will be displayed in IIS Manager.

# Creating Newsgroups in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use the New Newsgroup Wizard to create a newsgroup. When you create a new newsgroup, the NNTP service creates the directory for the newsgroup automatically. If you want a moderator to review new articles before they are posted, you can create a moderated newsgroup.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To create a newsgroup**

1. In IIS Manager, expand the local computer, and then expand the NNTP virtual server that you want.
2. Right-click **Newsgroups**, point to **New**, and then click **Newsgroup**.
3. Follow the steps in the New Newsgroup Wizard:
   - In **Name**, type the name of the newsgroup you want to create.
   - In **Description**, type a brief description of the newsgroup function.
   - If you want, in **Pretty name** type another name for the newsgroup, which will be returned by the **List Prettynames NNTP** command. The pretty name is another alias for the newsgroup that can be displayed by clients.
   - Click **Finish**.

**Related Information**

- For information about moderated newsgroups, see Moderating Newsgroups in IIS 6.0.
- For information about editing and deleting newsgroups, see Editing and Deleting Newsgroups.
- For information about defining newsgroup limits and expirations, see Defining Newsgroup Limits and Expirations.
- For information about limiting newsgroup enumeration, see Limiting Newsgroup Enumeration in IIS 6.0.

# Moderating Newsgroups in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you want to control what articles are posted to a newsgroup, you should create a moderated newsgroup. Articles submitted to a moderated newsgroup are not posted until they are approved by the moderator you have chosen for that newsgroup.

| **Note** |
| --- |
| Microsoft recommends having a moderator for every newsgroup, especially if users outside your organization are allowed to make postings on your server. A moderator can filter inappropriate material and he or she can detect if someone is trying to compromise information on the server or compromise the server itself. |

When a user submits an article to a moderated newsgroup, the NNTP service sends the article to the newsgroup moderator. The moderator can either approve the article and send it back to the NNTP service to be posted or discard the article. For discarded articles, the moderator can send a message to the article's author to explain why the article was rejected.

Any NNTP client can be used to post messages to a moderated newsgroup. However, the moderator needs to use an NNTP client that supports moderating functions.

To use moderated newsgroups, you must specify either a Simple Mail Transfer Protocol (SMTP) mail server for sending articles directly to the moderators or a directory where the articles are stored for the moderators.

You can also specify a default moderator domain. If you choose to use the default moderator for a newsgroup, articles are sent to *newsgroup_name@default_domain*, where *newsgroup_name* is the name of the newsgroup (the periods have been replaced by underscores). For example, articles posted to the newsgroup rec.sports.tennis, with a default domain of contoso.com, are sent to rec_sports_tennis@contoso.com.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

### To enable moderated newsgroups

1. In IIS Manager, expand the local computer, right-click the NNTP virtual server, and then click **Properties**.
2. On the **Settings** tab, in **SMTP server for moderated groups**, type the DNS name or the IP address of the SMTP server, or type the path to the directory where articles are stored for the moderators. The directory path must be a local directory. You should normally set this value to the pickup directory of the SMTP server. By default, this directory is *localdrive*\Inetpub\Mailroot\Pickup.
3. On the **Settings** tab, in **Default moderator domain**, type the e-mail domain for default moderators.
4. Click **OK**.
5. If you specified an SMTP server, be sure that the user ID under which the NNTP service is running (by default, the System Account) is defined as an account on the SMTP server.

### To create a moderated newsgroup

1. If necessary, create the newsgroup. After you finish the New Newsgroup Wizard, the procedure is the same for both new and existing newsgroups.
2. In IIS Manager, expand the local computer, expand the NNTP virtual server, and then click **Newsgroups**.
3. In the details pane, right-click the newsgroup that you want, and then click **Properties**.
4. On the **General** tab, select the **Moderated** check box.

5. In **Moderator**, type the e-mail address of the moderator, or click **Set Default** to use the default moderator.
6. Click **OK**.

**Related Information**

- For information about creating newsgroups, see Creating Newsgroups in IIS 6.0.
- For information about editing and deleting newsgroups, see Editing and Deleting Newsgroups.
- For information about limiting newsgroup enumeration, see Limiting Newsgroup Enumeration in IIS 6.0.

# Editing and Deleting Newsgroups

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can edit the properties of an existing NNTP service newsgroup or delete a newsgroup that you no longer need.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

### To edit or delete a newsgroup

1. In IIS Manager, expand the local computer, expand the NNTP virtual server, and then click **Newsgroups**.
2. In the details pane, right-click the newsgroup that you want, and then click one of the following:
   - **Properties**, to edit the newsgroup properties.
   - **Rename**, to rename the newsgroup.
   - **Delete**, to remove the newsgroup.

**Related Information**

- For information about creating newsgroups, see Creating Newsgroups in IIS 6.0.

# Defining Newsgroup Limits and Expirations

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can limit how long articles are kept in an NNTP service newsgroup by defining expiration policies for newsgroups. An expiration policy can apply to a single newsgroup or to any number of newsgroups. You can define as many policies as you need. In each case, the oldest articles are deleted first.

If you do not specify an expiration policy for a newsgroup, you should delete articles manually when they are no longer needed.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

#### Procedures

### To create an expiration policy

1. In IIS Manager, expand the local computer, and then expand the NNTP virtual server that you want.
2. Right-click **Expiration Policies**, point to **New**, and then click **Expiration Policy**.
3. Follow the steps in the New NNTP Expiration Policy Wizard.

You can modify an existing expiration policy, including changing the newsgroups to which the policy applies, with the **Expiration Policy** dialog box.

### To modify an expiration policy

1. In IIS Manager, expand the local computer, expand the NNTP virtual server that you want, and then click **Expiration Policies**.
2. In the details pane, right-click the expiration policy that you want to modify, and then click **Properties**.
3. Change the options in the **Expiration Policy** box as needed.

**Note**

Use the **Move Up** and **Move Down** buttons to specify which newsgroups the expiration policy should apply to and in what order. For example, if you want to include all of the alt.tv newsgroups (alt.tv.*) in the policy, but exclude the alt.tv.cable newsgroup from the policy, meaning that you want to apply an expiration policy to all of the alt.tv newsgroups except the alt.tv.cable newsgroup, use the **Move Up** and **Move Down** buttons to include alt.tv.* first and exclude alt.tv.cable second.

#### Related Information

- For information about editing and deleting newsgroups, see Editing and Deleting Newsgroups.

# Limiting Newsgroup Enumeration in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use the **Find Newsgroups** dialog box to limit the number of newsgroups that will be displayed when you select **Newsgroups**, which is beneath the NNTP virtual server node.

Potentially, a server can store thousands of newsgroups; in some cases, it might not be possible to enumerate all of them. Administrators may want to filter the newsgroups that will be enumerated. You can filter newsgroups by type, by number, or both.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To limit the number of enumerated newsgroups**

1. In IIS Manager, expand the local computer, and then expand the NNTP virtual server that you want.
2. Right-click **Newsgroups**, and then click **Limit groups enumeration**.
3. In the **Newsgroups** field, type the kind of the newsgroup you want to display when **Newsgroup** is selected. All other types will be filtered out. Use wildcards, such as **alt.***. In this example, only newsgroups under the **alt** hierarchy would be visible to users. By default, every kind of newsgroup is enumerated.

   | **Note** |
   | --- |
   | You can also type the name of a specific newsgroup in this space, but then only that newsgroup will be visible. Only one wildcard or one newsgroup can be entered at a time. |

4. If you do not want to have a limit on the number of enumerated newsgroups, clear the **Limit number of items on the result pane** check box. This check box is selected by default.
5. In **Maximum number of items**, type the maximum number of newsgroups that you want to enumerate on this virtual server. This limit will only apply when the **Limit number of items on the result pane** check box is selected. The default is 100 newsgroups.

**Related Information**

- For information about creating newsgroups, see Creating Newsgroups in IIS 6.0.
- For information about editing and deleting newsgroups, see Editing and Deleting Newsgroups.

# Configuring Expiration Policies

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Expiration policies can be set separately for each virtual server. Expiration policies specify the article age limit for newsgroups; they also specify the newsgroups to which the policy applies. If a newsgroup is assigned to more than one expiration policy, the more restrictive policy applies.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To create a new expiration policy**

1. In IIS Manager, expand the local computer, and then expand the NNTP virtual server that you want.
2. Right-click **Expiration Policies**, point to **New**, and then click **Expiration Policy**.
3. Follow the steps in the New NNTP Expiration Policy Wizard. The wizard will prompt you for the name of an expiration policy, the newsgroups it will affect, and the expiration period. These properties are described in the table below.

**To edit an existing expiration policy**

1. In IIS Manager, expand the local computer, expand the NNTP virtual server that you want, and then click **Expiration Policies**.
2. In the details pane, right-click the expiration policy that you want to edit, and then click **Properties**.
3. Change the options in the **Expiration Policy** box as needed.

| **Note** |
| --- |
| Use the **Move Up** and **Move Down** buttons to specify which newsgroups the expiration policy should apply to and in what order. For example, if you want to include all of the alt.tv newsgroups (alt.tv.*) in the policy, but exclude the alt.tv.cable newsgroup from the policy, meaning that you want to apply an expiration policy to all of the alt.tv newsgroups except the alt.tv.cable newsgroup, use the **Move Up** and **Move Down** buttons to include alt.tv.* first and exclude alt.tv.cable second. |

The following properties can be set for expiration policies:

| Option | Description |
| --- | --- |
| Articles older than (Hours) | Removes articles that are older than a specified number of hours. The default is 168 hours (7 days). To have no age limit, clear the check box. |
| Affected newsgroups | A list of the newsgroups to which the policy applies. The asterisk (*) wildcard character specifies multiple newsgroups. For example, rec.* denotes and includes all newsgroups starting with "rec.". |
| Add | Click this button to open the **Add Newsgroup** dialog box where you can type in the names of newsgroups to add to this expiration policy. Use the asterisk (*) wildcard character to specify multiple newsgroups. |
| Remove | To remove a newsgroup from an expiration policy, select the newsgroup in the list of **Affected newsgroups** and click **Remove**. |

| | |
|---|---|
| Move Up | To move a newsgroup up in an expiration policy, select the newsgroup in the list of **Affected newsgroups** and click **Move Up**. |
| Move Down | To move a newsgroup down in an expiration policy, select the newsgroup in the list of **Affected newsgroups** and click **Move Down**. |

**Related Information**

- For information about creating expiration policies, see Defining Newsgroup Limits and Expirations.

# Rebuilding the IIS NNTP Service

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can rebuild the IIS NNTP service by using IIS Manager.

You can choose one of two rebuild types:

- **Standard**. Rebuilds only group.lst files, based on the contents of the virtual directories. This is the faster of the two options.
- **Thorough**. Rebuilds all internal files, such as .hsh and .lst files.

First run the standard rebuild. If the problem is not fixed when you run the standard rebuild, run a thorough rebuild.

| **Note** |
| --- |
| You must stop the NNTP service news server before you can rebuild it. |

**To rebuild the NNTP service by using IIS Manager**

1. In IIS Manager, click the local computer, right-click the NNTP virtual server, and then click **Stop**.
2. Right-click the NNTP virtual server again, point to **All Tasks**, and then click **Rebuild Server**. If **Rebuild Server** is not available, then the server might still be running. Check to make sure that it is stopped.
3. In the **Rebuild NNTP Virtual Server** dialog box, do one of the following:
   - To run a standard rebuild, in **Rebuild type**, move the slider to **Standard**, and then click **Start**.
   - To run a thorough rebuild, in **Rebuild type**, move the slider to **Thorough**, and then click **Start**.

For more information about common problems that you can fix by rebuilding the NNTP service, see Rebuilding the NNTP Service.

# Enabling Newsfeeds

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Newsfeeds send articles between the IIS NNTP service and other NNTP servers. With newsfeeds, the articles that are posted to one server can be read by users of the other servers. Newsfeeds are not enabled by default.

**To enable newsfeeds**

1. In IIS Manager, click the local computer, right-click the NNTP virtual server, and then click **Properties**.
2. Click the **Settings** tab, select the **Allow feed posting** check box, and then do any of the following:
   - To limit the size of articles posted to this news site, select the **Limit post size (KB)**check box, and type or select the size (1 to 32,000 kilobytes) of the largest article that is accepted.
   - To limit the size of a newsfeed, select the **Limit connection size (MB)**check box, and type or select the size (1 to 4000 megabytes) of the largest newsfeed to accept.
   - To allow servers to pull articles from this news site, select the **Allow servers to pull news articles from this server**check box.

For information about the different kinds of newsfeeds, and adding, deleting, and modifying newsfeeds with Rfeed.vbs, see Managing Newsfeeds.

# SMTP Administration

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The Internet-standard Simple Mail Transfer Protocol (SMTP) can be used to transport and deliver messages based on specifications in Request for Comments (RFC) 821 and RFC 822. The SMTP server also includes enhancements that build upon the basic delivery functions of the protocol. There are options available that give you control over the routing and delivery of messages, and that provide secure communications.

This section includes the following information:

- Configuring SMTP Virtual Servers: Describes how to set an SMTP virtual server display name and the IP address/TCP port combination.
- Starting, Stopping, or Pausing SMTP Virtual Servers: Introduces the concepts of starting, stopping, and pausing an SMTP virtual server and how it differs from the same actions on a service.
- Starting, Stopping, or Pausing the SMTP Service: Describes the concept of multiple virtual servers and how to start, stop, or pause them individually.
- Configuring Startup Settings: Describes how to configure the default state of the SMTP service at startup.
- Setting Connections: Describes how to set incoming and outgoing connection limits.
- Creating Additional SMTP Virtual Servers: Describes how to create new SMTP virtual servers.
- Setting Up Virtual Servers for Clustering: Introduces the concept of clustered servers and how to configure virtual servers for that environment.
- Enabling Protocol Logging: Describes how to enable logging in ASCII or ODBC formats.
- SMTP Security: Introduces security and access concepts.
- Delivering Messages: Describes the settings that determine how delivery occurs, including routing, transmission, and security options.
- Managing Messages_IIS_SP1_Ops: Describes how to set connection limits to maximize performance, how to set limits for message size and number of recipients, and how to manage undeliverable messages.
- LDAP Routing: Describes how to configure the SMTP service so that it will consult an LDAP server to resolve senders and recipients.
- Monitoring Message Transactions: Describes four protocol log formats and how to implement them.
- SMTP Domains: Introduces local and remote domain concepts.

# Configuring SMTP Virtual Servers

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

There are two identifying features for a Simple Mail Transfer Protocol (SMTP) virtual server: the display name and the IP address/TCP port combination. Setup assigns a Microsoft Management Console display name for the default SMTP virtual server. You can keep the name (Default SMTP Virtual Server) or change it using the following steps. You can also select the IP address that will be associated with this SMTP virtual server.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**.

**Procedures**

**To identify an SMTP virtual server**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Rename**.
2. Type a new name for the virtual server name if you want to change it from the default. Do not use extended characters when naming your SMTP virtual server.
3. Right-click the SMTP virtual server, and click **Properties**.
4. On the **General** tab, in the **IP address** list, click the IP address for this virtual server. The SMTP virtual server can respond to connection requests for all IP addresses configured on the computer. To identify the TCP port for each IP address configured for the virtual server, click **Advanced**. Port 25 is the SMTP standard TCP port and is recommended. More than one virtual server can use Port 25, provided they are associated with different IP addresses.

**Note**

When you change an SMTP virtual server's configuration, you may want to use the **Pause** command. Pausing prevents new client connections but enables Microsoft SMTP Service to continue to process existing client connections and deliver queued messages.

# Starting, Stopping, or Pausing SMTP Virtual Servers

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The Default SMTP Virtual Server starts upon installation of the SMTP service. You can pause, stop, and start it in IIS Manager.

You can also start, stop, and pause the entire SMTP service. However, if you have more than one virtual server, stopping the service affects all of the Simple Mail Transfer Protocol (SMTP) virtual servers running on your computer. When the SMTP service is stopped, you cannot use IIS in Microsoft Management Console (MMC) to perform administrative functions on any SMTP virtual server.

| **Important** |
| --- |
| Make sure only trusted administrators in your organization have the necessary permissions to start or stop an SMTP virtual server. For more information, see Setting Operator Permissions. |

You can stop and start the SMTP service manually. However, while it is operating, you must be careful when stopping, pausing, or restarting the service to minimize the impact on users.

If the default startup setting is **Manual**, you can use IIS in Microsoft Management Console (MMC) to start a Simple Mail Transfer Protocol (SMTP) virtual server.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To start an SMTP virtual server**

- In IIS Manager, expand the local computer, right-click the SMTP virtual server, and click **Start**.

You can stop a Simple Mail Transfer Protocol (SMTP) virtual server for configuration changes and maintenance.

**To stop an SMTP virtual server**

- In IIS Manager, expand the local computer, right-click the SMTP virtual server, and click **Stop**.

You can pause a Simple Mail Transfer Protocol (SMTP) virtual server for configuration changes and maintenance. Pausing prevents new client connections, but it enables the virtual server to continue processing existing client connections and delivering queued messages.

**To pause an SMTP virtual server**

- In IIS Manager, expand the local computer, right-click the SMTP virtual server, and click **Pause**.

**Related Information**

- For information about managing the SMTP service, see Starting, Stopping, or Pausing the SMTP Service.

# Starting, Stopping, or Pausing the SMTP Service

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The SMTP service runs as a service on Windows Server 2003, Standard Edition and Windows Server 2003, Enterprise Edition, and it starts upon installation. Although there is only one SMTP service on a computer, it is possible to have more than one Simple Mail Transfer Protocol (SMTP) virtual server. You can start, stop, or pause each virtual server independently of one another while the SMTP service is running.

If you have more than one SMTP virtual server, it is important to remember that pausing or stopping the entire SMTP service will affect all of the SMTP virtual servers. When the service is stopped, you cannot use IIS in Microsoft Management Console (MMC) to perform administrative functions on any SMTP virtual server.

| **Note** |
| --- |
| The one exception is that you can start a virtual server while the SMTP service is stopped. Starting an SMTP virtual server will also restart the entire SMTP service. This, in turn, will start all other SMTP virtual servers that had been running when the SMTP service was originally stopped. |

When you start the SMTP service, it accepts new connections from users. When you stop the SMTP service, it does not accept new connections. When you pause the SMTP service, every running SMTP virtual server will cease accepting new connections but will continue to service existing connections.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To start, stop, or pause the SMTP service**

1. From the **Start** menu, point to **Administrative Tools**, and then click **Component Services**.
2. In the console tree, click **Services (Local)**.
3. In the details pane, right-click **Simple Mail Transfer Protocol (SMTP)**, and then click **Start**, **Stop**, or **Pause**.

| **Note** |
| --- |
| When you restart the SMTP service, all SMTP virtual servers that had been running when you shut down the service will automatically restart. However, an SMTP virtual server that was already stopped when the service was shut down will remain stopped, even after the SMTP service restarts. |

**Related Information**

- For information about starting, stopping, or pausing an SMTP virtual server, see Starting, Stopping, or Pausing SMTP Virtual Servers.

# Configuring Startup Settings

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use Administrative Tools to configure the default state of the SMTP service at startup.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in theAdministrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**To set SMTP Startup Type**

1. From the Start menu, point to Administrative Tools, and then click Component Services.
2. In the console tree, click Services (Local).
3. In the details pane, right-click Simple Mail Transfer Protocol (SMTP), and then click Properties.
4. On the General tab, in the Startup type list, click Automatic, Manual, or Disabled.

# Setting Connections

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

A connection is initiated whenever a message is sent to or received from a remote server.

| **Note** |
| --- |
| Designating the TCP port that the SMTP service uses to receive incoming messages is done when you configure the Simple Mail Transfer Protocol (SMTP) virtual server. |

Setting connection limits and imposing connection time-outs can make it more difficult for someone to initiate a malicious attack (such as denial of service) against your virtual server.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To configure incoming connections**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. On the **General** tab, select the **Limit number of connections to** check box (the default is no limit), and set the following options.

| Option | Description |
| --- | --- |
| **Limit number of connections to** | When the check box is selected, this option specifies the number of concurrent connections for incoming message delivery. The minimum is 1 connection. When the check box is not selected, no limit is imposed. |
| **Connection time-out (minutes)** | Specifies the time allowed before an inactive connection is closed. The default is 10 minutes. |

**To configure outbound connections**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Delivery** tab, and click **Outbound connections**.
3. In the **Outbound Connections** dialog box, select a check box and set the following options.

| Option | Description |
| --- | --- |
| **Limit number of connections to** | When the check box is selected, this option specifies the total number of simultaneous outbound connections to all remote domains that can exist at one time. The default is 1,000 connections. The minimum is 1.<br><br>This setting can be used to improve system performance in conjunction with the **Limit number of messages per connection to** check box on the **Messages** tab. |
| **Time-out (minutes)** | Specifies the time allowed before an inactive connection is closed. The default is 10 minutes. |

| | |
|---|---|
| **Limit number of connections per domain to** | When the check box is selected, this option limits connections to any single remote domain. The default is 100 connections. This number should be less than or equal to the value for the **Limit number of connections to** option. |
| **TCP port** | Designates the TCP port used for outgoing transmissions. The default is port 25. The outgoing port setting can be the same as that for incoming transmissions or it can be different. |

**Related Information**

- For information about configuring an SMTP virtual server, see Configuring SMTP Virtual Servers.
- For information about limiting the number of messages per connection, see Limiting the Number of Messages per Connection.

# Creating Additional SMTP Virtual Servers

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In most cases, you should need only one Simple Mail Transfer Protocol (SMTP) virtual server. However, if you are hosting multiple domains and want to have more than one default domain, for example, you can create multiple SMTP virtual servers. To an end user, each SMTP virtual server appears as a separate server with a unique IP address/TCP port combination.

When you create an SMTP virtual server, you are prompted to enter a path to your home directory. This directory must be local to the computer on which the SMTP service runs.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To create a new SMTP virtual server**

1. If the SMTP virtual server will be using a new IP address, configure an IP address. From the **Start** menu, click **Control Panel**, and then double-click **Network Connections**. See Windows Server 2003 family Help for more information about Network Connections.
2. After you configure the IP address, in IIS Manager, right-click an existing SMTP virtual server, point to **New**, and then click **Virtual Server**.
3. Follow the steps in the **New SMTP Virtual Server Wizard**. Be sure to select an IP address/TCP port combination that is not being used by another SMTP virtual server. The recommended TCP port is 25, which is the SMTP standard TCP port. More than one virtual server can use the same TCP port provided they are configured with different IP addresses.
4. If the default startup setting for SMTP Service is set to **Automatic**, the new SMTP virtual server will start automatically. If it doesn't start, it is because you selected an IP address/TCP port combination that is already in use.
5. Configure the new SMTP virtual server.

**Related Information**

- For information about configuring an SMTP virtual server, see Configuring SMTP Virtual Servers.

# Setting Up Virtual Servers for Clustering

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

A server cluster is a group of independent computer systems, known as nodes, working together as a single system to ensure that mission-critical applications and resources remain available to clients. Server clusters provide high availability. High availability in a Simple Mail Transfer Protocol (SMTP) server cluster means that, if one virtual server fails, its work is dispersed to the remaining virtual servers in the cluster, ensuring mail service is not interrupted. The other benefit of server clusters is the failover of server resources, which is when a virtual server goes down and another one comes online to assumes its role.

In clustering, a node is a system that has a working installation of Windows Server 2003, Enterprise Edition and the Cluster service. Microsoft recommends creating a new virtual server on your node for clustering, rather than reconfiguring your default SMTP virtual server.

For more information about Windows Clustering and server clusters, see Windows Server 2003, Enterprise Edition Help. That documentation contains detailed information about setting up and administrating server clusters.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set up an SMTP virtual server for clustering**

1. If necessary, change the default startup setting of the SMTP Service to **Manual**.
2. Before creating a new virtual server, in IIS Manager, right-click **Default SMTP Virtual Server**, and then click **Properties**.
3. On the **General** tab, click **Advanced**.
4. Under **Address**, double-click **All Unassigned**.
5. In the **Identification** box, change the TCP port number from 25, which is the default setting, to another port number -- any unassigned port will work. Type in the new port number, making sure it is unique, and then click **OK**.
6. Create a new SMTP virtual server. After it is created, you will have to manually start the new virtual server. Use the default TCP port on the new virtual server, which is port 25.

   | **Important** |
   | --- |
   | When you get to the **Select Home Directory and Default Domain** screen of the New SMTP Virtual Server Wizard, be sure to type paths to the shared resource that will be used in clustering. Do not type paths to a local hard drive. |

7. Run the **iiscnfg /copy** command to copy the IIS configuration on your node to the other nodes in the server cluster. At a command prompt, navigate to the systemroot\System32\Inetsrv directory on your node, and then type **iiscnfg /copy /ts target server /tu userid /tp password** where the following is true:
   - **/ts** is another node in the same cluster.
   - **/tu** is the user ID to use when connecting to the target server.
   - **/tp** is the password associated with the specified user ID.

| **Important** |
| --- |

The **/copy** operation does not copy the server content, such as Web pages and FTP files, that is associated with the IIS configuration. This command changes the computer-specific and system-specific properties in the metabase so that they are valid on the target computer. However, it does not adjust the directory or file paths. As a result, you might need to configure valid paths on the target computer.

Repeat the **iiscnfg /copy** command for each node in the server cluster. For more information about the **iiscnfg /copy** command, see Copying IIS Configurations Using Iiscnfg.vbs.

1. Check the TCP port numbers on your newly created SMTP virtual server and on the default virtual server. Specifically, view your local node from other nodes in the server cluster, and make sure that the TCP port settings are identical to the settings on the local node. On all nodes, the default SMTP virtual server should no longer point to the default TCP port (25), but the new SMTP virtual server should be assigned port 25. Settings must be identical on every node for clustering to work.

2. Start **Cluster Administrator**. Follow the wizard and associate a resource type to the new SMTP virtual server.

**Note**

In the **Parameters** box, be sure to select your new SMTP virtual server from the list, and not the default SMTP virtual server. See Windows Server 2003 Enterprise Edition Help for more information about Cluster Administrator.

**Related Information**

- For information about configuring the default startup setting, see Configuring Startup Settings
- For information about creating additional SMTP virtual servers, see Creating Additional SMTP Virtual Servers.
- For information about starting, stopping, or pausing SMTP virtual servers, see Starting, Stopping, or Pausing SMTP Virtual Servers.

# Enabling Protocol Logging

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use the **General** tab to enable transaction logging and to select the format. When setting up the log file, keep in mind that the log formats and default file names are the same as those used by other IIS services. If you choose the default names, all transactions for all services are recorded in the same file. You can set up a separate file for each service if you want to maintain separate records.

If you set up the file in a location other than the default, make sure it is stored on a local drive and not on a network.

Auditing server activity with log files is a good way to detect if unauthorized external users are attempting to access your virtual server, or if internal users are trying to access resources they do not have permission to access. For more information about auditing and using Event Viewer, see Windows Server 2003 family Help.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To enable logging that uses one of the ASCII text formats**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. On the **General** tab, select the **Enable logging** check box.
3. In the **Active log format** list, click a transaction log format. If you chose the **W3C Extended Log File Format**, click the **Advanced** tab, and then click the items you want to track.
4. Click **Properties**, and then set the log file size and location.

**To enable logging that uses the ODBC format**

1. Set up an ODBC-compliant database.
2. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
3. On the **General** tab, select the **Enable logging** check box.
4. In the **Active log** format list, click **ODBC Logging**.
5. Click **Properties**, and then set the log file size and location.

**Related Information**

- For information about monitoring message transactions, see Monitoring Message Transactions.
- For information about setting up an ODBC-compliant database, see Setting Up an ODBC-Compliant Database.

# SMTP Security

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can specify security settings for a Simple Mail Transfer Protocol (SMTP) virtual server on the two security tabs. These settings apply to all domains on the virtual server.

| Tab | Settings |
|---|---|
| **Security** | Designates the user accounts that have operator permissions to run the SMTP service. Operators have the ability to configure SMTP virtual server properties. |
| **Access** | Contains settings to require authentication and the use of Transport Layer Security (TLS) for all incoming connections. You can also grant or deny access to specific computers or networks. |

This section includes the following information:

- Setting Operator Permissions: Describes how to assign and remove operator permission on SMTP virtual servers.
- Requiring Authentication for Incoming Connections: Describes how to disable authentication for incoming messages, set clear text authentication for incoming messages, and use integrated Windows authentication to authenticate incoming messages.
- Requiring Authentication for Outbound Messages: Describes how to disable authentication for outgoing messages, set Basic authentication for outgoing messages, and set Integrated Windows authentication for outgoing messages.
- Setting IP Access Restrictions to Servers: Describes how to set IP address access restrictions.
- Configuring SMTP Virtual Server Relay Restrictions: Describes how to add and remove relay restrictions from an SMTP virtual server.
- Requiring TLS Encryption: Describes how to create and manage key certificates and how to set TLS encryption levels for the server.

# Setting Operator Permissions

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can designate which user accounts can have operator permissions for the Simple Mail Transfer Protocol (SMTP) virtual server. After Windows user accounts are set up, you can grant permissions by selecting the account from a list. These permissions can be rescinded by removing the account from the list of virtual server operators.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To assign operator permissions**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Security** tab, and click **Add**.
3. Select a Windows user account, and then click **OK**. The selected account will now appear in Operators.

**To remove operator permissions**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Security** tab, and in the Operators list, click the operator you want to remove.
3. Click **Remove**.

| **Note** |
| --- |
| You can also remove operator permissions from the Windows user accounts that are listed in Operators. |

**Related Information**

- For information about requiring authentication for incoming connections, see Requiring Authentication for Incoming Connections.
- For information about requiring authentication for outbound messages, see Requiring Authentication for Outbound Messages.

# Requiring Authentication for Incoming Connections

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

There are three authentication methods available. You can choose one, two, or all three methods. All three are set by default.

| **Important** |
| --- |
| The default mail relay settings on the SMTP virtual server allow only mail from authenticated users to be relayed. Therefore, to allow users in your organization to send mail through the virtual server, users must first be authenticated. By choosing one of the methods in the Authentication dialog box, your users will be able to send mail and, at the same time, unauthorized users will not be able to use your virtual server to relay mail. |

| Authentication option | Description |
| --- | --- |
| **Anonymous access** | An account name or password is not required. You can use this option to disable authentication for the Simple Mail Transfer Protocol (SMTP) virtual server. |
| **Basic authentication** | An account name and a password are sent using plaintext. Specify a Windows domain that is appended to the account name for authentication. |
| **Integrated Windows authentication** | A Windows account name and password are authenticated using this option. |

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To disable authentication for incoming messages**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Access** tab, and under **Access control**, click **Authentication**.
3. Select the **Anonymous access** check box, and then clear the remaining check boxes for the other options.

**To set clear text authentication for incoming messages**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Access** tab, and under **Access control**, click **Authentication**.
3. Select the **Basic authentication** check box.
4. In the **Default domain** box, type a Windows domain name. This default domain differs from the SMTP virtual server default domain.

**To use Integrated Windows authentication to authenticate incoming messages**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Access** tab, and under **Access control**, click **Authentication**.
3. Select the **Integrated Windows Authentication** check box.

**Related Information**

- For information about requiring authentication for outbound messages, see Requiring Authentication for Outbound Messages.

# Requiring Authentication for Outbound Messages

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure the Simple Mail Transfer Protocol (SMTP) virtual server to provide the authentication credentials required by a receiving server. There are three types of authentication available: anonymous, Basic (plaintext), and Integrated Windows authentication. Anonymous requires no authentication. With the plaintext option, the account name and password of the server you're connecting to are transmitted in plaintext. The Integrated Windows authentication option requires a Windows account name and password.

The option set here can be overridden for a specific remote domain. Overriding the authentication settings for a remote domain enables you to set the virtual server authentication level to handle most of the transmissions, while allowing exceptions for individual addresses. The following table describes several configuration examples.

| SMTP transmissions | Authentication option |
|---|---|
| Messages are commonly sent to multiple addresses. | Disable authentication for the SMTP virtual server. If attempts to deliver messages to an address fail because of authentication requirements, add a remote domain for the address. Then enable authentication for the domain at the same level required by the server. |
| Messages are commonly sent to one address, which requires authentication. | Determine what level of authentication is required to connect. Then enable authentication for the SMTP virtual server using the same level. If you want to then send messages to other addresses, set up remote domains and set different authentication options. If you use this option, it is likely that the account name used is the one that identifies the computer set up as the smart host. |

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To disable authentication for outgoing messages**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Delivery** tab, and click **Outbound Security**.
3. Click **Anonymous access**.
4. Clear all other options.

**To set Basic authentication for outgoing messages**

1. In IIS Manager, select the SMTP virtual server, and then click **Properties** on the **Action** menu.
2. On the **Delivery** tab, click **Outbound Security** to open the **Outbound Security** dialog box.
3. Click **Basic authentication**.
4. Under **User name** and **Password**, type the account name and password that will grant you access to the computer you are connecting to.

**Important**

If Basic authentication is your only authentication method, it is strongly recommended that you also require TLS encryption to avoid unauthorized detection of user names and passwords.

**To set Integrated Windows authentication for outgoing messages**

1. In IIS Manager, select the SMTP virtual server, and then click **Properties** on the **Action** menu.
2. On the **Delivery** tab, click **Outbound Security** to open the **Outbound Security** dialog box.
3. Select the **Integrated Windows Authentication** check box.
4. Under **Account** and **Password**, type a Windows account name and password that will grant you access to the computer you're connecting to.

**Related Information**

- For information about requiring authentication for incoming connections, see Requiring Authentication for Incoming Connections.
- For information about encrypting outgoing messages, see Requiring TLS Encryption.

# Setting IP Access Restrictions to Servers

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can grant or deny Simple Mail Transfer Protocol (SMTP) virtual server access to specific IP addresses. By default, the SMTP virtual server is accessible to all IP addresses. You can set restrictions by specifying a single IP address, a group of addresses using a subnet mask, or a domain name.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set IP address access restrictions**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Access** tab, and under **Connection control**, click **Connection**.
3. Click either **Only the list below** or **All except the list below**.
4. To add to the list of computers, click **Add**.
5. To delete from the list of computers, select a listing, and then click **Remove**.

**Related Information**

- For information about setting or removing relay restrictions from a virtual server, see Configuring SMTP Virtual Server Relay Restrictions.
- For information about requiring TLS encryption, see Requiring TLS Encryption.

# Configuring SMTP Virtual Server Relay Restrictions

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS includes a full-featured SMTP virtual server that you can use to receive and relay e-mail messages to other SMTP servers on your network or to servers on the Internet. The relay function is useful for internal network clients that might have to forward mail to other SMTP servers, and it is useful for IIS programs that need access to an SMTP server to forward mail.

For a user or computer to relay e-mail messages through an SMTP virtual server, the following two conditions must be met:

- The user or computer can access the SMTP virtual server.
- The SMTP virtual server is configured to relay e-mail messages to other domains.

When an SMTP virtual server relays e-mail messages, it can forward mail that is addressed to any e-mail domain. With this feature, an SMTP virtual server can forward mail to any internal or external network SMTP server for which it can resolve an MX record. However, if the SMTP virtual server is accessible to Internet users, mail relay should not be enabled. With mail relay enabled, malicious users might forward e-mail to your SMTP virtual server, distributing unwanted messages to other computers and reducing the available bandwidth for your internal connection.

By default, the SMTP service blocks computers from relaying unwanted mail through the virtual server. To enable relay access through the SMTP virtual server, click **Relay** on the **Access** tab. By default, all computers are blocked except those that meet the authentication requirements that are designated in the **Authentication** box, which you can view by clicking **Authentication** on the **Access** the tab.

You can also allow messages to be relayed to a specific remote domain. The domain setting overrides the SMTP virtual server setting. For more information about relaying messages to a remote domain, see Configuring Remote Domains.

If you enable mail relay on your SMTP virtual server, then you can specify the relay restrictions that are described in the following table.

| Option | Description |
|---|---|
| **Only the list below** | This option allows only the computers specified in the list to relay messages through the SMTP virtual server. |
| **All except the list below** | This option allows all computers, except the computers that are specified in the list, to relay messages through the SMTP virtual server. This option is set by default, along with the **Allow all computers which successfully authenticate to relay, regardless of the list above** option. |
| **Add** and **Remove** | Clicking these buttons allows you to grant or deny relay access by adding to or removing from the list of computers. |
| **Allow all computers which successfully authenticate to relay, regardless of the list above** | This option allows computers that meet authentication requirements set in the **Authentication** box to relay messages to the SMTP virtual server. This option is set by default. |

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To add relay restrictions to an SMTP virtual server**

1. In IIS Manager, right-click the SMTP Virtual Server for which you want to add relay restrictions, and then click **Properties**.
2. Click the **Access** tab, and then click **Authentication**.
3. To enable the appropriate level of authentication for your server, select either (or both) the **Basic authentication** or the **Integrated Windows Authentication** check box, clear the **Anonymous access** check box, and then click **OK**.

| **Note** |
| --- |
| If you enable Anonymous access and do not enable Basic authentication and Integrated Windows authentication, then authentication is no longer enabled, which means that all users and computers can access the SMTP virtual server. |

4. On the **Access** tab, under **Relay restrictions**, click **Relay**.
5. In the **Relay Restrictions** box, click **Add**, and then do the following to add a single computer, a group of computers, or a domain:
   - To add a single computer, click **Single computer**, type the IP address of the computer that you want to add, and then click **OK**.
   - To add a group of computers, click **Group of computers**, type the subnet address and the subnet mask of the group into the corresponding boxes, and then click **OK**.
   - To add a domain, click **Domain**, type the domain name that you want to add, and then click **OK**.
6. To apply your configuration changes, click **OK** twice.

**To remove relay restrictions from an SMTP virtual server**

1. In IIS Manager, right-click the SMTP virtual server for which you want to remove relay restrictions, and then click **Properties**.
2. Click the **Access** tab, and then click **Relay**.
3. In the **Relay Restrictions** box, select either the **Only the list below** or the **All except the list below** check box.
4. If you want to add exceptions, click **Add** and then specify the computer, group of computers, or domain for which you want to retain relay restrictions.

**Related Information**

- For information about setting IP access restrictions to the server, see Setting IP Access Restrictions to Servers.
- For information about requiring TLS encryption, see Requiring TLS Encryption.

# Requiring TLS Encryption

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can require that all clients use Transport Layer Security (TLS) encryption, a generic security protocol similar to Secure Sockets Layer (SSL), to connect to the default Simple Mail Transfer Protocol (SMTP) virtual server. This option secures the connection, but it is not used for authentication.

When requiring Basic authentication on your virtual servers, it is strongly recommended that you also use TLS encryption. Without encryption, user names and passwords can be easily intercepted.

To use TLS encryption for the virtual server, you must create key pairs and configure key certificates. Clients can then use TLS to encrypt the session with the SMTP service, therefore, all messages sent. The SMTP service can also use TLS to encrypt sessions with remote servers.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**.

**Procedures**

**To create and manage key certificates**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Access** tab, and under **Secure communication**, click **Certificate** to set up new key certificates and manage installed key certificates for the SMTP virtual server.

Key pairs consist of a number of bits that indicate the key's security level. You can strengthen security by increasing the encryption level from 40 bits (the default) to 128 bits. The greater the number of bits, the more difficult the item is to decrypt. Users attempting to secure access must use the same encryption level that you set or messages will be returned with a non-delivery report (NDR).

**To set TLS encryption levels for the server**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Access** tab, and under **Access control**, click **Authentication**.
3. Click **Basic authentication**.
4. Select the **Require TLS encryption** check box.

**Note**

There are two additional TLS options available. To use TLS for all outgoing connections, click **Outbound Security** on the **Delivery** tab, and then click **TLS encryption**. Also, if a server you commonly connect to requires the use of TLS for all incoming connections, you can create a remote domain and click **TLS encryption** when creating the domain.

**Related Information**

- For information about setting IP access restrictions to the server, see Setting IP Access Restrictions to Servers.
- For information about setting or removing relay restrictions from a virtual server, see Configuring SMTP Virtual Server Relay Restrictions.

# Delivering Messages

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

After a connection has been opened and the receiving server has acknowledged that it is ready to receive data, messages can be transmitted for delivery. This section describes the settings that determine how delivery occurs.

This section includes the following information:

- Message Delivery Options: Provides an overview of routing, transmission, and security options.
- Configuring Retry Attempts and Intervals: Describes how to configure the server for mail that can't be delivered on the first attempt.
- Setting the Message Hop Count: Describes how to limit the number of servers a message is allowed to pass through before delivery.
- Setting the Masquerade Domain: Describes how to replace a local domain name used in the Mail From lines.
- Setting Fully Qualified Domain Names: Describes the concept of fully qualified domain names and how to change them.
- Configuring Smart Hosts: Describes how to route all outgoing messages for remote domains through a smart host instead of sending them directly to the domain.
- Enabling Reverse DNS Lookup: Describes how to enable reverse DNS lookup.

# Message Delivery Options

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use the **Delivery** tab to set all delivery and routing options. Settings can be grouped into three categories, which are listed below.

**Routing Options**

- Smart host: Designates a server through which to route all outgoing messages.
- Message hop count: Determines the maximum number of servers a message is routed through before being considered undeliverable.
- Fully qualified domain name (FQDN): Clarifies the address to use in message exchanger (MX) records.

**Transmission Options**

- Retry attempts and retry interval: Determines how many times to resend a message, and at what intervals, before the message is considered undeliverable.
- Delivery using Pickup directory: Allows you to transmit messages composed as a text file.

**Security Options**

- Outbound security: Allows you to use authentication and Transport Layer Security (TLS) encryption for outgoing messages.
- Reverse DNS lookup: Verifies that the message actually originated from the computer and the domain listed in the From field.
- Masquerade domains: Replaces any local domain name used in any Mail From lines in the protocol with a different domain name. This is the name you want stamped on outgoing messages.

# Configuring Retry Attempts and Intervals

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If a message cannot be delivered on the first attempt, the SMTP service sends it again from the Queue directory after a specified time. You can set the interval between delivery attempts. You can also designate the number of times to attempt to deliver a message. After the limit is reached, the message is returned to the sender with a non-delivery report (NDR) and copies of the message and NDR are sent to the location you designate. The NDR is placed in the Queue directory and goes through the same delivery process as messages. When the NDR reaches the maximum number of retry attempts, the NDR and message are sent to the Badmail directory.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To configure retry attempt and interval settings**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Delivery** tab.
3. In the **First retry interval (minutes)** box, type a value for the amount of time to wait before retrying message delivery. The default is 15 minutes.
4. In the **Second retry interval (minutes)** box, type a value for the amount of time to wait before retrying message delivery. The default is 30 minutes, which is 30 minutes after the **First retry interval**.
5. In the **Third retry interval (minutes)** box, type a value for the amount of time to wait before retrying message delivery. The default is 60 minutes, which is 60 minutes after the **Second retry interval**.
6. In the **Subsequent retry interval (minutes)** box, type a value for the amount of time to attempt delivery before posting a notification. The default is 240 minutes.

**Delay Notification**

To allow for network delays, you can set a delay period to expire before sending the delivery notification. The minimum value is 1 minute, the default is 12 hours, and the maximum value is 9999 days. Use the drop-down menu beside the value field to use minutes, hours, or days.

**Expiration Timeout**

Type a value for messages that have not been delivered after all retries and delays have expired. The minimum value is 1 minute, the default is 2 days, and the maximum value is 9999 days. Use the drop-down menu beside the value field to use minutes, hours, or days.

# Setting the Message Hop Count

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When a message is delivered, it may be routed to a number of servers before reaching its final destination. You can designate how many servers the message is allowed to pass through. This is called the *hop count*.

After the hop count is set, the Simple Mail Transfer Protocol (SMTP) server counts the hops listed in the Received lines of the message header. When the number of Received fields exceeds the maximum hop count setting, the message is returned to the sender with a non-delivery report (NDR).

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set the message hop count**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Delivery** tab, and click **Advanced**.
3. In the **Maximum hop count** box, type a value for the number of hops a message can take between the source and destination servers. The default is 15 hops.

**Related Information**

- For information about designating a server for all outgoing messages, see Configuring Smart Hosts.
- For information about setting a fully qualified domain name, see Setting Fully Qualified Domain Names.

# Setting the Masquerade Domain

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The masquerade domain replaces any local domain name used in any Mail From lines in the protocol. The replacement occurs on the first hop only.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set the masquerade domain**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Delivery** tab, and click **Advanced**.
3. In the **Masquerade domain** box, type a domain name that you want to appear in message headers, instead of the actual name of the domain.

| **Note** |
| --- |
| All replies to such messages will be routed through the SMTP virtual server that uses the masquerade domain. |

**Related Information**

- For information about enabling reverse DNS lookup, see Enabling Reverse DNS Lookup.

# Setting Fully Qualified Domain Names

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

An e-mail domain must be able to be resolved through Domain Name System (DNS). There are two DNS records that are used to resolve an e-mail domain. In most cases, a mail exchanger (MX) record is set up to associate an e-mail domain with the fully qualified domain name (FQDN) of one or more Simple Mail Transfer Protocol (SMTP) virtual servers that serve that domain. Each SMTP server referenced in the MX record must have an address (A) record. The A record maps a given FQDN to its IP address.

It is possible to just have an A record set up for an e-mail domain. In this scenario, the A record maps the domain to the IP address or addresses of the SMTP virtual server or servers that serve that domain. Adding an MX record, however, is recommended over using an A record by itself, because an MX record allows an SMTP administrator to specify an ordered list of servers to use for clients sending mail to that e-mail domain. Microsoft SMTP Service always checks first for an MX record before falling back to an A record, so setting up MX records on your virtual server can improve performance. And, in some cases, the A record is used for other purposes, such as HTTP, although the MX record is generally used only for SMTP. The MX record allows one server to handle http://example.com (HTTP clients use the A record) and another server to handle someone@example.com (SMTP clients use the MX record).

On the SMTP service, there are two options for specifying an FQDN. You can use the name specified on the **Network Identification** tab of System Properties in Control Panel, or you can specify a unique FQDN for the SMTP virtual server you are configuring.

At startup, the name designated on the **Network Identification** tab of System Properties is automatically used for the FQDN. If you change the name (either manually or by joining a domain), the new name is automatically used for the FQDN the next time the computer is restarted. No action is required to update the FQDN for the virtual server.

To override the automatic use of the computer and domain names on the **Network Identification** tab, change the FQDN in the **Advanced Delivery** dialog box, accessed through the **Delivery** tab. The SMTP service can then use the designated name instead of the one specified on the **Network Identification** tab.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To change the FQDN**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Delivery** tab, and click **Advanced**.
3. In the **Fully-qualified domain name** box, type the FQDN.

**Related Information**

- For information about setting the message hop count, see Setting the Message Hop Count.
- For information about designating a server for all outgoing messages, see Configuring Smart Hosts.

# Configuring Smart Hosts

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can route all outgoing messages for remote domains through a smart host instead of sending them directly to the domain. This enables you to route messages over a connection that may be more direct or less costly than other routes. The smart host is similar to the route domain option for remote domains. The difference is that, after a smart host is designated, all outgoing messages are routed to that server. With a route domain, only messages for the remote domain are routed to a specific server.

| **Important** |
| --- |
| Make sure your designated smart host is secure and administered by a trusted authority, especially when forwarding sensitive information. |

If you set up a smart host, you can still designate a different route for a remote domain. The route domain setting overrides the smart host setting.

You can identify the smart host by fully qualified domain name (FQDN) or an IP address (but if you change the IP address, you would have to change it on every virtual server as well). If you use an IP address, enclose it in brackets ([ ]) to increase system performance. The SMTP service checks first for a server name, and then an IP address. The brackets identify the value as an IP address, so the DNS lookup is bypassed.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set up a smart host**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Delivery** tab, and click **Advanced**.
3. In the **Smart host** box, type the name of the smart host server. You can type a string to represent a name or enter an IP address.
4. If you want the SMTP service to attempt to deliver remote messages directly before forwarding them to the smart host server, select the **Attempt direct delivery before sending to smart host** check box. The default is to send all remote messages to the smart host, not to attempt direct delivery.

**Related Information**

- For information about setting the message hop count, see Setting the Message Hop Count.
- For information about setting a fully qualified domain name, see Setting Fully Qualified Domain Names.

# Enabling Reverse DNS Lookup

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you select this option, the SMTP service will attempt to verify that the client's IP address matches the host/domain submitted by the client in the EHLO/HELO command. If the reverse DNS lookup is successful, the RECEIVED header will remain intact. If the verification is unsuccessful, "unverified" appears after the IP address in the RECEIVED header of the message. If the reverse DNS lookup fails, "RDNS failed" will appear in the RECEIVED header of the message.

Because this feature verifies addresses for all incoming messages, its use could affect SMTP service performance. Clear the check box to disable the feature.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

### To enable reverse DNS lookup

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Delivery** tab, and click **Advanced**.
3. Select the **Perform reverse DNS lookup on incoming messages** check box.

**Related Information**

- For information about setting the masquerade domain, see Setting the Masquerade Domain.

# Managing Messages_IIS_SP1_Ops

Updated: August 22, 2005

Applies To: Windows Server 2003 R2, Windows Server 2003 with SP1

This section describes how to set connection limits to maximize performance, how to set limits for message size and number of recipients, and how to manage undeliverable messages.

This section includes the following information:

- Setting Message Size Limits: Describes how to set message and session limits.
- Setting Recipient Limits: Describes how to set the maximum number of recipients for a single message sent in one connection.
- Limiting the Number of Messages per Connection: Describes how to limit the number of messages sent in a single connection.
- Storing Non-Delivery Reports: Describes how to set a storage location for non-delivery reports (NDRs).

# Setting Message Size Limits

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

There are two message size limit settings. The first, **Limit message size to**, is a preferred message limit for the virtual server. This is what the SMTP service will advertise as the maximum message size this Simple Mail Transfer Protocol (SMTP) virtual server will accept. If a mail client sends a message that exceeds the limit, they will get an error. If a remote server supports EHLO, it will detect the advertised maximum message size value when it connects to the SMTP virtual server and won't attempt to deliver a message that exceeds the limit. Instead it will simply send a non-delivery report (NDR) to the sender of the message. A remote server that does not support EHLO will try to send a message that exceeds the size limit, but will still end up sending an NDR to the sender when the message doesn't go through.

**Limit session size to** is the maximum amount of data accepted during the total connection. This is the sum of all messages sent during the connection (applying to the message body only).

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set message size limits**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Messages** tab, select the **Limit message size to (KB)** check box, and then type a value (in kilobytes) for the maximum size of a message. The default is 2048 KB. The minimum value is 1 KB.
3. Select the **Limit session size to (KB)** check box, and then type a value to indicate the maximum total size (in kilobytes) of all messages in a given connection. This number will always be larger than the maximum message size and should be set carefully because the connecting message transfer agent (MTA) is likely to resubmit the message repeatedly. The default size is 10240 KB. This value should be greater than or equal to the value entered for **Limit message size to (KB)**.

**Related Information**

- For information about setting recipient limits, see Setting Recipient Limits.
- For information about limiting the number of messages per connection, see Limiting the Number of Messages per Connection.
- For information about storing non-delivery reports, see Storing Non-Delivery Reports.

# Setting Recipient Limits

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can determine the maximum number of recipients for a single message sent in one connection. The default is 100, which is the minimum number specified in Request for Comment (RFC) 821. Many clients return messages with a non-delivery report (NDR) after an error message is received, indicating that the maximum number of recipients has been exceeded. The SMTP service does not return messages in this instance. It opens a new connection immediately and processes the remaining recipients. For example, if the recipient limit is set to 100 and a message with 105 recipients is received, the first 100 are delivered in one connection. Then, a new connection is opened, and the message is processed for the remaining five recipients.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set recipient limits**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Messages** tab, select the **Limit number of recipients per message to** check box, and then type a number to represent the recipient limit. To impose no limit, clear the check box.

**Related Information**

- For information about setting message size limits, see Setting Message Size Limits.
- For information about limiting the number of messages per connection, see Limiting the Number of Messages per Connection.
- For information about storing non-delivery reports, see Storing Non-Delivery Reports.

# Limiting the Number of Messages per Connection

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This option enables you to limit the number of messages sent in a single connection. It also provides a method to improve system performance by allowing the use of multiple connections to deliver messages to a remote domain. When the set limit is reached, a new connection is automatically opened and the transmission continues until all messages are delivered.

For example, if you commonly send a large number of messages to certain remote domains, you could set the **Limit number of messages per connection to** value to a relatively small number, such as 20. As a result, when sending 100 messages in one session, the SMTP service immediately opens a new connection after the first 20 are sent, another after the next 20 are sent, and so on. In this case, there could be up to five simultaneous connections delivering queued messages to one destination. Message delivery would be faster because fewer messages are delivered simultaneously, instead of in one long stream over one connection.

To determine a value for the limit, review the **Messages Sent/sec** performance counter for the SMTP Server object in System Monitor. The **Limit number of messages per connection to** value should be less than the value indicated by the performance counter. If the counter indicates a value of 30, and you set your maximum connections to 50, no simultaneous connection would be opened because the server would not exceed 30 messages per second. It would work as though the messages were sent in one long stream over one connection. This setting affects outgoing messages only. You can use it to increase your server output speed, but it has no effect on the rate that other servers process incoming messages.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To limit the number of messages sent in one connection**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Messages** tab, select the **Limit number of messages per connection to** check box, and then type a value in the box. The default is 20.

**Related Information**

- For information about setting message size limits, see Setting Message Size Limits.
- For information about setting recipient limits, see Setting Recipient Limits.
- For information about storing non-delivery reports, see Storing Non-Delivery Reports.

# Storing Non-Delivery Reports

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When a message is undeliverable, the SMTP service returns it to the sender with a non-delivery report (NDR). You can also designate that copies of the NDR be sent to a location of your choice. If the NDR cannot be delivered to the sender, a copy of the message is put in the Badmail directory.

All NDRs go through the same delivery process as other messages, including attempts to resend the message. If the NDR has reached the retry limit and cannot be delivered to the sender, a copy of the message is placed in the Badmail directory. Messages placed in the Badmail directory cannot be delivered or returned.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

### To set a storage location for NDRs

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **Messages** tab, in the **Send copy of Non-Delivery Report to** box, type the e-mail address of the mailbox you want to use to store copies of the NDRs. This address can be any valid SMTP e-mail address and is optional. To disable the feature, clear the text box.
3. In the **Badmail directory** box, type the directory you want to use to store undeliverable messages. The default location is *X*:\Inetpub\Mailroot\Badmail, where *X* is the drive on which IIS is installed. Click **Browse** to select another folder. You can designate a different directory, provided it is on the same computer as the SMTP service.

**Related Information**

- For information about setting message size limits, see Setting Message Size Limits.
- For information about setting recipient limits, see Setting Recipient Limits.
- For information about limiting the number of messages per connection, see Limiting the Number of Messages per Connection.

# LDAP Routing

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Lightweight Directory Access Protocol (LDAP) is an Internet protocol that enables you to access directory information from an LDAP server. With permission to use LDAP, you can browse, read, and search directory listings on the LDAP server.

With the **LDAP Routing** tab, you can configure the SMTP service so that it will consult an LDAP server to resolve senders and recipients. For example, you can use Active Directory directory service as an LDAP server, and use Active Directory Users and Computers to create a group mailing list that is automatically expanded on the Simple Mail Transfer Protocol (SMTP) virtual server.

This section describes how to configure the SMTP service as an LDAP client so you can gain access to directory information on an LDAP server.

This section includes the following information:

- Determining Authentication Levels: Describes the four binding types that determine the level of authentication used for connections.
- Preliminary Steps to Configuring LDAP Connections: Describes how to plan before configuring Lightweight Directory Access Protocol (LDAP).
- Setting LDAP Routing Information: Describes how to enable Lightweight Directory Access Protocol (LDAP) routing, and set options for LDAP routing.
- Selecting Schema Types: Describes the schema types available from the **Schema** drop-down menu on the **LDAP Routing** tab.

# Determining Authentication Levels

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

There are four binding types that determine the level of authentication used for connections. The option selected affects other options.

| **Binding type** | **Description** |
|---|---|
| Anonymous | No authentication is required. Select this option when the server does not require account and password information. |
| Plaintext | This option allows the transmission of account information and passwords in plaintext. When this option is selected, account and password information is required. |
| Windows SSPI | The client and server negotiate to determine which level of authentication is acceptable by both, and use the strongest method available. When this option is selected, account and password information is required. |
| Service accounts | Uses the account information of the user under which the SMTP service is running. This is controlled by **Component Services**, under **Administrative Tools**. |

# Preliminary Steps to Configuring LDAP Connections

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Because some settings on the **LDAP Routing** tab affect others, it is recommended that you plan before configuring Lightweight Directory Access Protocol (LDAP).

1. Determine the schema type to use.

2. Determine the level of authentication that will be needed to bind to the LDAP directory. If the LDAP server you connect to does not require authentication, no account information is necessary.

3. Determine if you need to specify a naming context. A naming context may be necessary if the user accounts reside in a subcontainer within the LDAP directory. Specifying a naming context may allow the LDAP directory to return results more quickly and, in some cases, is necessary if there are multiple naming contexts on the LDAP server.

**Related Information**

- For information about determining the schema type to use, see Selecting Schema Types.

- For information about determining the level of authentication, see Determining Authentication Levels.

# Setting LDAP Routing Information

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This topic describes how to enable Lightweight Directory Access Protocol (LDAP) routing, and set options for LDAP routing.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set LDAP routing information**

1. In IIS Manager, right-click the SMTP virtual server, and then click **Properties**.
2. Click the **LDAP Routing** tab.
3. Select the **Enable LDAP routing** check box.
4. Set options as described in the following table.

| Option | Description |
| --- | --- |
| Server | Type the name of the computer running the LDAP directory. The field is not applicable when you use the Exchange LDAP Service schema type, because the service will find a nearby server and use it automatically. |
| Schema | Select a schema type. |
| Binding | Select the authentication method to use when binding to the LDAP server. **Plain text** transmits passwords in plaintext. To use the strongest authentication method available for the SMTP virtual server, select **Windows SSPI**. For no authentication, use **Anonymous**, which is the default. **Service accounts** will use the account information of whom ever is trying to bind to the LDAP server. |
| Domain | Type the domain of the account you want to use to bind to the LDAP directory. This option applies if you select the **Plaintext** or **Windows SSPI** binding types. |
| User name | Type the distinguished name of the account that you want to use to bind to the LDAP directory. For example, cn=user1, ou=users, o=company. This option applies if you select the **Plain text** or **Windows SSPI** binding types. |
| Password | Type the password used for logging on to the directory service. This option applies if you select the **Plain text** or **Windows SSPI** binding types. |
| Base | Type the distinguished name of a container in the directory service you're accessing. This setting specifies where you want the SMTP service to start searching in the LDAP directory. The search will begin in the container and will continue to subcontainers if necessary. |

**Related Information**

- For information about selecting a schema type, see Selecting Schema Types.
- For information about selecting the authentication method, see Determining Authentication Levels.

# Selecting Schema Types

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The following schema types are available from the **Schema** list box on the **LDAP Routing** tab.

| Schema type | Description |
|---|---|
| Active Directory | Select this option to use Active Directory directory service as the Lightweight Directory Access Protocol (LDAP) server. To manage mail boxes, use Active Directory Users and Computers. |
| Site Server Membership Directory | Use this option when you have installed Microsoft LDAP Service as part of Microsoft Commercial Internet System 2.0 Mail and you are using it to manage mailboxes. |
| Exchange LDAP Service | Select this option to use a Microsoft Site Server 3.0 or later LDAP server to manage mailboxes. |

**Related Information**

- For information, see Preliminary Steps to Configuring LDAP Connections.
- For information about setting LDAP routing information, see Setting LDAP Routing Information.

# Monitoring Message Transactions

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Protocol logs track the commands a Simple Mail Transfer Protocol (SMTP) virtual server receives from SMTP clients.

Four formats are available for tracking. For the most part, they track the same information. The differences among them are depth of detail, type of display, and analytical uses. When choosing a format, decide what you want to track, how you want to review the data, and how you want to track transactions from other Internet Information Services (IIS) services.

The default format is World Wide Web Consortium (W3C) Extended Log File Format, but you can choose a different one. For three of the formats, transactions are written to a text file. You can determine the logging period and maximum size of the file. When the size limit is reached, a new file is created. Back up and remove older files so the system doesn't run out of disk space when writing to the current transaction log file. There is also a format that enables you to collect data in an ODBC-compliant database.

| **Note** |
| --- |
| The log formats and default file names are the same as those used by other IIS services. Plan what you want to track for all the services, how many files to use, and how to set file size before choosing a format for the SMTP service. |

This section includes the following information:

- Log Formats: Describes the four formats available for transaction logs.
- Setting Up an ODBC-Compliant Database: Describes how to set up an open database connectivity (ODBC)-compliant dabase for protocol logging.

**Related Information**

- For information about enabling protocol logging, see Enabling Protocol Logging.

# Log Formats

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Four formats are available for transaction logs. The log formats and default file names are the same as those used by other IIS services. Plan what you want to track for all the services, how many files to use, and how to set file size before choosing a format for the SMTP service.

**Microsoft IIS Log File Format**

- Information is written to a comma-delimited ASCII text file.
- Data is fixed; you cannot customize the log.
- There are multiple records for a single transmission.

**NCSA Common Log File Format**

- Information is written to an ASCII text file that uses the National Center for Supercomputing Applications (NCSA) format.
- Data is fixed; you cannot customize the log.
- There are multiple records for a single transmission.

**W3C Extended Log File Format**

- The World Wide Web Consortium (W3C) Extended Log File Format is the default logging format for the SMTP service, as well as other IIS services.
- Data is variable; you can choose what you want to track.
- This format is a good option for limiting log size.
- Information is written to an ASCII text file.
- This format includes some field options that apply to the Web and file transfer protocol (FTP) services only.
- There are multiple entries for a single transmission.

**ODBC Logging**

- You must set up an open database connectivity (ODBC)-compliant database before using this format.
- Information is written to a database.
- There are multiple records for a single transmission.

The following table describes the fields and data types for an ODBC transaction log file.

| Field name | Data type | Description |
|---|---|---|
| ClientHost | varchar(255) | Client IP address |
| Username | varchar(255) | Client domain name |

| | | |
|---|---|---|
| LogTime | datetime | Connection date and time |
| Service | varchar(255) | Internet Information Services (IIS) service |
| Machine | varchar(255) | Computer name |
| ServerIP | varchar(50) | Server IP address |
| ProcessingTime | Integer | Processing time in milliseconds |
| BytesRecvd | integer | Bytes received by server |
| BytesSent | Integer | Bytes sent by server |
| ServiceStatus | Integer | Simple Mail Transfer Protocol (SMTP) protocol reply code |
| Win32Status | integer | Windows Server 2003 status or error code (a 0 valueindicates success) |
| Operation | varchar(255) | SMTP protocol command |
| Target | varchar(255) | Recipient |
| Parameters | varchar(255) | |

**Related Information**

- For information about monitoring message transactions, see Monitoring Message Transactions.
- For information about enabling protocol logging, see Enabling Protocol Logging.

# Setting Up an ODBC-Compliant Database

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This topic describes how to set up an open database connectivity (ODBC)-compliant database for protocol logging.

1. Create an ODBC-compliant database by using a database program such as Microsoft Access or Microsoft SQL Server-TM-.

2. Create a table in the database that contains the fields listed in the following table.

| Field name | Data type |
|---|---|
| ClientHost | varchar(255) |
| Username | varchar(255) |
| LogTime | datetime |
| Service | varchar(255) |
| Machine | varchar(255) |
| ServerIP | varchar(50) |
| ProcessingTime | integer |
| BytesRecvd | integer |
| BytesSent | integer |
| ServiceStatus | integer |
| Win32Status | integer |
| Operation | varchar(255) |
| Target | varchar(255) |
| Parameters | varchar(255) |

# SMTP Domains

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Domains in the SMTP service are different from DNS domains and Windows domains. The SMTP service domains are used for organizing messages for delivery.

The Simple Mail Transfer Protocol (SMTP) virtual server has at least one domain--the default local domain. You can add more domains and configure them to be local or remote. You can delete any domain except the default domain.

**Local Domains**
A local domain is a DNS domain that is serviced by the local SMTP server. Any message with a local domain name that arrives at an SMTP server must be delivered locally to a Drop directory or returned to the sender with a non-delivery report (NDR). Local domains are sometimes referred to as service domains or supported domains. E-mail addresses with local domain names are often referred to as local addresses.

If the domain is local, you can designate it as default or alias. There is one default domain. It is used to stamp message headers that lack a domain specification. An alias domain is an alias of the default domain. If you add a domain and assign it as the new default, the previous default changes to an alias domain.

**Remote Domains**
Domains that are not local are known as remote or nonlocal domains, and e-mail addresses with remote domain names are referred to as nonlocal addresses. The SMTP service looks up remote domains in DNS.

If you want to set unique delivery requirements for a specific remote domain, you can add a remote domain and configure it accordingly. For example, you can add a remote domain and require that the SMTP service always use Transport Layer Security (TLS) encryption in sessions with that domain. Or, you can change the routing so that messages sent to one remote domain are routed to another remote domain. Use the **Domain Properties** dialog box to configure domains.

This section includes the following information:

- Creating SMTP Domains: Describes how to create alias and remote domains.
- Deleting SMTP Domains: Describes how to delete an SMTP domain.
- Configuring Local SMTP Domains: Introduces the concept of configuring local domains.
- Configuring Remote Domains: Introduces the concept of configuring remote domains.

# Creating SMTP Domains

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can create two types of domains in the SMTP service: alias and remote. Alias domains allow you to create secondary domains that point to the default domain and use its settings, including the Drop directory. Any message sent to an alias domain is stamped with the default domain name.

Remote domains can be set for domains to which you commonly send messages. For each remote domain, you can set a predetermined delivery route and require that Transport Layer Protocol (TLS) encryption be used in all sessions with that domain. You can also use a wildcard character in the name so that all inclusive domains for the domain you are creating use the same settings. Use an asterisk (*) as the first character, followed by a period (.). For example, you can use the asterisk as a wildcard in the following format:

```
*.example.com
```

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

### To create an alias domain

1. In IIS Manager, expand the SMTP virtual server, right-click **Domains**, point to **New**, and then click **Domain**.
2. Use the **New SMTP Domain Wizard** to set up a local (alias) domain.

### To create a remote domain

1. In IIS Manager, expand the SMTP virtual server, right-click **Domains**, point to **New**, and then click **Domain**.
2. In **Welcome to the New SMTP Domain Wizard**, ensure that the **Remote** option is selected, and click **Next**.
3. In **Domain Name**, in the **Name** text box, type a name for the new domain, and then click **Finish**.

   You can use a wildcard character. For example, type ***.contoso.com**if you want mail to be delivered to any of the contoso.com SMTP servers.
4. Right-click the domain you just created, and then click **Properties**.
5. Select the **Allow incoming mail to be relayed to this domain**check box.
6. Click **Outbound Security**, and then configure the authentication and provide the credentials required by the SMTP server to which the smart host will connect.

**Related Information**

- For more information about alias and remote domains, see Organizing Messages Using SMTP Domains.
- For information about deleting SMTP domains, see Deleting SMTP Domains.

# Deleting SMTP Domains

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can delete domains that you have added. You cannot delete the default domain, unless you first add an alias domain and then make that domain the default domain.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

### To delete a domain

1. In IIS Manager, expand the SMTP virtual server, and click **Domains**.
2. In the details pane, right-click the domain you want to delete, and click **Delete**.

**Related Information**

- For information about creating SMTP domains, see Creating SMTP Domains.

# Configuring Local SMTP Domains

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This section describes how to set options for existing local domains.

This section includes the following information:

- Designating Default Domains: Describes how to rename the default domain.
- Configuring Alias Domains: Describes how to set up alias domains that use the same settings as the default domain.
- Configuring Drop Directories: Describes how to identify a directory in which to drop all incoming messages.

# Designating Default Domains

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The default domain is used to stamp messages from addresses that do not have a domain. A Simple Mail Transfer Protocol (SMTP) virtual server can have one default domain that cannot be deleted.

To name a default domain, you can use the name specified on the **DNS** tab for the TCP/IP protocol in the Network application in Control Panel. This domain name is also used for all other services. Alternatively, you can specify a unique domain to serve as the default for the SMTP service only.

At startup, the name designated on the **DNS** tab for the TCP/IP protocol in the Network application in Control Panel is automatically used for the default domain. If you change the name on the **DNS** tab, the new name is used automatically for the default domain the next time the service is started. No action is required to update the default domain for the SMTP service.

To override the automatic use of the network domain, specify the default domain on the **General** tab. The SMTP service can then use the designated name instead of the network domain.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To rename the default domain**

1. In IIS Manager, expand the SMTP virtual server, and then click **Domains**.
2. In the details pane, right-click a domain name, and then click **Rename**.
3. Type a new name for the default domain.

**Related Information**

- For information about configuring an alias domain, see Configuring Alias Domains.
- For information about configuring a drop directory, see Configuring Drop Directories.

# Configuring Alias Domains

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can set up alias domains that use the same settings as the default domain. Messages received by the SMTP service for the alias domain are placed in the Drop directory designated for the default domain.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

### To configure an alias domain

1. In IIS Manager, expand the SMTP virtual server, right-click **Domains**, point to **New**, and then click **Domain**. The **New SMTP Domain Wizard** starts.
2. Click **Alias**, and then click **Next**.
3. In the **Name** box, type a name for the alias domain, and then click **Finish**.

**Related Information**

- For information about designating a default domain, see Designating Default Domains.
- For information about configuring a drop directory, see Configuring Drop Directories.

# Configuring Drop Directories

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

For the default domain, you must identify a directory in which to drop all incoming messages. The SMTP service places messages for alias domains in the Drop directory used for the default domain. You can designate any directory as the Drop directory, provided it is local to the computer for the SMTP service and is not already assigned as the Pickup directory. By default, this is a subdirectory of the SMTP Mailroot directory.

Be sure your Drop directory is in a secure location and can be accessed only by trusted administrators. Otherwise, unauthorized users may be able to access messages in the directory.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

### To designate a Drop directory

1. In IIS Manager, expand the SMTP virtual server, and then click **Domains**.
2. In the details pane, right-click the default domain, and then click **Properties**.
3. In the **Drop directory** box, type the directory used to drop all incoming messages. The default location is *LocalDrive*:\Inetpub\mailroot\Drop. Or click **Browse** and select the directory. Make sure that you select the Drop directory and not the Pickup directory.

# Configuring Remote Domains

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can set unique delivery requirements for a specific remote domain by adding a domain and configuring it accordingly. For example, you can set a predetermined delivery route, set authentication, and require that Transport Layer Security (TLS) encryption be used on all connections to the domain. If the remote domain is not specifically configured, the SMTP service will not perform any of these operations when delivering to this domain. It will, however, complete a normal DNS lookup.

This section includes the following information:

- Configuring ATRN for Remote Domains: Describes how to create a remote domain for an address that periodically reviews messages and enable ATRN for the domain.
- Configuring Authentication for Remote Domains: Describes how to configure the Simple Mail Transfer Protocol (SMTP) virtual server to provide the authentication credentials required by the remote domain.
- Configuring SMTP Virtual Server Relay for Remote Domains: Describes how to configure an SMTP virtual server to relay mail to a remote domain.
- Enabling TLS Encryption for Remote Domains: Describes how to enable TLS encryption for a remote domain.

# Configuring ATRN for Remote Domains

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The SMTP service can hold mail for clients that connect periodically to download messages. In this case, the client issues an ATRN command. The remote Simple Mail Transfer Protocol (SMTP) service then starts sending messages to the ATRN domain. You can create a remote domain for an address that periodically reviews messages and enable ATRN for the domain.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To enable ATRN transmissions for a remote domain**

1. In IIS Manager, expand the SMTP virtual server, and then click **Domains**.
2. In the details pane, right-click the remote domain you want to change, and click **Properties**.
3. Click the **Advanced** tab, and then select the **Queue messages for remote triggered delivery** check box.
4. Click **Add** or **Remove** as necessary to select Windows user accounts that will be allowed to use the ATRN command in this domain.

# Configuring Authentication for Remote Domains

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure the Simple Mail Transfer Protocol (SMTP) virtual server to provide the authentication credentials required by the remote domain. There are two types of authentication available: basic (plaintext) and Integrated Windows authentication. With the basic option, the account name and password of the server you're connecting to is transmitted in clear text. The Integrated Windows Authentication option requires a Windows account name and password. You can also disable authentication, which is the default option.

The selected option overrides the SMTP virtual server authentication setting on the **Access** tab. The following table describes several configuration examples.

| **SMTP virtual server transmissions** | **Authentication option** |
|---|---|
| Messages are commonly sent to multiple addresses. | Disable authentication for the SMTP virtual server. If attempts to deliver messages to an address fail because of authentication requirements, add a remote domain for the address. Then enable authentication for the domain at the same level required by the server. |
| Messages are commonly sent to one address, which requires authentication. | Determine what level of authentication is required to connect. Then enable authentication for the SMTP virtual server using the same level. If you want to then send messages to other addresses, set up remote domains and set different authentication options. If you use this option, it is likely that the account name used is the one that identifies the computer set up as the smart host. |

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**.

**Procedures**

### To disable authentication for outgoing messages

1. In IIS Manager, expand the SMTP virtual server, and then click **Domains**.
2. In the details pane, right-click the remote domain you want to change, and click **Properties**.
3. On the **General** tab, click Outbound Security.
4. Click **Anonymous access**, and then click **OK**.

### To set Basic authentication for outgoing messages

1. In IIS Manager, expand the SMTP virtual server, and then click **Domains**.
2. In the details pane, right-click the remote domain you want to change, and click **Properties**.
3. On the **General** tab, click **Outbound Security**.
4. Click **Basic authentication**.
5. In the **User name** box, type the user name; and in the **Password** box, type the password of the computer to which you are connecting.
6. Click **OK**.

**Important**

If Basic authentication is your only authentication method, it is strongly recommended that you also require TLS encryption to avoid unauthorized detection of user names and passwords.

**To set Integrated Windows authentication for outgoing messages**

1. In IIS Manager, expand the SMTP virtual server, and then click **Domains**.
2. In the details pane, right-click the remote domain you want to change, and click **Properties**.
3. On the **General** tab, click **Outbound Security**.
4. Click **Integrated Windows Authentication**.
5. In the **Account** box, type the Windows account name; and in the **Password** box, type the password.
6. Click **OK**.

# Configuring SMTP Virtual Server Relay for Remote Domains

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure an SMTP virtual server to relay incoming mail to your SMTP/POP3 server. The SMTP virtual server can also accept and relay mail to other domains within your organization.

Specifying a relay server overrides the smart host setting in the Advanced Delivery box of the SMTP virtual server.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To configure an SMTP virtual server to relay mail to a remote domain**

1. In IIS Manager, double-click the SMTP virtual server that you want to configure, right-click **Domains**, point to **New**, and then click **Domain**. The New SMTP Domain Wizard starts.
2. Click **Remote**, and then click **Next**.
3. In the **Name** box, type a name for the remote domain, and then click **Finish**.

   | **Note** |
   | --- |
   | You can specify a single domain, or you can specify more than one domain by using an asterisk (*) as a wildcard character. The asterisk must be at the beginning of the name and be separated from the rest of the name by a period. |

4. In IIS Manager, right-click the new remote domain, and then click **Properties**.
5. On the **General** tab, select the **Allow incoming mail to be relayed to this domain** check box to allow the SMTP server to act as a mail relay.
6. On the **General** tab under **Route domain**, click **Forward all mail to smart host**, and then type the fully qualified domain name or the IP address of the internal network corporate mail server through which you would like to route messages for this remote domain.

   | **Note** |
   | --- |
   | If you use an IP address, enclose the IP address in brackets []. The brackets identify the value as an IP address, bypassing DNS lookup and increasing performance. |

7. Click **OK**, and then stop and restart the SMTP virtual server.

After you configure the remote domain, all mail that is addressed to the remote domain is relayed to the smart host that you configured. Mail that is not deliverable is stored in the Inetpub\Mailroot\Badmail folder.

# Enabling TLS Encryption for Remote Domains

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you choose not to use Transport Layer Security (TLS) encryption for the Simple Mail Transfer Protocol (SMTP) virtual server, but you select the **TLS encryption** check box for this remote domain, SMTP will use it when connecting to the remote domain. Domain configurations always override the virtual server configurations.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To enable TLS encryption for a remote domain**

1. In IIS Manager, expand the SMTP virtual server, and then click **Domains**.
2. In the details pane, right-click the remote domain you want to change, and click **Properties**.
3. On the **General** tab, click **Outbound Security**.
4. Click **Integrated Windows Authentication**.
5. In the **Account** box, type the Windows account; and in the **Password** box, type the password.
6. Select the **TLS** encryption check box, and then click **OK**.

| **Note** |
| --- |
| If the remote domain does not support TLS encryption, all messages will be returned with a non-delivery report (NDR). |

# Configuring Applications in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This section identifies some of the configuration options that are available to Web-based applications through IIS Manager, including performance, caching, and debugging options.

This section includes the following information:

- About Configuring Applications: Defines Web-based applications and explains how your Web site's directory structure is related to them.
- Creating Applications in IIS 6.0: Explains how to set up a directory so that it is the starting point, or root, of an application.
- Setting Application Mappings in IIS 6.0: Describes how to associate a file name extension with the program that processes those files.
- Configuring ASP.NET Applications in Worker Process Isolation Mode: Describes how to configure Microsoft ASP.NET applications when running in worker process isolation mode. In worker process isolation mode, attributes defined in the Machine.config file can now only be defined through Internet Information Services (IIS).
- Configuring ASP Applications: Outlines how to set properties for Microsoft Active Server Pages (ASP) applications.
- Enabling ASP Debugging: Explains how to check and correct ASP pages that are run in worker process isolation mode.
- Configuring CGI Applications: Provides information about installing and configuring Common Gateway Interface (CGI) applications on the Web server.
- Configuring ISAPI Extensions: Explains how to fine-tune server performance by caching Internet Server API (ISAPI) extensions.
- Installing ISAPI Filters: Describes ISAPI filters and explains how to associate them with a Web server event.
- Installing Wildcard Application Mappings: Describes how to configure a Web site to run an ISAPI application regardless of the extension of the requested file.
- Configuring Applications to Use COM+ Services: Describes how to configure ASP applications to use component services.

**Related Information**

- For information about setting application-related server configurations that are dependent on an isolation mode, see Configuring Servers for Applications.

# About Configuring Applications

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When you create an application, you use IIS Manager to designate the application's starting-point directory, which is also called the application root, in your Web site. You can have more than one application per Web site. The default Web site that is created when you install IIS is an application starting point. Every file and directory that is beneath the starting-point directory in your Web site is considered part of the application until another starting-point directory is found. Thus, you use directory boundaries to define the scope of an application.

| **Important** |
| --- |
| To help minimize the attack surface of the server, IIS 6.0 is not installed on Windows Server 2003 by default. When you first install IIS 6.0, it is locked down -- which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable these features, IIS returns a 404 error. You can enable these features through the Enabling Web Service Extensions node in IIS Manager. For more information about how to troubleshoot 404 errors and other issues, see Troubleshooting in IIS 6.0. |

IIS 6.0 supports many types of applications and their configuration options. You can create and then configure your applications for optimal performance and debugging; define a default script language; enable caching, buffering, and parent paths; and associate a file name extension with a type of program. These options can be configured using IIS Manager or the metabase.

An important change in IIS 6.0 that may affect your current Active Server Pages (ASP) applications is that parent paths are not enabled for ASP applications by default. For information about how to enable parent paths, see Configuring ASP Applications.

**Application Modes**

IIS 6.0 runs in one of two distinct modes of operation: worker process isolation mode and IIS 5.0 isolation mode. Application code runs in an isolated environment, but without the performance penalty of previous versions of IIS. Application isolation is the separation of applications by process boundaries that prevent the applications from affecting one another. Application isolation is configured differently for each of the two IIS isolation modes.

By default, after a clean install of IIS 6.0, IIS runs in worker process isolation mode. In worker process isolation mode, you have the option of pooling application processes. Also, for ASP.NET applications, application configuration is defined through the Web.config or Machine.config files. If you are running in worker process isolation mode, then you must configure the attributes defined in the Machine.config file through IIS.

**Related Information**

- For more information about the configuration options that are available to Web-based applications through IIS Manager, see Configuring Applications in IIS 6.0.
- For information about configuring application isolation modes, see Configuring Isolation Modes.
- For information about the advantages of pooling application processes, and on how to create and configure application pools, see Configuring Application Pools in IIS 6.0.

# Creating Applications in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

To create an application, you must first designate a directory as the starting point, which is also called the application root, for the application. You can then set properties for the application. Each application can have a friendly name. This name appears in IIS Manager and gives you a way to distinguish between applications. The application name is not used anywhere else.

| **Note** |
| --- |
| Web sites are root-level applications by default. When you create a Web site, a default application is created at the same time. You can use this root-level application, remove it, or replace it with a new application. |

You can remove a directory from the application boundaries so that requests to files in that directory and its subdirectories cannot start the application. Removing a directory from an application boundary does not delete the directory from either your Web site or from your computer's hard disk.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To create an application**

1. In IIS Manager, expand the local computer, right-click the starting-point directory of the application you are creating, and then click **Properties**.
2. Click the appropriate tab: **Home Directory**, **Virtual Directory**, or **Directory**.
3. In the **Application settings** area, click **Create**.
4. In the **Application name** box, type a name for your application.
5. In the **Execute Permissions** list box, set permissions by doing one of the following:
   - Click **None** to prevent any programs or scripts from running.
   - Click **Scripts only** to enable applications mapped to a script engine to run in this directory without having permissions set for executables. Setting permissions to **Scripts only** is more secure than setting them to **Scripts and Executables** because you can limit the applications that can be run in the directory.
   - Click **Scripts and Executables** to allow any application to run in this directory, including applications mapped to script engines and Windows binaries (.dll and .exe files).
6. Click **OK**.

| **Note** |
| --- |
| If you see the **Remove** button instead of the **Create** button, an application has already been created. |

**To remove a directory from the application**

1. In IIS Manager, expand the local computer, right-click the directory that you want to remove, and then click **Properties**.
2. Click the appropriate tab: **Home Directory**, **Virtual Directory**, or **Directory**.
3. In the **Application settings** area, click **Remove**.

| **Note** |
| --- |

To stop an application and unload it from memory, click **Unload**. If the **Unload** button is dimmed, you are not in the application's starting-point directory.

**Related Information**

- For information about configuring application isolation modes, see Configuring Isolation Modes.
- For more information about pooling application processes, see Configuring Application Pools in IIS 6.0.

# Setting Application Mappings in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

There are many programming and scripting languages that you can use to develop Web applications. Thus, IIS uses the file name extension of a requested resource on your Web site to determine which Internet Server API (ISAPI) or Common Gateway Interface (CGI) program to run to process a request. For example, a request for a file ending with a .aspx extension causes the Web server to call the ASP.NET program (aspnet_isapi.dll) to process the request. The association of a file name extension with an ISAPI or CGI program is called *application mapping*.

IIS 6.0 is preconfigured to support common application mappings. You can add or remove mappings for all of the applications on a Web site or for an individual application.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To map an extension to one or more applications**

1. In IIS Manager, double-click the local computer, right-click the **Web Sites** folder or an individual Web site folder, and then click **Properties**.

   **Note**

   Configuration settings made at the Web Sites level are inherited by all of the Web sites on the server. You can override inheritance by configuring the individual site or site element.

2. Click the appropriate tab: **Home Directory**, **Virtual Directory**, or **Directory**.
3. In the Application settings area, click **Configuration**, and then click the **Mappings** tab.
4. On the **Mappings** tab, click **Add**.
5. In the **Executable** box, type the path to the ISAPI or CGI program that will process the file. You must specify a program in a local directory on the Web server.
6. In the **Extension** box, type the file name extension that you want to be associated with the ISAPI or CGI program. When the Web server receives a URL identifying a file with this extension, it calls the associated program to process the request.
7. To allow processing for files of this type in a directory with Script permission, select the **Script engine** check box. When a directory has Script permission set (instead of Execute permission), only files associated with applications that are designated script engines can be processed in the directory.
8. Select the **Verify that file exists** check box to allow the server to check that the requested script exists before mapping an extension to an application.

**Note**

On the **Mappings** tab there is a **Verbs** column, which was formerly called **Exclusions** in IIS 4.0. Changing to the word *verbs* addresses the issue of future compatibility, as more new HTTP verbs will be added to the Hypertext Transfer Protocol.

**To remove an application mapping**

1. In IIS Manager, double-click the local computer, and then click the starting-point directory of the application you want.
2. Right-click the **Web Sites** folder, and then click **Properties**.

3. Click the appropriate tab: **Home Directory**, **Virtual Directory**, or **Directory**.
4. In the **Application settings** area, click **Configuration**, and then click the **Mappings** tab.
5. On the **Mappings** tab, click **Remove**.

   Requests for files with this file name extension are no longer processed in this Web site or directory.

**Related Information**

- For information about how to configure a Web site to run an ISAPI application regardless of the extension of the requested file, see Installing Wildcard Application Mappings.

# Configuring ASP.NET Applications in Worker Process Isolation Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When you install ASP.NET on a computer running Windows Server 2003, there are two process model modes that you can choose. By default, ASP.NET uses the IIS 6.0 worker process isolation mode. This mode allows you to configure application pools, recycle worker processes, enable Web gardening, set idle time-outs and processor affinity, and use a variety of application health maintenance features. On computers running a member of the Windows Server 2003 family, your ASP.NET applications should use the worker process isolation mode unless you encounter specific compatibility issues.

The **<processModel>** element configures the ASP.NET process model settings on an IIS Web server. The **<processModel>** section can be set only within the Machine.config file, and it affects all ASP.NET applications running on the server.

**Configuring the <processModel> Element Using IIS Manager**

| **Important** |
| --- |
| These features of IIS 6.0 are available only when running in worker process isolation mode. |

**timeout Equivalent Setting in IIS 6.0 Worker Process Isolation Mode**

The **timeout** attribute specifies the number of minutes until ASP.NET launches a new worker process to take the place of the current one. The default setting is **Infinite**. The **Recycle worker processes** entry is set to 120 minutes, as shown below, and is on by default.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

### To configure the ASP.NET attribute timeout using IIS Manager

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and click **Properties**.
2. On the **Recycling** tab, select the **Recycle worker processes (in minutes)** check box.
3. Click the up or down arrow to set the number of minutes you want to elapse before the worker process is recycled.
4. Click **OK**.

**idleTimeout Equivalent Setting in IIS 6.0 Worker Process Isolation Mode**

The worker processes or application pools in IIS 6.0 can be shut down after remaining idle for a specific amount of time. The **Shutdown worker process** entry is set to 20 minutes and is on by default.

### To configure the ASP.NET attribute idleTimeout using IIS Manager

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and then click **Properties**.
2. Click the **Performance** tab, and under **Idle timeout**, select the **Shutdown worker processes after being idle for** check box.
3. In the **minutes** box, type the number of idle (no processing requests) minutes that you want to elapse before shutting down the idle worker process.
4. Click **OK**.

**shutdownTimeout Equivalent Setting in IIS 6.0 Worker Process Isolation Mode**

The **shutdownTimeout** attribute specifies the amount of time the worker process is given to shut itself down gracefully. The

time is expressed in hr:min:sec string format. The worker process **Shutdown time limit** is set to 90 seconds, as shown below.

**To configure the ASP.NET attribute shutdownTimeout using IIS Manager**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and click **Properties**.
2. Click the **Health** tab, and under **Shutdown time limit**, in the **seconds** box next to **Worker process must shutdown within**, type the desired number of seconds.
3. Click **OK**.

**requestLimit Equivalent Setting in IIS 6.0 Worker Process Isolation Mode**

The worker processes or application pools in IIS 6.0 can be set to recycle after a specific number of requests. This feature is not on by default.

**To configure the ASP.NET attribute requestLimit using IIS Manager**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and then click **Properties**.
2. Select **Recycle worker process (in requests)** and type the maximum amount of virtual memory allowed before the worker process is recycled.
3. Click **OK**.

**requestQueueLimit Equivalent Setting in IIS 6.0 Worker Process Isolation Mode**

The **requestQueueLimit** attribute specifies the maximum allowed number of requests that will be queued in the Internet Server API (ISAPI) while waiting for the worker process to start after an abnormal termination. Note that this setting does not apply in the case of a clean shut down or normal cycle. The queue limit in IIS 6.0 is set in the kernel and is set to 1000 by default.

**To configure the ASP.NET attribute requestQueueLimit using IIS Manager**

1. In IIS Manager, expand the local computer, expand the **Application Pools** folder, right-click the application, and then click **Properties**.
2. Click the **Performance** tab.
3. In the **Request queue limit** section, select the **Limit the kernel request queue to** check box, and click the up and down arrows in the **requests** box to set the maximum number of queued requests.
4. Click **Apply**, and then click **OK**.

**memoryLimit Equivalent Setting in IIS 6.0 Worker Process Isolation Mode**

In IIS 6.0 worker process isolation mode, worker processes can be recycled based on both virtual memory and physical memory. Unlike the Machine.config files, the memory limit is not a percentage value, it is a finite value measured in megabytes.

Recycling based on physical or virtual memory is not on by default, but if selected, the default value is 500 megabytes (MB) for the virtual memory and 192 MB for the physical memory.

**To configure the ASP.NET attribute memoryLimit using IIS Manager**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and click **Properties**.
2. On the **Recycling** tab, under Memory recycling, select the **Maximum virtual memory (in megabytes)** or **Maximum used memory (in megabytes)** check box.
3. Click the up or down arrow to set memory limits.
4. Click **OK**.

**webGarden and cpuMask Equivalent Settings in IIS 6.0 Worker Process Isolation Mode**

The **webGarden** attribute controls Web garden mode, or using multiple affinitized worker processes. The **cpuMask** controls the number of processes and the way the Web garden works.

Since **webGarden** enables the use of multiple processes, it means that all processes will have their own copy of things like

application state, in-process session state, caches, and static data.

When using Web gardens, keep in mind the following:

- If your application uses session state, it must choose an out-of-process provider (NT Service or SQL).
- Application state and application statics are per process, not per computer.
- Caching is per process, not per computer.

Web gardens can be also set up in IIS 6.0 worker process isolation mode by increasing the maximum number of worker processes per application pool from 1 to n (as required).

**To configure the ASP.NET attribute webGarden and cpuMask**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and then click **Properties**.
2. Click the **Performance** tab, and under **Web garden**, in the **Maximum number of worker processes** box, type the number of worker processes that you want to assign to the application pool.
3. Click **OK**.

**userName and password Equivalent Settings in IIS 6.0 Worker Process Isolation Mode**

The **userName** attribute allows the worker process to run with a different Windows identity than the default process identity. By default, this attribute is empty and the process runs as the IIS identity. If valid credentials are presented in the **userName** and **password** attributes, the process runs as the given account. When present, these attributes cause the worker process to run as the configured Windows identity. The default is blank attributes. In worker process isolation mode, the default is to run as Network Service. However, they can be set to a configurable account as follows.

**To configure the ASP.NET attributes userName and password**

1. In IIS Manager, expand the local computer, expand the **Application Pools** folder, right-click the application pool you would like to configure, and click **Properties**.
2. Click the **Identity** tab.
3. Click **Configurable**.
4. Click **Browse**, and under **Enter the object name to select**, type the account name in which you want your worker process to run, and click **OK**.
5. In the **Password** box, type the password associated with this account. If there is no password associated with the account, leave the **Password** box blank.
6. Click **OK**.

| **Important** |
| --- |
| When you configure a worker process identity for an application pool using a configurable account, you must add the account you created to the IIS_WPG group in order for the worker process to run. |

**pingFrequency and pingTimeout Equivalent Settings in IIS 6.0 Worker Process Isolation Mode**

The **pingFrequency** attribute is the time interval in standard process model format (hr:min:sec). The default is 30 seconds. The **pingTimeout** attribute is the time interval in standard process model format (hr:min:sc). The default is 5 seconds.

In IIS 6.0 worker process isolation mode, pinging is enabled by default. The default value of **pingFrequency** is 30 seconds after the response comes back from the worker process. The equivalent setting for **pingTimeout** is PingResponseTime Metabase Property, which is 90 seconds and can be changed directly in the metabase.

**To configure the ASP.NET attribute pingFrequency and pingTimeout**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and then click **Properties**.

2. Click the **Health** tab, and select the **Enable pinging** check box.
3. In the **seconds** box next to **Ping worker process**, type the number of seconds that you want to elapse between pings.
4. Click **OK**

**Related Information**

- For information about configuring the ASP.NET worker process for a hosted environment so that users cannot obtain privileged access to information on the server, see Configuring ASP.NET Process Identity.
- For more information about the ASP.NET configuration system, see ASP.NET Configuration.

# Configuring ASP Applications

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can set properties that control performance and other factors of the Active Server Pages (ASP) applications that you have installed on your Web server. For example, you can turn on the use of session state in the application or set the default scripting language. Application properties apply to all ASP pages in the application unless you directly override the property on an individual page. You can also set these properties in the metabase. If the property in the metabase conflicts with the property you set in the property sheet then the last property setting overrides.

**Important**

To help minimize the attack surface of IIS, IIS 6.0 is not installed on Windows Server 2003 by default. When you first install IIS 6.0, it is locked down -- which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable these features, IIS returns a 404 error. You can enable these features through the Web Service Extensions node in IIS Manager. For more information about how to troubleshoot 404 errors and other issues, see Troubleshooting in IIS 6.0.

**In This Section**

This section includes the following information:

- Enabling Session State Persistence: Describes how to enable session state persistence for ASP applications.
- Enabling Buffering: Describes how to enable buffering for an ASP application.
- Enabling Parent Paths: Describes how to enable parent paths.
- Changing the Default ASP Language: Describes how to change the default ASP language.
- Setting the ASP Script Timeout: Describes how to change the ASP script timeout.
- Configuring ASP Template Caching: Describes how to change the settings for caching ASP script files and how to create a disk cache directory.

**Related Information**

- For information about side-by-side assemblies, see What's New in ASP.
- For information about NTFS and Web site permissions, see Securing Files with NTFS Permissions and Securing Sites with Web Site Permissions.
- For information about changing ASP configuration options programmatically, see Metabase Property Reference.
- For more information about pooling applications, see Configuring Application Pools in IIS 6.0.

# Enabling Session State Persistence

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can enable session state persistence for ASP applications. If you enable session state persistence, the server will create a new Session object for each connection and session state will be accessible, session storage will be allowed, **Session_OnStart** and **Session_OnEnd** will occur, and **ASPSessionID** cookie will be sent to the client. If you do not enable session state persistence, state access and storage are not allowed, events are not processed, and no cookie is sent. By default, session state persistence is enabled with the session timeout at 20 minutes. The corresponding metabase property is AspAllowSessionState Metabase Property.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To enable session state persistence for an ASP application**

1. In IIS Manager, double-click the local computer, right-click the **Web Sites** folder or an individual Web site folder, and then click **Properties**.

   | **Note** |
   | --- |
   | Configuration settings made at the Web Sites level are inherited by all of the Web sites on the server. You can override inheritance by configuring the individual site or site element. |

2. Click the appropriate tab: **Home Directory**, **Virtual Directory**, or **Directory**.
3. In the **Application settings** area, click **Configuration**, and then click the **Options** tab.
4. On the **Options** tab, in the **Application configuration** section, select the **Enable session state** check box.
5. In the **Session timeout** box, click the up or down arrow to set the number of minutes until the session expires.
6. Click **OK**.

# Enabling Buffering

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Enabling buffering on an ASP application specifies whether output from an ASP application will be buffered. All output from the application is collected in the buffer before the buffer is flushed to the client browser. If you do not enable buffering, output from an ASP script is written to the client browser as it becomes available. By default, buffering is enabled. The corresponding metabase property is AspBufferingOn Metabase Property.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To enable buffering for an ASP application**

1. In IIS Manager, double-click the local computer, right-click the starting-point directory of the application you want to configure, and then click **Properties**.
2. Click the appropriate tab: **Home Directory**, **Virtual Directory**, or **Directory**.
3. In the **Application settings** area, click **Configuration**, and then click the **Options** tab.
4. On the **Options** tab, in the **Application configuration** section, select the **Enable buffering** check box.
5. Click **OK**.

# Enabling Parent Paths

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Enabling parent paths specifies whether an ASP page allows paths relative to the current directory (using the ..\ notation). If set to true, this property constitutes a potential security risk, because an include path could access critical or confidential files outside the root directory of the application.

In IIS 6.0, parent paths are no longer enabled by default. This affects your application if it has a Web page that contains the #include server-side include directive and uses ".." notation to refer to a parent directory. Enabling parent paths corresponds to the metabase setting, AspEnableParentPaths Metabase Property.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To enable parent paths**

1. In IIS Manager, double-click the local computer, right-click the starting-point directory of the application you want to configure, and then click **Properties**.
2. Click the **Directory** tab, and then click **Configuration**.
3. Click the **Options** tab.
4. In the **Application configuration** section, select the **Enable parent paths** check box.
5. Click **OK**.

# Changing the Default ASP Language

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The default ASP language affects ASP files that do not use the <%@Language%> directive. The default language is Microsoft Visual Basic® Scripting Edition (VBscript). Changing the default ASP language corresponds to the metabase setting, AspScriptLanguage Metabase Property.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To change the default ASP language**

1. In IIS Manager, double-click the local computer, right-click the starting-point directory of the application you want to configure, and then click **Properties**.
2. Click the **Directory** tab, and then click **Configuration**.
3. Click the **Options** tab.
4. In the **Application configuration** section, in the **Default ASP language** box, type the language you want to use.
5. Click **OK**.

# Setting the ASP Script Timeout

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When you set the ASP script timeout, you specify, in seconds, the default length of time that ASP pages allow a script to run before terminating the script and writing an event to the Microsoft Windows® Event Log. The minimum value for this property is one second and the default value is 90 seconds. The corresponding metabase property is AspScriptTimeout Metabase Property.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To change ASP script timeout**

1. In IIS Manager, double-click the local computer, right-click the starting-point directory of the application you want to configure, and then click **Properties**.
2. Click the **Directory** tab, and then click **Configuration**.
3. Click the **Options** tab.
4. In the **Application configuration** section, in the **ASP script timeout** box, click the up or down arrow to set the number of seconds before an error message is returned.
5. Click **OK**.

# Configuring ASP Template Caching

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

ASP processes the files that contain ASP scripts, stores these processed files in a cache, and then serves the cached files to clients. Caching ASP script files enhances performance because cached ASP scripts are not compiled each time they are called. The corresponding metabase property is AspScriptFileCacheSize Metabase Property. AspScriptFileCacheSize Metabase Property specifies the number of precompiled script files to cache.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**To change the settings for caching ASP script files**

1. In IIS Manager, double-click the local computer, double-click the **Web Sites** folder, and then click **Properties**.
2. Click the appropriate tab: **Home Directory**, **Virtual Directory**, or **Directory**.
3. In the **Application Settings** area, click **Configuration**, and then click the **Cache Options** tab.

   **Note**

   If the **Configuration** button is not active, the directory or starting point does not contain an isolated application. You can create a new application by clicking **Create**.

4. In the **ASP File Cache** section, configure the ASP cache setting by doing one of the following:
   - To cache all requested .asp files, select the **Cache all ASP files in memory** check box. The maximum amount of files that can be cached is 2,000,000,000.
   - To set the maximum number of files cached in memory, select the **Cache limited ASP files in memory** check box, and then click the up or down arrow to set the maximum number of files. Files in excess of this number are persisted to the disk cache if you select the **Cache remaining ASP files on disk** check box. Or you can limit the total number of ASP files cached by selecting the **Cache limited ASP files on disk** check box, and then clicking the up or down arrow to set the maximum number of files.
   - To turn off the cache, select the **Do not cache ASP files** check box.
5. Click **OK**.

The ASP disk cache begins caching files into a directory when the ASP memory cache is full. Furthermore, a file has to be requested at least twice before it becomes a candidate for the ASP disk cache. The corresponding metabase property, AspMaxDiskTemplateCacheFiles Metabase Property, specifies the maximum number of compiled ASP templates that can be stored. AspDiskTemplateCacheDirectory Metabase Property contains the name of the directory that ASP uses to store compiled ASP templates to disk after overflow of the in-memory cache.

**Important**

In order for disk caching to work, ASP needs a properly configured disk cache directory in which to store the compiled ASP files. This means that the Administrators and IIS_WPG groups have full control on the disk cache directory and that the disk cache directory is a local directory on the Web server.

**To create a disk cache directory**

1. In IIS Manager, double-click the local computer, double-click the **Web Sites** folder, right-click the Web site that you want, and then click **Properties**.

2. Click the appropriate tab: **Home Directory**, **Virtual Directory**, or **Directory**.
3. In the **Application Settings** area, click **Configuration**.
4. Click the **Cache Options** tab, and in the **Disk cache directory** box browse to the directory used for disk caching.
5. Click **OK**.

| **Note** |
| --- |
| ASP requests might fail unless the IIS_WPG group has Read/Write and Delete permission for the ASP template cache directory.<br><br>For more information about ASP template caching and the ASP disk cache, see ASP Template Caching. |

# Configuring ASP Script Engine Caching

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

ASP code is compiled and executed by Microsoft® Visual Basic® Scripting Edition (VBScript) by default. To improve performance and scalability of ASP code, ASP creates script engines. ASP script engines contain the object and marshalling data that VBScript.dll needs to execute the request. Each entry in the ASP script file cache can point to one or more entries in the ASP script engine cache.

**To change the settings for caching ASP script engines**

1. In IIS Manager, right-click the **Web Sites** folder, and then click **Properties**.
2. Click the **Home Directory** tab.
3. In the **Application Settings** area, click **Configuration**, and then click the **Cache Options** tab.

| **Note** |
| --- |
| If the **Configuration** button is not active, the directory or starting point does not contain an isolated application. You can create a new application by clicking **Create**. |

4. Set the value for **Number of script engines cached**.

To programmatically change the maximum number of script engines ASP pages will keep cached in memory, use the AspScriptEngineCacheMax Metabase Property.

# Enabling ASP Debugging

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| For security and performance reasons, do not enable debugging in a production environment. |

You can set debugging options for ASP pages and control which types of error messages are sent. In order to enable debugging for ASP pages in worker process isolation mode, you must also configure the Access permissions and the Launch permissions for the debugger.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

### To enable ASP debugging

1. In IIS Manager, double-click the local computer, right-click the **Web Sites** folder or an individual Web site folder, and then click **Properties**.

   | **Note** |
   | --- |
   | Configuration settings made at the Web Sites level are inherited by all of the Web sites on the server. You can override inheritance by configuring the individual site or site element. |

2. Click the **Home Directory** tab, and then click **Configuration**.
3. Click the **Debugging** tab, and then select the **Enable ASP server-side script debugging** check box.
4. Click **Send detailed ASP error messages to client** if you want to send the client very detailed debugging information, or click **Send the following text error message to client** and type the text you want to send to the client.
5. Click **OK**.

Because the worker process identity runs as the Network Service account in worker process isolation mode, you must follow these directions to debug ASP applications.

| **Note** |
| --- |
| It is recommended that you do not change the worker process identity to run as LocalSystem. |

### To configure Launch and Access permissions to enable ASP debugging in worker process isolation mode for Script Debugger and Visual InterDev

1. If you haven't done so already, install Microsoft® Script Debugger or Microsoft Visual InterDev® debugger.
2. From the **Start** menu, click **Run**, and then type the following: **dcomcnfg**
3. In the **Console Root** file, double-click **Component Services**, double-click **Computers**, double-click **My Computer**, and double-click **DCOM Config**.
4. Right-click **Machine Debug Manager** and then click **Properties**.
5. Click the **Security** tab.
6. Under **Launch Permissions**, click **Edit**, click **Add**, type **Network Service**, and then click **OK**. If you are joined to a

domain, you might need to click **Locations** and change the location to the local computer.

7. Under **Access Permissions**, click **Edit**, click **Add**, type **Network Service**, and then click **OK**. If you are joined to a domain, you might need to click **Locations** and change the location to the local computer.

8. Click **OK** to apply the changes.

| **Note** |
| --- |
| To enable ASP debugging for Microsoft Visual Studio® .NET, you must add the Network Service account to the Debugger Users group. |

**Related Information**

- For more information about the Microsoft Script Debugger tool, see Microsoft Script Debugger on MSDN® Online.

- For more information about debugging in Visual Studio, see Adding Debugger Users and Configuring DCOM.

# Configuring CGI Applications

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS 6.0 supports Common Gateway Interface (CGI) applications. This topic provides administrative information about installing and configuring CGI applications on the Web server, and setting the timeout value for a CGI script.

**Important**

To help minimize the attack surface of the server, IIS 6.0 is not installed on Windows Serve 2003 by default. When you first install IIS 6.0, it is locked down -- which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable these features, IIS returns a 404 error. You can enable these features through the Enabling Web Service Extensions node in IIS Manager. For more information about how to troubleshoot 404 errors and other issues, see Troubleshooting in IIS 6.0.

CGI programs are executed when the Web server receives a URL that contains the CGI program name and any parameters that it requires. If your CGI program is compiled into an executable (.exe) file, you must give the directory that contains the program Execute permissions so that users can run the program. If your CGI program is written as a script, for example a Perl script, then you can give the directory either Execute permissions or Script permissions. To use Script permissions, the script interpreter must be marked as a script engine.

**Note**

The IIS_WPG group does not have the right to start CGI processes by default. If you create a new account and add it to the IIS_WPG group to run a worker process identity, you still must grant this new account two user rights to start CGI processes. These user rights are **Adjust memory quotas for a process** and **Replace a process level token**. For more information about how to modify user rights, see "Edit local security settings" or "Edit a security setting on a Group Policy object" in Help and Support Center for Windows Server 2003.

If you want to develop new CGI applications, Microsoft provides several alternatives. For faster execution, consider developing an Internet Server API (ISAPI) extension instead. For ease of development, consider developing an ASP.NET application.

This section contains the following information:

- Installing CGI Applications in IIS 6.0: Explains how to install CGI applications on your Web server.
- Configuring the Maximum Number of Concurrent CGI Requests: Explains how to configure the maximum number of concurrent CGI requests.
- Configuring CGI Application Timeouts: Explains how to configure timeout values for CGI applications.

# Installing CGI Applications in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To install and configure CGI applications**

1. Set up a directory for your CGI programs. For extra security, separate your CGI programs from your content files. You do not need to name the directory Cgi-bin, although you can do so if you want. For more information, see Using Virtual Directories.

2. If your CGI programs are scripts, obtain and install the appropriate script interpreter. For example, to run Perl scripts, obtain a Perl interpreter. Windows operating systems do not provide versions of Perl, SED, or AWK. Instead, you must obtain these interpreters from third-party developers.

3. If your CGI programs are .exe files, give the directory Execute permissions. If your CGI programs are scripts, you can give the directory either Execute permissions or Script permissions. For more information, see Access Control in IIS 6.0.

   If you choose to give the directory Script permissions, you must mark the script interpreter as a script engine in the directory properties. Only interpreters that are marked as script engines are allowed to execute in the directory. Executable files (.dll and .exe files) cannot be directly executed; that is, a browser request cannot launch an executable file on the Web server by including the program name in the URL. By enabling **Scripts only** permissions and selecting the **Script engine** check box, you can safely put content files (such as .htm or .gif files) in the same directory as your CGI scripts. Content files are displayed in the browser and scripts are executed, but no one can run an unauthorized program and script commands are not displayed in the browser.

4. For CGI scripts, create an application mapping between the file name extension of your script and the script interpreter.

   IIS maps file name extensions to an interpreter. For example, if you are using Perl scripts stored in files with a .pl extension, map the .pl extension to the program that runs Perl scripts. Map .bat and .cmd files to the command interpreter (Cmd.exe). For more information, see Setting Application Mappings in IIS 6.0.

5. Set NTFS permissions. If you are using NTFS access permissions, verify that all users who need to run the program have Execute permissions for the directory. If your Web site accepts anonymous users, make sure that the anonymous user (the IUSR_*computername* account) has Execute permissions.

IIS supports most of the standard server environment variables.

For greater security, the Web server does not pass the command interpreter's special characters to a mapped CGI application. By default, the following characters cannot be included in the URL that calls the CGI application:

```
| ( , ; % < >
```

**Related Information**

- For general information about programming CGI applications, refer to the MSDN Online Library.

# Configuring the Maximum Number of Concurrent CGI Requests

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

To prevent performance degradation and to decrease the possibility of security exposures on your Web server, you can configure the maximum number of simultaneous CGI requests allowed to run at one time.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

| **Important** |
| --- |
| Using Registry Editor incorrectly can cause serious problems that require reinstalling the operating system. Because Registry Editor bypasses the standard safeguards that prevent you from entering settings that are conflicting or likely to degrade performance or damage your system, exercise caution when making changes to the registry. Microsoft cannot guarantee that problems resulting from the incorrect use of Registry Editor can be solved. For information about how to edit the registry, see "Changing Keys and Values" in Registry Editor Help. |

**Procedures**

**To configure the maximum number of concurrent CGI requests**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **Regedit.exe**, and click **OK**.
3. Navigate to the following location in the registry:
   HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\W3SVC\Parameters.
4. From the **Edit** menu, point to **Add**, click **DWORD Value** and then add the following registry value:

   Name: **MaxConcurrentCgisExecuting**

   Type: **REG_DWORD**

   Data: IIS uses a default value of 256 if this registry key does not exist. You can set the value between 0 and 4294967295 (unlimited) depending on your needs. Using a low value means that fewer CGI requests can run concurrently on the Web server; however, using a high value can cause performance degradation.
5. Quit Registry Editor.

**Related Information**

- For more information about the registry key **MaxConcurrentCgisExecuting**, see WWW Service Registry Entries.
- For general information about programming CGI applications, refer to the MSDN Online Library.

# Configuring CGI Application Timeouts

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Setting the timeout value for a CGI application involves manually setting the CGITimeout metabase property.

For information about this metabase property, see the CGITimeout Metabase Property.

The CGITimout property can be set at a global level and at the individual site and site element levels. This gives you the flexibility to configure an overall CGITimeout level, and then customize the setting for individual sites and site elements.

If you will be editing this setting while IIS is running, make sure to enable the Metabase Edit-While Running setting. See Enabling Edit-While-Running in IIS 6.0 for more information.

# Configuring User Rights for Nondefault Identities to Run CGI Processes

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS 6.0 worker processes use the CreateProcessAsUser API to start CGI processes. The CreateProcessAsUser API must have the SE_ASSIGNPRIMARYTOKEN_NAME and SE_INCREASE_QUOTA_NAME user rights to succeed. The Network Service, Local Service, and LocalSystem user accounts have these user rights. If you change the identity of a worker process and want to run CGI processes, ensure that the new identity has these two user rights.

**To assign user rights to an account on the local computer**

1. From the **Start** menu, point to **Administrative Tools**, and then click **Local Security Policy**.
2. In the **Local Security Settings** dialog box, double-click **Local Policies**, and then double-click **User Rights Assignment**.
3. In the details pane, double-click **Adjust memory quotas for a process**. This is the SE_INCREASE_QUOTA_NAME user right.
4. Click **Add User or Group**, and, in the **Enter the object names to select** box, type the user or group name to which you want to assign the user right, and then click **OK**.
5. Click **OK** again, and then, in the details pane, double-click **Replace a process level token**. This is the SE_ASSIGNPRIMARYTOKEN_NAME user right.
6. Click **Add User or Group**, and, in the **Enter the object names to select** box, type the user or group name to which you want to assign the user right, and then click **OK**.

# Configuring ISAPI Extensions

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

By adjusting several settings that are associated with the ISAPI extensions (ISAPI DLLs) that run on your server, you can fine-tune server performance. Logging usage data, such as the number of requests and the time they were made, can help you determine how to make the adjustments.

| **Important** |
| --- |
| To help minimize the attack surface of the server, IIS 6.0 is not installed on Windows Server 2003 by default. When you first install IIS 6.0, it is locked down -- which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable these features, IIS returns a 404 error. You can enable these features through the Enabling Web Service Extensions node in IIS Manager. For more information about how to troubleshoot 404 errors and other issues, see Troubleshooting IIS 6.0. |

#### Caching ISAPI extensions

ISAPI DLLs can be loaded and cached so that additional requests can be processed without calling them again. Otherwise, the DLLs are unloaded after they are run. Caching reduces the time a user waits for a DLL to load, and most ISAPI extensions benefit from caching. You should clear this option only for special circumstances, such as debugging ISAPI extensions.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

### To enable caching

1. In IIS Manager, expand the local computer, and then click the starting-point directory of the application you want.
2. Right-click the directory, and then click **Properties**.
3. Click the appropriate tab: **Home Directory**, **Virtual Directory**, or **Directory**.
4. In the **Application settings** area, click **Configuration**, and then click the **Mappings** tab.
5. On the **Mappings** tab, select the **Cache ISAPI extensions** check box.

#### Related Information

- For more information about logging server activity, see Logging Site Activity.

# Working with ISAPI Filters

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Like Internet Server API (ISAPI) extensions, ISAPI filters are programs that respond when the application server receives an HTTP request. However, unlike ISAPI extensions, ISAPI filters are always run in the server process. ISAPI filters are different from applications because they are driven by Web server events instead of a client request. You can associate an ISAPI filter with a particular Web server event; the filter is then notified every time its associated event occurs. For example, a filter could be notified when a Read or Write event occurs and then encrypt the raw data to be returned to the client.

| **Note** |
| --- |
| If an HTTP request triggers an event for which the filter is registered, the filter will receive the data contained in the request regardless of whether the request is for a file, a CGI application, or an ISAPI extension. |

This section contains the following information:

- Installing ISAPI Filters: Explains how to install ISAPI filters on a server and how to change the load order of the filters.
- Checking ISAPI Filter Status: Explains how to view the status for ISAPI filters.

# Installing ISAPI Filters

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can install filters for all of the sites on an application server (global filters), and you can install filters for individual Web sites (site filters). If you install both global filters and site filters, the two filter lists are merged for the site.

When several filters have registered for the same event, they are called sequentially. Filters with a higher priority are run before filters with a lower priority. If several filters have the same priority, global filters that are set in the master properties are run before the filters that are set at the site level. Filters with the same priority at the same inheritance level are run in the order in which they were loaded. You can change the filter load order by adjusting the properties for the Web server or the Web site.

**Procedures**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To add a filter to a Web server or Web site**

1. In IIS Manager, expand the local computer, right-click the Web server or Web site to which you want to add a filter, and then click **Properties**.
2. Click the **ISAPI Filters** tab, and then click **Add**.

| **Note** |
| --- |
| If you are adding filters to a Web site, you will not see any global filters inherited from the Web server's master properties. You will see only the filters installed for the Web site, even though both sets of filters are run. |

3. In the **Filter name** text box, type the name of the filter.
4. In the **Executable** text box, type the name of the DLL file or click **Browse** to navigate to it, and then click **OK**.
5. Click the up or down arrow to change the load order of a filter.

| **Note** |
| --- |
| You can only change the load order of filters that have the same priority. |

6. If you have added or changed a global filter, you must stop and restart the Web server to load the new filters into memory.

**Related Information**

- For information about checking the status of ISAPI filters, see Checking ISAPI Filter Status.
- For information about how to fine-tune server performance by caching ISAPI extensions, see Configuring ISAPI Extensions.
- For more information about ISAPI filters, see ISAPI Reference in the IIS Software Development Kit (SDK).

# Checking ISAPI Filter Status

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When you add an ISAPI filter to a site on IIS 6.0, the Status column in the list of filters is empty. Until a request is made for the site and an attempt is made to load the filter, the status of the filter is not known. After the request is made, the status of the filter is displayed either as a red arrow if the filter did not load or as a green arrow if the filter loaded successfully.

| **Note** |
| --- |
| This behavior is different from the behavior in IIS 5.0, where the filter was loaded dynamically as soon as it was added to the site, regardless of whether a request was made to the site. |

**Procedures**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

### To check the ISAPI filter status

1. In IIS Manager, right-click the Web site or virtual server on which the ISAPI filter is installed, and then click **Properties**.
2. Click the **ISAPI Filters** tab, and then, in the **Status** column, check the ISAPI filter status.

   A green arrow indicates that the last ISAPI filter installed correctly. A red arrow indicates that a filter failed the last time the worker process started.

**Related Information**

- For information about adding ISAPI filters and changing the load order of filters, see Installing ISAPI Filters.
- For information about how to fine-tune server performance by caching ISAPI extensions, see Configuring ISAPI Extensions.
- For more information about ISAPI filters, see ISAPI Reference in the IIS Software Development Kit (SDK).

# Installing Wildcard Application Mappings

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In IIS 6.0, administrators can configure a Web site or virtual directory to run an Internet Server API (ISAPI) application at the beginning of every request to that Web site or virtual directory, regardless of the extension of the requested file.

When an IIS Web server receives a request from a client, the Web server looks at the extension of the file that is named in the request to determine which ISAPI or Common Gateway Interface (CGI) application handles that file. For example, if a request comes in for a Web page called Default.asp, IIS knows from the application mapping list that Default.asp is handled by the Asp.dll ISAPI application.

If you want certain tasks to be executed for every client request before the requested page is sent to its mapped application, you can write an ISAPI Filter which intercepts requests as they arrive. However, ISAPI filters have the following limitations:

- They cannot access the body of a request, only the headers.
- They can only be configured per site, not per virtual directory.
- They should not contain long-running operations because ISAPI filters are synchronous.
- They are less flexible because the ISAPI filter API has less functionality than the ISAPI extension API, which is used to write ISAPI applications.
- They are difficult to manage over time.
- They are event-driven.

By using wildcard application maps, you can intercept every request before the requested page is sent to its mapped application. The effect is like having an Installing Wildcard Application Mappings that handles every file name extension. This is why the term *wildcard* is used to name this feature. Applications using wildcard application mapping can only be ISAPI applications.

A client request takes the following route:

- An incoming request is handled by any existing ISAPI filters that are installed on the root Web site. The ISAPI filters are executed in order.
- The request is sent to any existing wildcard application map applications, which are also executed in order. If the incoming request is for a Web file that is in a virtual directory, and there are wildcard application maps installed on the virtual directory and the root Web site, then only the wildcard application maps that are installed on the virtual directory are executed. If there are no wildcard application maps installed on the virtual directory, then the wildcard application maps that are installed on the Web site are executed. In other words, wildcard application maps are only inherited if none exist in the application where the requested Web file resides.
- The IIS server looks at the application mappings table to determine which ISAPI application or CGI script specifically processes the requested file.
- The response can be appended to at each stage and then sent back to the client.

**Using Wildcard Application Mappings**

Wildcard application maps can be used in the following scenarios:

- Highly secure Web applications, such as banking applications, that require that every user who makes a request is authenticated against a database of user names, passwords, and account numbers. For example, once the user is authenticated, certain rules are created that specify what information the user can access. If the wildcard application map determines that the user has no rights, it can prevent the request from going any further, or it can send the request to a

Web page other than the one that was requested. This custom authentication and authorization scheme can be implemented in an ISAPI application and installed as a wildcard application map. This way, all users must go through authentication, regardless of the file name extension they request.

- E-commerce Web sites that display advertisements targeted to the interests of individual users. For example, when returning users make a request for a page, a wildcard application map application can examine their identity and then look up items that they previously viewed or purchased. Once the wildcard script map transfers control to the page that was requested, an advertisement that is appropriate to the user can be displayed.

**Inserting Wildcard Application Mappings**

By inserting wildcard application mapping, you can instruct IIS to allow ISAPI applications known as interceptors to intercept and examine every request before the requested page is sent to its mapped application. The effect is an application mapping that handles every file name extension.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**To add a wildcard application mapping to a Web server or Web site**

1. In IIS Manager, expand the local computer, expand the **Web Sites** folder, right-click the Web site or virtual directory that you want, and then click **Properties**.
2. Click the appropriate tab: **Home Directory**, **Virtual Directory**, or **Directory**.
3. In the **Application settings** area, click **Configuration**, and then click the **Mappings** tab.
4. To install a wildcard application map, do the following:
   - On the **Mappings** tab, click **Insert**.
   - Type the path to the DLL in the **Executable** text box or click **Browse** to navigate to it, select the **Application Engine** check box if the DLL is a script engine, and then click **OK**.
5. To edit or delete a wildcard application map, do the following:
6. In the **Application extensions** list, click the script map that you want to change.
7. Click **Edit** to alter the script map, or click **Remove** to remove the script map.
8. To change the order in which the wildcard application maps execute, rearrange the wildcard application maps in the **Wildcard application maps (order of implementation)** box by clicking the **Move Up** or **Move Down** button until they match the execution order you want.

   | **Note** |
   | --- |
   | Do not list the same application more than once in your list of wildcard application maps. |

**Related Information**

- For information about developing wildcard application mappings, see Developing ISAPI Extensions and Filters and ISAPI Reference in the IIS Software Development Kit (SDK).
- For information about regular application mappings, see Setting Application Mappings in IIS 6.0.

# Configuring Applications to Use COM+ Services

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

COM+ provides a number of services that can be used by Active Server Pages (ASP) applications, and it provides one service, transaction processing, that can be used by ASP pages. For more information about COM+ Services in ASP, see Improvements to the ASP Programming Environment. For information about how to configure these services in COM+, either programmatically or by using Component Services Manager, see the related information in the COM+ Software Development Kit (SDK) or online at COM+ (Component Services).

| **Note** |
| --- |
| Batch Logon is required for COM+ server-activated application identities. COM+ will add this automatically when you enter a new account for the identity of a COM+ application using the UI. Batch Logon gives your application the ability to execute code across servers, but does not allow the account to logon interactively to home server. |

This section contains the following information:

- Enabling Side-by-Side Assemblies using IIS Manager: Explains how to enable side-by-side assemblies using IIS Manager.
- Configuring Launch Permissions for COM+ Server Objects: Explains how to configure launch permissions for distributed Web applications.

# Enabling Side-by-Side Assemblies using IIS Manager

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Side-by-side (SxS) assemblies allow ASP applications to specify which version of a SxS-supported system DLL to use, such as MSVCRT, MSXML, COMCTL, GDIPLUS, and so on. For example, if your ASP application relies on MSVCRT version 2.0, you can ensure that your application still uses MSVCRT version 2.0 even after service packs are applied to the server. Any new version of MSVCRT is still installed on the computer, but version 2.0 remains and is used by your application. SxS-supported DLLs are stored in %WINDIR%\WinSxS.

Configuring SxS assemblies requires that you know the path to the DLL, and that the COM+ manifest file exists in every virtual directory that needs to use the DLL. The COM+ manifest is an XML file that has information about where a DLL is installed. IIS does not verify that the manifest exists.

You can enable side-by-side assemblies on the IIS side programmatically or by using IIS Manager.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To enable side-by-side assemblies on the IIS side using IIS Manager**

1. In IIS Manager, right-click a Web site or virtual directory and click **Properties**.
2. Click the **Virtual Directory** tab, and click **Configuration**.
3. If the configuration button is not available, it is because you have not created an application for this virtual directory. Click **Create** to create an application.
4. In the **Application Configuration** dialog box, click the **Options** tab.
5. Select the **Enable Side by Side assemblies** check box.
6. In the **Manifest file name** box, type the name of the COM+ manifest file.
7. Click **OK** twice.

**Related Information**

For information about enabling side-by-side assemblies on the IIS side programmatically, see Improvements to the ASP Programming Environment.

# Configuring Launch Permissions for COM+ Server Objects

Updated: August 22, 2005

Applies To: Windows Server 2003 R2, Windows Server 2003 with SP1

Changes in Windows Server 2003 Component Object Model (COM) services and IIS 6.0 have security implications for COM+ objects in ASP pages, ISAPI extensions, or any other application that runs on IIS. To minimize security risks, the new process model for IIS 6.0 requires all worker processes to run under an identity other than LocalSystem. If the identity of the worker process does not have launch permissions for that object, the object will not be successfully created. You must grant sufficient user rights to allow the IIS worker process to successfully create the object without granting so many rights that the identity poses a security risk.

**Important**

For Windows Server 2003, the IUSR_*computername* and IWAM_*computername* accounts are created and granted launch permissions to DCOM components by default when installing IIS. For Windows Server 2003 Service Pack 1 (SP1), the accounts are still created, but are no longer granted launch permissions to DCOM components by default when installing IIS. If you had IIS installed prior to upgrading to SP1, the permissions will not be changed. However, if you install IIS after upgrading to SP1, COM objects will fail to launch under the IUSR_*computername* and IWAM_*computername* accounts if your application uses default launch permissions for those accounts. In this situation you will receive an access denied error. Use the procedure below to grant explicit launch permissions to specific user(s) or group(s) to launch COM objects instead of using default launch permissions.

The following recommendations can provide sufficient security while reducing administrative overhead:

- Instead of adding individual users directly to the launch permissions for an object, create a group on the computer on which the COM+ object runs, and then add the individual users to this group. Then, add this group to the launch permissions for the object.

- If a COM+ object was created from the **GetExtensionVersion** method of an ISAPI extension, from an ISAPI filter, or from an ISAPI extension that is running as the identity of the current process, add the IIS_WPG group to the launch permissions for the object.

  **Note**

  You cannot use this approach with COM+ objects that are running in-process.

**Procedures**

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**To configure launch permissions for distributed Web applications**

1. Click **Start**, and then click **Control Panel**.
2. Double-click **Administrative Tools**, and then click **Component Service**.
3. In the left pane of Component Services, double-click **Component Services**, double-click **Computers**, and then click **My Computer**.
4. Click the **DCOM Config** folder.
5. In the details pane, find the object for which you want to modify the default launch permissions, right-click the icon for the object, and then click **Properties**.
6. Click the **Security** tab.

7. Under **Launch Permissions**, click **Customize**, and then click **Edit**.

| **Important** |
| --- |
| You should not modify the default launch permissions for an application. |

# Configuring IIS to Run 32-bit Applications on 64-bit Windows

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Windows Server 2003™, Service Pack 1 enables IIS 6.0 to run 32-bit Web applications on 64-bit Windows using the Windows-32-on-Windows-64 (WOW64) compatibility layer. IIS 6.0 using WOW64 is intended to run 32-bit personal productivity applications needed by software developers and administrators, including 32-bit Internet Information Services (IIS) Web applications. For more information about running 32-bit applications on 64-bit Windows, see Running 32-bit Applications on 64-bit Windows.

**To enable IIS 6.0 to run 32-bit applications on 64-bit Windows**

1. Open a command prompt and navigate to the %systemdrive%\Inetpub\AdminScripts directory.
2. Type the following command:

   **cscript.exe adsutil.vbs set W3SVC/AppPools/Enable32BitAppOnWin64 "true"**

3. Press ENTER.

Configuring IIS to Run 32-bit ASP.NET Applications on 64-bit Windows

# Configuring IIS to Run 32-bit FrontPage Server Extensions on 64-bit Windows

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you intend to run 32-bit applications that use FrontPage Server Extensions on 64-bit Windows, you must configure IIS to create 32-bit worker processes. For more information about running 32-bit applications on 64-bit Windows, see Running 32-bit Applications on 64-bit Windows.

IIS cannot run 32-bit and 64-bit applications concurrently on the same server.

**To enable IIS 6.0 to run 32-bit FrontPage Server Extensions on 64-bit Windows**

1. Open a command prompt and navigate to the %systemdrive%\Inetpub\AdminScripts directory.
2. Type the following command:

   **cscript.exe adsutil.vbs set W3SVC/AppPools/Enable32BitAppOnWin64 "true"**
3. Press ENTER.
4. Download and install the FrontPage Server Extensions 2002 Web Download.

Configuring IIS to Run 32-bit Applications on 64-bit Windows

# Synchronizing the Application Path of a Web Site

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you use **SqlServer** or **StateServer** session state mode, session state might be lost when you run an ASP.NET Web application in a Network Load Balancing server cluster. To maintain session state across different Web servers in the cluster, the application path of the Web site (for example, \LM\W3SVC\2) in the IIS metabase must be the same for all of the Web servers in the cluster.

You can change the Web site instance ID by manually editing the metabase on each Web server or by using the script Moveinstance.vbs as described in this section. For more information about manually editing the IIS metabase, see Working with the Metabase.

**Important**

You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any known parameters).

**To synchronize the application path of a Web site**

1. Create a text file, and then name the file Moveinstance.vbs.
2. Add the following script code to Moveinstance.vbs. This code modifies the instance IDs of the Web sites so that they are the same:

```
Dim WebService
Dim oldstr
Dim newstr
Dim args
Set args = WScript.Arguments
If args.Count < 1 Then
    Wscript.Echo "Must have original instance id and new instance id" &     chr(10)
& chr(13) & _
    "usage:  moveinstance.vbs 1 5"  & chr(10) & chr(13) & _
"Moves instance 1 to instance 5"
    WScript.Quit()
End If
Set WebService = GetObject("IIS://LocalHost/W3SVC")
oldstr = args(0) 'old instance
newstr = args(1) 'new instance
WebService.MoveHere oldstr,newstr
WebService.SetInfo
Set WebService = nothing
Set args=nothing
WScript.echo "DONE"
```

3. Save Moveinstance.vbs.
4. From the same directory in which you saved Moveinstance.vbs, run the script from a command prompt. For example, at the command prompt, type the following:

   **cscript moveinstance.vbs 1 5**

   and then press ENTER. This changes the instance ID of a Web site from 1 to 5 in the metabase.

   **Note**

When you use **StateServer** mode, make sure that the [machineKey] section in the Machine.config file has the same keys on every server in the Web farm.

For more information about session state and ASP.NET Web applications, see Preserving Session State with ASP.NET Web Applications in Network Load Balancing.

# Configuring FastCGI Applications

Updated: February 16, 2009

Applies To: Windows Server 2003

**In This Section**

This topic includes links to the following information:

- Configuring the FastCGI Extension for IIS 6.0: Describes how to configure the FastCGI module for IIS 6.0.
- Using FastCGI to Host PHP Applications on IIS 6.0: Describes how to use FastCGI to host PHP applications on IIS 6.0.

# Configuring the FastCGI Extension for IIS 6.0

Updated: February 16, 2009

Applies To: Windows Server 2003

Since version 1.0, the Microsoft® Internet Information Services (IIS) Web server has supported the Common Gateway Interface (CGI) protocol specification. CGI, in its basic form, is a standards-based protocol that allows information servers, such as IIS, to interface with external applications. FastCGI was introduced to the market to address scalability shortcomings of CGI.

This article describes the shortcomings of earlier versions of CGI and defines the need for the FastCGI extension for Internet Information Services 6.0. In addition, this article describes configurations settings of the FastCGI extension.

**CGI, ISAPI, and FastCGI on IIS 6.0**

**CGI**

As stated in the introduction, CGI is a protocol that allows information servers to interface with external applications. Because HTTP is stateless, it makes sense that any requests made over HTTP create a new instance of the external application in a new operating system process.

Within the new process, the stdin handle is remapped so that it receives request data from the client, the stdout handle is remapped so that it writes response data to the client, and the command-line and operating system environment variables are set to provide other server and request information to the CGI process.

The disadvantage with CGI on IIS is the relatively expensive process creation on Windows® operating systems. Every HTTP request creates a new process, performs the work inside the CGI application, and shuts down the process. On operating systems with very lightweight process creation, the performance is bound by the work done inside the CGI application. On operating systems such as Windows where process creation is expensive, the performance of the CGI application is bound by spinning up the new process. That is why CGI has performed well in UNIX-based systems but has not been recommended for IIS.

**ISAPI**

Despite the disadvantage of CGI on Windows, IIS can keep up with, and often surpass, the performance of other Web servers. Use of Internet Server Application Programming Interface (ISAPI) enables this performance. Unlike CGI, ISAPI is internal to the Web server process. When a new request is made for an ISAPI application, a new process is not created. Instead, the Web server calls an entry point in a dynamic-link library (DLL) that is loaded into the Web server process. If the ISAPI application is written with an understanding of how the operating system threading model works, the performance is very fast.

For many years, PHP has run on IIS, both through ISAPI and CGI implementations. However, both implementations have disadvantages when they run on IIS. As with all CGI applications, the CGI implementation of PHP has a disadvantage due to the performance characteristics of process creation on Windows. The ISAPI implementation has a disadvantage caused by threading issues.

When PHP runs as an ISAPI, it runs inside the Web server process in a highly multithreaded environment. While the PHP implementation is thread-safe, many popular extensions to PHP are not thread-safe. If you use a non-thread-safe extension to PHP with ISAPI, the server could become unstable. Hence, many applications cannot run in the ISAPI PHP implementations whereas others run very well in this environment.

**FastCGI**

FastCGI offers a compromise solution that delivers both performance and stability. FastCGI allows the host CGI process to remain alive after one request finishes so that the process may be reused for another request. Since the process can be reused many times over, the cost of process creation on Windows drops out of the equation.

The technical difference between ordinary CGI and FastCGI is that FastCGI has a layer in the process that maps the FastCGI protocol into the stdin, stdout, and the other standard streams that CGI uses. Many third-party libraries can be linked into existing CGI source code with very minor modifications that will enable them to work with FastCGI.

FastCGI on IIS runs on top of ISAPI. It is comprised of applications, the Application Manager, and FastCGI protocol support code.

Because Web servers handle multiple, concurrent requests, they must have a pool of processes available that are ready to handle incoming requests. In the FastCGI handler, this pool of processes is called an application (to avoid confusion with IIS applications, this article uses the term *process pool*). There are several properties of a process pool that you may want to

manage. For example, you probably want to specify the number of processes in the pool, or the number of requests that a process can accept before it is shut down and recycled.

The FastCGI handler supports multiple process pools. This capability lets you run more than one kind of FastCGI on one server—for example, both PHP and Ruby. You may also have multiple sites on your server, and you may not want requests for those sites to share the same processes, especially if you want the site processes to run as different users. The application manager is the part of FastCGI that handles multiple process pools.

**Configuring FastCGI**

## Script Maps

To route requests to the FastCGI handler, you must associate the FastCGI handler with IIS. In IIS 6.0, you do this by using an IIS configuration setting called a script map. Script maps associate file name extensions with the ISAPI handler that executes when that file type is requested. In addition, the script map has an optional setting that verifies that the physical file associated with the request exists before allowing the request to be processed. For security reasons, this is the default setting.

However, sometimes you need to allow a request to be processed that is not associated with a physical file. The ISAPI extension that contains the FastCGI handler is called fcgiext.dll. To configure the FastCGI handler to accept PHP requests, create a new script map that associates the ".php" file name extension with fcgiext.dll. For Ruby, map the ".rb" extension to fcgiext.dll and so on. In IIS 6.0 it is also possible to use a wildcard in the script map. In this situation, all requests are routed to a single ISAPI extension. If you create a wildcard script map for fcgiext.dll, all requests will use FastCGI, regardless of the file name extension requested.

**To create a script map for FastCGI handler on IIS 6.0**

1. Start inetmgr.exe.
2. Double-click the icon for the local computer.
3. Right-click **Web Sites** and select **Properties**.
4. Click **Home Directory** tab.
5. Click **Configuration**.
6. Click **Add**.
7. Browse to %*windir*%\system32\inetsrv\ to select fcgiext.dll as the Executable.
8. Enter **.php** in the **Extension** field.
9. Select **Limit to** and enter **GET,HEAD,POST**.
10. Select **Script Engine** and **Verify that file exists**.
11. Click **OK**.

**FCGIEXT.ini**

Once you have created a script map, you must configure the FastCGI extension settings. Use the Fcgiext.ini file found in %*windir*%\system32\inetsrv\. This file contains various configuration sections and settings that change the behavior of the FastCGI handler.

Regardless of the FastCGI application type that you want to run, you must include a Types section in your configuration file. The purpose of the Types section is to associate a file name extension with a specific process pool and process. If you configure IIS script maps to point both .php and .rb files to the FastCGI handler, you must configure the Types section to tell FastCGI how these extensions differ from each other. Following is a sample configuration file that maps:

[Types]

php=c:\php\php-cgi.exe

php:123154536=PHP Site 1

php:123154537=PHP Site 2

*=Wildcard Mapping

The first line of this file shows that PHP file name extensions are associated with c:\php\php-cgi.exe, which is the PHP CGI application handler. The second and third lines of this sample use site instance identifiers to limit which sites have access to the PHP handler.

You can create configuration on a process-name basis, a file name extension (which is optionally site-specific), and a section name. The section name supports declaring arguments for the process. Since different pools running in the same process may require different arguments, you cannot depend on the process name alone to define all the settings for a given process pool. However, to maintain compatibility with previous technical preview releases of the FastCGI handler, the path of the executable is used to create the starting configuration, as in the following sample:

[c:\php\php-cgi.exe]

QueueLength=999

MaxInstances=20

InstanceMaxRequests=500

Since this section does not contain an ExePath setting, the FastCGI handler uses the section name for the path of the executable. The section below is for PHP Site 1, which only applies to the site that uses 123154536 as its ID:

[PHP Site 1]

ExePath=c:\php\php-cgi.exe

Arguments=site1

QueueLength=1001

MaxInstances=20

IdleTimeout=200

ActivityTimeout=20

RequestTimeout=60

InstanceMaxRequests=1000

In this section, .php requests are associated on that site with c:\php\php-cgi.exe. Additionally, when a process starts, "site1" is passed as an argument. This differs from the procedures followed on PHP Site 2, which looks like the following:

[PHP Site 2]

ExePath=c:\php\php-cgi.exe

Arguments=site2

QueueLength=1001

MaxInstances=20

IdleTimeout=400

ActivityTimeout=40

RequestTimeout=120

InstanceMaxRequests=1000

In this case, you pass "site2" as the argument when you start c:\php\php-cgi.exe.

**Note:** The Arguments setting is optional, and you can pass multiple arguments using a space delimiter.

If you need a space within a single argument, use quotation marks around the complete argument, just as you would do when using the command line.

**Note:** Every time that you change the FastCGI extension configuration in the Fcgiext.ini file, you must restart the application pools associated with Web sites that use FastCGI extension before the configuration changes will take effect.

**Application Pool Settings**

FastCGI extension has a set of configuration settings that control application pool behavior. This section lists all the settings supported by FastCGI and their formats:

- ExePath – This setting specifies the physical path of the process executable that will be used in the pool.

- Arguments – This setting specifies the arguments to pass to each process in the pool at start time. This setting is optional.

- EnvironmentVars – This setting specifies the environment variables that are set for the process executable associated with this pool. This setting uses the following format:

  EnvironmentVars=Name:Value,Name:Value,...,Name:Value

  Example:

  EnvironmentVars=VARIABLE1:10000,VARIABLE2:20000

If the environment variable value contains a space character, then enclose the value in quotation marks. If the environment variable value contains a comma character (","), then this character is escaped with "/". Similarly, if the environment variable value contains "/" then it should be escaped also.

Example:

EnvironmentVars=VARIABLE1:"C://PHP",VARIABLE2="1/,2/,3"

- Protocol – This setting specifies the protocol that must be used to communicate with the FastCGI process. The allowed values are **NamedPipe** and **Tcp**. If not specified, the default value is **NamedPipe**.

- QueueLength – This setting specifies the maximum number of requests to an application's process pool that are queued before the FastCGI handler starts returning errors to clients. This indicates that the application is too busy. If not specified, the default value is 1000.

- MaxInstances – This is the highest number of process instances allowed in the process pool. The default is 10. Note that the FastCGI handler will not create this number of processes unless they are needed. If your application never receives more than two concurrent requests, your application only creates two processes.

- InstanceMaxRequests – This is the number of requests sent to a process in the pool before it is shut down and recycled. The default value is 1000.

- IdleTimeout – This is the number of seconds that a process can remain idle without working on a request before it shuts down. The default is 300 seconds.

- ActivityTimeout – This is the number of seconds that the FastCGI handler waits for I/O activity from a process before it is terminated. The default is 30 seconds.

- RequestTimeout – This is the maximum amount of time that a FastCGI process is allowed to handle a request before it is terminated. The default is 90 seconds.

- ResponseBufferLimit – Data from FastCGI processes is buffered before it is returned to the client as a response. This property specifies the amount of response data, in bytes, that is buffered for requests to an application. This buffer is flushed to the client as soon as it is full or when the response is complete, whichever occurs first. If not specified, the default value is 4194304 (4 MB).

- FlushNamedPipe – There are some cases where a FastCGI application might not read all of the data from the named pipe that communicates with the Web server. If this occurs, the Web server waits for a read that does not come. This, in turn, causes a deadlock on that member of the process pool. This most often occurs when a FastCGI process exits abnormally. For instance, the maximum number of requests a process can handle may be set internally, but that number may be lower than the InstanceMaxRequests setting. Setting FlushNamedPipe to 1 causes FastCGI to flush data that could lead to

this condition. The default is 0.

- UnhealthyOnQueueFull – If the value of this variable is 1, the worker process hosting is flagged to IIS as unhealthy any time that the application's request queue is filled. IIS checks health whenever it pings the worker process. If that worker process has been flagged as unhealthy, it and everything it is hosting will be recycled. If not specified, the default value is 0.

**Wildcard Mapping**

The asterisk, "*", association is used for wildcard mapping. This applies to IIS 6.0, which allows a special kind of script map that applies to all requests. If you configure fcgiext.dll as a wildcard handler, this association catches any requests that do not have a more specific configuration associated with the request. For example, the Types section described earlier in this article does not have a ".py" extension configured. If you use the sample section earlier in this article to model a request for a file that is named "File.py," the "*" association is used and the request is routed to the process pool called "Wildcard Mapping."

Consider this section:

[Wildcard Mapping]

ExePath=c:\echo\echo.exe

QueueLength=1000

MaxInstances=20

InstanceMaxRequests=100

IgnoreExistingFiles=1

;IgnoreExistingDirectories=1

Most of this example resembles the other process pool sections, but it has two additional settings, IgnoreExistingFiles and IgnoreDirectories, that are only used for wildcard script maps.

Consider the situation where you have configured an IIS script map that does not verify that a physical file exists before executing the handler. In this scenario, it is convenient to let the FastCGI handler handle requests that are not associated with physical files, but still to let IIS handle other files in the directory. This scenario explains the reason and need for these two settings.

- IgnoreExistingFiles – When set to 1, the FastCGI handler checks if the requested URL is associated with a physical file. If the request is associated with a physical file, the FastCGI handler defers processing the request so that it will be processed externally from the FastCGI handler. The default value is 0.

- IgnoreExistingDirectories – When set to 1, the FastCGI handler checks whether the requested URL is associated with a physical directory. If the request is associated with a physical directory, the FastCGI handler defers processing the request so that it is processed externally from the FastCGI handler. This setting is useful for allowing default documents and directory listings to be served. The default value is 0.

**Site-Specific Wildcard Mappings**

It is also possible to set a site-specific wildcard mapping using the same site ID syntax that file name extensions use (that is, "*:12345678=Section Name"). Note, however, that the search order for file name extensions is significant. When a request reaches the FastCGI handler, the associations in the Types section are checked in the following order:

1. A specific file name extension association specific to the site ID.

2. A '*' association specific to the site ID.

3. A specific file name extension association that has no specified site ID.

4. A '*' association that has no specified site ID.

**Using FastCGI Configuration Script**
To simplify and automate the configuration steps described in previous sections, the configuration script (fcgiconfig.js) is provided with the installation of FastCGI extension. The script is found in %*windir*%\system32\inetsrv. This script adds and removes script maps and modifies application pool settings in the Fcgiext.ini file.

### Add New FastCGI Mapping

To add new FastCGI mapping, run fcgiconfig.js with the –add switch. When using this switch, you must provide the following parameters:

- -section:<Section name>. This parameter specifies the name of the section that will be added to the fcgiext.ini file in [Types] block.
- -extension:<file name extension>. This parameter specifies what file name extensions are associated with this section.
- -path:<file path of the CGI executable>. This specifies the absolute file path of the CGI executable that processes requests for files that have extension specified in –extension parameter.
- -site:<site id>. This optional parameter specifies the site to which the section should be added. If not specified, then the section is added to all sites on your Web server.
- -norecycle. By default, the configuration script recycles all applications pools on IIS 6.0 so that configuration changes can take effect. This optional parameter prevents this recycling.

Examples:

>cscript fcgiconfig.js -add -section:"PHP" -extension:php -path:"C:\PHP\php-cgi.exe"

The example given earlier in this section adds script map for .php extension and updates the Fcgiext.ini file.

As an option, you can specify the site to which the script map is applied:

>cscript fcgiconfig.js -add -section:"PHP" -extension:php -path:"C:\PHP\php-cgi.exe" –site:1

This example adds script map to "Default Web Site" only.

### Remove Existing FastCGI Mapping

To remove existing FastCGI mapping, run fcgiconfig.js with –remove switch. When using this switch, you must provide the following parameters:

- -section:<Section name>. This parameter specifies the name of the section that is removed to the Fcgiext.ini file in [Types] block.
- -norecycle. By default, configuration script recycles all applications pools on IIS 6.0 so that configuration changes take effect. This optional parameter can be used to prevent this recycling.

This example removes the FastCGI mapping for PHP applications.

>cscript fcgiconfig.js -remove -section:"PHP"

### Configuring Existing FastCGI Mapping

You can use the configuration script for all FastCGI configuration properties that were described earlier in this article. To set the configuration properties, use the –set switch. When using this switch, you must provide the following parameters:

- -section:<Section name>. This parameter specifies the section to which the configuration change is applied.
- -<Parameter Name>:<Parameter Value>. This specifies the name of the parameter to change and its new value. The complete list of possible parameters is found in the Application Pool Settings section.
- -norecycle. Use this parameter if you do not want configuration script to recycle application pools after applying

configuration change.

This example sets the FastCGI process pool configuration property InstanceMaxRequests for the PHP section:

```
>cscript fcgiconfig.js -set -section:"PHP" –InstanceMaxRequests:10000
```

# Using FastCGI to Host PHP Applications on IIS 6.0

Updated: February 16, 2009

Applies To: Windows Server 2003

This article describes how to use the Microsoft® Internet Information Services (IIS) 6.0 FastCGI extension to set up and run PHP applications on Windows XP and Windows Server 2003 operating systems.

**What is FastCGI?**
FastCGI is a standard protocol that allows the Common Gateway Interface (CGI) executables in application frameworks to interface with the Web server. It differs from the standard CGI protocol in that FastCGI reuses CGI processes for multiple requests, which provides a significant performance boost compared to CGI. IIS FastCGI support enables IIS to host common CGI programs such as PHP or Ruby on Rails by using the FastCGI protocol and, by doing so, offer high performance and stability for production deployment of such application frameworks. IIS FastCGI support involves the following items:

- The IIS Web server (FastCGI Extension Go Live release supports IIS 6.0)
- The IIS FastCGI extension
- The CGI program (such as Php-cgi.exe)

The Web server dispatches HTTP requests to your application to the FastCGI component, which in turn starts the CGI program executable and forwards the request for processing. Once the request is finished and the response is returned back to the server and sent to the client, the CGI process is reused for a subsequent request. This helps avoid the performance penalty of starting a new process for each request, which gives you much better performance and scalability in a production environment.

To learn more about the FastCGI protocol, see the FastCGI Specification.

**Installing the FastCGI Extension for IIS 6.0**
The FastCGI extension for 32–bit and 64–bit Windows XP and Windows Server 2003 can be downloaded here: http://www.iis.net/downloads/default.aspx?tabid=34&g=6&i=1521.

When you run the FastCGI installer, it copies FastCGI specific files to the "%*windir*%\system32\inetsrv" folder and then registers and enables the FastCGI Web Server Extension. Of the files that the installer copies, the following files are of particular significance:

- fcgiext.dll — This is the actual FastCGI handler that communicates with FastCGI-enabled processes for processing requests.
- fcgiext.ini — This is the configuration file that contains mapping for file name extensions to FastCGI processes. It also contains the configuration of FastCGI process pools.
- fcgiconfig.js — This configures the FastCGI extension. The script updates the Fcgiext.ini file, modifies the IIS metabase, and recycles the Web service application pools if there have been changes.

**Download and Install PHP**
The FastCGI extension is fully compatible with the current official PHP 4.4.x and PHP 5.x distribution for Windows®. It is available from www.php.net/downloads. Since the FastCGI extension hosts and executes PHP processes in a single-threaded manner, you should download and install the non-thread-safe PHP build available for Windows. The non-thread-safe PHP build provides a major performance boost for a single-concurrency environment like FastCGI where a lack of thread safety is acceptable. After downloading the package, extract it to c:\php\. Navigate to c:\php\, and rename php.ini-recommended to php.ini.

You can also use the FastCGI extension with existing PHP 4.4.x or PHP 5.x installations.

**Note:** PHP distributions starting from PHP 5.2.1 contain the performance enhancements developed by Zend that will improve the performance of the PHP engine on Windows. These latest versions provide the optimal PHP performance on the IIS/FastCGI platform.

Zend Core provides a commercial PHP distribution that contains the PHP performance improvements for Windows.

**Configuring the FastCGI Extension to Work with PHP**

Once PHP is installed on Windows, you have two options for configuring FastCGI: you can use the configuration script provided with the installation of the FastCGI extension, or you can perform all the configuration tasks manually by modifying IIS configuration settings and the Fcgiext.ini file. Depending on the option that you select, see the corresponding sections in the remainder of this topic.

**Option 1: Using Script for Configuring the FastCGI Extension to Work with PHP**

The configuration script with the name fcgconfig.js is provided with the installation of the FastCGI extension and is located in %*windir*%\system32\inetsrv.

### To configure the FastCGI extension to work with PHP

1. Open a command-line window, change the current directory to %*windir*%\system32\inetsrv, and run the configuration script to register the PHP CGI program as the one that will be processing .php extensions:

   cscript fcgiconfig.js -add -section:"PHP" -extension:php -path:"C:\PHP\php-cgi.exe"

   (Replace C:\PHP\php-cgi.exe with the path of php-cgi.exe if you installed to a directory other than C:\PHP.)

   **Note:** If you do not want to register the PHP extension to be processed by the FastCGI component on your entire server, and you only want to register it for a specific Web site, then add a "–site:[siteId]" argument.

   Example:

   cscript fcgiconfig.js -add -section:"PHP" -extension:php -path:"C:\PHP\php-cgi.exe" –site:1

   **Note:** For a complete list of configuration parameters supported by the FastCGI extension, see the FastCGI extension documentation.

**Option 2: Manually Configuring the FastCGI Extension to Work with PHP**

To configure the IIS and FastCGI extension manually, you must create script mappings for the PHP extension in the IIS metabase and modify Fcgiext.ini file located in %*windir*%\system32\inetsrv.

### To create script mapping

1. Start Inetmgr.exe.
2. Double-click the icon for the local computer.
3. Right-click **Web Sites** and select **Properties**.
4. Click the **Home Directory** tab.
5. Click **Configuration**.
6. Click **Add**.
7. Browse to the fcgiext.dll located in %*windir*%\system32\inetsrv.

   **Note:** If you must use FastCGI in 32–bit mode on a 64–bit computer, then browse to %*windir*%\SysWOW64\inetsrv.
8. Enter **.php** in the **Extension** field.
9. Select **Limit to** and enter **GET,HEAD,POST**.
10. Select **Script Engine** and **Verify that file exists**.
11. Click **OK**.

### To modify the fcigext.ini file

1. Once the script mapping is added, modify the %*windir*%\System32\inetsrv\fcgiext.ini file.
2. Add an extension to application mapping (php=PHP) to the [Types] section.
3. Add [PHP] section with ExePath=c:\php\php-cgi.exe (assuming you installed PHP files to C:\PHP folder).

[Types]

...

php=PHP

...

[PHP]

ExePath=c:\php\php-cgi.exe

After all the changes to the Fcgiext.ini file are saved, restart the application pool associated with the Web site that hosts your PHP applications.

**Configuring the Default Document in IIS**

After configuring the FastCGI Extension to work with PHP by either of the two methods detailed earlier in this section, configure a default application document in IIS. Most PHP applications use a file that is named Index.php as the default application document. Configure IIS to treat this file as the default content page.

### To configure the default document in IIS

1. Start Inetmgr.exe.
2. Double-click the icon for the local computer.
3. Right-click **Web Sites**, and select **Properties**.
4. Click the **Documents** tab.
5. Click **Add**, and then enter **index.php** in the Default content page field.
6. Click **OK**.
7. If prompted for Inheritance Overrides, select the child nodes, and then click **OK**.

**Setting FastCGI Configuration for Optimal Functionality, Security, and Performance with PHP**

Full PHP functionality support and performance of PHP applications that are running on the FastCGI extension were the focus and main goal for the Microsoft IIS team. During the IIS team's internal testing and collaboration with Zend Technologies, they identified the set of configuration settings for the FastCGI extension and PHP that provides optimal functionality and performance for PHP applications when they are running on Windows and are using the FastCGI extension.

### To configure your server

1. Modify the php.ini file as follows:

   **Note:** Remove the ";", if it is present at the beginning of the following configuration lines.

   - Set **fastcgi.impersonate = 1**. FastCGI under IIS supports the ability to impersonate the security tokens of the calling client. This lets IIS define the security context under which the request runs.

   - Set **cgi.fix_pathinfo=1**. cgi.fix_pathinfo provides *real* PATH_INFO/PATH_TRANSLATED support for CGI. PHP's previous behavior was to set PATH_TRANSLATED to SCRIPT_FILENAME and not care what PATH_INFO is. For more information about PATH_INFO, see the CGI specifications. Setting this to 1 causes PHP CGI to fix its paths to comply with the specification.

   - Set **cgi.force_redirect = 0**.

2. Set the FastCGI configuration settings for the PHP section by running fcgiconfig.js as follows:

   **Note:** These commands should be run from the %*windir*%\system32\inetsrv\ folder.

   - Set the FastCGI process pool property InstanceMaxRequests to 10000. This setting specifies that the FastCGI extension will recycle Php-cgi.exe after it has processed 10000 requests successfully.

```
> cscript fcgiconfig.js -set -section:"PHP" -InstanceMaxRequests:10000
```

3. Configure the FastCGI extension to set PHP_FCGI_MAX_REQUESTS environment variables for the PHP process to 10000. This setting instructs Php-cgi.exe to recycle itself after it has processed 10000 requests successfully.

   ```
   > cscript fcgiconfig.js -set -section:"PHP" -EnvironmentVars:PHP_FCGI_MAX_REQUESTS:10000
   ```

   **Note:** You can configure **InstanceMaxRequests** and **PHP_FCGI_MAX_REQUESTS** to use numbers other than 10000. As a rule, always make sure that the value of **InstanceMaxRequests** is less than or equal to the value of **PHP_FCGI_MAX_REQUESTS**.

**Testing PHP CGI**

After installing the FastCGI extension and registering and configuring PHP CGI, you can request and use your PHP application.

To test, create and request a phpinfo.php page in your C:\inetpub\wwwroot folder that contains the following:

```
<?php

phpinfo();

?>
```

Note that the Server API indicates that PHP is hosted in FastCGI mode.

**Installing phpBB Application for Ase with the FastCGI Extension**

The phpBB Internet forum solution is a popular open-source application that provides a large and very customizable set of features. These include powerful permissions systems, private messaging, search functions, a customizable template and language system, and support for multiple databases. For more information about phpBB, see http://www.phpbb.com. For phpBB community–specific information, see http://www.phpbb.com/community/.

This section describes the steps that are required to install phpBB to work with the FastCGI extension on IIS 6.0.

The following steps assume that you have completed the setup and configuration of the FastCGI extension and PHP libraries as described in the previous sections.

**Download and Unpack the Application**

First, download the latest stable release of phpBB. As of January, 2009, the current release of phpBB (phpBB 3.0.2) is available at http://www.phpbb.com/downloads/?sid=ee349e0ae5950a30df04461023f7e34f. Once you download the package, uncompress it and copy all the files and folders to C:\Inetpub\wwwroot\phpBB2.

**Set Up the Database**

In order to use phpBB, you must have access to a database. For this walkthrough, we use Microsoft® SQL Server® 2005 Express Edition with mixed authentication. You can also use Microsoft® SQL Server® 2005, Microsoft® Office Access®, MySQL, or other databases.

Before starting the installation, create a database on the database server. Also create a database user and grant this user database ownership permission to the database.

Open **Microsoft SQL Server Management Studio**, and then click the **New Query** button. Enter the following script into the query window, and then click **Execute**. This script creates the database and user necessary for the phpBB application and should return "Command(s) completed successfully." in the messages pane.

```
USE [master]

GO

CREATE DATABASE phpbb3

GO

CREATE LOGIN [phpbb3]

WITH PASSWORD=N'phpbb3',

DEFAULT_DATABASE=[phpbb3],

CHECK_EXPIRATION=OFF,
```

```
CHECK_POLICY=OFF

GO

USE [phpbb3]

GO

CREATE USER [phpbb3] FOR LOGIN [phpbb3] WITH DEFAULT_SCHEMA=[dbo]

USE [phpbb3]

GO

sp_addrolemember 'db_owner','phpbb3'
```

**Set Up ODBC Connection to the phpBB3 Database**
To form the connection between the phpBB3 application and the database, create an ODBC connection. In the example used in this article, we use SQL Server 2005 Express Edition with an ODBC connection.

**To create an ODBC connection**

1. Click **Start**, **Administrative Tools**, **Data Source (ODBC)**.
2. Click the **System DSN** tab.
3. Click **Add**.
4. Select **SQL Server**, and then click **Finish**.
    a. Name: **phpbb3**
    b. Description:
    c. Server: **<HOSTNAME>\SQLEXPRESS**
    d. Click **Next**.
5. Select **With SQL Server authentication using a login ID and password entered by the user**.
    - Check **Connect to SQL Server to obtain default settings for the additional configuration options**.
    - Login ID: **sa**
    - Password: **<sa password>**
    - Click **Next**.
6. Select **Change the default database to:**, and select **phpbb3** from the drop-down menu.
7. Click **Next**.
8. Click **Finish**.
9. Click **Test Data Source**. The results should be "TESTS COMPLETED SUCCESSFULLY!"
10. Click **OK**.
11. Click **OK**.
12. Click **OK**.

**Set Up and Configure the Application**
Open your Web browser and browse to http://localhost/phpBB3/index.php. This redirects you to the phpBB setup page. Enter the required installation information and replace the Database Server Hostname with the name of your database server.

**To set up and configure the application**

1. Click **Install** tab.
2. Click **Proceed to next step**.
3. Requirements:
    a. **Files and Directories** may appear as "Unwritable."
    b. Navigate to c:\inetpub\wwwroot\phpbb3\ folder.
    c. Change NTFS security for the following folders so that **Internet Guest Account** has **write** access to the following folders:
        i. Cache/
        ii. Files/
        iii. Store/
    d. Click **Test again**.
    e. All compatibility requirements should pass.
    f. Click **Start Install**.
4. Database settings: (SQL Server 2005 Express, mixed authentication)
    a. Database type: **MSSQL Server 2000+ via ODBC**
    b. Database server hostname or DSN: **phpbb3** (created earlier in ODBC configuration section)
    c. Database name: **phpbb3**
    d. Database username: **phpbb3**
    e. Database password: **phpbb3**
    f. Click **Proceed to next step**.
    g. "Successful connection" message should be displayed. Click **Proceed to next step**.
5. Administrator details
    a. Administrator username: **admin**
    b. Administrator password: <create admin password>
    c. Confirm administrator password: <create admin password>
    d. Contact e-mail address: <enter contact e-mail>
    e. Confirm contact e-mail address: <enter contact e-mail>
    f. Click **Proceed to next step**.
    g. Results should be "Tests passed." Click **Proceed to next step**.

6. Configuration file
    a. To download configuration file, click **Download**.
    b. Save config.php to c:\inetpub\wwwroot\phpbb3\ folder. Overwrite, if you are prompted,.
    c. Click **Done**.
    d. Click **Proceed to next step**.
7. Advanced settings
    a. Leave default settings for this installation.
    b. Click **Proceed to next step**.
8. Click **Proceed to next step**.
9. Click **Login**.
10. You will be redirected to the Welcome page. Click **Logout** in the left column.

**Note:** If your Web site is configured to allow anonymous users, then you must grant access permissions to "Internet Guest Account."

#### Test the phpBB Application

### To test that phpBB has been installed successfully and create a forum

1. Navigate to http://localhost/phpBB3, and then click **Login**.
2. Enter the administrator username and password (this walkthrough used username: admin).
3. Once logged in, click on the **Administration Control Panel** link at the bottom of the page to view the administration panel.
4. This causes phpBB to ask you to re-authenticate. It then takes you to the administration panel.
5. On this panel, click **Manage Forums** under the **Quick Access** group.
6. Enter the desired forum name, and then click **Create new forum**.
7. Leave the default settings on the Create new forum page, and then click **Submit**.
8. You will then be redirected to the Forum permissions page. You can assign permissions later. Click the **Manage forums** link in the left column.
9. You can now see your new forum listed on the Forum administration page.

#### Getting More Information

To discuss the FastCGI extension for IIS 6.0 or file bug reports, use the IIS.NET FastCGI forum.

To see a list of known issues with the IIS 6.0 FastCGI, see this forum: http://forums.iis.net/1103/ShowForum.aspx.

To get more information about running various PHP applications on IIS, see:

PHP support in IIS 6.0 and IIS 7.0

# Configuring Servers for Applications

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In Web development, Web site and application code is complex and ever changing. Web sites and applications change as frequently as every week or month. Consequently, you require hosting services that actively manage your run-time environment, while safeguarding applications and managing performance.

This section explains how to use IIS Manager to configure your server to manage and execute Web-based applications.

This section includes the following information:

- About Configuring Servers for Applications: Discusses things to consider when you configure your server to run Web-based applications.
- Configuring IIS For Dynamic Content: Describes the necessary tasks to enable and disable the Web service extensions that process dynamic information.
- Configuring Isolation Modes: Describes configuring a server's modes of operation, and explains the ramifications of each mode.
- Worker Process Isolation Mode: Describes the WWW Service Administration and Monitoring features of Internet Information Services (IIS) 6.0 running in worker process isolation mode, and provides procedures for using them.
- IIS 5.0 Isolation Mode: Explains how to use the features of IIS 6.0 running in IIS 5.0 isolation mode.

**Related Information**

- For information about creating and configuring applications, see Configuring Applications in IIS 6.0.

# About Configuring Servers for Applications

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Internet Information Services (IIS) 6.0 delivers Web hosting services through an adjustable architecture that you can use to manage server resources with improved stability, efficiency, and performance. IIS separates applications into isolated pools and automatically detects memory leaks, defective processes, and over-utilized resources. When problems occur, IIS manages them by shutting down and redeploying faulty resources and connecting faulty processes to analytical tools.

IIS can run in either of two mutually exclusive modes of operation:

- Worker process isolation mode. This is the default mode of IIS 6.0, isolates key components of the World Wide Web Publishing Service (WWW service) from the effects of errant applications, and it protects applications from each other by using the worker process component. Use worker process isolation mode unless you have a specific compatibility issue that makes the use of IIS 5.0 isolation mode necessary. Web sites that serve static content or simple ASP applications should be able to move to IIS 6.0 running in worker process isolation mode with little or no modification.

- IIS 5.0 isolation mode. With this mode, you can run applications that are incompatible with worker process isolation mode because they were developed for earlier versions of IIS. Applications that run correctly on IIS 5.0 should run correctly on IIS 6.0 in IIS 5.0 isolation mode.

Worker process isolation mode provides better default security for running Web applications than IIS 5.0 isolation mode. By default, worker processes run with the Network Service identity. The Network Service account has lower access rights than the default account for IIS 5.0 isolation mode. Web applications that run in-process in IIS 5.0 application mode run as LocalSystem. The LocalSystem account can read, execute, and change most of the resources on the computer.

The default isolation mode upon installing IIS 6.0 depends on whether you perform a clean installation or an upgrade.

- After a clean install of IIS 6.0, IIS runs in worker process isolation mode.

- After an upgrade from an earlier version of IIS 6.0, the isolation mode is the same as configured on the previously-installed version of IIS 6.0.

- After an upgrade from IIS 5.0 or IIS 4.0, IIS 6.0 runs in IIS 5.0 isolation mode by default to maintain compatibility with your existing applications.

For information about switching from one isolation mode to the other, see Configuring Isolation Modes.

**Worker Process Isolation Mode**

IIS 6.0 introduces worker process isolation mode, which runs all Web applications in an isolated environment. When you run IIS in worker process isolation mode, applications can be configured to run in separate application pools. Each application pool is a logical representation of a configurable worker process and links to the applications in the pool. Worker processes operate independently of each other; they can fail without affecting other worker processes. The pooling of applications protects applications from the effects of worker processes that support other application pools. In this way, applications are protected from each other.

In worker process isolation mode, Hypertext Transfer Protocol (HTTP) requests are routed directly to an in-kernel application pool queue serving the configured application. Worker processes that serve an application pool pull the requests directly from the queue, avoiding process-switching overhead.

To further protect your WWW service, IIS 6.0 isolates critical World Wide Web Publishing Service (WWW service) components, such as the HTTP protocol stack (HTTP.sys) and WWW Service Administration and Monitoring, from the effects of third-party code running in worker processes. HTTP.sys receives and queues requests for WWW services. When a worker process enters an unhealthy state, and thus stops processing requests, HTTP.sys continues to process requests. Meanwhile, the WWW service detects that the worker process is unhealthy and shuts it down. If there is demand for a new worker process to serve requests (HTTP.sys has requests queued), the WWW service starts a new worker process to pick up the queued requests from HTTP.sys. Even though a worker process has failed, the WWW service continues to process requests and shields the user from experiencing a loss of service.

IIS 6.0 worker process isolation mode delivers the following specific improvements over earlier versions of IIS:

- **Robust performance** Isolation prevents Web applications and Web sites from affecting each other or the WWW service. Reboots of the operating system and restarting of the WWW service are avoided.

- **Self-healing** Automated management provides auto-restart of failed worker processes and periodic restart of deteriorating worker processes.

- **Scalability** Web gardens allow more than one worker process to serve the same application pool.

- **Process affinity** enables the connection of worker processes to specific processors on multi-CPU servers.

- **Automated debugging** The debugging feature enables the automatic assignment of failing worker processes to debugging tools.

- **CPU limiting** This monitoring feature enables controlling the amount of CPU resources that an application pool consumes in a configured amount of time.

**IIS 5.0 Isolation Mode**

If your server must run applications that are incompatible with worker process isolation mode, you can configure IIS to run in IIS 5.0 isolation mode, which supports the process model and features of IIS 5.0. If you run IIS in IIS 5.0 isolation mode, some features of worker process isolation mode are not available.

**Related Information**

- For information about creating application pools, see Configuring Application Pools in IIS 6.0.

- For more information about when to use IIS 5.0 isolation mode and how to configure IIS for IIS 5.0 isolation mode, see Configuring Isolation Modes.

# Configuring Isolation Modes

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can run IIS 6.0 in one of two modes: *worker process isolation mode* or *IIS 5.0 isolation mode*. Worker process isolation mode is the default mode, that is, the mode that the server runs in on a clean installation. You can use IIS 5.0 isolation mode to run applications developed for older versions of IIS that are determined to be incompatible with worker process isolation mode.

This topic includes the following information:

- Configuring IIS for worker process isolation mode.
- Configuring IIS for IIS 5.0 isolation mode.

**Configuring IIS for Worker Process Isolation Mode**

Worker process isolation mode is the default service mode in IIS. Worker process isolation mode delivers all the benefits of IIS 6.0 new architecture: robust application pooling; automated restarts, scalability, debugging; and finely-tuned performance tuning. Web applications run with the Network Service identity, which provides a security advantage: the Network Service account has lower access privileges than LocalSystem. Use worker process isolation mode unless you must run applications that might conflict with it, as stated below in "Configuring IIS for IIS 5.0 Isolation Mode."

To complete the following procedure, you must restart IIS, which will temporarily interrupt the World Wide Web Publishing Service (WWW service).

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To configure IIS for worker process isolation mode**

1. In IIS Manager, expand the local computer, right-click **Web Sites**, and then click **Properties**.
2. Click the **Service** tab, clear the **Run WWW service in IIS 5.0 isolation mode** check box, and then click **OK**.
3. To start the WWW service, click **Yes**.

If the switch to worker process isolation mode is successful, a folder named **Application Pools** appears in the **IISManager** listing for your local computer. You can always determine which isolation mode IIS is running by the presence (worker process isolation mode) or absence (IIS 5.0 isolation mode) of the **Application Pools** folder.

**Configuring IIS for IIS 5.0 Isolation Mode**

You must use IIS 5.0 isolation mode for applications that conflict with worker process isolation mode until the applications are modified.

The following application characteristics conflict with worker process isolation mode:

- Dependency on Inetinfo.exe: If the application must run in the Inetinfo.exe process, it must be run in IIS 5.0 isolation mode because applications do not run in Inetinfo.exe in worker process isolation mode.
- Requires Read Raw Data Filters: Read Raw Data Filters are available in IIS 5.0 isolation mode only.
- Requires Dllhost.exe: Applications that must be run in a Dllhost.exe environment can be run only in IIS 5.0 isolation mode because Dllhost.exe is not available in worker process isolation mode.

If the IIS 6.0 service is running in worker process isolation mode (the IIS 6.0 default mode), and you must run applications that

do not meet the requirements for worker process isolation mode, switch to IIS 5.0 isolation mode. This means you will not be able to take advantage of worker process isolation and the other features of worker process isolation mode.

After you complete the following procedure, you must restart the WWW service, which will temporarily interrupt the service.

**To configure IIS for IIS 5.0 isolation mode**

1. In IIS Manager, expand the local computer, right-click **Web Sites**, and then click **Properties**.
2. Click the **Service** tab, select the **Run WWW service in IIS 5.0 isolation mode** check box, and then click **OK**.
3. To start the WWW service, click **Yes**.

**Configuring IIS for an application mode using Adsutil.vbs**

You can also configure IIS for an application isolation mode by setting the metabase property **IIs5IsolationModeEnabled** to **true** or **false**. Use the following procedure to configure this metabase property from a command line.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any known parameters). |

**To configure IIS for an application isolation mode by using Adsutil.vbs**

1. In the **Run** dialog box, type **cmd**, and then click **OK**.
2. To set the application isolation mode, type one of the following commands at the command prompt:
   - To configure the server to run in worker process isolation mode, type:

     **cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/IIs5IsolationModeEnabled FALSE**

   - To configure the server to run in IIS 5.0 isolation mode, type:

     **cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/IIs5IsolationModeEnabled TRUE**

   | **Note** |
   | --- |
   | If you configured the server to run in IIS 5.0 isolation mode, you will need to set the level of application protection, or isolation, for each application running on the server. For instructions, see Isolating Applications in IIS 6.0. |

3. To restart IIS, at the command prompt, type:

   **iisreset /noforce**

   For more information about restarting IIS from the command line, see Restarting IIS.

To verify that you successfully changed to worker process isolation mode, check whether an **Application Pools** folder appears when you open IIS Manager on your local computer. You can always determine which isolation mode that IIS is running by the presence (in worker process isolation mode) or absence (in IIS 5.0 isolation mode) of the Application Pools folder.

| **Important** |
| --- |
| Do not confuse the **DefaultAppPool** application pool, which appears by default when you configure a computer to run in worker process isolation mode, with the **MSSharePointAppPool** application pool, which appears by default when you install FrontPage2002 Server Extensions or SharePoint™ Team Services from Microsoft. |

| **Note** |
| --- |

Do not use, delete, or make changes to the **MSSharePointAppPool** application pool. It holds files that are used internally by FrontPage Server Extensions and SharePoint Team Services. For more information, see Using FrontPage 2002 Server Extensions with IIS 6.0.

# Worker Process Isolation Mode in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This section explains how use IIS Manager to configure Internet Information Services (IIS) to execute Web-based applications with IIS in worker process isolation mode.

This section includes the following information:

- Configuring Application Pools in IIS 6.0: Explains the advantages of pooling application processes, and describes how to create and configure application pools.
- Recycling Worker Processes with IIS 6.0: Describes how to configure IIS to periodically restart worker processes in an application pool.
- Configuring Worker Processes for Idle Timeout: Describes how to configure idle process timeout, which is a resource management feature.
- Processor Affinity: Explains the concept of process/processor affinity.
- Configuring Web Gardens with IIS 6.0: Describes how to configure multiple application pools running under one worker process.
- Application Pool Health: Explains the concepts of application pool health and health monitoring.
- Configuring Health Monitoring: Describes how to enable IIS to monitor the health of each worker process.
- Configuring Rapid-Fail Protection in IIS 6.0: Describes how to protect resources when the requests to a worker process fail rapidly.
- Configuring Startup and Shutdown Time Limits: Explains how to configure a worker process to startup on demand when the first request for a Uniform Resource Locator (URL) is received.
- Configuring Application Pool Identity with IIS 6.0: Describes the security considerations that are related to configuring the identity of an application pool.

**Related Information**

- For an overview of IIS worker process isolation mode, see About Configuring Servers for Applications.
- For information about configuring applications, see Configuring Applications in IIS 6.0.

# Configuring Application Pools in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| This feature of IIS 6.0 is available only when running in worker process isolation mode. |

An application pool is a configuration that links one or more applications to a set of one or more worker processes. Because applications in an application pool are separated from other applications by worker process boundaries, an application in one application pool is not affected by problems caused by applications in other application pools.

By creating new application pools and assigning Web sites and applications to them, you can make your server more efficient and reliable, as well as making your other applications always available, even when the worker process serving the new application pool has problems.

**Guidelines for Creating Application Pools**

Consider the following guidelines when configuring application pools:

- To isolate Web applications on a Web site from Web applications on other sites running on the same computer, create an individual application pool for each Web site.
- For enhanced security, configure a unique user account (process identity) for each application pool. Use an account with the least user rights possible, such as Network Service in the IIS_WPG group.
- If there is a test version of an application on the same server with the production version of the application, separate the two versions into different application pools. This isolates the test version of the application.
- As a design consideration, if you want to configure an application to run with its own unique set of properties, create a unique application pool for that application.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To create a new application pool**

1. In IIS Manager, expand the local computer, right-click **Application Pools**, point to **New**, and then click **Application Pool**.
2. In the **Application pool name** box, type the name of the new application pool.
3. If the ID that appears in **Application pool ID** box is not the ID that you want, type a new ID.
4. Under **Application pool settings**, click the appropriate setting. If you click **Use existing application pool as template**, in **Application pool name** box, right-click the application pool that you want to use as a template.
5. Click **OK**.

Application pools allow you to apply configuration settings to groups of applications and the worker processes that service those applications. Any Web site, Web directory, or virtual directory can be assigned to an application pool.

**To assign an application to an application pool**

1. In IIS Manager, right-click the application that you want to assign to an application pool, and then click **Properties**.
2. Click the **Virtual Directory**, **Directory**, or **Home Directory tab**.

3. If you are assigning a directory or virtual directory, verify that Application name is filled in. If the **Application name** box is not filled in, click **Create**, and then type a name.

4. In the **Application pool** list box, click the name of the application pool to which you want to assign the Web site.

# Configuring Application Pool Identity with IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| This feature of IIS 6.0 is available only when IIS is running in worker process isolation mode. |

The identity of an application pool is the name of the account under which the application pool's worker process runs. By default, application pools operate under the Network Service account, which has low-level user access rights. That is, this account provides better security against attackers or malicious users who might attempt to take over the computer on which the World Wide Web Publishing Service (WWW service) is running. The LocalService account also has low-level user access rights, which is helpful for situations that do not require access to resources on remote computers. You can configure application pools to run as LocalSystem, which is an account with more user rights than the Network Service or LocalService account. However, be mindful that running an application pool under an account with increased user rights presents a high security risk.

For example, suppose that an Internet Service Provider (ISP) wants to allow customers to upload Common Gateway Interface (CGI) applications and then add them to an application pool. Running CGI-enabled applications in a separate application pool under the Network Service account, with its lower user rights, reduces the risk that these applications will be used to attack the server.

For more information about application pool identities, see Configuring Application Pool Identity in IIS 6.0.

For more information about issues that can arise when you use a configurable account as the application pool identity, see Knowledge Base article 871179, "You receive an 'HTTP Error 401.1 - Unauthorized: Access is denied due to invalid credentials' error message when you try to access a Web site that is part of an IIS 6.0 application pool."

For more information about using a configurable account with Kerberos authentication, see the following resources:

- Knowledge Base article 326985, "HOW TO: Troubleshoot Kerberos-Related Issues in IIS"
- Troubleshooting Kerberos Delegation
- Kerberos authentication for load-balanced Web sites

**Procedures**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To change the account under which an application pool runs using IIS Manager**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and then click **Properties**.
2. Click the **Identity** tab, and click either **Predefined** or **Configurable**. **Predefined** refers to standard service names, such as Network Service (the default), LocalSystem, or Local Service. **Configurable** refers to registered user names.
   - If you click **Predefined**, click a predefined account in the list box.
   - If you click **Configurable**, in the **User name** and **Password** boxes, type the user name and password of the account under which you want the worker process to operate. Then, add the account to the IIS_WPG group.
3. Click **OK**.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any known parameters). |

**To change the account under which an application pool runs using the Adsutil.vbs administration script**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd**, and click **OK**.
3. Switch to the %systemroot%\system32\inetsrv directory.
4. At the command prompt type **cscript adsutil.vbs SET W3SVC/AppPools/***AppPoolName***/WAMUserName** *Username*
5. At the command prompt type **cscript adsutil.vbs SET W3SVC/AppPools/***AppPoolName***/WAMUserPass** *Password*

**To programmatically change the account under which an application pool runs**

- In order to change the identity of a worker process in IIS 6.0, set three properties in the metabase under the application pool key that you want to change. Using "TestPool" as an example, and assuming the application pool named "TestPool" already exists, the following JScript snippet would change the application pool identity.

```
var appPool = GetObject("IIS://localhost/w3svc/AppPools/TestPool" );
// Tell IIS to use configurable identity for worker process
appPool.AppPoolIdentityType = 3;
// Set user name
appPool.WAMUserName = "myuser";
// Set password
appPool.WAMUserPass = "myuserpass";
// Save changes to the IIS metabase
appPool.SetInfo();
```

# Configuring Worker Processes for Idle Timeout

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| This feature of IIS 6.0 is available only when IIS is running in worker process isolation mode. |

When it is necessary to conserve system resources by terminating unused worker processes, you can configure a worker process to gracefully close after a specified period of time. You can use this feature to better manage the resources when the processing load is heavy, when identified applications consistently fall into an idle state, or when new processing space is not available. You can also start additional worker processes to replace a worker process that is finished.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To configure application pool idle timeout**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and then click **Properties**.
2. On the **Performance** tab, under **Idle timeout**, select the **Shutdown worker processes after being idle for** check box.
3. In the **minutes** box, type the number of idle minutes (with no processing requests) that you want to elapse before shutting down the idle worker process. The default value is 20 minutes.
4. Click **OK**.

Optionally, you can configure idle timeout by setting the **IdleTimeout** metabase property.

**To configure application pool idle timeout by using Adsutil.vbs**

1. In the **Run** dialog box, type **cmd**, and then click **OK**.
2. At the command prompt, type:

   ```
   cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set
   W3SVC/AppPools/ApplicationPoolName/IdleTimeout n
   ```

   Replace *n* with the number of minutes of idle time to allow before shutting down the idle worker process; the default time-out interval is 20 minutes.

For more information about setting application pool idle timeout, see the IdleTimeout Metabase Property.

**Related Information**

- For information about application pool settings affecting starting and stopping of a worker process, see Configuring Startup and Shutdown Time Limits.

# Processor Affinity

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| This feature of IIS 6.0 is available only when IIS is running in worker process isolation mode. |

On multi-CPU servers, application pools can be configured to establish affinity between worker processes and multiple CPUs to more efficiently use CPU caches. Processor affinity is used in conjunction with the processor affinity mask setting to specify CPUs.

You can set processor affinity from the command line by using the **set** command with Adsutil.vbs. To set processor affinity, configure the **SMPAffinitized** and **SMPProcessorAffinityMask** metabase properties. Assigning processor affinity involves these steps:

- Enable processor affinity. Set the **SMPAffinitized** metabase property to **true**, which indicates that a particular worker process assigned to an application pool can also be assigned to a specified CPU.

- Assign processor affinity. Set the **SMPProcessorAffinityMask** metabase property, which configures a hexadecimal processor mask that indicates which CPU the worker processes in an application pool are bound to.

**Procedures**

**To enable processor affinity for an application pool**

1. In the **Run** dialog box, type **cmd**, and then click **OK**.

2. At the command prompt, type:

   **cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AppPools/** *ApplicationPoolName* **/SMPAffinitized TRUE**

**To assign processor affinity by binding an application pool to a specified processor**

- At a command prompt, type:

  **cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AppPools/** *ApplicationPoolName* **/SMPProcessorAffinityMask** *MaskValue*

  Replace *MaskValue* with the hexadecimal value that binds the application pool to the appropriate processor or processors. See Table 3.8 for sample hexadecimal mask values.

For example, if you want to bind the worker processes that serve your FinanceAppPool to processors 0, 1, 2, and 3 of an eight-processor computer, type the following command:

**cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AppPools/FinanceAppPool/SMPProcessorAffinityMask 0xF**

**Related Information**

- For more information about processor affinity, see Assigning Processor Affinity.

- For information about processor affinity mask settings, see SMPProcessorAffinityMask Metabase Property and SMPAffinitized Metabase Property.

# Configuring Web Gardens with IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| This feature of IIS 6.0 is available only when IIS is running in worker process isolation mode. |

In IIS 6.0 worker process isolation mode, application pools enhance Web site or application reliability by isolating applications and the worker processes that service those applications. For even greater reliability, you can configure an application pool to be supported by multiple worker processes. An application pool that uses more than one worker process is called a Web garden. The worker processes in a Web garden share the requests that arrive for that particular application pool. If a worker process fails, another worker process can continue to process requests.

| **Note** |
| --- |
| Web gardens are different from Web farms. A Web garden is configured on a single server by specifying multiple worker processes for an application pool. Web farms use multiple servers for a Web site. |

Creating a Web garden for an application pool can also enhance performance in the following situations:

- Robust processing of requests: When a worker process in an application pool is tied up (for example, when a script engine stops responding), other worker processes can accept and process requests for the application pool.
- Reduced contention for resources: When a Web garden reaches a steady state, each new TCP/IP connection is assigned, according to a round-robin scheme, to a worker process in the Web garden. This helps smooth out workloads and reduce contention for resources that are bound to a worker process.

**Procedures**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

### To configure a Web garden by using IIS Manager

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and then click **Properties**.
2. Click the **Performance** tab, and under **Web garden**, in the **Maximum number of worker processes** box, type the number of worker processes that you want to assign to the application pool. (You must type a number greater than 1 for the application pool to become a Web garden.
3. Click **OK**.

Optionally, you can configure a Web garden by setting the metabase property **MaxProcesses**. The **MaxProcesses** property determines the maximum number of worker processes that an application pool allows to service its requests. A value of zero indicates an unmanaged application pool that is not served by a worker process.

The default value for the **MaxProcesses** property is 1, which is the default number of worker processes that service an application pool. To configure an application pool so that it is a Web garden, set the **MaxProcesses** property to a value greater than 1.

| **Important** |
| --- |

You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any known parameters).

**To configure a Web garden by using Adsutil.vbs**

1. In the **Run** dialog box, type **cmd**, and then click **OK**.
2. At the command prompt, type:

   **cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AppPools/** *ApplicationPoolName* **/MaxProcesses** *n*

   Replace *n* with the number of worker processes that you want to service the application pool.

For more information about configuring Web gardens, see MaxProcesses Metabase Property.

**Related Information**

- For information about resource allocation, see Processor Affinity.

# Application Pool Health

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| This feature of IIS 6.0 is available only when running in worker process isolation mode. |

In worker process isolation mode, application pools can be configured to monitor the health of their worker processes as well as the health of the entire pool. Monitoring the health of a worker process includes detecting that the worker process is not able to serve requests and taking appropriate action. For example, if a worker process fails to respond to a ping request by the World Wide Web Publishing Service (WWW service,) the worker process probably does not have threads available for processing incoming requests. When this happens, the WWW service will either terminate the worker process, or release the worker process and leave it running, and start a new worker process to replace it. An administrator can pre-configure an action to take when an unhealthy worker process is released, such as attaching the worker process to a debugger.

In addition to monitoring the health of worker processes, the WWW service can also detect ongoing problems with the entire application pool. For example, if worker processes are terminating abnormally every few seconds, the WWW service can determine that the worker process is unhealthy and stop it, preventing the unhealthy applications from affecting applications in other pools.

The following conditions cause an application pool to start or stop:

- Initiation of rapid-fail protection causes an application pool to stop.
- A job object hitting it's time limit causes an application pool to stop, followed by a start when the time window expires.
- A configuration error caused by trying to use a nonexistent identity causes an application pool to stop.
- A Windows administrator performs a demand stop or start on an application pool.

**Monitoring Application Pool Health**

Worker process pinging enables the WWW service to detect that a worker process is unable to respond to requests (In other words, the worker process is unhealthy). The ping is a message sent between the WWW service and the worker process. If the ping succeeds, then the WWW service assumes the application pool is healthy. If the ping fails (no response from the worker is received), then the WWW service assumes that a problem exists with the worker process. If a problem exists, the WWW service will either terminate the worker process or release it, and then will start a new worker process when it is needed to serve new requests. If the worker process is released but still running, then the WWW service will run the action configured by the administrator.

The setting of the WWW service pinging feature and the frequency of the ping are controlled by the PingingEnabled Metabase Property and the PingInterval Metabase Property.

**ISAPI Extensions Can Declare Themselves Unhealthy**

An ISAPI extension application can be built to programmatically signal IIS that it needs to be recycled. This can be accomplished through the new Server Support function: HSE_REQ_REPORT_UNHEALTHY. See ServerSupportFunction Extension Function at MSDN Online.

To use this function effectively, the IIS server that is running your application must have worker process pinging enabled (see Configuring Worker Process Pinging), because it is during the ping operation that the WWW service detects that the ISAPI is unhealthy and the worker process should be recycled. The ISAPI will need an internal mechanism for determining its unhealthy state, such as monitoring the status of its internal thread pool. You should consider that this type of programming shuts down the worker process the ISAPI extension is running in. Therefore, all applications running in that worker process will be restarted.

The ASP ISAPI extension implements logic that takes advantage of this feature as it monitors the status of its internal thread pool. If too many of its threads enter a blocking state, it will signal a recycle.

**Limitations of Health Detection**

Health detection cannot be used to determine application failures that do not cause the worker process to crash nor block the

available threads in the worker process. As an example, an application that is returning invalid response codes such as HTTP 500 errors, but otherwise functioning normally, will still respond to a ping from the WWW service, unless the application was a custom ISAPI extension that implemented specific code to indicate its unhealthy state.

**Enabling Debugging Action**

When a worker process is determined to be unhealthy, instead of terminating it, you might want the WWW service to keep it running for the purpose of debugging it, while bringing up a new worker process to serve requests. By enabling debugging on an application pool, you signal the WWW service not to terminate the worker process, but to release it from serving an application pool, and leave it running.

In addition to running an unhealthy worker process in a released state, you can configure the WWW service to launch an executable application or script (for example, an application that sends e-mail to administrators notifying them that the failure could be configured as an enable-debugging feature). The *process id* of the process deemed unhealthy is the first argument sent to the executable application or script.

| **Note** |
| --- |
| A worker process that has been released and left running may still terminate. The WWW service will have left it running. If the worker process recovers from its unhealthy state, it will detect that it has no relationship to the WWW service, and self-terminate. It would then be possible to find a log entry stating that a worker process was released, but find no evidence of the worker process running. |

If you enable running unhealthy worker processes to be released, consider that you will need to deal with blocked worker processes, as they will not be removed from memory by IIS. There could be large numbers of failed worker processes running on your computer if administrators are not properly handling worker processes that are kept alive for debugging purposes. Also, consider that these worker processes may be tying up resources needed by other processes. You may need to terminate them quickly in order to free up those resources.

**Rapid-Fail Protection**

Rapid-fail protection stops application pools when too many worker processes assigned to it are found to be unhealthy in a specified period of time.

When an application pool is stopped, HTTP.sys will either return an out-of-service message (503: Service Unavailable) or connection resets based on the configuration of the **LoadBalancerCapabilities** property of the application pool. Also, when an application pool is stopped automatically, you can configure an action (a debugging action, for example) to notify the administrator that the application pool has stopped.

| **Note** |
| --- |
| If you host multiple applications on a single computer, you should be careful to configure load balancers or switching hardware to reroute only the traffic intended for a failed application pool. Do not route requests away from healthy application pools; they are still able to receive and process requests. |

Rapid-fail protection reduces processing overhead for problematic applications as the requests do not enter user-mode processing. Thus, other application pools are protected from the unhealthy application pool.

You can set rapid-fail protection two ways:

1. Configure IIS to place the application in a rapid-fail state based on the number of the worker process failures in a given time period, measured in minutes.

2. Place an application in a rapid-fail state manually.

**Scenario for Monitoring Application Pool Health**

Monitoring application pool health and taking corrective actions requires, at a minimum, that you take the following steps:

1. Allow the WWW service to detect unhealthy applications by enabling the WWW service to ping worker processes. See Configuring Worker Process Pinging.

2. Configure rapid-fail protection to allow the disabling of application pools when the worker processes assigned to them crash a set number of times in a specified period. See Configuring Rapid-Fail Protection in IIS 6.0.

**Related Information**

- For more information about configuring IIS for application pool health monitoring, see Configuring Worker Process Pinging.

- For information about setting rapid-fail protection, see Configuring Rapid-Fail Protection in IIS 6.0.

# Configuring Health Monitoring

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| This feature of IIS 6.0 is available only when IIS is running in worker process isolation mode. |

The World Wide Web Publishing Service (WWW service) monitors the health of worker processes by periodically pinging them to determine their responsiveness. If a worker process fails to respond to a ping, the WWW service terminates the worker process and creates another worker process as a replacement. Additionally, the WWW service maintains a communication channel to each worker process, and it can detect a drop in the communication channel, which indicates a worker process failure. When a worker process fails on its own accord, the WWW service starts another worker process in its place.

**Procedures**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To enable application pool health monitoring by using IIS Manager**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and then click **Properties**.
2. Click the **Health** tab, and select the **Enable pinging** check box.
3. In the box next to **Ping worker process every (frequency in seconds):**, type the number of seconds that you want to elapse between pings.
4. Click **OK**.

You can also configure the WWW service pinging feature and the frequency of the ping by setting the metabase properties **PingingEnabled** and **PingInterval**. Use the following procedures to configure these metabase properties from the command line.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any known parameters). |

**To enable application pool health monitoring by using Adsutil.vbs**

1. In the **Run** dialog box, type **cmd**, and then click **OK**.
2. At the command prompt, type:
   - **cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AppPools/** *ApplicationPoolName* **/PingingEnabled TRUE**

**To change the ping interval by using Adsutil.vbs**

- At the command prompt, type:
  - **cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AppPools/** *ApplicationPoolName*

**/PingInterval** *n*

In the preceding syntax, replace *n* with the number of seconds that you want to elapse between pings.

For more information about setting these metabase properties see PingingEnabled Metabase Property, PingInterval Metabase Property, and Using the Adsutil.vbs Administration Script.

# Configuring Rapid-Fail Protection in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| This feature of IIS 6.0 is available only when IIS is running in worker process isolation mode. |

When an application pool detects that too many worker processes assigned to it have become unhealthy in a given period of time, rapid-fail protection is initiated. The communication channel with the World Wide Web Publishing Service (WWW service) is dropped. The WWW service detects the loss of communication and initiates the appropriate actions, typically sending an error or warning to the event log and then restarting the worker process. Worker process isolation mode can be configured so that if a particular application pool experiences consecutive multiple failures, the application pool can be automatically disabled, allowing for rapid-fail protection to start. The application pool is taken out of service and placed in a state such that the kernel-mode driver immediately returns an out-of-service message (503: Service Unavailable) to any requests to that application pool.

**Procedures**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To configure rapid-fail protection by using IIS Manager**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and then click **Properties**.
2. Click the **Health** tab, and select the **Enable rapid-fail protection** check box.
3. In the **Failures** box, type the number of worker process failures to be detected before disabling the worker process.
4. In the **Time period** box, type the number of minutes during which failure totals are accumulated.
5. Click **OK**.

**Configuring Rapid-Fail Protection from the Command Line**

Use the following procedures to configure rapid-fail protection from the command line, and to change the default settings for rapid-fail protection in the **RapidFailProtectionInterval** metabase property and the **RapidFailProtectionMaxCrashes** metabase property.

**To configure rapid-fail protection for an application pool by using Adsutil.vbs**

1. In the **Run** dialog box, type **cmd**, and then click **OK**.
2. At the command prompt, type:

   **cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AppPools/** *ApplicationPoolName* **/RapidFailProtection TRUE**

By default, rapid-fail protection is activated if five process failures occur within a five-minute interval. You can reset the accumulation interval by updating the **RapidFailProtectionInterval** metabase property, or you can reset the maximum number of crashes to allow during the interval by updating the **RapidFailProtectionMaxCrashes** metabase property.

**To specify the maximum number of minutes during which worker process failures are accumulated**

- At the command prompt, type:

  **cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AppPools/** *ApplicationPoolName* **/RapidFailProtectionInterval** *n*

In the preceding syntax, replace *n* with the number of minutes that you want to set for the accumulation interval.

The **RapidFailProtectionMaxCrashes** property specifies the maximum number of worker process failures that are allowed within the minutes specified by the **RapidFailProtectionInterval** property. The default value for the **RapidFailProtectionMaxCrashes** property is 5.

**To specify the maximum number of worker process failures before rapid-fail protection occurs**

- At the command prompt, type:

  **cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AppPools/** *ApplicationPoolName* **/RapidFailProtectionMaxCrashes** *n*

  In the preceding syntax, replace *n* with the maximum number of worker process failures you want to allow before rapid-fail protection occurs.

If you set the **RapidFailProtection** metabase property to **true** but do not set either the **RapidFailProtectionInterval** property or the **RapidFailProtectionMaxCrashes**property, IIS applies the default settings for these properties.

For more information about the rapid-fail metabase properties, see RapidFailProtection Metabase Property, RapidFailProtectionInterval Metabase Property, and RapidFailProtectionMaxCrashes Metabase Property.

**Related Information**

- For information about Web gardens, see Configuring Web Gardens with IIS 6.0.

# Configuring Startup and Shutdown Time Limits

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When the World Wide Web Publishing Service (WWW service) detects that a worker process is unhealthy, it marks the worker process for termination, and then, within configured time limits, it terminates the worker process and starts a new worker process to replace it. Worker processes shut down gracefully (finish request processing) when the shutdown time period is long enough to allow for this. It is important to tune the shutdown time period to fit the load characteristics of the applications that are being processed.

**Procedures**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To configure a new worker process to start up within a specified time by using IIS Manager**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and click **Properties**.
2. Click the **Health** tab, and under **Startup time limit**, in the box next to **Worker process must startup within (time in seconds)**, type the desired number of seconds.
3. Click **OK**.

**To configure a worker process to shut down within a specified time by using IIS Manager**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and click **Properties**.
2. Click the **Health** tab, and under **Shutdown time limit**, in the box next to **Worker process must shutdown within (time in seconds)**, type the desired number of seconds.
3. Click **OK**.

Optionally, you can configure shutdown and startup time limits by setting the **StartupTimeLimit** or **ShutdownTimeLimit** metabase properties.

**To set a worker process to shut down or start up within a specified time by using Adsutil.vbs**

1. In the **Run** dialog box, type **cmd**, and then click **OK**.
   - To set a shutdown time limit, at the command prompt, type:

     **cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AppPools/***ApplicationPoolName***/ShutdownTimeLimit** *n*

   - To set a startup time limit, at the command prompt, type:

     **cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AppPools/***ApplicationPoolName***/StartupTimeLimit** *n*

     Replace *n* with the number of seconds that you want to elapse before shutting down or starting the worker process.

For more information about setting startup and shutdown times for the worker processes, see StartupTimeLimit Metabase Property and ShutdownTimeLimit Metabase Property.

# Identifying the Worker Process Process ID

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The nature of some problems, especially those in which an application is hanging, leaking memory, or generally misbehaving, make it necessary to know which application pool goes with which worker process (or processes, if Web gardens are enabled). With the advent of the new worker process isolation mode in IIS 6.0, a Web server potentially can have thousands of individual instances of W3wp.exe running at any given time. Looking for the process ID in Task Manager is pointless in such a case because it is impossible to differentiate between the different worker processes servicing the application pools.

**Procedures**

In worker process isolation mode, you can find the process ID by using the command-line script Iisapp.vbs, which is stored in *systemroot*\System32, and is designed specifically to obtain a list of running worker processes, their process IDs, and the application pool names.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any known parameters). |

**To find a worker process ID by using Iisapp.vbs**

- Run Iisapp.vbs with no parameters.

For more information about using Iisapp.vbs, see Listing Running Web Applications Using Iisapp.vbs.

In earlier versions of IIS and when IIS 6.0 is running in IIS 5.0 isolation mode, identifying the process ID is relatively easy. If a component installed in a COM+ library application has been activated from a worker process, the procedure for identifying the process ID is the same.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To find the process ID in versions prior to IIS 6.0 and in IIS 5.0 isolation mode**

- From the **Start** menu, point to **Administrative Tools**, and then click **Component Services**.
- In the console tree of the **Component Services** window, double-click **Component Services**, double-click **Computers**, double-click **My Computer**, and then double-click **Running Processes**.
- Under this node, you see the various COM+ applications and their associated process IDs.

# Recycling Worker Processes with IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| This feature of IIS 6.0 is available only when IIS is running in worker process isolation mode. |

In worker process isolation mode, IIS can be configured to periodically restart worker processes, so that you can recycle faulty Web applications. This helps ensure that applications in those pools remain healthy and that system resources are recovered.

You can configure worker processes to restart based on elapsed time, number of requests served, scheduled times, and two types of memory usage.

This section includes the following information:

- How Worker Process Recycling Works in IIS 6.0
- Determining When to Use Worker Process Recycling
- Configuring Worker Processes for Recycling
- Logging Worker Process Recycling Events in IIS 6.0

# How Worker Process Recycling Works in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Depending on how an application pool is configured for recycling, the World Wide Web Publishing Service (WWW service) in IIS 6.0 can recycle the assigned worker process in two ways:

1. By default, the WWW service establishes an *overlapped recycle*, in which the worker process that is to be terminated is kept running until after a new worker process is started.

2. Alternatively, the WWW service can terminate a worker process and then start a new worker process if the workload justifies this action.

| **Note** |
| --- |
| When the WWW service recycles a worker process, it does not disconnect the existing TCP/IP connection. The HTTP protocol stack (HTTP.sys) establishes and maintains TCP/IP connections. |

In an overlapped recycle scenario, the process that is targeted for a recycle continues to process requests while the WWW service simultaneously creates a replacement worker process. The new worker process is started before the old worker process stops, and requests are then directed to the new process. This design prevents service interruptions, because the old process remains in communication with HTTP.sys to handle requests until it shuts down. Because the shutdown timeout value of an overlapped shutdown or startup is configurable, the worker process can be terminated while it is still serving requests, if it does not finish draining requests within the time limit.

When you configure an application pool to recycle worker processes based on elapsed time, all the worker processes are recycled during the elapsed time set, but they are not recycled all at once. Application recycling is spread over the time set to reduce interruptions of service to client requests.

Similarly, when you configure an application pool to recycle applications based on the number of requests processed, recycling takes place at intervals to spread the overhead that is associated with the worker-process recycling.

# Determining When to Use Worker Process Recycling

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Consider the following general guidelines when you decide whether to enable worker process recycling. The optimal solution is to fix the application that is causing the problem. However, recoding is not always an option, especially in cases when other application code is running that cannot be modified.

Consider using worker process recycling under the following circumstances:

- Your Web server is hosting problematic applications that you cannot fix.
- An application is failing unexpectedly or experiencing undetermined or intermittent problems.
- An application is leaking memory as a result of performance monitoring.
- You have previously implemented a temporary reset solution, such as scheduled execution of the **IISReset** command-line utility.

You might not need to use worker process recycling under the following circumstances:

- Your Web server is hosting a Web site that contains only static content and no custom ISAPI applications.
- Your Web server is hosting an application that has already been thoroughly tested and does not suffer from memory or resource allocation problems.

To effectively use worker process recycling, review the criteria on which recycling can be based, as listed in the following table.

| **Recycle Method** | **Description** | **When to Use** |
|---|---|---|
| ISAPI request | Recycles the worker process based on a request from an ISAPI in the application pool. | Use this method when ISAPI extensions can declare themselves unhealthy. |
| Elapsed time | Recycles the worker process based on a time frame that is specified by the user in minutes. | Use this method when applications have problems running for extended time periods. |
| Number of requests | Recycles the worker process when the number of Hypertext Transfer Protocol (HTTP) requests exceeds a certain threshold. | Use this method when applications are failing based on the number of requests they receive. |
| Scheduled times | Recycling can occur at specified times within a 24-hour period. | Use this method when conditions are similar to the conditions for elapsed time. |
| Virtual memory (reserved plus used) | Recycles the worker process when the worker process virtual memory reaches a certain threshold. | Use this method when the memory heap becomes highly fragmented, which is caused by applications reserving memory multiple times. The symptom is a steady increase in virtual memory. |
| Used memory | Recycles the worker process when the memory that is used by the W3wp.exe process reaches a certain threshold. | Use this method when some applications have memory leaks. |

| | | |
|---|---|---|
| Demand | Recycling happens when an IIS administrator can control the recycling of an entire application pool by using Microsoft® Management Console (MMC) or a script. | Use this method when there is an application pool that is causing problems while the other sites are up and running. Consider recycling the application, as opposed to resetting the entire WWW service. |

# Configuring Worker Processes for Recycling

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure worker processes to restart based on one of several options, including elapsed time, number of requests served, scheduled times, and memory usage; or you can configure worker processes to start on demand. In IIS 6.0, worker process recycling is available only when IIS is running in worker process isolation mode.

For more information about recycling worker processes, see Running IIS 6.0 as an Application Server.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To recycle a worker process immediately on demand**

- In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool for which you want to recycle the worker process, and then click **Recycle**.

**To configure a worker process to be recycled after a set elapsed time**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and then click **Properties**.
2. On the **Recycling** tab, select the **Recycle worker processes (in minutes)** check box.
3. In the box to the right of **Recycle worker processes (in minutes)**, type the number of minutes that you want to elapse before the worker process is recycled, and then click **OK**.

**To configure a worker process to be recycled after a set number of processing requests**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and then click **Properties**.
2. On the **Recycling** tab, select the **Recycle worker process (number of requests)** check box.
3. In the box to the right of **Recycle worker process (number of requests)**, type the number of requests to be processed before the worker process is recycled, and then click **OK**.

**To configure a worker process to be recycled at scheduled times**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and then click **Properties**.
2. On the **Recycling** tab, select the **Recycle worker processes at the following times** check box.
3. To schedule or adjust the time at which the worker process will be recycled, do one of the following:
   - Click **Add** to add a time to the list, and then click **OK**.
   - Click **Remove** to delete a scheduled time, and then click **OK**.
   - Click **Edit** to change an existing time, and then click **OK**.

**Note**

When recycling is set to occur at scheduled times, it might occur off-schedule if the system time is altered. To avoid unintended changes in the time that recycling occurs, recycle the scheduled worker processes soon after the system time is changed.

**To configure a worker process to be recycled after consuming a set amount of memory**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and then click **Properties**.
2. On the **Recycling** tab, under **Memory recycling**, select the **Maximum virtual memory (in megabytes)** check box.
3. In the box to the right of **Maximum virtual memory (in megabytes)**, type the maximum amount of virtual memory allowed before the worker process is recycled.
4. Select the **Maximum used memory (in megabytes)** check box.
5. In the box to the right of **Maximum used memory (in megabytes)**, type the maximum amount of memory allowed before the worker process is recycled, and then click **OK**.

# Logging Worker Process Recycling Events in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

By default, IIS does not log worker process recycling events. You can, however, enable logging of the worker process recycling events that you specify. Unlike other IIS activity, which is logged in a location and file that you specify, worker process recycling events are written to the system event log.

Logging worker process recycling events can help you with troubleshooting IIS. For example, when troubleshooting an ISAPI extension that implements the new server support function REPORT_UNHEALTHY, you can specify that IIS logs an event for each instance that the ISAPI reports itself unhealthy.

The following table describes the worker process recycling events for which you can enable logging. To enable logging for an event, set the corresponding metabase property to **true**.

| Metabase Property | Description |
|---|---|
| **AppPoolRecycleTime** | Logs event on time-based recycles. |
| **AppPoolRecycleRequests** | Logs event on number of request-based recycles. |
| **AppPoolRecycleSchedule** | Logs event on schedule-based recycless. |
| **AppPoolRecycleMemory** | Logs event on memory-based recycle. |
| **AppPoolRecycleIsapiUnhealthy** | Logs event when worker processes request recycles because an ISAPI reported unhealthy. |
| **AppPoolRecycleOnDemand** | Logs event when an administrator requests a recycle of all processes in the application pool. |
| **AppPoolRecycleConfigChange** | Logs an event if an application pool is recycled because one of the application pool properties that requires a recycle to take effect has changed. |
| **AppPoolRecyclePrivateMemory** | Logs an event if an application pool is recycled based on private memory. |

**Important**

You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer***\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters).

**Procedures**

**To enable logging of worker process recycling**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd**, and then click **OK**.
3. At the command prompt, type the following and then press **ENTER**: **cd %systemroot%\inetpub\adminscripts**
4. At the command prompt, type the following and then press **ENTER**: **cscript adsutil.vbs set w3svc/AppPools/***AppPoolName/EventName* **true**

   Replace *AppPoolName* with the name of the application pool and *EventName* with the name of the event for which you want to enable logging. For example, the following command enables logging of memory-based recycling events for the default AppPool: cscript adsutil.vbs set w3svc/AppPools/DefaultAppPool/AppPoolRecycleMemory true

| Note |
| --- |
| To disable logging of worker process recycling events, end the command-line with **false**. |

The following table shows an example system event log entry along with the event ID for each type of recycling event.

| Recycling Event | Log Entry Generated | Event ID |
| --- | --- | --- |
| **AppPoolRecycleTime** | A worker process with process ID *IDNumber* serving application pool *AppPoolName* has requested a recycle because the worker process reached its allowable processing limit. | 1074 |
| **AppPoolRecycleRequests** | A worker process with process ID *IDNumber* serving application pool *AppPoolName* has requested a recycle because it reached its request limit. | 1075 |
| **AppPoolRecycleSchedule** | A worker process with process ID *IDNumber* serving application pool *AppPoolName* has requested a recycle because it reached its scheduled recycle time. | 1076 |
| **AppPoolRecycleMemory** | A worker process with process ID *IDNumber* serving application pool *AppPoolName* has requested a recycle because it reached its virtual memory limit. | 1077 |
| **AppPoolRecycleIsapiUnhealthy** | A worker process with process ID *IDNumber* serving application pool *AppPoolName* has requested a recycle because an ISAPI it loaded reported unhealthy and requested a recycle. | 1078 |
| **AppPoolRecycleOnDemand** | An administrator has requested a recycle of all worker processes in application pool *AppPoolName*. | 1079 |
| **AppPoolRecycleConfigChange** | The worker processes serving application pool *AppPoolName* are being recycled due to one or more configuration changes in the application pool properties which necessitate a restart of the processes. | 1080 |
| **AppPoolRecyclePrivateMemory** | A worker process with process ID *IDNumber* serving application pool *AppPoolName* has requested a recycle because it reached its private bytes memory limit. | 1177 |

**Related Information**

- For information about setting the LogEventOnRecycle metabase property, see LogEventOnRecycle Metabase Property.
- For information about viewing the system event log, see "Event Viewer" in Help and Support Center for Windows Server 2003.

# IIS 5.0 Isolation Mode in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This section explains how to use IIS Manager to configure Internet Information Services (IIS) to execute Web-based applications in IIS 5.0 isolation mode.

This section includes the following information:

- Isolating Applications in IIS 6.0: Describes how to run an application in a memory space that is separate from the Web server memory space.
- Stopping Isolated Applications: Describes how to stop execution of an isolated application.

**Related Information**

- For information about creating or configuring applications, see Configuring Applications in IIS 6.0.
- For an overview of IIS 5.0 isolation mode, see About Configuring Servers for Applications.

# Isolating Applications in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| This feature of IIS 6.0 is available only when IIS is running in IIS 5.0 isolation mode. |

*Isolating* applications means configuring them to run in a process (memory space) that is separate from the Web server and other applications. You can configure applications to have one of three levels of application protection:

- Low (in-process) application protection.
- Medium (pooled) application protection.
- High (isolated) application protection.

Note that server-side include (SSI) and Internet Database Connector (IDC) applications cannot be run in a memory space that is separate from the Web server.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set or change the level of application protection**

1. In IIS Manager, expand the local computer, right-click the Web site or the starting-point directory for an application, and then click **Properties**.
2. Click the **Home Directory**, **Virtual Directory**, or **Directory** tab. If you are in the directory that is listed as the **Starting Point** directory, the **Application name** box is filled in.
3. In the **Application protection** box, click the appropriate level of protection.
4. Click **OK**.

The Web server finishes processing any current requests for the application before it creates a separate process. At the next request for the application, the application will run in the appropriate memory space.

You can also configure isolation by updating the **AppIsolated** metabase property setting for each application. For information about how to do this, see the AppIsolated Metabase Property, and Code Examples to Configure Metabase Properties.

| **Note** |
| --- |
| If you need to stop an application that has isolation set to Medium (pooled) or High, see Stopping Isolated Applications. |

# Stopping Isolated Applications

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| This feature of IIS 6.0 is available only when IIS is running in IIS 5.0 isolation mode. |

You can stop and unload isolated applications from memory without stopping the Web server, which makes it easier to test and debug applications.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /***User:Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To stop and unload an isolated application**

1. In IIS Manager, expand the local computer, right-click the Web site or the starting-point directory (the directory on which the application is set) for an application, and then click **Properties**.
2. Click the **Home Directory**, **Virtual Directory**, or **Directory** tab. If you are in the directory that is listed as the **Starting Point** directory, the **Application name** box is filled in.
3. Click **Remove**. If the **Remove** button is unavailable, you are not in the application's starting-point directory.

# Configuring IIS For Dynamic Content

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

When you install IIS 6.0, it is locked down—only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. By default, features, such as ASP, ASP.NET, Server-Side Includes Events, WebDAV publishing, and FrontPage® Server Extensions do not work unless they are enabled. If you do not enable this functionality after installing IIS, IIS returns a 404 error.

| **Note** |
| --- |
| If you install the Microsoft Visual Studio .NET 2003 development system with IIS 6.0 to host Web applications or XML Web services, you must enable ASP and FrontPage Server Extensions. |

You can configure these request handlers, which are called Web service extensions, by manipulating the Web Service Extensions node in IIS Manager.

This section includes the following information:

- Enabling and Disabling Dynamic Content in IIS 6.0: Explains how to enable or disable an individual Web service extension that is registered in the Web Service Extensions node in IIS Manager. Also discusses how to disable all Web Service extensions at once.
- Adding a Web Service Extension: Describes how to register a Web service extension so that it appears in the Web Service Extensions node in IIS Manager.
- Renaming a Web Service Extension: Explains how to rename a Web service extension that you have added to the list of Web service extensions in IIS.
- Configuring an Application to Call a Web Service Extension: Describes how to specify which Web service extensions an application can call.

# Enabling and Disabling Dynamic Content in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

You can enable or disable Web service extensions individually if they are registered in the Web Service Extensions node in IIS Manager. When enabled features are no longer required, you can disable them through the Web Service Extensions node in IIS Manager.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**
**To enable or disable dynamic content**

1. In IIS Manager, expand the local computer, and then click **Web Service Extensions**.
2. In the details pane, click the Web service extension that you want to enable or disable.
3. Do one of the following:
   - To enable a disabled Web service extension, click **Allow**.
   - To disable an enabled Web service extension, click **Prohibit**.
   - To view the properties of a Web service extension, click **Properties**.
4. Click **OK**.

| **Important** |
| --- |
| If you choose to allow all unknown ISAPI extensions or CGI extensions to run on your Web server, your Web server could be susceptible to computer viruses or worms that exploit these technologies. Instead, select only those specific ISAPI extensions or CGI extensions that you need to run on your Web server. |

You can disable all Web service extensions that are registered on the local computer with one setting in the Web Service Extensions node of IIS Manager.

**To disable all Web service extensions**

1. In IIS Manager, expand the local computer, and then click **Web Service Extensions**.
2. Click **Prohibit all extensions**. A warning message appears.
3. To disable all extensions, click **Yes**. To cancel the action, click **No**. To see more information, click **Help**.
4. If you click **Yes**, the status of each Web service extension is disabled.

# Adding a Web Service Extension

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

Before you can use, or to deny the use of, an HTTP request handler that is not in the list of Web service extensions, you must first register it by adding the HTTP request handler to the list of Web service extensions.

**Procedures**
**To add a new Web service extension**

1. In IIS Manager, expand the computer name, and then click **Web Service Extensions**.
2. In the **details** pane, click **Add a new Web service extension**.
3. In the **Extension name** box, type the name of the new Web service extension.
4. Click **Add**.
5. In the **Path to file** box, type the path or click **Browse** to navigate to any files that the new Web service extension requires, and click **OK**.
6. Optionally, select the **Set extension status to Allowed** check box to automatically set the status of the new Web service extension to **Allowed**.
7. Click **OK**.

# Renaming a Web Service Extension

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

You can rename a Web service extension you have added to IIS. Web service extensions included with IIS, however, cannot be renamed.

You can rename a Web service extension either in IIS Manager, or by directly editing the MetaBase.xml file. Using IIS Manager, the Web service extension you want to rename must first be removed, and then added using the new name. Renaming a Web service extension by editing the MetaBase.xml file is a more direct approach. Both methods are explained here.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To rename a Web service extension using IIS Manager**

1. In IIS Manager, expand the local computer, and then click **Web Service Extensions**.
2. In the details pane, right-click the Web service extension that you want to rename, and then click **Delete**.
3. At the confirmation prompt, click **Yes**.
4. Add the Web service extension, using the new name for the extension.

**To rename a Web service extension by editing the MetaBase.xml file**

1. Make sure that the metabase edit-while-running feature enabled.
2. Open the \Windows\System32\Inetsrv\MetaBase.xml file in a text editor.
3. Search for the name of the Web service extension that you want to rename, and then edit the name.
4. Save and close the MetaBase.xml file.
5. To verify that the Web service extension was renamed, in IIS Manager, right-click the **Web Service Extensions** folder, and click **Refresh**.

   The Web service extension is displayed with the new name in the details pane.

**Related Information**

- For more information about adding a Web service extension, see Adding a Web Service Extension.

# Configuring an Application to Call a Web Service Extension

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008

Before an application can call a Web service extension, you must configure the application to make calls to that extension. A Web service extension can accept calls from more than one application.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**
**To allow an application to call a Web service extension**

1. In IIS Manager, expand the local computer, and then click **Web Service Extensions**.
2. Click **Add and allow extensions for a specific application**.
3. From the **Application list** box, click the name of the application. The Web service extension that the application is allowed to call appears in the **Extensions to be allowed** box.
4. Click **OK**.

# Using Command-Line Administration Scripts

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can extend administrative control by using scripts to perform server administration tasks. You can use scripts to automate tasks, remotely administer sites and resources, and take advantage of batch files to create and manage objects. For additional information about using command lines, see the "Command-Line Reference" in Help and Support Center for Windows Server 2003.

Internet Information Services (IIS) contains eight supported command-line scripts that use the IIS Windows Management Instrumentation (WMI) provider to configure and manage IIS metabase configurations. Microsoft supports the command-line scripts that are included in IIS, as long as the scripts are not modified. If you need to modify a supported script, you must save it under a new file name, leaving the original script unmodified.

This section includes the following information:

- Managing Web Sites Using Scripts: Describes how to create and manage Web sites by using a command-line script.
- Managing FTP Sites Using Scripts: Describes how to create and manage FTP sites by using a command-line script.
- Managing Web Virtual Directories Using Scripts: Describes how to create and manage Web virtual directories by using a command-line script.

# Using the Adsutil.vbs Administration Script

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Adsutil.vbs is an IIS administration utility that uses Microsoft Visual Basic Scripting Edition (VBScript) with Active Directory Service Interfaces (ADSI) to manipulate the IIS configuration. This script should be run using CScript, which is installed with Windows Script Host.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. From the command prompt, type **runas /profile /***user:mymachine******administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

**Usage**

Cscript.exe adsutil.vbs COMMAND <path> [<param>...]

Cscript.exe adsutil.vbs COMMAND [<path> [<parameters>...]]

| **Command** | **Description** |
| --- | --- |
| GET Path | Display chosen parameter. |
| SET Path Value | Assign a new value. |
| ENUM Path "/P" | Enumerate all parameters for the path. /P Enumerate the paths only (no data). |
| ENUM_ALL "/P" | Enumerate all parameters. /P Enumerate the paths only (no data). |
| DELETE Path | Delete the path or parameter. |
| CREATE Path [KeyType] | Create the path and assign it the **KeyType**. |
| APPCREATEINPROC Path | Create an in process application. |
| APPCREATEOUTPROC Path | Create an out-of-process application. |
| APPDELETE Path | Delete the application (if present). |
| APPUNLOAD Path | Unload an out-of-process application. |
| APPGETSTATUS Path | Get status of the application. |
| FIND Path | Find the paths where a parameter is set. |
| START_SERVER Path | Start the Web site. |
| STOP_SERVER Path | Stop the Web site. |
| PAUSE_SERVER Path | Pause the Web site. |
| CONTINUE_SERVER Path | Unpause the Web site. |
| HELP | Print all available commands. |

**Notes**

- <Path> is the path of the node for which you are setting the property, combined with the name of the property that you are setting. For example, if you want to set the **ServerComment** for Web server number 1, the command would be as

follows:

```
adsutil SET w3svc/1/ServerComment "Web Server Number 1"
```

The next time IIS Manager is opened, it will reflect the name of the Web server as "Web Server Number 1."

- The switch "-s:*server name*" can be used after any command to execute the command on a remote computer. (See first example below.)

**Examples**

- Cscript.exe adsutil.vbs GET W3SVC/1/ServerBindings -s:remotecomputer1
- Cscript.exe adsutil.vbs SET W3SVC/1/ServerBindings ":81:"
- Cscript.exe adsutil.vbs CREATE W3SVC/1/Root/MyVdir "IIsWebVirtualDir"
- Cscript.exe adsutil.vbs START_SERVER W3SVC/1
- Cscript.exe adsutil.vbs ENUM /P W3SVC

# Managing Web Sites Using Scripts

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisweb.vbs, which is stored in *systemroot*\System32, to create and manage Web sites on computers running a member of the Microsoft Windows Server™ 2003 family with Internet Information Services (IIS) 6.0.

Iisweb.vbs performs some of the same operations that are available in IIS Manager. You can use either tool to administer IIS Web sites.

This section contains the following information:

- Creating Web Sites: Describes how to create Web site configurations on local or remote computers by using iisweb.vbs.
- Deleting Web Sites: Describes how to delete Web site configurations on local or remote computers by using iisweb.vbs.
- Starting Web Sites: Describes how to start Web sites on local or remote computers by using iisweb.vbs.
- Stopping Web Sites: Describes how to stop Web sites on local or remote computers by using iisweb.vbs.
- Pausing Web Sites: Describes how to pause Web sites on local or remote computers by using iisweb.vbs.
- Listing Web Sites: Describes how to list Web sites on local or remote computers by using iisweb.vbs.

# Creating Web Sites Using Iisweb.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisweb.vbs, which is stored in *systemroot*\System32, to create Web site configurations on local or remote computers running a member of the Windows Server 2003 family with IIS 6.0. This command does not create or destroy content, but it sets up the directory structure and some IIS configuration files.

When you use iisweb.vbs to create a new Web site, you specify only the basic properties that are needed to create the site and identify its contents. Iisweb.vbs uses the same default properties that IIS Manager uses when establishing new Web sites, and it adheres to the same rules for inheriting properties. To configure the more advanced properties of the Web site, use IIS Manager.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**

**iisweb /create** *Path SiteName* [**/b** *Port*] [**/i** *IPAddress*] [**/d** *HostHeader*] [**/dontstart**] [**/s** *Computer* [**/u** [*Domain*\]*User***/p** *Password*]]

**Parameters**

*Path*

Specifies the location of content files for the Web site. The path must be local, such as C:\Projects\HTML. If the specified path does not exist, then iisweb.vbs creates the path.

The **Path** parameter must immediately precede the **SiteName** parameter in the command. Otherwise, iisweb.vbs does not interpret the site information correctly.

*SiteName*

Required. Specifies a name for the Web site.

**/b** *Port*

Specifies a TCP port number for the Web site. The default port is 80.

**/i** *IPAddress*

Specifies an IP address for the Web site. The default is **All Unassigned**, which assigns to the site all of the IP addresses on the computer that are not assigned to other sites. Only one site on each IIS server can be set to **All Unassigned**.

**/d** *HostHeader*

Specifies the host header name for the Web site, such as www.microsoft.com. By default, the site does not have a host header name and must be identified by its IP address or port number.

Your DNS server must be configured to associate the host header name with the Internet server. Otherwise, the site will not start.

**/dontstart**

Indicates that the Web site should not be started automatically as soon as it is created, which is contrary to the IIS default.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

| **Note** |
| --- |
| Iisweb.vbs does not verify the port number, IP address, or host header of a Web site, and it does not verify that these bindings are unique within the server. If you create a site with invalid or conflicting bindings, the site will not start. |

**Examples**
**Example 1:**
The following example creates a single Web site configuration on a local computer. The source files for the "My Vacations" Web site are located in the C:\Rome directory. The command uses the **/d** parameter to specify a host header for the Web site. It also uses the **dontstart** parameter so that the Web site is not started automatically, providing time to add the host header name to DNS before starting the site.

**iisweb /create C:\Rome "My Vacations" /d www.reskit.com /dontstart**

In response, **iisweb** displays the following message, along with the basic properties of the new Web site. In this example, "Server" represents the machine name where drive C: is found, "Site Name" is the name you assigned to your Web site, "Metabase Path" represents the metabase key assigned by IIS and is analogous to a registry key in the system registry, "IP" is unassigned by default, "Host" is the header name you assigned, "Port" is set to 80 by default, "Root" is the directory where the Web files reside, and "Status" is set to "STOPPED" as directed.

```
Connecting to server ...Done.

Server = IIS-TEST

Site Name = My Vacations

Metabase Path = W3SVC/1211348328

IP = ALL UNASSIGNED

Host = www.reskit.com

Port = 80

Root = C:\Rome

Status = STOPPED
```

**Example 2:**
The following example creates the Marketing Web site configuration on a remote server (SVR01). It associates the site with files stored in the D:\New Initiatives\Marketing\HTMFiles directory on SVR01. The command uses the **/i** parameter to specify an IP address for the site. It uses the **/s** parameter to specify the remote computer, and the **/u** and **/p** parameters to run the script with the permissions of the user's Administrator account.

**iisweb /create C:\New Initiatives\Marketing\HTMFiles "Marketing" /i 172.30.163.244 /s SVR01 /u Admin6 /p A76QVJ32#**

In response, **iisweb** displays the basic properties of the new Web site. In this example, "Server" represents the server machine name, "Site Name" is the name you assigned to your Web site, "Metabase Path" represents the metabase key assigned by IIS and is analogous to a registry key in the system registry, "IP" represents the assigned DNS address, "Host" is unspecified, "Port" is set to 80 by default, "Root" is the directory where the Web files reside, and "Status" is set to "STARTED" by default.

```
Server = SVR01

Site Name = Marketing

Metabase Path = W3SVC/1907510956

IP = 172.30.163.244

Host = NOT SPECIFIED

Port = 80

Root = C:\New Initiatives\Marketing\HTMFiles

Status = STARTED
```

# Deleting Web Sites Using Iisweb.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisweb.vbs, which is stored in *systemroot*\System32, to delete IIS Web site configurations on local or remote computers running a member of the Windows Server 2003 family with IIS 6.0.

This command is useful if you plan to move the site to a new URL or server, or remove it entirely. The content within the site is unaffected by this command, but the site will be inaccessible to users.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:MyComputer\Administrator cmd** to open a command window with administrator rights and then type cscript.exe ScriptName (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**

**iisweb /delete** *WebSite* [*WebSite*...][**/s** *Computer* [**/u**[*Domain*\]*User***/p** *Password*]]

**Parameters**

*WebSite*

Required. Specifies the site name or metabase path of the Web site. Web sites must be uniquely identified. If more than one Web site has the same descriptive name, you must use the metabase path to identify the Web site.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** [*Domain*\]*User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Examples**

**Example 1:**

The following example deletes a single Web site configuration on a local computer. The **/s** parameter is omitted because the local computer is the default setting. The **/u** and **/p** parameters are omitted because the current user of the local computer must be logged on as an administrator to run the command.

**iisweb /delete "My First Novel"**

In response, **iisweb** displays the following message indicating that the site configuration has been deleted, and identifying the Web site by its metabase path:

```
Connecting to server ...Done.
```

```
Server W3SVC/409413479 has been DELETED.
```

**Example 2:**
The following example deletes multiple Web site configurations from a remote computer. The "Finance", "Work Group", and "Logo" Web sites reside on SRV01. The command identifies the first two sites by name and the "Logo" Web site by its metabase path, "W3SVC/79116006". In addition, the command uses the **/s** parameter to specify the remote computer and the **/u** and **/p** parameters to run the commands with the permissions of the user's administrator account.

**iisweb /delete Finance "Work Group" W3SVC/79116006 /s SRV01 /u Alice /p p@##word**

In response, **iisweb** displays the following message indicating that the site configurations have been deleted, and identifying each Web site by its metabase path:

```
Connecting to server ...Done.

Server W3SVC/1977437537 has been DELETED.

Server W3SVC/1509060625 has been DELETED.

Server W3SVC/79116006 has been DELETED.
```

# Starting Web Sites Using Iisweb.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS starts Web sites automatically when they are created, unless the administrator specifically prohibits it with the **/dontstart** parameter. An administrator might prohibit an automatic start, for example, to allow time for the site to be added to DNS.

An administrator might also pause or stop a Web site for troubleshooting purposes. In cases like these, you can use the command-line script iisweb.vbs, which is stored in *systemroot*\System32, to start or restart a Web site.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**
**iisweb/start** *WebSite [WebSite...] [* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

Parameters

*WebSite*

Required. Specifies the site name or metabase path of the Web site. Web sites must be uniquely identified. If more than one Web site has the same descriptive name, you must use the metabase path to identify the Web site.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Examples**
**Example 1:**
The following example starts the "Products" Web site on the local computer. The command identifies the site by its name. In this example, the **/s** parameter is omitted because the server is local. The **/u** and **/p** parameters are omitted because the current user of the local computer must be logged on as an administrator in order to run the command.

**iisweb /start Products**

In response, **iisweb** displays the following message confirming that the site has been started, and identifying it by its metabase path:

```
Connecting to server ...Done.
```

```
Server W3SVC/1977437537 has been STARTED.
```

**Example 2:**
The following example starts the "Products" and "Marketing" Web sites on the SVR01 remote computer. The command identifies the "Products" site by its metabase path, "W3SVC/1509060225", and the "Marketing" site by name. In addition, the command uses the **/s** parameter to specify the remote computer, and the **/u** and **/p** parameters to run the commands with the permissions of the user's administrator account.

**iisweb /start w3svc/1509060225 Marketing /s SVR01 /u Alice /p p@##word**

In response, **iisweb** displays the following message confirming that the sites have been started, and identifying each by its metabase path:

```
Connecting to server ...Done.

Server W3SVC/1509060225 has been STARTED.

Server W3SVC/1977437537 has been STARTED.
```

# Stopping Web Sites Using Iisweb.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If your Web site is not behaving as expected, or if the site is slow or unresponsive, stopping and restarting the site might clear a temporary problem with the software—for example, a faulty worker process.

In cases like these, you can use the command-line script iisweb.vbs, which is stored in *systemroot*\System32, to stop a Web site from responding. The content of the site is unchanged, but it will be inaccessible to users until the site is restarted.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**
**iisftp/stop** *WebSite [WebSite...] [* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**Parameters**
*WebSite*

Required. Specifies the site name or metabase path of the Web site. Web sites must be uniquely identified. If more than one Web site has the same descriptive name, you must use the metabase path to identify the Web site.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Examples**
**Example 1:**
The following example stops the "Products" Web site on the local computer. The command identifies the site by its name. In this example, the **/s** parameter is unnecessary because the server is local. The **/u** and **/p** parameters are omitted because the current user of the local computer must be logged on as an administrator in order to run the command.

**iisweb /stop Products**

In response, **iisweb** displays the following message confirming that the site has been stopped, and identifying it by its metabase path:

```
Connecting to server ...Done.
```

```
Server W3SVC/1977437537 has been STOPPED.
```

**Example 2:**
The following example stops the "Products" and "Marketing" Web sites on the SVR01 remote computer. The command identifies the "Products" site by its metabase path, "W3SVC/1509060225", and the "Marketing" site by name. In addition, the command uses the **/s** parameter to specify the remote computer, and the **/u** and **/p** parameters to run the commands with the permissions of the user's administrator account.

**iisweb /stop w3svc/1509060225 Marketing /s SVR01 /u Alice /p p@##word**

In response, **iisweb** displays the following message confirming that the sites have been stopped, and identifying each by its metabase path:

```
Connecting to server ...Done.

Server W3SVC/1509060225 has been STOPPED.

Server W3SVC/1977437537 has been STOPPED.
```

# Pausing Web Sites Using Iisweb.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Pausing a Web site is similar to stopping it, except that pausing allows existing processes to continue to their conclusion. Administrators might want to use this function to troubleshoot situations where stopping the Web site abruptly would result in severe issues for users.

You can use the command-line script iisweb.vbs, which is stored in *systemroot*\System32, to pause a Web site indefinitely. Pausing prevents Internet services from accepting new connections, but does not affect requests that are already being processed.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you must type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**
**iisweb/pause** *WebSite [WebSite...] [* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**Parameters**
*WebSite*

Required. Specifies the site name or metabase path of the Web site. Web sites must be uniquely identified. If more than one Web site has the same descriptive name, you must use the metabase path to identify the Web site.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Examples**
**Example 1:**
The following example pauses the "Products" Web site on the local computer. The command identifies the site by its name. In this example, the **/s** parameter is omitted because the server is local. The **/u** and **/p** parameters are omitted because the current user of the local computer must be logged on as an administrator in order to run the command.

**iisweb /pause Products**

In response, **iisweb** displays the following message confirming that the site has been paused, and identifying it by its metabase path:

```
Connecting to server ...Done.

Server W3SVC/1977437537 has been PAUSED.
```

**Example 2:**
The following example pauses the "Products" and "Marketing" Web sites on the SVR01 remote computer. The command identifies the "Products" site by its metabase path, "W3SVC/1509060225", and the "Marketing" site by name. In addition, the command uses the **/s** parameter to specify the remote computer, and the **/u** and **/p** parameters to run the commands with the permissions of the user's administrator account.

**iisweb /pause w3svc/1509060225 Marketing /s SVR01 /u Alice /p p@##word**

In response, **iisweb** displays the following message confirming that the sites have been paused, and identifying each by its metabase path:

```
Connecting to server ...Done.

Server W3SVC/1509060225 has been PAUSED.

Server W3SVC/1977437537 has been PAUSED.
```

# Listing Web Sites Using Iisweb.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Administrators frequently need to check the status and/or properties of their Web sites. To check the status of your Web site, you can use the command-line script iisweb.vbs, which is stored in *systemroot*\System32, to query or list Web sites on remote or local computers.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:MyComputer\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**

**iisweb/query** *[WebSite [WebSite...]]*

*[* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**Parameters**

*WebSite*

Limits the query to the specified Web site. Type the name or metabase path of the Web site. The default displays all of the Web sites on the IIS server. Web sites must be uniquely identified. If more than one Web site has the same descriptive name, you must use the metabase path to identify the Web site.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

| **Note** |
| --- |
| The query output includes the site name, metabase path, and the IP address, or **All** to indicate all unassigned addresses. |

**Examples**

**Example 1:**

The following example displays the Web sites on the local computer. Omitting the **WebSite** parameter limits the search to the local computer, eliminating the need for the **/s** parameter. The **/u** and **/p** parameters are omitted because the user running the command prompt must be logged on as an administrator for the local machine.

**iisweb /query**

In response, **iisweb** displays all of the IIS Web sites that are on the local computer, including their site names, metabase paths, status, IP addresses, ports, and host names.

```
Site Name (Metabase Path) Status IP Port Host

Default Web Site (W3SVC/1) STARTED ALL 90 N/A

Products (W3SVC/1948497947) STARTED 172.30.163.244 80 N/A

Finance (W3SVC/1211348328) STARTED 172.30.152.249 80 N/A

Marketing (W3SVC/1907510956) STARTED ALL 95 www.contoso.com
```

**Example 2:**
The following example searches for the "Marketing" Web site on the remote computer SVR01. It uses the **/s** parameter to specify the remote computer, and the **/u** and **/p** parameters to run the script with the permissions of the user's administrator account.

**iisweb /query Marketing /s SVR01 /u Admin6 /p A76QVJ32#**

In response, **iisweb** displays the "Marketing" Web site on SVR01.

```
Site Name (Metabase Path) Status IP Port Host

Marketing (W3SVC/1907510956) STOPPED ALL 80 www.contoso.com
```

**Example 3:**
The following example displays the status of the "Marketing" and "Finance" Web sites on the local computer. It uses site names to identify the Web sites, although metabase paths are also valid.

**iisweb /query Marketing Finance**

In response, **iisweb** displays the status of the "Marketing" and "Finance" Web sites.

```
Site Name (Metabase Path) Status IP Port Host

Marketing (W3SVC/1907510956) STARTED ALL 80 www.contoso.com

Finance (W3SVC/1509060625) STARTED 192.168.125.225 80 www.contosofinance.com
```

# Managing FTP Sites Using Scripts

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisftp.vbs, which is stored in *systemroot*\System32, to create and manage File Transfer Protocol (FTP) sites on computers running a member of the Microsoft Windows Server™ 2003 family with Internet Information Services (IIS) 6.0.

Iisftp.vbs performs some of the same operations that are available in IIS Manager. You can use either tool to administer IIS FTP sites.

This section includes the following information:

- Creating FTP Sites Using Iisftp.vbs: Describes how to create and isolate FTP sites on local or remote computers by using iisftp.vbs.
- Deleting FTP Sites Using Iisftp.vbs: Describes how to delete FTP sites on local or remote computers by using iisftp.vbs.
- Starting FTP Sites Using Iisftp.vbs: Describes how to start FTP sites on local or remote computers by using iisftp.vbs.
- Stopping FTP Sites Using Iisftp.vbs: Describes how to stop FTP sites on local or remote computers by using iisftp.vbs.
- Pausing FTP Sites Using Iisftp.vbs: Describes how to pause FTP sites on local or remote computers by using iisftp.vbs.
- Listing FTP Sites Using Iisftp.vbs: Describes how to list FTP sites on local or remote computers by using iisftp.vbs.
- Setting Active Directory User Isolation Using Iisftp.vbs: Describes how to get and set user isolation on local or remote computers by using iisftp.vbs.

# Creating FTP Sites Using Iisftp.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisftp.vbs, which is stored in *systemroot*\System32, to create File Transfer Protocol (FTP) site configurations on local or remote computers running a member of the Windows Server 2003 family with IIS 6.0. This command does not create or destroy content, but it sets up the directory structure and IIS configuration files.

When you use iisftp.vbs to create a new FTP site, you specify only the basic properties that are needed to create the site and identify its contents. Iisftp.vbs uses the same default properties that IIS Manager uses when establishing new FTP sites, and it adheres to the same rules for inheriting properties. To configure the more advanced properties of the FTP site, use IIS Manager.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**

**iisftp /create** *Path SiteName* **iisftp /create** *Path SiteName*[**/b** *Port*] [**/i** *IPAddress*] [**/dontstart**] [**/isolation** *{AD|Local}* [**/ADdomain DomainName /ADadmin** *[Domain\]User* **/ADpass** *Password]]* [**/s** *Computer* [**/u** *[Domain\]User* **/p** *Password]]*

**Parameters**

*Path*

Specifies the location of content files for the FTP site. The path must be local, such as C:\Projects\HTML. If the specified path does not exist, then iisftp.vbs creates the path.

The **Path** parameter must immediately precede the **SiteName** parameter in the command. Otherwise, iisftp.vbs does not interpret the site information correctly.

*SiteName*

Required. Specifies a name for the FTP site.

**/b** *Port*

Specifies a TCP port number for the FTP site. Port 21 is the default.

**/i** *IPAddress*

Specifies an IP address for the FTP site. The default is **All Unassigned**, which assigns to the site all of the IP addresses on the computer that are not assigned to other sites. Only one site on each IIS server can be set to **All Unassigned**.

**/dontstart**

Indicates that the FTP site should not be started automatically as soon as it is created, which is contrary to the IIS default.

**/isolation** *{AD|Local}*

Provides for one of two user isolation modes, AD (Active Directory) and Local. If the **/isolation** switch is not present, the site will not use user isolation.

**/ADdomain** *DomainName*

Only valid when the **/isolation** switch is set to AD. This value is the name of the Active Directory domain.

**/ADadmin** *[Domain\]User*

Only valid when the **/isolation** switch is set to AD. This value is the name of the administrator in the *user*, *domain\user*, or *user@domain* format.

**/ADpass** *Password*

Only valid when the **/isolation** switch is set to AD. This value is the administrator's password.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. The default is the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

| **Note** |
| --- |
| Iisftp.vbs does not verify the port number or IP address of an FTP site, and it does not verify that these bindings are unique within the server. If you create a site with invalid or conflicting bindings, the site will not start. |

**Examples**

**Example 1**

The following example creates the "Archive" FTP site on the local computer, and associates it with content in the D:\Public\Archives directory. The command omits all optional parameters and accepts the default values. The "Archives" subdirectory does not exist, so iisftp.vbs will create it in the "Public" directory.

**iisftp /create D:\Public\Archives Archive**

In response, **iisftp** displays the following message along with the basic properties of the new FTP site. In this example, "Server" represents the machine name where drive D: is found, "Site Name" is the name you assigned to your FTP site, "Metabase Path" represents the metabase key assigned by IIS and is analogous to a registry key in the system registry, "IP" is unassigned by default, "Port" is set to 21 by default, "Root" is the directory where the FTP files reside, and "Status" is set to "STARTED" by default.

```
Connecting to server ...Done.

Server = RESKIT

Site Name = Archive

Metabase Path = MSFTPSVC/1452008083

IP = ALL UNASSIGNED

Port = 21

Root = D:\Public\Archives

Status = STARTED
```

**Example 2**

The following example creates the "Drivers" FTP site configuration on a remote server. It associates the site with files stored in the C:\Public\Download directory on SVR16. The command uses the **/i** parameter to specify an IP address for the site and the **/dontstart** parameter to prevent the site from starting automatically. It uses the **/s** parameter to specify the remote computer, and the **/u** and **/p** parameters to run the script with the permissions of the user's administrator account.

**iisftp /create C:\Public\Download Drivers /i 172.31.69.150 /dontstart /s SVR16 /u Admin6 /p p@ssWor#**

In response, **iisftp** displays the following message along with the basic properties of the new FTP site. In this example, "Server" represents the server machine, "Site Name" is the name you assigned to your FTP site name, "Metabase Path" represents the metabase key assigned by IIS and is analogous to a registry key in the system registry, "IP" represents the assigned DNS address, "Port" is set to 21 by default, "Root" is the directory where the FTP files reside, and "Status" is set to "STOPPED" as directed.`Connecting to server ...Done.`

```
Server = SVR16

Site Name = Drivers

Metabase Path = MSFTPSVC/1932955329

IP = 172.31.69.150

Port = 21

Root = C:\Public\Download

Status = STOPPED
```

Example 3

The following example creates the "ChangePages" FTP site configuration on a remote server using Active Directory isolation. It associates the site with files stored in the C:\Public\Update directory on SVR16. The command uses the **/dontstart** parameter to prevent the site from starting automatically. The command also uses the **/isolation** parameter with a value of AD to specify Active Directory isolation, and uses the **ADdomain**, **ADadmin**, and **ADpass** parameters to provide the name of the Active Directory domain, as well as the domain administrator name and password.The **/s** parameter specifies the server name, and the **/u** and **/p** parameters specify the user account and password for the administrator of the remote server, under whose permissions the iisftp.vbs script runs.

**iisftp /create C:\Public\Update ChangePages /dontstart /isolation AD /ADdomain DomainA /ADadmin Admin5 /ADpass p@ssWor# /s SVR16 /u Admin6 /p p@SSwor#**

In response, iisftp displays the following message along with the basic properties of the new FTP site. In this example, "Server" represents the server machine; "Site Name" is the name assigned to the FTP site, in this example, ChangePages; "Metabase Path" represents the metabase key assigned by IIS and is analogous to a registry key in the system registry; "IP" is unassigned by default; "Port" is set to 21 by default; "Root" is the directory where the FTP files reside; "IsoMode" is the isolation mode, which is Active Directory; and "Status" is set to STOPPED as specified in the command.

```
Connecting to server....Done.

Server = SVR16

Site Name = ChangePages

Metabase Path = MSFTPSCV/945765436

IP = ALL UNASSIGNED

Port = 21

Root = C:\Public\Update

IsoMode = AD

Status = STOPPED
```

# Deleting FTP Sites Using Iisftp.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisftp.vbs, which is stored in *systemroot*\System32\, to delete IIS File Transfer Protocol (FTP) site configurations on local or remote computers running a member of the Windows Server 2003 family with IIS 6.0.

This command is useful if you plan to move the site to a new URL or server, or if you intend to remove it entirely. The content within the site is unaffected by this command, but the site will be inaccessible to users.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:MyComputer\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**

**iisftp /delete** *FTPSite [FTPSite...] [* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**Parameters**

*FTPSite*

Required. Specifies the site name or metabase path of the FTP site. FTP sites must be uniquely identified. If more than one FTP site has the same descriptive name, you must use the metabase path to identify the FTP site.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Examples**

**Example 1:**

The following example deletes a single FTP site configuration on a local computer. The content of the "Downloads" FTP site remains unchanged, but will be unavailable to users. The **/s** parameter is omitted because the local computer is the default setting. The **/u** and **/p** parameters are omitted because the current user of the local computer must be logged on as an administrator to run the command.

**iisftp /delete Downloads**

In response, **iisftp** displays the following message indicating that the site configuration has been deleted, and identifying the FTP site by its metabase path. The metabase path is the IIS equivalent of an entry in the system registry.

```
Connecting to server ...Done.
```

```
Server MSFTPSVC/2109607139 has been DELETED.
```

**Example 2**

The following example deletes multiple FTP site configurations from a remote computer. The "Downloads", "Drivers", and "Library" FTP sites reside on SVR01. The command identifies the first two sites by name and the "Logo" FTP site by its metabase path, "MSFTPSVC/1932955329". In addition, the command uses the **/s** parameter to specify the remote computer and the **/u** and **/p** parameters to run the commands with the permissions of the user's administrator account.

**iisftp /delete Downloads Drivers MSFTPSVC/2109607139 /s Svr01 /u Tom /p p@##word**

In response, **iisftp** displays the following message indicating that the site configurations have been deleted, and identifying each FTP site by its metabase path.

```
Connecting to server ...Done.

Server MSFTPSVC/2109607139 has been DELETED.

Server MSFTPSVC/1879143292 has been DELETED.

Server MSFTPSVC/1932955329 has been DELETED.
```

# Starting FTP Sites Using Iisftp.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS starts File Transfer Protocol (FTP) sites automatically when they are created, unless the administrator specifically prohibits it with the **/dontstart** parameter. An administrator might prohibit an automatic start, for example, to allow time for the site to be added to DNS.

An administrator might also pause or stop an FTP site for troubleshooting purposes. In cases like these, you can use the command-line script iisftp.vbs, which is stored in *systemroot*\System32, to start or restart an FTP site.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:MyComputer\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**
**iisftp/start** *FTPSite [FTPSite...] [* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**Parameters**
*FTPSite*

Required. Specifies the site name or metabase path of the FTP site. FTP sites must be uniquely identified. If more than one FTP site has the same descriptive name, you must use the metabase path to identify the FTP site.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Examples**
**Example 1:**
The following example starts the "Products" FTP site on the local computer. The command identifies the site by its name. In this example, the **/s** parameter is omitted because the server is local. The **/u** and **/p** parameters are omitted because the current user of the local computer must be logged on as an administrator in order to run the command.

**iisftp /start Products**

In response, **iisftp** displays the following message confirming that the site has been started, and identifying it by its metabase path. The metabase path is the IIS equivalent of an entry in the system registry.

```
Connecting to server ...Done.
```

```
Server MSFTPSVC/1452008085 has been STARTED.
```

**Example 2:**
The following example starts the "Products" and "Marketing" FTP sites on the SVR01 remote computer. The command identifies the "Products" site by its metabase path, "MSFTPSVC/1452008085", and the "Marketing" site by name. In addition, the command uses the **/s** parameter to specify the remote computer, and the **/u** and **/p** parameters to run the commands with the permissions of the user's administrator account.

**iisftp /start MSFTPSVC/1452008085 Marketing /s SVR01 /u Jim /p p@##word**

In response, **iisftp** displays the following message, confirming that the sites have been started, and identifying each site by its metabase path:

```
Connecting to server ...Done.

Server MSFTPSVC/1452008085 has been STARTED.

Server MSFTPSVC/1879143292 has been STARTED.
```

# Stopping FTP Sites Using Iisftp.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If your File Transfer Protocol (FTP) site is not behaving correctly, or if the site is slow or unresponsive, stopping and restarting the site might clear a temporary problem with the software—for example, a faulty worker process.

In cases like these, you can use the command-line script iisftp.vbs, which is stored in *systemroot*\System32, to stop an FTP site from responding. The content of the site is unchanged, but it will be inaccessible to users until the site is restarted.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**
**iisftp/stop** *FTPSite [FTPSite...] [* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**Parameters**
*FTPSite*

Required. Specifies the site name or metabase path of the FTP site. FTP sites must be uniquely identified. If more than one FTP site has the same descriptive name, you must use the metabase path to identify the FTP site.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Examples**
**Example 1:**
The following example stops the "Drivers" FTP site on the local computer. The command identifies the site by its name. In this example, the **/s** parameter is omitted because the server is local. The **/u** and **/p** parameters are omitted because the current user of the local computer must be logged on as an administrator in order to run the command.

**iisftp /stop Drivers**

In response, **iisftp** displays the following message confirming that the site has been stopped, and identifying the site by its metabase path. The metabase path is the IIS equivalent of an entry in the system registry.

```
Connecting to server ...Done.
```

```
Server MSFTPSVC/1879143292 has been STOPPED.
```

**Example 2:**
The following example stops the "Downloads" and "Drivers" FTP sites on the SVR01 remote computer. The command identifies the "Downloads" site by its metabase path, "MSFTPSVC/2109607139", and the "Drivers" site by name. In addition, the command uses the **/s** parameter to specify the remote computer, and the **/u** and **/p** parameters to run the commands with the permissions of the user's administrator account.

**iisftp /stop MSFTPSVC/2109607139 Drivers /s SVR01 /u Tom /p p###word**

In response, iisftp displays the following message confirming that the sites have been stopped, and identifying each site by its metabase path:

```
Connecting to server ...Done.

Server MSFTPSVC/2109607139 has been STOPPED.

Server MSFTPSVC/1879143292 has been STOPPED.
```

# Pausing FTP Sites Using Iisftp.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Pausing a File Transfer Protocol (FTP) site is similar to stopping it; except that pausing the FTP site lets existing processes continue to their conclusion. Administrators might want to use this function to troubleshoot situations where stopping the FTP site abruptly would result in severe issues for users.

You can use the command-line script iisftp.vbs, which is stored in *systemroot*\System32, to pause a Web site indefinitely. Pausing prevents FTP services from accepting new connections, but it does not affect requests that are already being processed.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you must a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**
**iisftp/pause** *FTPSite [FTPSite...] [* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**Parameters**
*FTPSite*

Required. Specifies the site name or metabase path of the FTP site. FTP sites must be uniquely identified. If more than one FTP site has the same descriptive name, you must use the metabase path to identify the FTP site.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Examples**
**Example 1:**
The following example pauses the "Drivers" FTP site on the local computer. The command identifies the site by its name. In this example, the **/s** parameter is omitted because the server is local. The **/u** and **/p** parameters are omitted because the current user of the local computer must be logged on as an administrator in order to run the command.

**iisftp /pause Drivers**

In response, **iisftp** displays the following message confirming that the site has been paused, and identifying the site by its metabase path. The metabase path is the IIS equivalent of an entry in the system registry.

```
Connecting to server ...Done.

Server MSFTPSVC/1879143292 has been PAUSED.
```

**Example 2:**
The following example pauses the "Downloads" and "Drivers" FTP sites on the SVR01 remote computer. The command identifies the "Downloads" site by its metabase path, "MSFTPSVC/2109607139", and the "Drivers" site by name. In addition, the command uses the **/s** parameter to specify the remote computer, and it uses the **/u** and **/p** parameters to run the commands with the permissions of the user's administrator account.

**iisftp /pause MSFTPSVC/2109607139 Drivers /s SVR01 /u Tom /p pa##word**

In response, **iisftp** displays the following message confirming that the sites have been paused, and identifying each site by its metabase path:

```
Connecting to server ...Done.

Server MSFTPSVC/2109607139 has been PAUSED.

Server MSFTPSVC/1879143292 has been PAUSED.
```

# Listing FTP Sites Using Iisftp.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Administrators frequently need to check the status and/or properties of their File Transfer Protocol (FTP) sites. To check the status of your site, you can use the command-line script iisftp.vbs, which is stored in *systemroot*\System32, to query or list FTP sites on remote or local computers.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**

**iisftp/query** *[FTPSite [FTPSite...]]*

*[* **/s** *Computer [* **/u** *[Domain* **** *]User* **/p** *password]]*

**Parameters**

*FTPSite*

Required. Specifies the site name or metabase path of the FTP site. FTP sites must be uniquely identified. If more than one FTP site has the same descriptive name, you must use the metabase path to identify the FTP site.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain* **** *]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

| **Note** |
| --- |
| The query output includes the site name, metabase path, port, status, and the IP address, or *All* to indicate all unassigned addresses. |

**Examples**

**Example 1:**

The following example displays the FTP sites that are on the local computer. Omitting the *FTPSite* parameter limits the search to the local computer, eliminating the need for the **/s** parameter. The **/u** and **/p** parameters are omitted because the user running the command prompt must be logged on as an administrator for the local machine.

**iisftp /query**

In response, **iisftp** displays all of the IIS FTP sites that are on the local computer, including site names, metabase paths, status, IP addresses, and ports.

```
Connecting to server ...Done.

Site Name (Metabase Path) Status IP Port

Default FTP Site (MSFTPSVC/1) STARTED ALL 21

My Site (MSFTPSVC/858812021) STOPPED ALL 21

Drivers (MSFTPSVC/1932955329) STARTED 172.30.163.249 21

Downloads (MSFTPSVC/1879143292) STARTED ALL 25

Library (MSFTPSVC/2109607139) STARTED 172.30.163.126 21
```

**Example 2:**
The following example searches for the "Download" FTP site on the remote computer, SVR01. It uses the **/s** parameter to specify the remote computer, as well as the **/u** and **/p** parameters to run the script with the permissions of the user's administrator account.

**iisftp /query Download /s SVR01 /u Admin6 /p A76QVJ32#**

In response, **iisftp** displays the "Download" FTP site on SVR01.

```
Site Name (Metabase Path) Status IP Port

Downloads (MSFTPSVC/1879143292) STARTED ALL 25
```

**Example 3:**
The following example displays the status of the "Downloads" and "Drivers" FTP sites on the local computer. It uses site names to identify the FTP sites, although metabase paths are also valid.

**iisftp /query Downloads Drivers**

In response, **iisftp** displays the status of the "Downloads" and "Drivers" FTP sites.

```
Site Name (Metabase Path) Status IP Port

Downloads (MSFTPSVC/1879143292) STARTED ALL 25

Drivers (MSFTPSVC/1932955329) STARTED 172.30.163.249 21
```

# Setting Active Directory User Isolation Using Iisftp.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisftp.vbs, which is stored in *systemroot*\System32, to query and set Active Directory directory service properties for a user's File Transfer Protocol (FTP) home directory. For more information about user isolation, see Isolating FTP Users.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:MyComputer\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**

**iisftp /GetADProp** *UserID [* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**iisftp /SetADProp** *UserID {msIIS-FTPDir|msIIS-FTPRoot} PropertyValue [* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**Parameters**

**/GetADProp**

Returns property values for a specific Active Directory user.

**/SetADProp**

Sets the property values for a specific Active Directory user.

*UserID*

Required. Specifies the logon ID of the Active Directory user.

*msIIS-FTPDir|msIIS-FTPRoot*

Required to set the home directory properties. Specifies isolation at either the directory or root level.

*PropertyValue*

Required to set the home directory properties. Specifies the value of the home directory and relative path.

**/s** *Computer*

Specifies the name or IP address of a remote computer (with no backslashes). The default is the local computer.

**/u** *[Domain\]User*

Connects to the Active Directory with the permissions of the specified user account in the user or *domain\user* format. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Examples**
**Example 1:**
The following example returns the Active Directory properties of user "BSmith" on the local computer:

**iisftp /GetADProp BSmith**

In response, **iisftp** displays the following message, which is followed by the Active Directory properties for BSmith in the default domain. In this example, "Server" represents the machine name where drive D: is found, "Site Name" is the name you assigned to the FTP site, "Metabase Path" represents the metabase key assigned by IIS, "IP" is unassigned by default, "Port" is set to 21 by default, "Root" is the directory where the FTP files reside, "IsoMode" is set to "FTPRoot", and "Status" is set to "STARTED" by default.

```
Connecting to server ...Done.

Server = FTPServer

Site Name = Smittys

Metabase Path = MSFTPSVC/1452008083

IP = ALL UNASSIGNED

Port = 21

Root = D:\Public\Archives

IsoMode = FTPRoot

Status = STARTED
```

**Example 2:**
The following example sets the home directory properties in the Active Directory User object properties for user "Sales\MJones" on a remote computer:

**iisftp /SetADProp Sales\MJones FTPDir MikesDir /s SVR16 /u Sales\Admin6 /p p@ssWor#**

In response, **iisftp** displays the following message, which includes the Active Directory properties for MJones. In this example, "Server" represents the machine name where drive D: is found, "Site Name" is the name you assigned to the FTP site, "Metabase Path" represents the metabase key assigned by IIS, "IP" is unassigned by default, "Port" is set to 21 by default, "Root" is the directory where the FTP files reside, "IsoMode" is set to "FTPDir", and "Status" is set to "STARTED" by default.

```
Connecting to server ...Done.

Server = SVR16

Site Name = MikesDir

Metabase Path = MSFTPSVC/1452004045

IP = ALL UNASSIGNED

Port = 21

Root = D:\Public\Archives

IsoMode = FTPDir

Status = STARTED
```

# Managing Web Virtual Directories Using Scripts

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisvdir.vbs, which is stored in *systemroot*\System32 to create, delete, and list Web virtual directories on computers running a member of the Microsoft Windows Server™ 2003 family with Internet Information Services (IIS) 6.0.

Iisvdir.vbs performs some of the same operations that are available in IIS Manager. You can use either tool to administer IIS Web virtual directories.

This section includes the following information:

- Creating Web Virtual Directories Using Iisvdir.vbs: Describes how to create Web virtual directories on local or remote computers by using iisvdir.vbs.
- Deleting Web Virtual Directories Using Iisvdir.vbs: Describes how to delete Web virtual directories on local or remote computers by using iisvdir.vbs.
- Listing Web Virtual Directories Using Iisvdir.vbs: Describes how to list Web virtual directories on local or remote computers by using iisvdir.vbs.

# Creating Web Virtual Directories Using Iisvdir.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script Iisvdir.vbs, which is stored in *systemroot*\System32, to create a new Web virtual directory on local or remote computers running a member of the Windows Server 2003 family with IIS 6.0. This command does not create or destroy content, but it sets up the virtual directory structure and IIS configuration files.

When you use Iisvdir.vbs to create a new Web virtual directory, you specify only the basic properties that are needed to create the site and identify its contents. Iisvdir.vbs uses the same default properties that IIS Manager uses when establishing new virtual directories, and it adheres to the same rules for inheriting properties. To configure the more advanced properties of the virtual directory, use IIS Manager.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /**User:MyComputer****Administrator **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**

**iisvdir /create** *WebSite[/VirtualPath] Name PhysicalPath [* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**Parameters**

*WebSite*

Required. Specifies the descriptive name, or the metabase path, of the Web site.

*VirtualPath*

Specifies a path, if necessary, to the virtual directory within the Web site. This parameter is required when the virtual directory is not located at the root of the Web site.

*Name*

Required. Specifies a name for the virtual directory. Virtual directory names do not have to be unique. However, when a Web site includes a virtual directory and a physical directory with the same name, the physical directory will not be visible on the Internet.

*PhysicalPath*

Specifies a physical directory where the content for the virtual directory resides. You must specify a path on the local computer, such as C:\Project\HTML. If the specified directory does not exist, **iisvdir** will create it.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. The default is the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

| **Note** |
| --- |
| The **WebSite** (or **WebSite/VirtualPath**), **Name**, and **PhysicalPath** parameters must always appear in the specified order on the command line. Otherwise, Iisvdir.vbs does not interpret the information correctly. |

**Examples**

**Example 1:**

The following example creates the "Insurance" virtual directory at the root of the "Finance" Web site on the local computer. It associates the directory with content that is currently stored in the C:\Projects\Insurance\HTML directory.

**iisvdir /create Finance Insurance c:\projects\insurance\html**

In response, **iisvdir** displays the following success message along with the basic properties of the new virtual directory. In this example, "Virtual Path" reflects the virtual directory structure, "ROOT" represents the physical directory where the content resides, and "Metabase Path" represents the metabase key that is assigned by IIS.

```
Connecting to server ...Done.

Virtual Path = Finance/Insurance

ROOT = c:\projects\insurance\html

Metabase Path = W3SVC/1509060625/ROOT/Insurance
```

**Example 2:**

The following example creates the "Updates" virtual subdirectory on the "Finance" Web site on the remote computer. The command uses the metabase path of the "Finance" Web site, "W3SVC/1509060625", to identify the Web site, and it indicates the virtual path, "Finance/Insurance", by appending it to the Web site name. In addition, the command associates the "Updates" directory with content that is stored in C:\Newstuff\Web on the remote computer.

The example also uses the **/s** parameter to identify the remote computer, as well as the **/u** and **/p** parameters to run Iisvdir.vbs with the permissions of the user's administrator account.

**iisvdir /create W3SVC/1509060625/Insurance Updates C:\Newstuff\Web /s SVR01 /u Admin01 /p p@SSw#rD2**

In response, **iisvdir** displays the basic properties of the new Web site.

```
Connecting to server ...

Virtual Path = Finance/Insurance/Updates

ROOT = C:\Newstuff\Web

Metabase Path = W3SVC/1509060625/ROOT/Insurance/Updates
```

**Related Information**

# Deleting Web Virtual Directories Using Iisvdir.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisvdir.vbs, which is stored in *systemroot*\System32, to delete a virtual directory on local or remote computers running a member of the Windows Server 2003 family with IIS 6.0. This command does not create or destroy content, but simply deletes the virtual directory structure.

You should not use this command to delete Web sites, as the sites may still be listed, but partially disabled. To delete a Web site, use Deleting Web Sites Using Iisweb.vbs

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:MyComputer\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**
**iisvdir /delete** *WebSite[/VirtualPath] Name [* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**Parameters**
*WebSite*

Required. Specifies the descriptive name, or the metabase path, of the Web site.

*VirtualPath*

Specifies a path, if necessary, to the virtual directory within the Web site. This parameter is required when the virtual directory is not located at the root of the Web site.

*Name*

Required. Specifies a name for the virtual directory. Virtual directory names do not have to be unique. However, when a Web site includes a virtual directory and a physical directory with the same name, the physical directory will not be visible on the Internet.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. The default is the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Examples**
**Example 1:**

The following example deletes the "Insurance" virtual directory from the "Finance" Web site on the local computer. As a result, not only is the "Insurance" directory deleted, but all of the physical and virtual subdirectories are deleted as well.

**iisvdir /delete Finance/Insurance**

The **/s**, **/u**, and **/p** parameters are unnecessary in this instance because the default computer is local and the user running the command must be logged on as an administrator.

In response, **iisvdir** displays the following message:

```
Connecting to server ...Done.

Web directory Finance/Insurance has been DELETED.
```

**Example 2:**
The following example deletes the "Updates" virtual subdirectory called on the "Finance" Web site of the remote computer. The command uses the metabase path of the "Finance" Web site, "W3SVC/1509060625", to identify the Web site. It indicates the virtual path, "Finance/Insurance", by appending it to the Web site name.

The example also uses the **/s** parameter to identify the remote computer, as well as the **/u** and **/p** parameters to run iisvdir.vbs with the permissions of the user's administrator account.

**iisvdir /delete W3SVC/1509060625/Insurance/Updates /s SVR01 /u Admin01 /p p@SSw#rD2**

In response, **iisvdir** displays the following message:

```
Connecting to server ...Done.

Web directory Finance/Insurance/Updates has been DELETED.
```

**Related Information**

- For information about creating Web virtual directories, see Creating Web Virtual Directories Using Iisvdir.vbs.
- For information about Listing Web virtual directories, see Listing Web Virtual Directories Using Iisvdir.vbs.

# Listing Web Virtual Directories Using Iisvdir.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisvdir.vbs, which is stored in *systemroot*\System32, to list the virtual directory on local or remote computers running a member of the Windows Server 2003 family with IIS 6.0.

The **/query** operation only displays virtual directories at the root of the Web site, or path, and does not search recursively. Also, it does not display physical directories.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**
**iisvdir /query** *WebSite[/VirtualPath][* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**Parameters**
*WebSite*

Required. Specifies the descriptive name, or the metabase path, of the Web site.

*VirtualPath*

Specifies a path, if necessary, to the virtual directory within the Web site. This parameter is required when the virtual directory is not located at the root of the Web site.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. The default is the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Examples**
**Example 1:**
The following example displays the virtual directories at the root of the "Finance" Web site on the local computer:

**iisvdir /query Finance**

The **/s**, **/u**, and **/p** parameters are unnecessary in this instance because the default computer is local and the user running the command must be logged on as an administrator.

In response, **iisvdir** displays the two virtual directories at the root of "Finance" Web site. These directories appear at the "Finance" root even though their physical locations are unrelated. In this example, "Alias" represents the names of the virtual directories, while "Physical Root" is their actual location.

| **Note** |
| --- |
| This display does not include virtual directories that are subdirectories of the site. The procedure for finding subdirectories is demonstrated below in Example 2. |

```
Alias Physical Root

/Personnel D:\Corpdir\FinanceWeb\People

/Insurance C:\Marketing\Insurance\HTMFiles
```

**Example 2:**
The following example displays the virtual directories that are subdirectories of the "Insurance" virtual directory on the "Finance" Web site. The command specifies the "Insurance" directory by using its virtual path.

The example also uses the **/s** parameter to identify the remote computer, as well as the **/u** and **/p** parameters to run iisvdir.vbs with the permissions of the user's administrator account.

**iisvdir /query Finance\Insurance**

In response, iisvdir.vbs reveals the "Current" subdirectory of the "Insurance" virtual directory, and its physical location.

```
Alias Physical Root

/Current C:\Insurance\Monthly\200204
```

Specifies a physical directory where the content for the virtual directory resides. You must specify a path on the local computer, such as C:\Project\FTP. If the specified directory does not exist, iisftpdr will create it.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. The default is the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

| **Note** |
| --- |
| The **FTPSite** (or **FTPSite/VirtualPath**), **Name**, and **PhysicalPath** parameters must always appear in the specified order on the command line. Otherwise, iisftpdr.vbs does not interpret the information correctly. |

**Examples**

**Example 1:**

The following example creates the virtual directory "Scripts" at the root of the "Test Downloads" FTP site on the local computer. It associates the directory with content that is currently stored in the C:\Libraries\Scripts directory.

**iisftpdr /create "Test Downloads" Scripts C:\Libraries\Scripts**

In response, **iisftpdr** displays the following success message along with the basic properties of the new virtual directory. In this example, "Virtual Path" reflects the virtual directory structure, "ROOT" represents the physical directory where the content resides, and "Metabase Path" represents the metabase key assigned by IIS and is analogous to a registry key in the system registry.

```
Connecting to server ...Done.

Virtual Path = Test Downloads/Scripts

ROOT = C:\Libraries\Scripts

Metabase Path = MSFTPSVC/577648624/ROOT/Scripts
```

**Example 2:**

The following example adds the virtual directory "Updates" to the FTP site of a remote server. The command creates the new virtual directory on the "Finance" FTP site as a subdirectory of the existing virtual directory, "Documents".

The first parameter in the command, **Finance\Documents**, identifies the FTP site and virtual path. The second parameter, **Updates**, specifies the name of the virtual directory, and the third parameter specifies the physical directory on the server that stores the content of the virtual directory.

The command uses the **/s** parameter to identify the server computer, as well as the **/u** and **/p** parameters to run iisftpdr.vbs with the permissions of the user's administrator account.

**iisftpdr /create Finance/Documents Updates C:\inetpub\ftproot\documents\updates /s SVR01 /u Admin01 /p p@SSw#rD2**

In response, **iisftpdr** displays the basic properties of the new FTP site. In this example, the "Finance" FTP site and its "Documents" subdirectory existed on the SVR01 IIS server before the command was issued. If the FTP site or the subdirectory did not exist, the command would have failed.

```
Connecting to server ...Done.

Virtual Path = Finance/Documents/Updates

ROOT = C:\inetpub\ftproot\documents\updates

Metabase Path = MSFTPSVC/2109607139/ROOT/Documents/Updates
```

# Deleting FTP Virtual Directories Using Iisftpdr.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisftpdr.vbs, which is stored in *systemroot*\System32, to delete an FTP virtual directory on local or remote computers running a member of the Windows Server 2003 family with IIS 6.0. This command does not create or destroy content, but simply deletes the virtual directory structure.

You should not use this command to delete FTP sites, as the sites may still be listed, but partially disabled. To delete an FTP site, use Deleting FTP Sites Using Iisftp.vbs.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:MyComputer\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**
**iisftpdr /delete** *FTPSite[VirtualPath]/Name [* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**Parameters**
*FTPSite*

Required. Specifies the descriptive name or the metabase path of the FTP site.

*VirtualPath*

Specifies a path to the virtual directory within the FTP site. This parameter is required when the virtual directory is not located at the root of the FTP site.

*Name*

Required. Specifies a name for the virtual directory. Virtual directory names do not have to be unique. However, when an FTP site includes a virtual directory and a physical directory with the same name, the physical directory will not be visible on the Internet.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. The default is the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Examples**
**Example 1:**

The following example deletes the "Insurance" virtual directory from the "Finance" FTP site on the local computer. As a result, not only is the directory deleted, but all of the physical and virtual subdirectories are deleted as well.

**iisftpdr /delete Finance/Insurance**

The **/s**, **/u**, and **/p** parameters are unnecessary in this instance because the default computer is local and the user running the command must be logged on as an administrator.

In response, **iisftpdr** displays the following message:

```
Connecting to server ...Done.

FTP directory Finance/Insurance has been DELETED.
```

**Example 2:**
The following example deletes the "Updates" virtual subdirectory on the "Finance" FTP site on the remote computer. The command uses the "Finance" FTP site metabase path, "MSFTPSVC/2109607139", to identify the FTP site. It indicates the virtual path, "Finance/Insurance", by appending it to the FTP site name.

The example also uses the **/s** parameter to identify the remote computer, as well as the **/u** and **/p** parameters to run iisftpdr.vbs with the permissions of the user's administrator account.

**iisftpdr /delete MSFTPSVC/2109607139/Insurance/Updates /s SVR01 /u Admin01 /p p@SSw#rD2**

In response, **iisftpdr** displays the following message:

```
Connecting to server ...Done.

FTP directory Finance/Insurance/Updates has been DELETED.
```

**Related Information**

- For information about listing FTP virtual directories, see Listing FTP Virtual Directories Using Iisftpdr.vbs.

# Listing FTP Virtual Directories Using Iisftpdr.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisftpdr.vbs, which is stored in *systemroot*\system32, to list FTP virtual directories on local or remote computers running a member of the Windows Server 2003 family with IIS 6.0.

The **/query** operation displays only virtual directories and not physical directories. Further, it displays only virtual directories at the root of the FTP site or path and does not search recursively.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you must type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**

**iisftpdr /query** *FTPSite[/VirtualPath][* **/s** *Computer [* **/u** *[Domain \ ]User* **/p** *Password]]*

**Parameters**

*FTPSite*

Required. Specifies the descriptive name or the metabase path of the Web site.

*VirtualPath*

Specifies a path, if necessary, to the virtual directory within the Web site. This parameter is required when the virtual directory is not located at the root of the Web site.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. The default is the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Examples**

**Example 1:**

The following example displays the virtual directories at the root of the "Test Downloads" FTP site on the local computer:

**iisftpdr /query "Test Downloads"**

The **/s**, **/u**, and **/p** parameters are unnecessary in this instance because the default computer is local and the user who is running the command must be logged on as an administrator.

In response, **iisftpdr** displays the "Scripts" virtual directory at the root of the "Test Downloads" FTP site. Note that the directory appears at the root even though its physical location is unrelated.

| **Note** |
| --- |
| This display does not include virtual directories that are subdirectories of the site. The procedure for finding subdirectories is demonstrated below in Example 2. |

```
Alias Physical Root

/Scripts C:\Libraries\Scripts
```

"Alias" represents the names of the virtual directories while "Physical Root" describes their actual locations.

**Example 2**
The following example displays the virtual directories that are subdirectories of the "Scripts" virtual directory on the "Test Downloads" FTP site. The command specifies the "Scripts" virtual directory by using its virtual path. Note that the quotation marks enclose only the path component that requires them.

### iisftpdr /query "Test Download"\Scripts

In response, iisftpdr displays the VBScripts subdirectory of the "Scripts" virtual directory.

```
Alias Physical Root

/VBScripts D:\Scripts\VBScripts
```

**Related Information**

# Managing IIS Configurations Using Scripts

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use two command-line scripts, which are stored in *systemroot*\System32, to create and manage Internet Information Services (IIS) configuration files on computers running a member of the Microsoft Windows Server™ 2003 family with IIS 6.0.

Iisback.vbs creates and manages backup copies of the IIS configuration (metabase and schema) of a remote or local computer.

Iiscnfg.vbs imports and exports all, or selected, elements of an IIS metabase on a local or remote computer, or it copies the entire IIS configuration (metabase and schema) to another computer.

This section includes the following information:

- Backing Up IIS Configurations Using Iisback.vbs: Describes how to back up configurations on local or remote computers by using iisback.vbs.
- Restoring IIS Configurations Using Iisback.vbs: Describes how to restore configurations on local or remote computers by using iisback.vbs.
- Deleting IIS Backup Configurations Using Iisback.vbs: Describes how to delete configurations on local or remote computers by using iisback.vbs.
- Listing IIS Backup Configurations Using Iisback.vbs: Describes how to list configurations on local or remote computers by using iisback.vbs.
- Copying IIS Configurations Using Iiscnfg.vbs: Describes how to copy configurations on local or remote computers by using iiscnfg.vbs.
- Importing IIS Configurations Using Iiscnfg.vbs: Describes how to import configurations on local or remote computers by using iiscnfg.vbs.
- Exporting IIS Configurations Using Iiscnfg.vbs: Describes how to export configurations on local or remote computers by using iiscnfg.vbs.
- Saving Configurations to Disk Using Iiscnfg.vbs: Describes how to save configurations to disk on local or remote computers by using iiscnfg.vbs.

# Backing Up IIS Configurations Using Iisback.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisback.vbs, which is stored in *systemroot*\System32, to create and manage backup copies of the IIS configuration (metabase and schema) of a remote or local computer. Administrators can use this script tool to create a backup copy of their IIS configuration, to restore an IIS configuration from a backup copy, and to list and delete backup copies.

Iisback.vbs performs the same backup and restore operations that are available in IIS Manager. You can use either tool to view and manage backup copies.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /**User:MyComputer**\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Overview: Key concepts in understanding the backup and restore procedures.
- Syntax: The order in which you must type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Overview**

Each **/backup** operation creates two files, an .MDx file to store the metabase and an .SCx file to store the schema, where the x is the version number of the backup copy. IIS and iisback.vbs store backup copy files in the **systemroot**\System32\inetsrv\MetaBack directory.

The metabase and schema of an IIS configuration include system-specific and session-specific properties. Do not copy or import the metabase or schema of one IIS server to another IIS server without modification. To copy all or part of a metabase configuration from one system to another, use Copying IIS Configurations Using Iiscnfg.vbs.

To prevent unauthorized use of backup copies, you can use IIS 5.1 or IIS 6.0, and iisback.vbs to encrypt the backup copy with a password. The password encrypts the session key which, in turn, encrypts all of the properties for which the secure attribute is set.

You can read an encrypted backup copy (only the session key and secure properties are encrypted) and you can delete the files. However, you cannot use the backup copy in a restore operation unless you provide the encrypting password. Also, you cannot remove the password encryption from a backup copy or change the encrypting password.

If you do not use password encryption, the session key and secure properties are encrypted with a blank password, which prevents you from reading these values but allows any member of the Administrators group to restore the metabase from the backup copy. IIS 5.1 and IIS 6.0 do not support machine key encryption of backup copies.

**Syntax**

**iisback /backup** *[* **/b** *BackupName] [* **/v** *{Integer* | **HIGHEST_VERSION | NEXT_VERSION** *}] [* **/overwrite** *] [* **/e** *EncryptingPassword] [* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**Parameters**

**/b** *BackupName*

Specifies the name of the backup copy. The default is *SampleBackup*.

**/v** {*Integer* | **NEXT_VERSION | HIGHEST_VERSION**}

Specifies the version number of the backup copy. NEXT_VERSION is the default.

| ***Integer*** | **Specifies the version number of the backup copy.** |
|---|---|
| NEXT_VERSION | Specifies the highest version number plus 1. NEXT_VERSION isthe default value. |
| HIGHEST_VERSION | Reuses the highest version number. Because this option replacesa backup copy, the **/overwrite** parameter is required whenusing this value. This parameter is only valid when previousversions of the file are stored on the computer. |

**/overwrite**

Permits iisback.vbs to replace an exiting backup copy with the newly created backup copy. Without this parameter, commands used to create a backup copy with the same name and version number as an existing backup copy fail.

**/e** *EncryptingPassword*

Encrypts the backup copy with the specified backup password. You can use any string as the password.

The **/e** parameter creates a secure backup by encrypting the session key and secure properties with the specified password. Administrators must provide the password to use the backup in a restore operation.

If you omit this parameter or omit the password argument, then the backup is encrypted with a blank password. As a result, only the secure properties are encrypted and any administrator can use the backup copy to restore the metabase.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. The default is the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Examples**
**Example 1:**
The following command creates a new backup copy of the IIS configuration on the local computer. It uses the **/b** parameter to assign the name ReskitBkp to the file.

**iisback /backup /b ReskitBkp**

In response, **iisback** displays the following success message indicating that the backup copy has been created, and that the default version value, NEXT_VERSION, is assigned to the file. Because this is the first backup copy named ReskitBkp, **iisback** assigns the version number 0 to the backup copy.

```
Backup ReskitBkp version NEXT_VERSION has been CREATED.
```

The new backup copy is displayed in the following list of backup copies on the server:

```
Backup Name Version # Date and Time

ReskitBkp 0 1/9/2001 5:00:04 AM
```

The ReskitBkp backup copy consists of two files, ReskitBkp.MD0, which contains the metabase and ReskitBkp.SC0, which contains the schema. Both files are stored in the **systemroot**\System32\inetsrv\MetaBack directory.

**Example 2:**
The following command creates a backup copy of the IIS configuration on the \\SVR01 remote server. It uses the **/s** parameter to provide the name of the remote computer, and the **/u** and **/p** parameters to run the script with the permissions of the user's Administrator account.

It also includes the **/b** parameter to assign the file name Svr01Bkp to the backup copy and the **/v** parameter to specify the

version number (15) of the new backup copy. The command uses the **/e** parameter to encrypt the backup copy with the backup password 7W*48Hv6#.

**iisback /backup /s svr01 /u admin21 /p Rrr3Qv7s /b Svr01Bkp /v 15 /e 7W*48Hv6#**

In response, iisback displays the following success message:

```
Backup Svr01Bkp version 15 has been CREATED.
```

This command created the Svr01Bkp, version 15 backup copy of the \\SVR01 IIS configuration and stored the data in the Svr01Bkp.MD15 and Svr01Bkp.SC15 files in the **systemroot**\System32\inetsvr\MetaBack directory of the remote computer.

Listing IIS Backup Configurations Using Iisback.vbs shows the backup copies that are stored on the remote server. The **backup** command created the final entry in the list.

```
Backup Name Version # Date and Time

AsiaSvr 1 1/8/2001 9:18:25 PM

Svr01Bkp 11 1/3/2001 3:00:42 AM

Svr01Bkp 12 1/4/2001 3:00:12 AM

Svr01Bkp 13 1/5/2001 3:01:00 AM

Svr01Bkp 14 1/6/2001 3:00:00 AM

Svr01Bkp 15 1/9/2001 5:18:04 AM
```

Although it is not evident from the list, the new backup copy is encrypted and you must provide the backup password, 7W*48Hv6#, in order to use the backup in a restore operation.

**Example 3:**
The following command replaces the most recent backup copy of the local IIS configuration with a newer backup. You can use this command format to update the backup copy that you maintain for the server.

The command uses the **/b** parameter to specify the name of the backup copy. It uses the **/v HIGHEST_VERSION** parameter to direct iisback.vbs to replace the latest version of the backup copy named CurrentBackup, instead of creating a new version. It also uses the **/overwrite** parameter, which is required with **/v HIGHEST_VERSION** to permit iisback.vbs to replace an existing backup.

**iisback /backup /b CurrentBackup /v HIGHEST_VERSION /overwrite**

In response, **iisback** displays the following success message:

```
Backup CurrentBackup version 0 has been CREATED.
```

The command created new versions of the CurrentBackup.md0 and CurrentBackup.sc0 files, which replaced files with the same names.

**Related Information**

- For information about restoring IIS configurations, see Restoring IIS Configurations Using Iisback.vbs.
- For information about deleting IIS configurations, see Deleting IIS Backup Configurations Using Iisback.vbs.
- For information about listing IIS configurations, see Listing IIS Backup Configurations Using Iisback.vbs.

# Restoring IIS Configurations Using Iisback.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisback.vbs, which is stored in *systemroot*\System32, to restore the IIS configuration of a server.

Iisback.vbs performs the same backup and restore operations that are available in IIS Manager. You can use either tool to view and manage backup copies.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Overview: Key concepts in understanding the backup and restore procedures.
- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Overview**

Each backup operation creates two files, an .MDx file to store the metabase and an .SCx file to store the schema, where the x is the version number of the backup copy. IIS and iisback.vbs store backup copy files in the *systemroot*\System32\inetsrv\MetaBack directory.

The metabase and schema of an IIS configuration include system-specific and session-specific properties. Do not copy or import the metabase or schema of one IIS server to another IIS server without modification. To copy all or part of a metabase configuration from one system to another, use Copying IIS Configurations Using Iiscnfg.vbs.

To prevent unauthorized use of backup copies, you can use IIS 5.1 or IIS 6.0, and iisback.vbs to encrypt the backup copy with a password. The password encrypts the session key which, in turn, encrypts all of the properties for which the secure attribute is set.

You can read an encrypted backup copy (only the session key and secure properties are encrypted), and you can delete the files. However, you cannot use the backup copy in a restore operation unless you provide the encrypting password. Also, you cannot remove the password encryption from a backup copy nor can you change the encrypting password.

If you do not use password encryption, the session key and secure properties are encrypted with a blank password, which prevents you from reading these values but allows any member of the Administrators group to restore the metabase from the backup copy. IIS 5.1 and IIS 6.0. do not support machine key encryption of backup copies.

| **Note** |
| --- |
| The **/restore** operation is a complex operation that can take several minutes to complete. A brief delay is normal for this operation. During **/restore**, Web pages, FTP sites, and SMTP and NNTP services are temporarily stopped. Service is restored when the operation completes. |

**Syntax**

**iisback /restore/b** *BackupName [* **/v** *{Integer* | **HIGHEST_VERSION** *}] [* **/e** *EncryptionPassword] [* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**Parameters**
**/b** *BackupName*

Specifies the name of the backup copy.

**/v** *{Integer* | **HIGHEST_VERSION** *}*

Specifies the version number of the backup copy. HIGHEST_VERSION is the default.

| **Integer** | **Specifies the version number of the backup copy.** |
|---|---|
| HIGHEST_VERSION | Specifies the backup copy with the highest version number. |

**/e** *Encryption Password*

Provides the password of an encrypted backup copy. When the session key in a backup copy is encrypted, you must provide its password to use the copy in the **/restore** operation.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. The default is the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Examples**
**Example 1:**
The following command restores the IIS configuration from the TestBkp, version 3 backup copy. It uses the **/b** parameter to specify the name of the backup copy and the **/v** parameter to specify the version.

**iisback /restore /b TestBkp /v 3**

In response, **iisback** displays the following success message, indicating that the IIS configuration is restored:

```
Backup TestBkp version 3 has been RESTORED.
```

To verify that the configuration is restored, compare the current configuration, which is stored in *systemroot*\System32\inetsrv\MetaBase.xml and MBSchema.xml, with the backup copy files, TestBkp.MD3 and TestBkp.SC3, in the *systemroot*\System32\inetsrv\MetaBack directory.

**Example 2:**
The following command restores the IIS configuration from the Svr01Bkp, version 15 backup copy. The **/b** parameter is required to specify the backup copy name and the **/e** parameter to specify the backup password, 7W*48Hv6#. This command omits the **/v** parameter and uses the default value, HIGHEST_VERSION.

**iisback /restore /b Svr01Bkp /e 7W*48Hv6#**

In response, **iisback** displays the following success message, indicating that the IIS configuration is restored:

```
Backup Svr01Bkp version HIGHEST_VERSION has been RESTORED.
```

**Related Information**

# Deleting IIS Backup Configurations Using Iisback.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisback.vbs, which is stored in *systemroot*\System32, to delete the backup IIS configuration of a local or remote computer.

Deleting backup files moves the files from the *systemroot*\System32\inetsrv\MetaBack directory to the Recycle Bin. It does not affect the files that are in the *systemroot*\System32\inetsrv\MetaBack\History directory.

Iisback.vbs performs the same delete operations that are available in IIS Manager. You can use either tool to view and manage backup copies.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Overview: Key concepts in understanding the backup and restore procedures.
- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Overview**

Each backup operation creates two files, an .MDx file to store the metabase and an .SCx file to store the schema, where the x is the version number of the backup copy. IIS and iisback.vbs store backup copy files in the *systemroot*\System32\inetsrv\MetaBack directory.

The metabase and schema of an IIS configuration include system-specific and session-specific properties. Do not copy or import the metabase or schema of one IIS server to another IIS server without modification. To copy all or part of a metabase configuration from one system to another, use Copying IIS Configurations Using Iiscnfg.vbs.

To prevent unauthorized use of backup copies, you can use IIS 5.1 or IIS 6.0, and iisback.vbs to encrypt the backup copy with a password. The password encrypts the session key which, in turn, encrypts all of the properties for which the secure attribute is set.

You can read an encrypted backup copy (only the session key and secure properties are encrypted), and you can delete the files. However, you cannot use the backup copy in a restore operation unless you provide the encrypting password. Also, you cannot remove the password encryption from a backup copy or change the encrypting password.

If you do not use password encryption, the session key and secure properties are encrypted with a blank password, which prevents you from reading these values but allows any member of the Administrators group to restore the metabase from the backup copy. IIS 5.1 and IIS 6.0. do not support machine key encryption of backup copies.

**Syntax**

**iisback /delete** *[* **/b** *BackupName] [* **/v** *{Integer* | **HIGHEST_VERSION}** *] [* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**Parameters**

**/b** *BackupName*

Required. Specifies the name of the backup copy.

**/v** *{Integer* | **HIGHEST_VERSION** *}*

Required. Specifies the version number of the backup copy.

| Integer | Specifies the version number of the backup copy. |
|---|---|
| HIGHEST_VERSION | Indicates the backup copy with the highest version number. |

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. The default is the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Examples**
**Example 1:**
The following command deletes the Svr01Bkp, version 0 backup copy. It uses the **/b** parameter to specify the Svr01Bkp series and the **/v** parameter to specify the version number. Both parameters are required to identify the backup copy.

**iisback /delete /b Svr01Bkp /v 0**

In response, **iisback** displays the following message, indicating that the backup copy is deleted:

```
Backup Svr01Bkp version 0 has been DELETED.
```

**Example 2**
This example demonstrates the use of a simple batch file command to delete a series of backup copies of the IIS configuration. You can use this command to delete old files from your archive. You can type the command at the command line or save it in a batch file.

```
For /L %%i in (0, 1, 15) do iisback /delete /b Svr01Bkp /v %%i
```

This batch command deletes Svr01Bkp versions 1 through 15 by issuing the **iisback /delete** command fifteen times, once for each version.

For a more practical application, make the backup name and version numbers variable. Or, use a **dir** or Listing IIS Backup Configurations Using Iisback.vbs command to detect the backup with the lowest version number, and then append a command that deletes the oldest backup copy (lowest version number) to each command to create a new backup copy.

**Related Information**

- For information about backing up IIS configurations, see Backing Up IIS Configurations Using Iisback.vbs.

# Listing IIS Backup Configurations Using Iisback.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisback.vbs, which is stored in *systemroot*\System32, to list backup copies of the IIS configuration (metabase and schema) of a remote or local computer.

The **/list** operation lists only the backup copies that are stored in the default location, *systemroot*\System32\Inetsrv\MetaBack. If you move the backup copy files to a different directory, the backup copy does not appear in the list.

Iisback.vbs performs the same backup and restore operations that are available in IIS Manager. You can use either tool to view and manage backup copies.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Example: Sample code and an explanation of the results.

**Syntax**

**iisback /list** *[* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**Parameters**

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. The default is the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Example**

The following command lists the backup copies that are stored on the remote server, Svr16. It uses the **/s** parameter to specify the server name, the **/u** parameter to specify the user's Administrator account, and the **/p** parameter to specify the password for the Administrator account.

**iisback /list /s Svr16 /u Domain06\User1 /p R34*9W@4b**

In response, **iisback** displays all of the backup copies that are on the remote server, Svr16:

```
Backup Name Version # Date and Time

AsiaSvr 0 12/8/2001 9:18:25 PM

AsiaSvr 1 1/14/2001 9:02:33 PM

Svr01Bkp 11 1/3/2001 3:00:42 AM
```

```
Svr01Bkp 12 1/4/2001 3:00:12 AM

Svr01Bkp 13 1/5/2001 3:01:00 AM

Svr01Bkp 14 1/6/2001 3:00:00 AM

Svr01Bkp 15 1/9/2001 5:18:04 AM
```

| **Note** |
| --- |
| **iisback /list** uses Coordinated Universal Time (UTC) for date and time stamps. Also, without parameters, the **iisback /list** command lists all of the backup copies that are stored on the local computer. |

**Related Information**

# Copying IIS Configurations Using Iiscnfg.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iiscnfg.vbs, which is stored in *systemroot*\System32, to copy the IIS metabase and schema from one computer to another. Both computers must be running a member of the Windows Server 2003 family with IIS 6.0.

By default, iiscnfg.vbs copies the metabase of the local computer to the target computer that is specified by the **/ts** parameter. However, you can use the **/s** parameter to copy the metabase of another computer to the target computer.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer\Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Overview: Key concepts in understanding the copy procedures.
- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Overview**

The **/copy** operation uses iisback.vbs to make a backup copy of the source metabase and the schema. Afterward, it copies the backup copy files (.MDx and .SCx) to the target computer and uses iisback.vbs to replace the metabase and schema of the target computer with the backup copy.

Although you can do these operations manually, **/copy** provides a convenient one-step method to replicate an IIS configuration. The **/copy** operation replaces the features of iissync.exe, a tool formerly included in Windows.

The **/copy** operation does not copy the server content, such as Web pages and FTP files, that is associated with the IIS configuration. Instead, **/copy** changes the computer-specific and system-specific properties in the metabase so that they are valid on the target computer. However, it does not adjust the directory or file paths. As a result, paths in the configuration might not be valid on the target computer.

**Syntax**

**iiscnfg /copy /ts** *TargetComputer* **/tu** *TargetUser* **/tp** *TargetPassword* **[/s** *Computer* **[/u** *[Domain\]User* **[/p** *Password]]]*

**Parameters**

**/ts** *TargetComputer*

Required. Copies the IIS metabase to the specified computer. Type the IP address or computer name without backslashes.

**/tu** *TargetUser*

Required (even when the current user of the local computer is an administrator of the target computer). Specifies the account used to connect to the target computer. Type a user account in *[Domain]\User* format. This account must be a member of the Administrators group on the target computer.

**/tp** *TargetPassword*

Required. Specifies the password for the account that is specified by the **/tu** parameter.

**/s** *Computer*

Copies the IIS metabase of the specified remote computer to the target computer. This parameter runs the script on the remote computer. Type the name or IP address of a remote computer without backslashes. The default is the local computer.

**/u** *[Domain\]User*

Required only when the current user is not an administrator of the remote computer. Runs the script with the permissions of the specified user account. The default is the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter. If you omit this parameter, the script prompts you for the password and obscures the text you type.

**Examples**
**Example 1:**
The following example copies the IIS configuration of the local computer to the Svr01 server. The command uses the **/ts** parameter to identify the target server, and the **/tu** and **/tp** parameters to provide the user's administrator account and password on the Svr01 server.

**iiscnfg /copy /ts SVR01 /tu SVR01\Admin06 /tp P@ssWord6**

In response, **iiscnfg** displays a list of the steps it takes to copy the IIS configuration.

```
Microsoft (R) Windows Script Host Version 5.6

Copyright (C) Microsoft Corporation 1996-2001. All rights reserved.

Backing up server 127.0.0.1

cmd /c iisback /backup /b iisreplback /overwrite

Backup complete.

Mapping local drive D: to admin share on server 127.0.0.1

Mapping local drive E: to admin share on server Svr01

Copying backup files...

cmd /c copy /Y D:\System32\inetsrv\metaback\iisreplback.* E:\System32\inetsrv\metaback

Unmapping local drive D:

Restoring on server Svr01

cmd /c iisback /restore /s svr01 /u SVR01\Admin06 /p P@ssWord6 /b iisreplback

Restore complete.

Unmapping local drive E:
```

This display shows that **iiscnfg** issues commands to Backing Up IIS Configurations Using Iisback.vbs, first to create a backup copy of the metabase and schema and then to restore (or paste) it to the target computer. To do so, it must copy the backup copy files (iisreplback.*) to the target computer.

The IP address, 127.0.0.1, is the loopback address and refers generically to the local computer. This address is used only when copying the configuration of the local computer.

**Example 2:**
The following example copies the IIS configuration of a remote computer, Svr06, to the MainBkp server. The command uses the **/s** parameter to identify the remote computer and the **/u** parameter to provide the user's administrator password on the Svr06 computer. It also uses the **/ts** parameter to identify the target server, and the **/tu** and **/tp** parameters to provide the user's administrator account and password on the MainBkp server.

Please note that although the **/p** parameter is optional, the **/tp** parameter is required. If you omit it, the command fails.

**iiscnfg /copy /s Svr06 /u Domain01\Admin01 /ts MainBkp /tu MainBkp\Admin01 /tp P@ssWord6**

In response, **iiscnfg** prompts you for the password for the account specified by the **/u** parameter, which specifies the permissions under which the script runs, and then it displays a list of the steps it takes to copy the IIS configuration. The phrase "Restore complete" indicates that the **/copy** operation was successful.

```

# Importing IIS Configurations Using Iiscnfg.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iiscnfg.vbs, which is stored in *systemroot*\System32, to add configuration settings from an Extensible Markup Language (XML) metabase export file to the metabase of an IIS server.

The computer issuing the command must be running Microsoft Windows XP or a member of the Windows Server 2003 family. The computer that the command affects must be running a member of the Windows Server 2003 family with IIS 6.0.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Overview: Key concepts in understanding the copy procedures.
- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Overview**

The metabase of an IIS server includes system-specific and computer-specific properties. Do not export the configuration of one IIS server to another IIS server without modification. Instead, use Backing Up IIS Configurations Using Iisback.vbs or the Importing IIS Configurations Using Iiscnfg.vbs**/copy** operation, which replaces system-specific and computer-specific properties so that the configuration is valid on the destination computer.

Changes made by using iiscnfg.vbs are effective immediately, but they aren't reflected in the MetaBase.xml file until the file is updated (every five minutes or every 50 changes). Use **iiscnfg /save** to review your changes immediately.

**Syntax**

**iiscnfg /import /f** *[Path\]FileName.xml* **/sp** *SourcePath* **/dp** *DestiniationPath[* **/d** *EncryptingPassword] [* **/inherited** *] [* **/children** *] [* **/merge** *][* **/s** *Computer [* **/u** *[Domain\]User [* **/p** *Password]]]*

**Parameters**

**/f** *[Path\]FileName.* **xml**

Required. Specifies the path and file name of the XML source file.

**/sp** *SourcePath*

Required. Specifies the location in the XML file of the keys being imported. Enter the metabase path as it appears in the XML file. To import all of the keys in the source file, enter the metabase path of the root key.

**/dp** *DestinationPath*

Required. Specifies the metabase path into which the keys are placed. Enter the metabase path as it appears in the XML file.

| **Note** |
| --- |

The imported key must be of the type expected in its new position in the metabase path. If the key is not of the expected type, the configuration will not operate properly. For example, do not import the event logging configuration (/LM/Logging) to a Web site configuration path, such as /LM/W3SVC/3. If you specify a path that already exists in the metabase, the imported keys overwrite and replace the keys currently in that metabase path, without warning.

**/d** *EncryptingPassword*

Required only when the configuration file is encrypted. Specifies the password that was used to encrypt the configuration data.

**/inherited**

Imports the inherited properties of the keys. This parameter is only effective when the source file includes inherited properties.

**/children**

Recursively imports the subkeys of the specified key.

**/merge**

Combines keys in the XML file with the existing metabase keys. Without this parameter, the keys in the XML file replace existing keys in the same metabase path. The **/merge** parameter adds keys to the metabase that appear only in the XML file, retains keys in the metabase that are not in the XML file, and applies the values in the XML file when a key appears in both the XML file and the metabase.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. The default is the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter. If you omit this parameter, the script prompts you for the password and obscures the text you type.

**Examples**
**Example 1:**
The following command imports the NewSite Web site configuration from C:\Config.xml file to the metabase. The command uses the **/f** parameter to specify the name and location of the source file. Next, it uses the **/sp** parameter to indicate that the configuration is in the /lm/w3svc/5/Root/NewSite path in the Config.xml file. Finally, it uses the **/dp** parameter to specify that the keys in that path should be placed in the /lm/w3svc/1/Root/401KApp location in the metabase.

**iiscnfg.vbs /import /f c:\config.xml /sp /lm/w3svc/5/Root/NewSite /dp /lm/w3svc/1/Root/401KApp**

In response, **iiscnfg** displays the following success message:

```
Configuration imported from /lm/w3svc/5/Root/NewSite in c:\config.xml to /lm/w3svc/1/Root/401KApp in the
Metabase.
```

As a result of this command, the NewSite configuration now appears in IIS as the first Web site, with metabase path W3SVC/1.

**Example 2:**
The following two-step example imports a custom logging configuration from C:\IISLogging.xml to the IIS metabase of a remote computer. You can use this method, or an extension of this method, to propagate a configuration to a group of servers.

The first command copies the IIsLogging.xml file to the remote server, Svr126.

**copy IIsLogging.xml \\Svr126\c$**

The second command imports IIsLogging.xml to the IIS configuration of Svr126. It uses the **/f** parameter to identify the source file, the **/sp** parameter to specify the /LM/Logging/Custom Logging metabase path to import, and the **/dp** parameter to place the imported keys in the same location in the target configuration, /LM/Logging/Custom Logging. (Use quotation marks to enclose path elements that include spaces.) Next, it uses the **/children** parameter to import all of the subkeys of the Logging

key. Finally, to act on Svr126, it uses the **/s** parameter to specify the server, and the **/u** and **/p** parameters to run the script with the permissions of the user's administrator account on the remote computer.

**iiscnfg /import /f C:\IISLogging.xml /sp "/lm/logging/custom logging" /dp "/lm/logging/custom logging" /children /s Svr126 /u Svr126\Administrator /p p@ssword1#**

In response, **iiscnfg** displays the following success message:

```
Connecting to server ... Done.

Configuration imported from /lm/logging/custom logging in file C:\IISLogging.xml to

/lm/logging/custom logging in the Metabase.
```

As a result, the /LM/Logging/Custom Logging key and its subkeys have been copied from the local metabase to the metabase of Svr126.

**Example 3:**
This example demonstrates how the **/merge** parameter works by comparing a standard **import** operation with an **import** operation that uses the **/merge** parameter. Both of the commands in this example update the properties of the Investments virtual directory of a Web site by using the same import file, Invest_vdir.xml.

The following sample shows the Investments metabase key before any import operations are run. (This sample is taken from a backup copy of the metabase created by using iisback.vbs).

**Metabase before import**

```
<IIsWebVirtualDir Location="/LM/W3SVC/1509060625/root/Investments"

AccessFlags="AccessRead | AccessScript"

AppFriendlyName="Investments"

AppIsolated="2"

AppRoot="/LM/W3SVC/1509060625/Root/Investments"

DirBrowseFlags="DirBrowseShowDate | DirBrowseShowTime | DirBrowseShowSize | DirBrowseShowExtension |
DirBrowseShowLongDate | EnableDefaultDoc"

Path="E:\public\Download"

>

</IIsWebVirtualDir>
```

The following sample shows the content of the Invest_vdir.xml file that will be used in the **/import** operations. (This sample was created by exporting the Investments metabase key and then editing the export file.) Please note that the following properties of the Investments key are changed in the XML file:

- The value of the **AccessFlags** property is changed.
- The **AuthFlags** property is added.
- The **DirBrowseFlags** property is omitted.

**Import File Content**

```
<IIsWebVirtualDir Location="/LM/W3SVC/1509060625/root/Investments"

AccessFlags="AccessRead"

AuthFlags="AuthAnonymous | AuthNTLM"

AppFriendlyName="Investments"

AppIsolated="2"

AppRoot="/LM/W3SVC/1509060625/Root/Investments"

Path="E:\public\Download"

>

</IIsWebVirtualDir>
```

Command 1: Standard Import

The following command imports the Invest_vdir.xml file to the metabase without using the **/merge** parameter. The command directs IIS to replace the Investments key in the metabase with the Investments key in the XML file. The command uses the **/f** parameter to specify the import file, and it uses the same metabase path in the source path (**/sp**) and destination path (**/dp**) parameters.

**iiscnfg /import /f e:\iistest\Invest_vdir.xml /sp /LM/W3SVC/1509060625/root/Investments /dp /LM/W3SVC/1509060625/root/Investments**

As a result of this command, the Investments key in the metabase is now identical to the Investments key in the Invest_vdir.xml import file.

Command 2: Import and merge

The following command merges the Investments key in the Invest_vdir.xml file to the metabase. The **/merge** parameter directs IIS to add new properties from the import file to the metabase, to leave the metabase properties that are not in the import file unchanged, and to apply the import file value when a property appears in both the import file and in the metabase. This command is identical to Command 1, except that the **/merge** parameter is added.

**iiscnfg /import /f e:\iistest\Invest_vdir.xml /sp /LM/W3SVC/1509060625/root/Investments /dp /LM/W3SVC/1509060625/root/Investments /merge**

As a result of this command, the content of the Investments key in the metabase is a combination of its sources, as shown in the following sample. Note that the following properties of the Investments key that are in the metabase are changed.

- The value of the **AccessFlags** property, which appeared in the metabase and the XML file, is changed. The value in the XML file now appears in the metabase.
- The **AuthFlags** property, which appeared only in the XML file, is added.
- The **DirBrowseFlags** property, which appeared only in the metabase, is unchanged.

```
<IIsWebVirtualDir Location="/LM/W3SVC/1509060625/root/Investments"

AccessFlags="AccessRead"

AppFriendlyName="Investments"

AppIsolated="2"

AppRoot="/LM/W3SVC/1509060625/Root/Investments"

AuthFlags="AuthAnonymous | AuthNTLM"

DirBrowseFlags="DirBrowseShowDate | DirBrowseShowTime | DirBrowseShowSize | DirBrowseShowExtension |
DirBrowseShowLongDate | EnableDefaultDoc"

Path="E:\public\Download"

>

</IIsWebVirtualDir>
```

# Exporting IIS Configurations Using Iiscnfg.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iiscnfg.vbs, which is stored in *systemroot*\System32, to copy all or part of an IIS metabase to an XML file, in an encrypted or unencrypted format. The XML file can be used in an **/import** operation to copy all or part of the metabase to another IIS configuration.

The computer issuing the command must be running Windows XP or a member of the Windows Server 2003 family. The computer that the command affects must be running a member of the Windows Server 2003 family with IIS 6.0.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Overview: Key concepts in understanding the export procedures.
- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Overview**

The metabase of an IIS server includes system-specific and computer-specific properties. Do not export the configuration of one IIS server to another IIS server without modification. Instead, use Backing Up IIS Configurations Using Iisback.vbs or the Exporting IIS Configurations Using Iiscnfg.vbs**/copy** operation, both of which replace system-specific and computer-specific properties so that the configuration is valid on the destination computer.

Iiscnfg.vbs provides an option to include inherited properties in the export file.

To prevent unauthorized use of export files, iiscnfg.vbs allows you to encrypt the export file with a password. The password encrypts the session key which, in turn, encrypts all of the properties for which the secure attribute is set.

You can read an encrypted export file (only the session key and secure properties are encrypted) and you can delete the file. However, you cannot use the export file in an **/import** operation unless you provide the encrypting password. Also, you cannot remove the password encryption from an export file or change the encrypting password.

The **/copy** operation changes the computer-specific and system-specific properties in the metabase so that they are valid on the target computer. However, it does not adjust the directory or file paths. As a result, paths in the configuration might not be valid on the target computer.

**Syntax**

**iiscnfg /export/f** *[Path\]FileName.***xml/sp** *SourcePath [***/d** *EncryptingPassword] [***/inherited***] [***/children***] [***/s** *Computer [***/u** *[Domain\]User [***/p** *Password]]]*

**Parameters**

**/f** *[Path\]FileName.* **xml**

Required. Specifies a unique name and location for the export file. If you specify an existing file or if the directories in the path you specify do not exist, the command fails. Also, the file path must be local. When exporting a file from a remote computer, the **/f** parameter refers to a path on the remote computer.

**/sp** *SourcePath*

Required. Specifies the metabase keys to export. Enter a metabase path, including /lm/ *root*, to indicate the selected keys.

**/d** *EncryptingPassword*

Encrypts the export file with the specified password. You can use any string as the password. The **/d** parameter creates a secure export file by encrypting the session key and secure properties with the specified password. You must provide the password to use the file in an **/import** operation.

If you omit this parameter or omit the password argument, then the export file is encrypted with a blank password. As a result, only the secure properties are encrypted and any administrator can use the export file to import a metabase configuration.

**/inherited**

Adds the inherited properties of the exported keys to the export file. Without this parameter, the export file does not include properties inherited from higher-level keys. If you select this option, iiscnfg.vbs adds the inherited properties of the exported keys to an IIsInheritedProperties key in the export file. When you import keys from this file, you can elect to import the inherited properties with the keys.

| **Note** |
| --- |
| When inherited properties are imported, the imported keys retain the properties they inherited in the exporting configuration. If inherited properties are not imported, the keys inherit the properties of the importing configuration. |

**/children**

Recursively adds the subkeys of the specified key to the export file.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. The default is the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter. If you omit this parameter, the script prompts you for the password and obscures the text you type.

**Examples**
**Example 1:**
The following example exports the configuration of the Finance Web site to the C:\Finance\Finance.xml file. The command uses the **/sp** parameter to specify the metabase path of the Web site, which is /lm/W3SVC/2, and the **/children** parameter to export all of the subkeys of the configuration. It also uses the **/inherited** parameter to include inherited properties in the export file. This ensures that the Web site configuration retains these properties even if it is imported into a different system.

**iiscnfg /export /f c:\finance\finance.xml /sp /lm/w3svc/2 /children /inherited**

In response, **iiscnfg** displays the following success message:

```
Configuration exported from /lm/w3svc/2 to file c:\finance\finance.xml
```

The resulting file includes all of the keys and subkeys within the /lm/w3svc/2 path. It also includes an IisInheritedProperties key that contains the values of all of the inherited properties.

**Example 2:**
The following example exports the IIS configuration of the local computer to the D:\IIStest\Config.xml file. It uses the **/f** parameter to specify the file name and location and the **/sp** parameter to specify the root key (**/**) of the metabase. The **/children** parameter adds all of the subkeys of the root key recursively to the export file. (Without the /children parameter, only the root key is exported.) Finally, the command uses the **/d** parameter and a password to encrypt the export file.

**iiscnfg /export /f d:\iistest\config.xml /sp / /children /d p@sswoRd61**

In response, **iiscnfg** displays the following success message:

```
Configuration / has been exported to d:\iistest\config.xml
```

Even a complete export of the configuration is not identical to the MetaBase.xml file for the system. The session key, access control lists (ACLs), and passwords differ.

You cannot tell by looking at the export file that it is encrypted. However, if you compare an encrypted and unencrypted version of the same file, you can see that the values of the secure properties are changed in the encrypted version. Therefore, the file cannot be used in an import command without the password.

**Related Information**

- For information about copying IIS configurations, see Copying IIS Configurations Using Iiscnfg.vbs.
- For information about importing IIS configurations, see Importing IIS Configurations Using Iiscnfg.vbs.
- For information about saving IIS configurations, see Saving Configurations to Disk Using Iiscnfg.vbs.

# Saving Configurations to Disk Using Iiscnfg.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iiscnfg.vbs, which is stored in *systemroot*\System32, to immediately save configuration changes to disk. Administrators can use this script tool to make changes immediately visible in the metabase.xml.

Iiscnfg.vbs performs the same backup and restore operations that are available in IIS Manager. You can use either tool to view and manage backup copies.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:MyComputer\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Overview: Key concepts in understanding the backup and restore procedures.
- Syntax: The order in which you type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Overview**

Any changes that are made to the metabase, whether by using scripts or IIS Manager, are written to memory first and to disk at the next scheduled update, which might be several minutes later. As a result, an administrator might make metabase changes and then open metabase.xml only to find the changes aren't reflected. The **/save** command in iiscnfg.vbs resolves the problem by saving changes to the disk immediately.

**Syntax**

**iiscnfg /save** *[* **/s** *Computer [* **/u** *[Domain\]User* **/p** *Password]]*

**Parameters**

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. The default is the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter.

**Examples**

**Example 1:**

The following command saves the IIS configuration to disk on the local computer:

**iiscnfg /save**

In response, **iiscnfg** displays the following message:

```
Configuration saved
```

**Example 2:**
The following command saves the IIS configuration to disk on the local computer:

**iiscnfg /save /s SourceServer /u Administrator /p Kj30W**

In response, **iiscnfg** displays the following message:

```
Configuration saved
```

**Related Information**

# Managing Applications and Web Service Extensions Using Scripts

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use two command-line scripts, which are stored in *systemroot*\system32, to configure and manage applications, Web service extensions, and individual files on computers running a member of the Microsoft Windows Server™ 2003 family with Internet Information Services (IIS) 6.0.

Iisext.vbs can enable and list applications; add and remove application dependencies; enable, disable, and list Web service extensions; and add, remove, enable, disable, and list individual files.

Iisapp.vbs can list applications that are running.

This section includes the following information:

- Enabling Applications Using Iisext.vbs: Describes how to enable applications on local or remote computers using iisext.vbs.
- Listing Applications Using Iisext.vbs: Describes how to list applications on local or remote computers using iisext.vbs.
- Adding Application Dependencies Using Iisext.vbs: Describes how to add application dependencies on local or remote computers using iisext.vbs.
- Removing Application Dependencies Using Iisext.vbs: Describes how to remove application dependencies on local or remote computers using iisext.vbs.
- Enabling Web Service Extensions Using Iisext.vbs: Describes how to enable Web service extensions on local or remote computers using iisext.vbs.
- Disabling Web Service Extensions Using Iisext.vbs: Describes how to disable Web service extensions on local or remote computers using iisext.vbs.
- Listing Web Service Extensions Using Iisext.vbs: Describes how to list Web service extensions on local or remote computers using iisext.vbs.
- Adding Web Service Extension Files Using Iisext.vbs: Describes how to add Web service extension files on local or remote computers using iisext.vbs.
- Enabling Web Service Extension Files Using Iisext.vbs: Describes how to enable Web service extension files on local or remote computers using iisext.vbs.
- Removing Web Service Extension Files Using Iisext.vbs: Describes how to remove Web service extension files on local or remote computers using iisext.vbs.
- Listing Web Service Extension Files Using Iisext.vbs: Describes how to list Web service extension files on local or remote computers using iisext.vbs.
- Listing Running Web Applications Using Iisapp.vbs: Describes how to list applications currently running on local or remote computers using iisapp.vbs.

# Enabling Applications Using Iisext.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisext.vbs, which is stored in *systemroot*\system32, to enable applications on computers running a member of the Windows Server 2003 family with IIS 6.0. The application must have at least one preexisting dependency in the ApplicationDependencies Metabase Property.

Iisext.vbs performs the same operations that are available in IIS Manager. You can use either tool to administer IIS Web sites.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:MyComputer\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you must type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**
**iisext /EnApp** *Application [* **/s** *Computer [* **/u** *[Domain\]User [* **/p** *Password]]]*

**Parameters**
*Application*

Required. Specifies the name of the application to be enabled.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter. If you omit this parameter, the script prompts you for the password and obscures the text you type.

**Examples**
**Example 1:**
The following command enables the application "Payroll" on the local computer:

**iisext /EnApp Payroll**

In response, **iisext** displays the following:

```
Connecting to server ...Done.

Enabling application complete.
```

**Example 2:**
The following command enables the application "TravelPlans" on a remote computer:

**iisext /EnApp TravelPlans /s RemoteComputer /u Manager /p Pa$$Werd**

In response, **iisext** displays the following:

```
Connecting to server ...Done.

Enabling application complete.
```

**Related Information**

- For information about listing applications, see Listing Applications Using Iisext.vbs.

# Listing Applications Using Iisext.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisext.vbs, which is stored in *systemroot*\system32, to list applications that can be enabled on computers running a member of the Windows Server 2003 family with IIS 6.0. These applications are listed in the ApplicationDependencies Metabase Property.

Iisext.vbs performs the same operations that are available in IIS Manager. You can use either tool to administer IIS Web sites.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you must type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Example: Sample code and an explanation of the results.

**Syntax**

**iisext /ListApp** *[* **/s** *Computer [* **/u** *[Domain* **** *]User [* **/p** *Password]]]*

**Parameters**

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain* **** *]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter. If you omit this parameter, the script prompts you for the password and obscures the text you type.

**Example**

The following command lists all of the applications that are in ApplicationDependencies Metabase Property on the local computer:

**iisext /ListApp**

In response, **iisext** displays all of the applications that are on the local computer.

```
Connecting to server ...Done

Active Server Pages

Internet Data Connector

Server Side Includes

WebDAV

Payroll
```

TravelPlans

# Adding Application Dependencies Using Iisext.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisext.vbs, which is stored in *systemroot*\system32, to add dependencies between applications and one or more Web service extensions on computers running a member of the Windows Server 2003 family with IIS 6.0. If the application does not exist in the ApplicationDependencies Metabase Property, **iisext** will create it.

Iisext.vbs performs the same operations that are available in IIS Manager. You can use either tool to administer IIS Web sites.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer***\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you must type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**

**iisext /AddDep** *Application ID [ID] [* **/s** *Computer [* **/u** *[Domain\]User [* **/p** *Password]]]*

**Parameters**

*Application*

Required. Specifies the name of the application that is dependent on a Web service extension.

*ID*

Required. Specifies the ID of the Web service extension upon which the application is dependent. Additional dependencies are optional.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter. If you omit this parameter, the script prompts you for the password and obscures the text you type.

**Examples**

**Example 1:**

The following command makes the application "Payroll" dependent on the Web service extension "timesheet" on the local computer. In this example, the files that are required for the Web service extension "timesheet" were previously added to and enabled on the local computer.

**iisext /AddDep Payroll timesheet**

In response, **iisext** displays the following:

```
Connecting to server ...Done.

Adding dependency complete.
```

**Example 2:**
The following command makes the application "TravelPlans" dependent on the Web service extensions "FlightSchedules" and "HotelRooms" on a remote computer. In this example, the files that are required for the Web service extensions "FlightSchedules" and "HotelRooms" were previously added to and enabled on the remote computer.

**iisext /AddDep TravelPlans FlightSchedules HotelRooms /s RemoteComputer /u Manager /p Pa$$Werd**

In response, **iisext** displays the following:

```
Connecting to server ...Done.

Adding dependency complete.
```

**Related Information**

- For information about removing application dependencies, see Removing Application Dependencies Using Iisext.vbs.

# Removing Application Dependencies Using Iisext.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisext.vbs, which is stored in *systemroot*\system32, to remove dependencies between applications and one or more Web service extensions on computers running a member of the Windows Server 2003 family with IIS 6.0.

Iisext.vbs performs the same operations that are available in IIS Manager. You can use either tool to administer IIS Web sites.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you must type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**

**iisext /RmDep** *Application ID [ID] [* **/s** *Computer [* **/u** *[Domain* **** *]User [* **/p** *Password]]]*

**Parameters**

*Application*

Required. Specifies the name of the application that is dependent on a Web service extension.

*ID*

Required. Specifies the ID of the Web service extension upon which the application is dependent. Additional dependencies are optional.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain* **** *]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter. If you omit this parameter, the script prompts you for the password and obscures the text you type.

**Examples**

**Example 1:**

The following command removes the dependency of the application "Payroll" on the Web service extension "timesheet" on the local computer:

**iisext /RmDep Payroll timesheet**

In response, **iisext** displays the following:

```
Connecting to server ...Done.

Removing dependency complete.
```

**Example 2:**
The following command removes the dependency of the application "TravelPlans" on the Web service extensions "FlightSchedules" and "HotelRooms" on a remote computer:

**iisext /RmDep TravelPlans FlightSchedules HotelRooms /s RemoteComputer /u Manager /p Pa$$Werd**

In response, **iisext** displays the following:

```
Connecting to server ...Done.

Removing dependency complete.
```

**Related Information**

- For information about adding application dependencies, see Adding Application Dependencies Using Iisext.vbs.

# Enabling Web Service Extensions Using Iisext.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisext.vbs, which is stored in *systemroot*\system32, to enable a Web service extension. The Web service extension must have at least one file associated with it in the WebSvcExtRestrictionList Metabase Property. The command can be executed on local or remote computers running a member of the Windows Server 2003 family with IIS 6.0.

Iisext.vbs performs the same operations that are available in IIS Manager. You can use either tool to administer IIS Web sites.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you must type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**

**iisext /EnExt** *ID [* **/s** *Computer [* **/u** *[Domain\]User [* **/p** *Password]]]*

**Parameters**

*ID*

Required. Specifies the ID of the Web service extension that is going to be enabled.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter. If you omit this parameter, the script prompts you for the password and obscures the text you type.

**Examples**

**Example 1:**

The following command enables the Web service extension "Payroll" on the local computer:

**iisext /EnExt Payroll**

In response, **iisext** displays the following:

```
Connecting to server ...Done.

Enabling extension complete.
```

**Example 2:**

The following command enables the Web service extension "Inventory" on a remote computer:

**iisext /EnExt Inventory /s RemoteComputer /u Manager /p Pa$$Werd**

In response, **iisext** displays the following:

```
Connecting to server ...Done.

Enabling extension complete.
```

**Related Information**

- For information about listing Web service extensions, see Listing Web Service Extensions Using Iisext.vbs.

# Disabling Web Service Extensions Using Iisext.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisext.vbs, which is stored in *systemroot*\system32, to disable a Web service extension by disabling all of the files with a specific Web service extension ID. The command can be executed on local or remote computers running a member of the Windows Server 2003 family with IIS 6.0.

Iisext.vbs performs the same operations that are available in IIS Manager. You can use either tool to administer IIS Web sites.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:MyComputer\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you must type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**
**iisext /DisExt** *ID [* **/s** *Computer [* **/u** *[Domain\]User [* **/p** *Password]]]*

**Parameters**
*ID*

Required. Specifies the ID of the Web service extension that is going to be disabled.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter. If you omit this parameter, the script prompts you for the password and obscures the text you type.

**Examples**
**Example 1:**
The following command disables the Web service extension "FlightTimes" on the local computer:

**iisext /DisExt FlightTimes**

In response, **iisext** displays the following:

```
Connecting to server ...Done.

Disabling extension complete.
```

**Example 2:**
The following command disables the Web service extension "PassengerList" on a remote computer:

**iisext /DisExt PassengerList /s RemoteComputer /u Manager /p Pa$$Werd**

In response, **iisext** displays the following:

```
Connecting to server ...Done.

Disabling extension complete.
```

**Related Information**

# Listing Web Service Extensions Using Iisext.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisext.vbs, which is stored in *systemroot*\system32, to list Web service extension IDs for all of the defined Web service extensions. The extensions must reside on a computer running a member of the Windows Server 2003 family with IIS 6.0.

Iisext.vbs performs the same operations that are available in IIS Manager. You can use either tool to administer IIS Web sites.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:MyComputer\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you must type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Example: Sample code and an explanation of the results.

**Syntax**

**iisext /ListExt** *[* **/s** *Computer [* **/u** *[Domain* **** *]User [* **/p** *Password]]]*

**Parameters**

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain* **** *]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter. If you omit this parameter, the script prompts you for the password and obscures the text you type.

**Example**

The following command lists all of the Web service extension IDs that are in the **WebSvcExtRestrictionList** property of the metabase on the local computer:

**iisext /ListExt**

In response, **iisext** displays all of the Web service extension IDs that are on the local computer.

```
Connecting to server ...Done

SSINC

Payroll

ASP

Inventory

ASP.NET
```

```
WEBDAV

HTTPODBC
```

# Adding Web Service Extension Files Using Iisext.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisext.vbs, which is stored in *systemroot*\system32, to add a single file to the WebSvcExtRestrictionList Metabase Property. The command can be executed on local or remote computers running a member of the Windows Server 2003 family with IIS 6.0. Web service extension files can be either ISAPI extensions or CGI files.

Iisext.vbs performs the same operations that are available in IIS Manager. You can use either tool to administer IIS Web sites.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:***MyComputer***\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you must type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**

**iisext /AddFile** *Drive:\Path\FileName Access {0|1} ID Deletable {0|1} ShortDesc*[**/s** *computer* [**/u** *[domain\]user***/p** *password]]*

**Parameters**

*Drive:\Path\FileName*

Required. Specifies the file name and the path of the Web service extension file that is going to be added.

*Access*

Required. Numerically designates whether the file is disabled (set to 0) or enabled (set to 1) after it is added.

*ID*

Required. Specifies the ID of the Web service extension that is associated with the file.

*Deletable*

Required. Numerically designates whether the file can be deleted from the Web service extension restriction list by using **iisext** or IIS Manager. Set to 0 to prevent the file from being deleted, or set to 1 to allow the file to be deleted.

*ShortDesc*

Required. A short description of the Web service extension that is associated with the file. This text can be localized, and it should be the same for all of the files that are associated with the same Web service extension.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter. If you omit this parameter, the script prompts you for the password and obscures the text you type.

**/?**

Displays Help at the command prompt.

**Examples**
**Example 1:**
The following command adds the file "Timesheet.exe" to the **WebSvcExtRestrictionList** property of the metabase on the local computer. The *Access* flag is set to "0" to disable the file on startup, the *ID* flag identifies the associated Web service extension as "Payroll", and the *Deletable* flag is set to "1" to allow the file to be deleted from the list of Web service extensions.

**iisext /AddFile c:\Source\Timesheet.exe 0 Payroll 1 Payroll**

In response, **iisext** displays the following:

```
Connecting to server …Done.

Adding extension file complete.
```

**Example 2:**
The following command adds the file "Payscale.dll" to the **WebSvcExtRestrictionList** property of the metabase on a remote computer. The *Access* flag is set to "1" to enable the file on startup, the *ID* flag identifies the associated Web service extension as "Payroll", and the *Deletable* flag is set to "0" to prevent the file from being deleted from the list of Web service extensions.

**iisext /AddFile c:\Source\Payscale.dll 1 Payroll 0 Payroll /s RemoteComputer /u Manager /p Pa$$Werd**

In response, **iisext** displays the following:

```
Connecting to server ...Done.

Adding extension file complete.
```

# Enabling Web Service Extension Files Using Iisext.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisext.vbs, which is stored in *systemroot*\system32, to enable a single file that is in the WebSvcExtRestrictionList Metabase Property property of the metabase. The command can be executed on local or remote computers running a member of the Windows Server 2003 family with IIS 6.0. Web service extension files can be either ISAPI extensions or CGI files.

Iisext.vbs performs the same operations that are available in IIS Manager. You can use either tool to administer IIS Web sites.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:MyComputer\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you must type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**
**iisext /EnFile** *Drive:\Path\FileName [* **/s** *computer [* **/u** *[domain\]user* **/p** *password]]*

**Parameters**
*Drive:\Path\FileName*

Required. Specifies the file name and the path of the Web service extension file that is going to be enabled.

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter. If you omit this parameter, the script prompts you for the password and obscures the text you type.

**Examples**
**Example 1:**
The following command enables the file "Timesheet.exe" in the WebSvcExtRestrictionList Metabase Property on the local computer:

**iisext /EnFile c:\Source\Timesheet.exe**

In response, **iisext** displays the following:

```
Connecting to server ...Done.

Enabling extension file complete.
```

**Example 2:**
The following command enables the file "Taxes.dll" in the WebSvcExtRestrictionList Metabase Property on a remote computer:

**iisext /EnFile c:\Source\Taxes.dll /s RemoteComputer /u Manager /p Pa$$Werd**

In response, **iisext** displays the following:

```
Connecting to server ...Done.

Enabling extension file complete.
```

**Related Information**

# Removing Web Service Extension Files Using Iisext.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisext.vbs, which is stored in *systemroot*\system32, to remove a single deleteable file from the WebSvcExtRestrictionList Metabase Property. The command can be executed on local or remote computers running a member of the Windows Server 2003 family with IIS 6.0. Web service extension files can be either ISAPI extensions or CGI files.

Iisext.vbs performs the same operations that are available in IIS Manager. You can use either tool to administer IIS Web sites.

**Important**

You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:MyComputer\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters).

This topic includes the following information:

- Syntax: The order in which you must type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**

**iisext /RmFile** *Drive:\Path\FileName [* **/s** *Computer [* **/u** *[Domain\]User [* **/p** *Password]]]*

**Parameters**

*Drive\Path\FileName*

Required. Specifies the file name and the path of the Web service extension file that is going to be removed from the Web service extension restriction list (**WebSvcExtRestrictionList**).

**Note**

If the file has been flagged as undeletable, **iisext** returns the error message, "Error trying to delete extension. Make sure it exists and is deletable."

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain\]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is specified in the **/u** parameter. If you omit this parameter, the script prompts you for the password and obscures the text you type.

**Examples**

**Example 1:**

The following command removes the file "Accounting.dll" from the **WebSvcExtRestrictionList** property of the metabase on the local computer:

**iisext /RmFile c:\Source\Accounting.dll**

In response, **iisext** displays the following:

```
Connecting to server ...Done.

Removing extension file complete.
```

**Example 2:**
The following command removes the file "Taxes.exe" from the **WebSvcExtRestrictionList** property of the metabase on a remote computer:

**iisext /RmFile c:\Source\Taxes.exe /s RemoteComputer /u Manager /p Pa$$Werd**

In response, **iisext** displays the following:

```
Connecting to server ...Done.

Removing extension file complete.
```

# Listing Web Service Extension Files Using Iisext.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisext.vbs, which is stored in *systemroot*\system32, to list the Web service extension files that are in the WebSvcExtRestrictionList Metabase Property. The command can be executed on local or remote computers running a member of the Windows Server 2003 family with IIS 6.0. Web service extension files can be either ISAPI extensions or CGI files.

Iisext.vbs performs the same operations that are available in IIS Manager. You can use either tool to administer IIS Web sites.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:MyComputer\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you must type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Example: Sample code and an explanation of the results.

**Syntax**

**iisext /ListFile** *[* **/s** *Computer [* **/u** *[Domain\]User [* **/p** *Password]]]*

**Parameters**

**/s** *Computer*

Runs the script on the specified remote computer. Type the computer name or IP address without backslashes. By default, the script runs on the local computer.

**/u** *[Domain* **** *]User*

Runs the script with the permissions of the specified user account. This account must be a member of the Administrators group on the remote computer. By default, the script runs with the permissions of the current user of the local computer.

**/p** *Password*

Specifies the password of the user account that is pecified in the **/u** parameter. If you omit this parameter, the script prompts you for the password and obscures the text you type.

**Example**

The following command lists all of the Web service extension files that are in the **WebSvcExtRestrictionList** property of the metabase on the local computer:

**iisext /ListFile**

In response, **iisext** displays all of the Web service extension files that are on the local computer.

```
Connecting to server ...Done

E:\Windows\system32\inetsrv\asp.dll

E:\Windows\system32\inetsrv\httpodbc.dll

E:\Windows\system32\inetsrv\ssinc.dll

E:\Windows\system32\inetsrv\httpext.dll
```

```
E:\Windows\system32\Microsoft.NET\Framework\v1.0.3705\aspnet_isapi.dll

c:\Source\Taxes.dll

c:\Source\Accounting.dll

c:\Source\Taxes.exe

c:\Source\Timesheet.exe

c:\Source\Payscale.dll
```

# Listing Running Web Applications Using Iisapp.vbs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the command-line script iisapp.vbs, which is stored in *systemroot*\system32, to view any worker processes that are currently running. This command is often used for troubleshooting.

The computer issuing the command must be running Windows XP or a member of the Windows Server 2003 family. The computer that the command affects must be running a member of the Windows Server 2003 family with IIS 6.0.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /***User:MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

This topic includes the following information:

- Syntax: The order in which you must type a command and any arguments and options that follow it.
- Parameters: The values that are given to variables in the command.
- Examples: Sample code and an explanation of the results.

**Syntax**
**iisapp** *[* **/a** *AppPoolName* | **/p** *PID]*

**Parameters**
**/a** *AppPoolName*

Optional. Specifies the name of a particular application pool.

**/p** *PID*

Optional. Specifies an application pool by its ID number.

**Examples**
**Example 1:**
The following command displays all of the application pools that are running on the local computer:

**iisapp**

In response, **iisapp** displays all of the currently running applications, identifying each application pool by its process ID (PID) and application pool ID (AppPoolID). **Iisapp** omits all of the optional parameters and accepts the default values.

```
W3wp.exe PID: 2232 AppPoolID: DefaultAppPool

W3wp.exe PID: 2608 AppPoolID: MyAppPool
```

**Example 2:**
Use the following command to view a specific application by entering its PID:

**iisapp /p 2608**

In response, **iisapp** displays the specified application.

**W3wp.exe PID: 2608 AppPoolID: MyAppPool**

# Administering IIS Programmatically

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Graphical user interfaces (GUIs) on your computer—such as Internet Information Services (IIS) Manager, Computer Management Console, Control Panel, or Windows Explorer—help you manage and configure your settings. However, if you manage systems frequently or access large amounts of data on numerous servers, then using a collection of GUIs can be time consuming. In these cases, it is faster to use command-line scripts that can change single or multiple systems programmatically.

For example, using IIS Manager to add a script mapping to 20 Web servers will take many mouse clicks and key strokes. However, using a command-line script that takes an input file containing the names of your Web servers and the name of the property you want to change, you can make all of these changes from one server with a single command.

IIS 6.0 comes with three programmatic interfaces (also called providers), Windows Management Instrumentation (WMI), Active Directory Service Interface (ADSI), and Administrative Base Objects (ABO). Because the ABO interface can only be accessed from a compiled application, ABO is only discussed in the IIS SDK.

By using the WMI and ADSI providers, you can efficiently monitor the IIS metabase, and access and configure settings from within a command-line script or compiled application.

**The IIS WMI Provider**

Windows Management Instrumentation (WMI) is a technology that allows administrators to programmatically manage and configure the Windows operating system and Windows applications. Beginning with IIS 6.0, IIS includes a WMI provider that exposes programming interfaces that can be used to query and configure the IIS metabase.

**The IIS ADSI Provider**

The IIS ADSI provider exposes COM Automation objects that you can use within command-line scripts, ASP pages, or custom applications to change IIS configuration values stored in the IIS metabase. IIS ADSI objects can be accessed and manipulated by any language that supports automation, such as Microsoft® Visual Basic® Scripting Edition (VBScript), Microsoft JScript®, Perl, Microsoft Active Server Pages (ASP), Visual Basic, Java, or Microsoft C++.

**Comparing the ADSI and the IIS WMI Providers**

The following table compares the architecture and features of the IIS ADSI provider with those of the IIS WMI provider.

| Issue | IIS ADSI provider | IIS WMI provider |
|---|---|---|
| Query capabilities | No. ADSI has no provision for queries. | Yes. By querying on metabase key types, the IIS WMI provider returns only the data you need. |
| Object model and access routes | COM: Scripts and programs. | COM: Scripts, programs, and UI tools; for example, the WMI Object Browser. |
| Extensible schema | Yes. ADSI provider supports metabase schema extensions. | No. The IIS WMI provider can return existing schema extensions, but cannot extend the metabase schema. |
| Association or containment of related data | Properties are related to IIS metabase keys by containment.<br><br>You can use the ADSI container object methods of the IIS Admin Objects to manipulate keys in the IIS metabase. You can create, delete, and move keys by creating, deleting, and moving IIS Admin Objects within container objects. You can also enumerate contained objects, such as virtual directories or servers with container object methods. ADSI supports property inheritance. | Properties are related to IIS metabase keys by containment or by association. Also, in conjunction with other providers, WMI supports associations with managed objects not in the metabase.<br><br>An association in WMI describes a relationship between classes and is in itself defined by a class. This powerful concept allows management information about an entire system of associated components to be viewed and traversed for tasks such as troubleshooting. Navigating associations to other classes is not limited by containment. |

**Related Information**

- For more information about the IIS ADSI and IIS WMI providers, see IIS 6.0 Administration Scripts, Tips, and Tricks.
- For a more detailed comparison of the IIS ADSI and IIS WMI providers, see IIS Administration Technologies on MSDN.
- For detailed information about developing administrative scripts and applications using the IIS ADSI and IIS WMI providers, see Using IIS Programmatic Administration on MSDN.

# Security in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This section describes how to configure your Web server to strengthen the security of your Web sites and to carry out other essential security functions.

**In This Section**

This section includes the following information:

- IIS 6.0 Security Best Practices: Provides a list of best practices for securing your Web site and server.
- Authentication in IIS 6.0: Provides information about how to confirm the identity of users that are attempting to establish connections to restricted content.
- Access Control with IIS 6.0: Provides information about how users access and manipulate your resources.
- IIS 6.0 Encryption: Provides information about how to protect the privacy of your information with Secure Sockets Layer (SSL) encryption features.
- Certificates_IIS_SP1_Ops: Provides information about how to establish secure connections by using certificates and SSL features.
- Auditing in IIS 6.0: Provides information about how to monitor security activities to prevent tampering and unauthorized access.

Related Information

- For information about isolating server applications so that they will be run in a process that is separate from the Web server process, see Isolating Applications in IIS 6.0.
- For information about verifying the network name and address of your computer, see Domain Name Resolution.

# IIS 6.0 Security Best Practices

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

**General Best Practices**

- Log on with the least credentials. Log on to your computer using an account that is not in the Administrators group, and then use the **Run as** command to run IIS Manager as an administrator.
- Reduce the attack surface. Disable all services you do not need, including IIS services such as FTP, NNTP or SMTP. If a feature or service is not enabled, then there is no need to secure it.
- Do not download or run programs from untrusted sources. Programs can contain instructions to violate security in a number of ways including data theft, denial of service, and data destruction.
- Keep virus scanners up to date. Virus scanners frequently identify infected files by scanning for a signature that is a known component of a previously identified virus. The scanners keep these virus signatures in a signature file, which is usually stored on the local hard disk. Because new viruses are discovered frequently, this file should also be updated frequently for the virus scanner to easily identify all current viruses.
- Keep current with all software updates. Software updates provide solutions to known security issues. Check software provider Web sites periodically to see if there are new updates available for software used in your organization.
    - The new process model in IIS 6.0 includes process recycling, which means an administrator can easily install most IIS updates and most new worker process DLLs without any interruption of service.
    - Auto Update version 1.0 provides three options to customers: notify update availability the moment it is available; download the update, and notify that it has been downloaded; and scheduled install. For more information, see "Windows Automatic Updates" in Help and Support Center for Windows Server 2003.
- Use NTFS. The NTFS file system is more secure than the FAT or FAT32 file system.
- Assign strong NTFS permissions for your resources.
- Exercise caution with domain controllers. If you use a domain controller as an application server, be aware that if security is compromised on the domain controller, then security is compromised on the entire domain.

**IIS Best Practices**

- Restrict write access permissions for the IUSR_*computername* account. This will help limit the access anonymous users have to your computer.
- Store executable files in a separate directory. This makes it easier to assign access permissions and audit for administrators.
- Create a group for all anonymous user accounts. You can deny access permissions to resources based on this group membership.
- Deny execute permissions for anonymous users to all executables in Windows directories and subdirectories.
- Use IP address restriction if administering IIS remotely. For more information, see Securing Sites with IP Address Restrictions.
- Assign the most restrictive permissions possible. For example, if your Web site is used only for viewing information,

assign only **Read** permissions. If a directory or site contains applications, assign **Scripts Only** permissions instead of **Scripts and Executables** permissions. For more information, see Securing Sites with Web Site Permissions.

- Do not assign **Write** and **Script source access** permissions or **Scripts and Executables** permissions. Use this combination with extreme caution. It can allow a user to upload potentially harmful executable files to your server and run them. For more information, see Securing Sites with Web Site Permissions.

- Enable data encryption in all WMI-based remote administration scripts. For more information, see Encrypting Data When Running WMI–Based Remote Administration Scripts.

- Ensure that the VeriSign Intermediate Root CA on your Web server is up to date. Verify the expiration date, and update the Intermediate Root CA if necessary. The new VeriSign Intermediate Root CA has the following properties:

  ```
  Issued to: www.verisign.com/CPS Incorp.by Ref. LIABILITY LTD.(c)97 VeriSign
  Issued by: Class 3 Public Primary Certification Authority
  Valid from: 4/16/97 to 10/24/11
  ```

  For information about verifying the expiration date, see Determining the Intermediate Root CA Version on a Web Server. For information about updating the Intermediate Root CA, see the VeriSign Support Web site.

**Related Information**

For information about security best practices for the Windows Server 2003 family, see "Security Best Practices" in Help and Support Center for Windows Server 2003.

# Authentication in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can require users to provide a valid Microsoft® Windows® user account name and password before they access any information about your server. This identification process is called authentication. Authentication can be set at the Web or FTP site, directory, or file level. IIS provides authentication methods to control access to your Web sites and FTP sites.

This section includes the following information:

- Anonymous Authentication in IIS 6.0: Describes how to configure anonymous authentication for IIS 6.0 and explains how to use the default anonymous user account, IUSR_*ComputerName*.
- Basic Authentication in IIS 6.0: Describes how to configure Basic authentication for IIS 6.0 and explains security considerations for the token cache.
- Digest Authentication in IIS 6.0: Describes how to configure both Digest authentication and sub-authentication in IIS 6.0.
- Advanced Digest Authentication in IIS 6.0: Describes how to configure Advanced Digest authentication in IIS 6.0.
- Integrated Windows Authentication in IIS 6.0: Describes how to configure Integrated Windows authentication in IIS 6.0. Integrated Windows authentication is the default authentication method for Windows Server™ 2003 operating systems.
- UNC Authentication in IIS 6.0: Describes how to configure UNC, or passthrough, authentication in IIS 6.0.
- .NET Passport Authentication in IIS 6.0: Describes how to configure .NET Passport authentication to work with IIS 6.0.
- FTP Site Authentication in IIS 6.0: Describes how to configure both anonymous and basic FTP site authentication in IIS 6.0.

# Anonymous Authentication in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Anonymous authentication gives users access to the public areas of your Web or FTP site without prompting them for a user name or password. By default, the IUSR_*computername* account is used to allow anonymous access.

In IIS 6.0, anonymous authentication no longer requires the Allow log on locally user right, because NETWORK_CLEARTEXT is now the default logon type for anonymous and basic authentication.

During setup, the IUSR_*computername* account is added to the Guests group on the computer running IIS. Guests have the same access as members of the Users group by default, except for the Guest account, which is further restricted.

This section includes the following information:

- Enabling Anonymous Authentication: Describes how to enable anonymous authentication for a Web site.
- Changing the Account Used for Anonymous Authentication: Describes how to configure an account for anonymous authentication.
- Configuring Subauthentication: Describes how to configure subauthentication to manage passwords for anonymous accounts.

# Enabling Anonymous Authentication

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use the following procedure to enable anonymous authentication for a Web site.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To enable Anonymous authentication**

1. In IIS Manager, double-click the local computer; right-click the **Web Sites** folder, an individual Web site folder, a virtual directory, or a file; and then click **Properties**.

   | **Note** |
   | --- |
   | Configuration settings made at the Web Sites level are inherited by all of the Web sites on the server. You can override inheritance by configuring the individual site or site element. |

2. Click the **Directory Security** or **File Security** tab, and then, in the **Authentication and access control** section, click **Edit**.
3. Select the **Enable anonymous access** check box.
4. Click **OK** twice.

**Related Information**

- For information about changing the account for anonymous authentication, see Changing the Account Used for Anonymous Authentication.
- For information about other types of authentication, see Authentication in IIS 6.0.

# Changing the Account Used for Anonymous Authentication

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can change the account that is used for Anonymous authentication in IIS Manager, either at the Web server service level or for individual virtual directories and files. You can also change the security settings for the IUSR_*computername* account in Windows by using the Group Policy Manager snap-in of the Microsoft Management Console (MMC). However, if the anonymous user account does not have permission to access a specific file or resource, your Web server will refuse to establish an anonymous connection for that resource. For more information, see Securing Sites with Web Site Permissions.

**Important**

When you change the IUSR_*computername* account, the changes affect every anonymous HTTP request that a Web server processes. Use caution if you modify this account.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To change the account used for anonymous authentication**

1. In IIS Manager, double-click the local computer; right-click the **Web Sites** folder, an individual Web site folder, a virtual directory, or a file; and then click **Properties**.

   **Note**

   Configuration settings made at the Web Sites level are inherited by all of the Web sites on the server. You can override inheritance by configuring the individual site or site element.

2. Click the **Directory Security** or **File Security** tab, and then, in the **Authentication and access control** section, click **Edit**.
3. Select the **Enable anonymous access** check box.
4. Click **Browse** and type or browse to the valid Windows user account that you want to use for anonymous access.
5. Click **OK** three times.

**Related Information**

- For information about enabling anonymous authentication, see Enabling Anonymous Authentication.
- For information about other types of authentication, see Authentication in IIS 6.0.

# Configuring Subauthentication

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Subauthentication enables IIS to manage passwords on anonymous accounts. In earlier versions of IIS, the subauthentication component, Iissuba.dll, was enabled by default.

Because using Iissuba.dll can create a security risk, IIS 6.0 does not enable subauthentication by default. However, you can use subauthentication to manage passwords for anonymous accounts by meeting the following requirements:

- For applications to which you grant anonymous access, the worker process runs as LocalSystem. For more information about configuring worker process identities, see Configuring Worker Process Identities.
- The subauthentication component, Iissuba.dll, is registered.
- The **AnonymousPasswordSync** metabase property on the IISWebService node is enabled (set to **true)**.

The process for configuring subauthentication differs depending on whether you are configuring it on a new installation of IIS 6.0 or after upgrading to IIS 6.0 from an earlier installation of IIS with subauthentication enabled.

This section includes the following information:

- Configuring Subauthentication on a New Installation of IIS 6.0: Describes how to configure subauthentication on a new installation of IIS 6.0.
- Configuring Subauthentication in IIS 5.0 Isolation Mode: Describes how to configure subauthentication on a new installation of IIS 6.0 that is configured to run in IIS 5.0 isolation mode.
- Configuring Subauthentication After Upgrading to IIS 6.0: Describes how to configure subauthentication after upgrading your server to IIS 6.0 from an earlier version of IIS that uses subauthentication.

# Configuring Subauthentication on a New Installation of IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

By default, after installing Windows Server 2003 and IIS 6.0, IIS runs in worker process isolation mode and subauthentication is disabled. Subauthentication is disabled when the AnonymousPasswordSync Metabase Property is set to **false**.

To enable anonymous password synchronization, ensure that your system meets the following requirements:

- The subauthentication component, Iissuba.dll, must be registered.
- The application pool of the Web site runs as the LocalSystem user account. However, running as the LocalSystem user account might be a security risk because it allows the worker process full access to the entire system.
- The AnonymousPasswordSync metabase property must be enabled (set to **true**).

**Procedures**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any known parameters). |

**To configure subauthentication and enable anonymous password synchronization**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd**, and click **OK**.
3. At the command prompt, type the following and then press ENTER:

   **rundll32 %systemroot%\system32\iissuba.dll,RegisterIISSUBA**

4. Set the identity of the application pool to the LocalSystem user account. For step-by-step information about setting the application pool identity, see Configuring Application Pool Identity in IIS 6.0.

   | **Important** |
   | --- |
   | Running as the LocalSystem user account might pose a security risk because it allows the worker process full access to the entire system. |

5. At the IisWebService node, set the AnonymousPasswordSync metabase property to **true**.

When you no longer want to use subauthentication, revoke the subauthentication components registration.

**To revoke the subauthentication components registration**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd**, and click **OK**.
3. At the command prompt, type the following and then press ENTER:

   **rundll32 %systemroot%\system32\iissuba.dll,UnregisterIISSUBA**

**Related Information**

- For information about configuring subauthentication on a new installation of IIS 6.0 that has been configured to run in IIS 5.0 isolation mode, see Configuring Subauthentication in IIS 5.0 Isolation Mode.

- For information about configuring subauthentication after upgrading your server to IIS 6.0 from an earlier version of IIS that uses subauthentication, see Configuring Subauthentication After Upgrading to IIS 6.0.

# Configuring Subauthentication in IIS 5.0 Isolation Mode

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When you perform a new installation of IIS 6.0 and then configure the server to run in IIS 5.0 isolation mode, the worker process that is assigned to in-process applications will run as LocalSystem by default. However, for subauthentication to work properly, you must still register Iissuba.dll and configure the AnonymousPasswordSync Metabase Property.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

**Procedures**

**To configure subauthentication after a new installation and after switching to IIS 5.0 isolation mode**

1. Register Iissuba.dll by opening a command prompt and then typing the following:

   **rundll32** *%windir%* **\system32\iissuba.dll,RegisterIISSUBA**

2. At the IisWebService node, set the AnonymousPasswordSync metabase property to **true**.

**Related Information**

- For information about configuring subauthentication on a new installation of IIS 6.0, see Configuring Subauthentication on a New Installation of IIS 6.0.

- For information about configuring subauthentication after upgrading your server to IIS 6.0 from an earlier version of IIS that uses subauthentication, see Configuring Subauthentication After Upgrading to IIS 6.0.

# Configuring Subauthentication After Upgrading to IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When you upgrade a server to IIS 6.0 from an earlier version of IIS that uses subauthentication to manage passwords on anonymous accounts, subauthentication is enabled by default. The AnonymousPasswordSync Metabase Property is set to **true**. However, two additional configuration tasks must be completed before subauthentication will work correctly in IIS 6.0. Your event log should have entries about this.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

**Procedures**

**To configure subauthentication after upgrading to IIS 6.0 from an earlier version of IIS configured to use subauthentication**

1. Register Iisuba.dll by opening a command prompt and then typing the following:

   **rundll32** *%windir%* **\system32\iissuba.dll,RegisterIISSUBA**

2. Run all worker processes that use Anonymous authentication as LocalSystem. For more information about configuring worker process identities, see Configuring Worker Process Identities.

**Related Information**

- For information about configuring subauthentication on a clean installation of IIS 6.0, see Configuring Subauthentication on a New Installation of IIS 6.0.

- For information about configuring subauthentication on a new installation of IIS 6.0 that is configured to run in IIS 5.0 isolation mode, see Configuring Subauthentication in IIS 5.0 Isolation Mode.

# Basic Authentication in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The Basic authentication method is a widely used, industry-standard method for collecting user name and password information. Basic authentication transmits user names and passwords across the network in an unencrypted form. You can use your Web server's encryption features, in combination with Basic authentication, to secure user account information transmitted across the network. For easier administration, add each user to a group that has access to the necessary files.

| **Important** |
| --- |
| Enabling Basic authentication does not automatically configure your Web server to authenticate users. You must also create Windows user accounts and set appropriate NTFS permissions. For more information about setting NTFS permissions, see Setting NTFS Permissions for Directories or Files. |

This section includes the following information:

- Enabling Basic Authentication and Configuring the Realm Name: Describes how to enable Basic authentication and configure the realm name.
- Setting the Default Logon Domain: Describes how to set the default logon domain for use with Basic authentication.
- Configuring Token Cache for Basic Authentication: Describes how to configure token caching so user tokens are not stored in the cache too long.

# Enabling Basic Authentication and Configuring the Realm Name

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Users that are authenticated with Basic authentication must log on with a valid Windows user name and password.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To enable Basic authentication and configure the realm name**

1. In IIS Manager, double-click the local computer; right-click the **Web Sites** folder, an individual Web site folder, a virtual directory, or a file; and then click **Properties**.

   Configuration settings made at the Web Sites level are inherited by all of the Web sites on the server. You can override inheritance by configuring the individual site or site element.

2. Click the **Directory Security** or **File Security** tab, and then, in the **Authentication and access control** section, click **Edit**.

3. In the **Authenticated access** section, select the **Basic authentication** check box.

4. Because Basic authentication sends passwords over the network unencrypted, a dialog box appears, asking if you want to proceed. Click **Yes** to proceed.

5. In the **Default domain** box, either type the domain name you want to use, or click **Select** to browse to a new default logon domain. If the **Default domain** box is filled in, the name is used as the default domain. If the **Default domain** box is left empty, IIS uses the domain of the computer that is running IIS as the default domain. IIS configures the value of the DefaultLogonDomain Metabase Property, which determines the default domain used to authenticate clients accessing your IIS server using Basic authentication. However, the domain specified by DefaultLogonDomain is used only when a client does not specify a domain in the logon dialog box that appears on the client computer.

6. Optionally, you can enter a value in the **Realm** box, which configures the value of the Realm Metabase Property. If the Realm property is set, its value appears on the client's logon dialog box, when Basic authentication is used. The value of Realm is sent to the client for informational purposes only, and is not used to authenticate clients using Basic authentication.

7. Click **OK** twice.

**Related Information**

- For information about setting the default logon domain, see Setting the Default Logon Domain.

- For more information about permissions, see "Access control" in Help and Support Center for Windows Server 2003.

# Setting the Default Logon Domain

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Users authenticated with Basic authentication must log on with a valid Windows user name and password. The user name usually includes:

- A Windows *domain* name.
- An account user name.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set the default logon domain**

1. In IIS Manager, right-click the **Web Sites** folder, Web site, directory, virtual directory, or file, and click **Properties**.

| **Note** |
| --- |
| Configuration settings made at the Web Sites folder level can be inherited by all Web sites. |

1. Click the **Directory Security** or **File Security** tab, depending on the level at which you want to configure security settings.
2. In the **Anonymous access and authentication** control section, click **Edit**.
3. In the **Authenticated access** section, select the **Basic authentication** check box.
4. Because Basic authentication sends passwords over the network unencrypted, a dialog box appears, asking if you want to proceed. Click **Yes** to proceed.
5. In the **Default domain** box, either type the domain name you want to use, or click **Select** to browse to a new default logon domain. If the **Default domain** box is filled in, the name is used as the default domain. If the Default domain box is left empty, IIS uses the domain of the computer that is running IIS as the default domain. IIS configures the value of the DefaultLogonDomain Metabase Property, which determines the default domain used to authenticate clients accessing your IIS server using Basic authentication. However, the domain specified by DefaultLogonDomain is used only when a client does not specify a domain in the logon dialog box that appears on the client computer.
6. Click **OK** twice.

**Related Information**

- For information about Basic authentication, see Basic Authentication.

# Configuring Token Cache for Basic Authentication

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Basic authentication stores user tokens in a token cache. If you log on using Basic authentication with an account that has a high level of user logon rights, a successful attacker could use the account to gain access to the resources on your computer. There are several ways to minimize this threat:

- Do not log on, or allow anyone to log on, using Basic authentication with an account that has a high level of user logon rights.

- Configure the token cache to flush all tokens by setting the HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\InetInfo\Parameters FlushTokenCache registry key to any non-zero value, or set a short time span for cached user tokens by setting the Global Registry entry, UserTokenTTL, to less than the default of 15 minutes. Setting UserTokenTTL to 0 disables TTL-based flushing of tokens. When TTL-based flushing is disabled, user tokens remain cached until either IIS is restarted or the worker process is recycled. See UserTokenTTL in Global Registry Entries.

Before you edit the registry, make sure you understand how to restore it if a problem occurs. For information about how to restore the registry, see the "Restoring the Registry" and the "Restoring a Registry Key" topics in Registry Editor Help.

| **Important** |
| --- |
| Using Registry Editor incorrectly can cause serious problems that require reinstalling the operating system. Because Registry Editor bypasses the standard safeguards that prevent you from entering settings that are conflicting or likely to degrade performance or damage your system, exercise caution when making changes to the registry. Microsoft cannot guarantee that problems resulting from the incorrect use of Registry Editor can be solved. For information about how to edit the registry, see "Changing Keys and Values" in Registry Editor Help. |

Note that you should back up the registry before you edit it. If you are running Microsoft® Windows NT® Server or newer server operating system from Microsoft, you should also update your Emergency Repair Disk (ERD).

For information about how to edit the registry, see the "Changing Keys and Values", "Add and Delete Information in the Registry", and "Edit Registry Data" topics in Registry Editor Help.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:***MyComputer***\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

**Procedures**

**To configure token caching**

1. From the **Start** menu, click **Run**.

2. In the **Open** box, type Regedit.exe, and click **OK**.

3. Navigate to and double-click the following key in the registry:

4. HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\InetInfo\Parameters.

5. From the **Edit** menu, point to **Add**, click DWORD Value and then add the following registry value:

   Name: **UserTokenTTL**

   Type: **REG_DWORD**

Data: *number of seconds* to cache user tokens, or **0** to disable token caching

6. Quit Registry Editor.
7. Restart IIS.

**Related Information**

- For information about setting the default logon domain, see Setting the Default Logon Domain.
- For information about the **DefaultLogonDomain** property, see DefaultLogonDomain Metabase Property.
- For more information about permissions, see "Access control" in Help and Support Center for Windows Server 2003.

# Digest Authentication in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Digest authentication offers the same functionality as Basic authentication; however, Digest authentication provides a security improvement in the way that a user's credentials are sent across the network. Digest authentication transmits credentials across the network as an MD5 hash, or message digest, where the original user name and password cannot be deciphered from the hash. Digest authentication is available to Web Distributed Authoring and Versioning (WebDAV) directories. Digest authentication requires HTTP 1.1 compliance.

This section includes the following information:

- Configuring Digest Authentication in IIS 6.0: Describes how to configure Digest authentication.
- Configuring Subauthentication in a Windows 2000 Domain: Describes how to configure subauthentication so that Digest authentication can be used in a Windows 2000 domain.

# Configuring Digest Authentication in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Configuring Digest authentication on the server running IIS requires the following two tasks:

- Enable Digest authentication for Windows domain servers.
- Configure the realm name.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To enable Digest authentication for Windows domain servers and configure the realm name**

1. In IIS Manager, right-click the **Web Sites** folder, Web site, directory, virtual directory, or file, and click **Properties**.

   | **Note** |
   | --- |
   | Configuration settings made at the Web Sites folder level can be inherited by all Web sites. |

2. Click the **Directory Security** or **File Security** tab, depending on the level at which you want to configure security settings.
3. In the **Anonymous access and authentication control** section, click **Edit**.
4. In the **Authenticated access** section, select the **Digest authentication for Windows domain servers** check box.
5. In the **Realm** box, type the realm name, or click **Select** to browse for a domain.
6. Click **OK** twice.
7. Restart the W3SVC service.

| **Note** |
| --- |
| If Basic authentication is enabled for the site, virtual directory, or folder you are configuring, the **Default domain** box will also be available. However, only **Realm** is meaningful to Digest authentication. |

**Related Information**

- For information about the **Realm** property, see Realm Metabase Property.
- For information about Advanced Digest authentication, see Advanced Digest Authentication in IIS 6.0.

# Configuring Subauthentication in a Windows 2000 Domain

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

To use Digest authentication in IIS 6.0 when the domain controller is running Windows 2000 Server, you must enable subauthentication, which is not installed by default on IIS 6.0. There are three steps required to enable subauthentication:

- Register the subauthentication component, Iissuba.dll.
- Set the UseDigestSSP Metabase Property to **false**. See Advanced Digest Authentication in IIS 6.0 for more information.
- Set the identity of the application pool to LocalSystem. See Configuring Application Pool Identity with IIS 6.0 for more information.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:***MyComputer***\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

**Procedures**

**To register the subauthentication component**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd**, and then click **OK**.
3. At the command prompt, type the following and then press ENTER:

   **rundll32 %systemroot%\system32\iissuba.dll,RegisterIISSUBA**.
4. For any application pools that use Digest authentication, set the identity as LocalSystem.

When you no longer want to use subauthentication, unregister the subauthentication component.

**To unregister the subauthentication component**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd**, and then click **OK**.
3. At the command prompt, type the following and then press ENTER:

   **rundll32 %systemroot%\system32\iissuba.dll,UnregisterIISSUBA**.

**Related Information**

- For more information about configuring subauthentication in IIS 6.0, see Configuring Subauthentication.

# Advanced Digest Authentication in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Under Advanced Digest authentication, user credentials are stored on the domain controller as an MD5 hash. Because credentials are stored in Active Directory as an MD5 hash, user passwords cannot be feasibly discovered by anyone with access to the domain controller, not even by the domain administrator. Advanced Digest authentication is available to Web Distributed Authoring and Versioning (WebDAV) directories. In IIS 6.0, Advanced Digest authentication is preferred over Digest authentication, but Digest authentication is still available. Advanced Digest authentication relies on the HTTP 1.1 protocol.

Advanced Digest authentication uses the UseDigestSSP Metabase Property. This metabase key is a switch between Digest and Advanced Digest Security Support Provider Interface (SSPI) code. After the key has been set, the only valid property values are 1 (**true**), 0 (**false**), or empty. If the property is set to **true**, the new SSPI code for Advanced Digest authentication is used. In all other cases (**false**, empty, or not set), IIS uses the Digest authentication code.

| **Note** |
| --- |
| The World Wide Web Publishing Service (WWW service) must be restarted before changes to UseDigestSSP take effect. |

Configuring Advanced Digest authentication on the server running IIS requires the following three tasks:

- Enable Digest authentication for Windows domain servers.
- Configure the realm name.
- Set the UseDigestSSP metabase property to **true**. You can configure the UseDigestSSP metabase property at the W3SVC level of the metabase. A child key inherits its configuration from the level above it.

| **Important** |
| --- |
| If you follow the first two procedures, but do not configure the UseDigestSSP metabase property, you will be using Digest authentication, not Advanced Digest authentication. |

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc** *%systemroot%***\system32\inetsrv\iis.msc"**. |

**Procedures**

**To enable Advanced Digest authentication and configure the realm name for Windows domain servers**

1. In IIS Manager, right-click the **Web Sites** folder, Web site, directory, virtual directory, or file, and click **Properties**.

   | **Note** |
   | --- |
   | Configuration settings made at the Web Sites folder level can be inherited by all Web sites. |

2. Click the **Directory Security** or **File Security** tab, depending on the level at which you want to configure security settings.
3. In the **Anonymous access and authentication control** section, click **Edit**.
4. In the **Authenticated access** section, select the **Digest authentication for Windows domain servers** check box.
5. In the **Realm** box, type the realm name, or click **Select** to browse for a domain. If Basic authentication is enabled for the site, virtual directory, or folder you are configuring, the **Default domain** box will also be available. However, only the

realm is meaningful for Advanced Digest authentication.

6. Click **OK** twice.
7. Restart the W3SVC service.

**Related Information**

- For more information about Digest authentication, see Digest Authentication in IIS 6.0, and the RFC 2617 specification as defined at the World Wide Web Consortium Web site.
- For more information about the **Realm** metabase property, see Realm Metabase Property.
- For more information about Advanced Digest Authentication, see Advanced Digest Authentication.
- For more information about Active Directory or domain controllers, see "Domains" in Help and Support Center for Windows Server 2003.

# Integrated Windows Authentication in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003 R2, Windows Server 2003 with SP1

Integrated Windows authentication (formerly called NTLM, and also referred to as Windows NT Challenge/Response authentication) is a secure form of authentication because the user name and password are hashed before being sent across the network. When you enable Integrated Windows authentication, the user's browser proves its knowledge of the password through a cryptographic exchange with your Web server, involving hashing.

| **Important** |
| --- |
| Integrated Windows authentication is disabled by default if you install Windows Server 2003 Service Pack 1 (SP1) as part of a slipstream installation of a Windows Server 2003 operating system. If you install Windows Server 2003 SP1 by itself as an upgrade to a Windows Server 2003 operating system, the setting for Integrated Windows authentication is unchanged from its Windows Server 2003 setting. Integrated Windows authentication is enabled by default for Windows Server 2003 operating systems. |

This section includes the following information:

- Configuring Integrated Windows Authentication in IIS 6.0: Describes how to configure Integrated Windows authentication.
- Configuring Constrained Delegation for Kerberos: Describes how to configure constrained delegation when using Kerberos as the authentication method.
- Forcing NTLM Authentication: Describes how to force Integrated Windows authentication to use NTLM instead of Kerberos.

# Configuring Integrated Windows Authentication in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003 R2, Windows Server 2003 with SP1

Integrated Windows authentication was formerly called NTLM. This authentication method sends a hash of the user name and password across the network.

Integrated Windows authentication is disabled by default if you install Windows Server 2003 Service Pack 1 (SP1) as part of a slipstream installation of a Windows Server 2003 operating system. If you install Windows Server 2003 SP1 by itself as an upgrade to a Windows Server 2003 operating system, the setting for Integrated Windows authentication is unchanged from its Windows Server 2003 setting. Integrated Windows authentication is enabled by default for Windows Server 2003 operating systems.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To configure Integrated Windows authentication**

1. In IIS Manager, double-click the local computer; right-click the **Web Sites** folder, an individual Web site folder, a virtual directory, or a file; and then click **Properties**.

   | **Note** |
   | --- |
   | Configuration settings made at the **Web Sites** level are inherited by all of the Web sites on the server. You can override inheritance by configuring the individual site or site element. |

2. Click the **Directory Security** or **File Security** tab, and then, in the **Authentication and access control** section, click **Edit**.
3. In the **Authenticated access** section, select the **Windows Integrated Authentication** check box.
4. Click **OK** twice.

**Related Information**

- For more information about Integrated Windows authentication, see Integrated Windows Authentication.
- For information about configuring Integrated Windows authentication to force NTLM authentication, see Forcing NTLM Authentication.
- For information about configuring worker process identity when using Kerberos authentication, see Configuring Constrained Delegation for Kerberos.

# Configuring Constrained Delegation for Kerberos

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

*Constrained delegation*, which is new in Windows Server 2003, is intended to be used by service accounts, which should have registered Service Principal Names (SPNs), instead of by a regular user account, which typically does not have an SPN.

The Setspn.exe command-line utility allows you to read, modify, and delete SPNs for an Active Directory property. Setspn.exe is available in the Support Tools pack located on your Windows Server 2003 CD-ROM.

**Important**

You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:***MyComputer\Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters).

**Important**

You must be a domain administrator to set an SPN.

**To configure constrained delegation**

1. Install the Support Tools pack on your Windows Server 2003 CD-ROM.
2. Click **Start**, point to **Programs** or **All Programs**, point to **Windows Support Tools**, and then click **Command Prompt**.
3. At the command prompt, type the following command:

   ```
   setspn -a http/SiteName.DomainName.com Domain \User
   ```

   where *SiteName.DomainName.com* is the Web site whose application pool runs with the custom identity you created.

   For example, the following command assigns "http/contosohr.contoso.com" to the custom identity CONTOSO\cd1hr. The **http/** prefix is a service class that identifies this as an SPN for a Web site.

   ```
   setspn -a http/contosohr.contoso.com CONTOSO\cd1hr
   ```

   Here is another way to specify the same SPN, using just the SiteName:

   ```
   setspn -a http/contosohr CONTOSO\cd1hr
   ```

If you register duplicate SPNs accidentally, you can use Setspn.exe to delete the duplicate SPN. For more information about Setspn.exe syntax, see Setspn Syntax.

**Note**

If you are configuring servers running IIS 6.0 in a Windows 2000 Server domain, you can use either the version of Setspn.exe that comes with Windows Server 2003 or the version that comes with Windows 2000 Server.

**Related Information**

- For more information about configuring application pool identity, see Configuring Application Pool Identity with IIS 6.0.
- For more information about Kerberos and service registration, see Integrated Windows Authentication.
- For more information about NTLM authentication, see "Authentication" in Help and Support Center for Windows Server 2003.
- For more information about Kerberos, see "Kerberos" in Help and Support Center for Windows Server 2003.

- For more information about constrained delegation, see "Delegating authentication" in Help and Support Center for Windows Server 2003.

# Forcing NTLM Authentication

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In the following situations, Kerberos authentication fails and you must force IIS to use NTLM authentication by setting the NTAuthenticationProviders Metabase Property to **NTLM**.

- Kerberos fails when you isolate Web sites on a virtual directory level by configuring worker process identities as different domain accounts.
- Kerberos authentication fails if you are using Integrated Windows authentication, are not using a WINS or DNS name for the server running IIS, and you want to use a local user account or the LocalService account as a worker process identity. It fails because Active Directory does not trust these accounts.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To force NTLM authentication**

1. In IIS Manager, right-click the local computer, and then click **Properties**.
2. Select the **Enable Direct Metabase Edit** check box, and then click **OK**.
3. Click **Start**, click **Run**, type **cmd**, and then click **OK**.
4. At the command prompt, type the following command to change to the directory where the MetaBase.xml file is located:

   **cd %systemroot%\system32\inetsrv**

5. To open the file with Notepad, at the command prompt, type the following:

   **notepad MetaBase.xml**

6. In the **<IISWebServer>** section, locate the **NTAuthenticationProviders** metabase property and modify its setting to read "NTLM".
7. Save and close the MetaBase.xml file.

**Related Information**

- For information about metabase edit-while-running, see Enabling Edit-While-Running in IIS 6.0.
- For more information about NTLM authentication, see "Authentication" in Help and Support Center for Windows Server 2003.
- For more information about Kerberos, see "Kerberos" in Help and Support Center for Windows Server 2003.

# UNC Authentication in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In IIS 6.0, you can use delegation of authentication, a feature of IIS 6.0 and the Windows Server 2003 family, to pass the authenticated credentials of the request user to a remote file server on which a Universal Naming Convention (UNC) share is located. Delegation of authentication, also called UNC authentication, allows virtual directories mapped to remote UNC shares to use local user authentication for access to the shares. This is preferable to the alternative of using a static user name and password, because you can limit access to specific portions of the UNC share for each user or group. Delegation of authentication works only with authentication methods that can perform delegation, for example, Basic authentication or Kerberos authentication.

IIS can be configured to secure a virtual directory as you create it or to configure an existing directory.

This section includes the following information:

- Creating a Virtual Directory with a UNC Path Describes how to create a secure virtual directory that uses a UNC path.
- Securing an Existing Virtual Directory with a UNC Path Describes how to configure a UNC path to secure an existing virtual directory.
- Configuring Constrained Delegation for IIS: Describes how to configure constrained delegation.

# Creating a Virtual Directory with a UNC Path

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use the following procedure to create a secure virtual directory with a UNC path.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To create a secure virtual directory with a UNC path**

1. In IIS Manager, expand the local computer, expand the **Web Sites** folder, right-click a Web site, Web application, directory, or virtual directory, point to **New**, and then click **Virtual Directory**.
2. Click **Next**.
3. In the **Alias** box, type the alias for the new virtual directory, and click **Next**.
4. In the **Path** box, type the path to the directory on the UNC share, and click **Next**.
5. The **Virtual Directory Creation Wizard** recognizes the path format as UNC and the **User Name and Password** dialog box appears.
6. To impersonate the requested user credentials to the remote computer, select the **Always use the authenticated user's credentials when validating access to the network resource** check box and leave the **User name** and **Password** boxes blank. Click **Next** and proceed to step 8.
7. To secure the virtual directory and share with a static user name and password, specify the user name as Domain\username in the **User name** box, specify a password in the **Password** box, and clear the **Always use the authenticated user's credentials when validating access to the network resource** check box.
8. Select the appropriate check boxes for the access permissions you want to allow, and clear the check boxes for the permissions you want to deny.
9. Click **Next** to complete the wizard.

**Related Information**

- For information about delegation, see "Delegation of Authentication" in Help and Support Center for Windows Server 2003.

# Securing an Existing Virtual Directory with a UNC Path

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use the following procedure to further secure an existing virtual directory with a UNC path.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To secure an existing virtual directory with a UNC path**

1. In IIS Manager, right-click the virtual directory you want to secure, and click **Properties**.
2. Click **Connect As...**.
3. To use delegation to pass the local user's credentials to the remote computer, select the **Always use the authenticated user's credentials when validating access to the network resource** check box and leave the **Username** and **Password** boxes blank. Proceed to step 5.
4. To secure the virtual directory and share with a static user name and password, specify the user name as Domain\username in the **User name** box, specify a password in the **Password** box, clear the **Always use the authenticated user's credentials when validating access to the network resource** check box, and click **Next**.
5. Click **OK**.

**Related Information**

- For information about delegation, see "Delegation of Authentication" in Help and Support Center for Windows Server 2003.

# Configuring Constrained Delegation for IIS

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure your server to allow clients to authenticate using any authentication protocol, and IIS will access content on the file server on behalf of the authenticated clients. For more information about constrained delegation, see UNC Authentication.

| **Important** |
| --- |
| You must be a domain administrator to perform the following procedure. |

**To configure constrained delegation for IIS**

1. From the **Start** menu, point to **Administrative Tools**, and then click **Active Directory Users and Computers**.
2. In the **Active Directory Users and Computers** dialog box, ensure that your domain is in the **Windows Sever 2003** mode by doing the following:
   - In the left pane, click your domain name.
   - From the **Action** menu, select **Raise Domain Functional Level**.
   - In the **Raise Domain Functional Level** dialog box, if your domain is in Windows 2000 native or Windows 2000 mixed mode, click **Windows Server 2003** from the **Select an available domain functional level** list box, and then click **Raise**.

| **Important** |
| --- |
| After you change your domain level, you cannot reverse the action. The change can take up to 15 minutes to propagate. For more information about domain functional levels, see "Domain and forest functionality" in Help and Support Center for Windows Server 2003. |

3. In each of the two **Raise Domain Functional Level** dialog boxes that appear, click **OK**.
4. Double-click the domain, and then click the **Computers** folder. A list of computers in the domain appears in the right pane.
5. Right-click the Web server computer name, and then select **Properties**.
6. Click the **Delegation** tab, and then select the **Trust this computer for delegation to specified services only** check box.
7. Click the authentication type that you want to use, and then click **Add**.
8. In the **Add Services** dialog box, click **Users or Computers**.
9. In the **Select Users or Computers** dialog box, in the **Enter the object names to select** text box, search for or type the name of the file server that you want to use, and then click **OK**.
10. In the **Properties** dialog box, click **Add** to add the HOST and CIFS services for the target file server. Add only the services that you are sure must present delegated credentials, and then click **OK**.

# .NET Passport Authentication in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Microsoft® .NET Passport is a user-authentication service and a component of the Microsoft .NET framework. The .NET Passport single sign-in service and express purchase service enable your business to deliver a fast, convenient, and secure way for consumers to sign in and make transactions on your site. With the .NET Passport single sign-in service, you can map sign-in names to information in your databases, which enables you to offer .NET Passport members a personal Web experience through targeted ads, promotions, and content. Using .NET Passport in this way potentially helps you increase customer loyalty, sales, and advertising revenues.

.NET Passport uses standard Web technologies and techniques, such as Secure Sockets Layer (SSL), HTTP redirects, cookies, Microsoft JScript®, and strong symmetric key encryption to deliver the single sign-in service. The .NET Passport service is compatible with both Microsoft Internet Explorer version 4.0 or later, and Netscape Navigator version 4.0 or later. In addition, .NET Passport is compatible with some versions of UNIX.

This section includes the following information:

- Setting Up .NET Passport in IIS 6.0: Describes how to configure and test your .NET Passport configuration in IIS 6.0 and against .NET Passport production servers.

- Enabling .NET Passport Authentication in IIS 6.0: Describes how to implement .NET Passport authentication on your Web sites through IIS Manager.

# Setting Up .NET Passport in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Before setting up Microsoft .NET Passport authentication on your Web sites in a production environment, you are required to test IIS against .NET Passport preproduction servers. By working through this process, you confirm that your IIS server and the .NET Passport server are communicating correctly, your site(s) is registered with .NET Passport (which might involve signing forms and agreements), and your Web sites have the required site IDs. You must complete each process for every Web site you want to enable with .NET Passport authentication.

This topic includes the following information:

- .NET Passport Environments
- Testing and Preproduction (PREP)
- Mapping to Active Directory
- Configuring for Preproduction (PREP)
- Configuring for Production
- Passport Manager Administration Utility

With .NET Passport authentication on members of the Windows Server 2003 family, the default .NET Passport **SecureLevel** setting is 10. This means that new sites using .NET Passport authentication (and default settings) require an Secure Sockets Layer (SSL) server certificate. You can change the **SecureLevel** setting for a site by changing a registry value.

| **Important** |
| --- |
| Using Registry Editor incorrectly can cause serious problems that require reinstalling the operating system. Because Registry Editor bypasses the standard safeguards that prevent you from entering settings that are conflicting or likely to degrade performance or damage your system, exercise caution when making changes to the registry. Microsoft cannot guarantee that problems resulting from the incorrect use of Registry Editor can be solved. For information about how to edit the registry, see "Changing Keys and Values" in Registry Editor Help. |

**Procedures**

**To change the SecureLevel setting for the default Web site**

- Enter a new value in the registry for the following key:

  HKEY_LOCAL_MACHINE\Software\Microsoft\Passport\SecureLevel

**To change the SecureLevel setting for any Web site other than the default Web site**

- Enter a new value in the registry for the following key:

  HKEY_LOCAL_MACHINE\Software\Microsoft\Passport\Sites\<*Site Name*>\SecureLevel

| **Note** |
| --- |
| This documentation is designed to be used in conjunction with the .NET Passport Software Development Kit (SDK) documentation (starting with version 2.1). If you have not already done so, review the SDK documentation, specifically the section titled "How to Implement .NET Passport." You may find it helpful to browse a sample .NET Passport Web site to better understand what a site running .NET Passport looks like. You can also review the code samples or simply use the code in the sample site as a template for your own site. For more information about the .NET Passport SDK and the sample Web site, see Microsoft .NET Passport for Developers. |

**.NET Passport Environments**
Setting up .NET Passport on your Web sites involves testing and configuring IIS against the following three .NET Passport environments:

- Default installation environment: By default, the Microsoft .NET Passport SDK and Internet Information Services (IIS) (with the Passport Manager object) are configured for testing. The test or default installation environment uses a site ID of 1 (one), and has a default encryption key instead of a private, site-specific key.

- Preproduction: The Preproduction (PREP) environment enables sites to verify their development efforts against .NET Passport servers without access to real-world .NET Passport user identifications and profiles. While in PREP mode, prospective .NET Passport participating sites can manipulate data, create new users, and run other tests against the user base without affecting existing deployed .NET Passport sites.

- Production: The .NET Passport Production environment is shared by all working and approved .NET Passport participating sites after they are deployed to the public.

**Testing and Preproduction (PREP)**
You can determine whether your site is in the default installation environment by checking the **Site ID** field in the Passport Manager Administration utility. If the value in the **Site ID** field is 1, your site is in the default installation environment. While your site is in this environment, you can perform an initial evaluation of the single sign-in service (SSI) and test any dynamic content on your site against the Passport Manager object. You can develop your Web site and any applications on your site before registering your site and requesting a site ID, or while you are waiting for the site ID and key after registration. After you have a site ID, there should be no reason to use the default installation environment again. The restrictions imposed by this mode are intended only to prevent developers from accessing certain .NET Passport features before having signed the necessary agreements or contracts.

| **Note** |
| --- |
| The preproduction environment requires a .NET Passport preproduction logon account. To set up a preproduction logon account, see Microsoft .NET Services Manager. |

**Limitations in the Default Installation Environment**
The following operational limitations exist in the default installation environment:

- Cannot read full core profile data or profile cookies: A Web site running in the default installation environment indicates that the administrator has not yet signed the necessary agreements that specify a site's requirements for privacy. For this reason, a site running in the default installation environment cannot access all .NET Passport user information. .NET Passport user information displayed on a test site contains several fields of default placeholder values, as generated by the logon server.

- Cannot use co-branding: Co-branding support is dependent on several URLs that you must provide when registering as a .NET Passport participating site. Until you register and provide these URLs, the co-branding logo and text exist as placeholders. For details about how to implement co-branding after your site has registered as a .NET Passport participating site, see ".NET Passport Cobranding Overview" in .NET Passport SDK Help.

- Cannot sign users out from sign-out page: On a registered .NET Passport site, when members choose to sign out by clicking the .NET Passport sign-out link, they are redirected to a central page that enables deletion of all .NET Passport cookies from all of the sites the member visited during the session. This is not the case in the default installation environment, so .NET Passport cookies remain on the user's browser until the user closes the browser entirely. If the .NET Passport user chose to save their password (thus making all session cookies persistent cookies), .NET Passport cookies written in the test site's domain are still not deleted. For this reason, when testing browser behavior in the default installation environment, you may occasionally need to quit the browser to reproduce a clean .NET Passport sign-in.

**Testing Passport with Active Server Pages**
If your Web site uses Active Server Pages (ASP) to query information from the Passport authentication ticket, you must create a Passport Manager object. The Passport Manager object is a server-side object for .NET Passport single sign-in and profile services. The Passport Manager object uses cookies and query string data as intermediaries for querying a central user store.

To create a Passport Manager object in an ASP page, use the ASP **Server.CreateObject** method to create a local object

reference as follows:

```
set oMgr = Server.CreateObject("Passport.Manager")
```

The Passport Manager object should only be created once on each ASP page. Multiple object instantiations on a single page can lead to unexpected results when the page loads or unloads. Also, multiple instantiations will slow performance with extra memory overhead and multiple encryption and decryption of the same cookies. One way to assure a single instantiation is to create the object only once in a header file that is included on each page.

Do not create the Passport Manager object in an ASP application in Session or Application scope, unless you are specifically using that instance for utility methods such as **GetDomainAttribute** or **DomainFromMemberName** (with input parameter).

The following code sample instantiates the Passport Manager object in an ASP page to obtain user information from a .NET Passport cookie. Web sites running in the default installation environment return generic values. Web sites running in PREP or Production environments return valid user information.

```
%
'
' Instantiate the Passport Manager.
'
Set oMgr = Server.CreateObject("Passport.Manager.1")
'
' Use HTTPS if SecureLevel > 1.
'
thisURL = Server.URLEncode("https://" & Request.ServerVariables("SERVER_NAME") &
Request.ServerVariables("SCRIPT_NAME") ) signoutURL = Server.URLEncode("https://" &
Request.ServerVariables("SERVER_NAME") & "/signout.asp")
If oMgr.IsAuthenticated(3600,FALSE) Then
'
' Convert the binary PUID to a hexadecimal format for displaying.
'
strMemberIDHigh = oMgr.Profile("MemberIDHigh")
strMemberIDLow = oMgr.Profile("MemberIDLow")
strHex = Hex(strMemberIDHigh)
strPUID = String(8 - Len(strHex), "0") & strHex
strHex = Hex(strMemberIDLow)
strPUID = strPUID & String(8 - Len(strHex), "0") & strHex
```

For more information, see "Passport Manager Methods" or "Passport Manager Properties" in .NET Passport SDK (starting with version 2.1) Help.

#### Testing ASP Against the .NET Passport Default Installation Environment

### To test ASP against the .NET Passport default installation environment

1. Enable .NET Passport authentication on a virtual directory. You can use the code sample above in the Default.asp page and include the Default.asp page in the virtual directory. To learn more about enabling .NET Passport authentication on a Web site or a virtual directory, see Enabling .NET Passport Authentication in IIS 6.0.

   | **Note** |
   | --- |
   | Microsoft Windows XP client computers used to test .NET Passport must be configured for .NET Passport default installation and PREP environments. To configure your Windows XP client computers to connect to these environments, see ".NET Passport SDK: System Requirements" in .NET Passport SDK (starting with version 2.1) Help. More specifically, read the section titled "Client Computer Requirements." |

2. On a remote client computer, open a Web browser, type the virtual directory URL in the address bar, and press ENTER. The client connects to the Web site and is then redirected to the .NET Passport server. Passport reads the site ID as 1, which tells the Passport service that your server is still in the default installation environment. You are then redirected to the .NET Passport test environment for credential authentication. Windows 2000 or earlier clients open a logon Web page. Windows XP clients (configured according to "Client Computer Requirements" in .NET Passport SDK Help) open the **Stored User Names and Passwords** dialog box.

3. Type valid .NET Passport credentials and click **OK**.

4. .NET Passport validates the credentials and displays hard-coded, generic user information. The server running IIS collects a cookie with the generic information. The display does not contain any confidential material. The .NET Passport User ID (PUID) is not real because, at this point, your IIS server has not established a contract with .NET Passport.

**Mapping to Active Directory**

In certain scenarios (for example Business-to-Business [B2B] or Business-to-Consumer [B2C]) you might want to set up Access Control Lists (ACL) on specific Web pages or content and then have selective members or groups access the Web pages using .NET Passport authentication. As an example, a large company with multiple vendors might establish a timecard reporting site for all contingent staff. By setting up the timecard reporting online, vendors can access the Web page from any Web browser, and the company can control security using Passport authentication.

To configure.NET Passport authentication that uses ACLs, the .NET Passport user must have a PUID mapped to an account in Active Directory directory service. A Passport ticket contains the PUID. The initial mapping of PUIDs to accounts in Active Directory is called provisioning. Provisioning is described later in this topic.

The Active Directory attribute **altSecurityIdentity** is used to map the Passport user to an Active Directory account. The value of **altSecurityIdentity** looks like this: **kerberos:***0124ABCD78787878***@domain.com**. This essentially is a User Principal Name (UPN) where the PUID is the UPN prefix and everything after the "@" is the UPN suffix. The UPN suffix determines where the mapping lives. The UPN suffix should be the domain where the mapping is created or exists. In other words, in the sample mapping **kerberos:***0124ABCD78787878***@domain.com**, *domain.com* is the UPN suffix. The UPN suffix can be configured in the IIS authentication dialog. The UPN suffix value must be the same as the value configured in the IIS authentication dialog or the same as the domain name of the server.

The IIS metabase property AuthFlags contains the available settings for Windows authentication schemes and the file access authentication flags. By default, IIS 6.0 with .NET Passport authentication enabled tries to map the .NET Passport user to an account in Active Directory. This default behavior can create performance overhead for sites that do not want to use .NET Passport Active Directory mapping. The mapping behavior can be controlled by the **PassportRequireADMapping** flag. The flag values are:

- PassportRequireADMapping set to 0: IIS does not attempt Active Directory mapping. The request is handled as Anonymous User.
- PassportRequireADMapping set to 1 (default setting): In this situation the worker process must have Trusted Computing Base (TCB) privileges, which means that the worker process acts as part of the operating system. IIS then attempts to map to an Active Directory account (called LsaLogonUser). If this attempt fails, the request is handled as Anonymous User.
- PassportRequireADMapping set to 2: IIS enforces a mapping from the .NET Passport account to an Active Directory account before returning the requested Web page. If the mapping fails, IIS returns a 401 error.

For .NET Passport mapping to work, the account used for the IIS worker process must meet the following criteria:

- The IIS worker process must be running as LocalSystem if the computer is a domain member. To change the account on the worker process, see Configuring Worker Process Identities.
- If using a service account, the domain account must have TCB privilege on the local box (meaning, the account acts as part of the operating system).
- The account must be a member of the pre-Windows 2000 compatible access group, or have Read access to list group memberships.

The following WMI script sets the **PassportRequireADMapping** flag in the IIS metabase:

```
dim g_PPADMapping : g_PPADMapping = 0
call ValidateArgs(WScript.Arguments)
Set g_Locator = CreateObject("WbemScripting.SWbemLocator")
Set g_IIS = g_Locator.ConnectServer ("","root\MicrosoftIISv2","", "")
Set g_NodeObj = g_IIS.Get("IIsWebVirtualDirSetting='" & WScript.Arguments(0) & "'")
g_NodeObj.PassportRequireADMapping.Value = g_PPADMapping
g_NodeObj.Put_
WScript.Echo WScript.Arguments(0) & "/PassportRequireADMapping changed to: " &
g_PPADMapping
sub ValidateArgs(args)
      if args.Count <> 2 then
            call Usage
      end if
      if args(1) = "no" then
            g_PPADMapping = 0
```

```
      elseif args(1) = "try" then
            g_PPADMapping = 1
      elseif args(1) = "enforce" then
            g_PPADMapping = 2
      else
            call Usage
      end if
end sub
sub Usage
      WScript.echo "Usage: " & WScript.ScriptName & " metabase_path no|try|enforce"
      WScript.Echo "Example: " & WScript.ScriptName & """w3svc/1/root/passportvdir
enforce"""
      WScript.Echo " ------- Enforces mapping for virtual directory passportvdir"
      WScript.Quit
end sub
```

**Provisioning**

To establish ACLs on a Web page for .NET Passport authentication, PUIDs need to be mapped to a corresponding account in Active Directory. This process is called provisioning. The sample code in this section provisions PUIDs to Active Directory accounts. To provision the Active Directory, you must have administrator credentials on the Active Directory server. Normally this provisioning is accomplished by a .NET Passport-enabled Web page that collects information about the .NET Passport user and then saves the data so an administrator can perform the provisioning against Active Directory.

The following sample code is taken from Subscribe.asp. Use this code on your .NET Passport-enabled ASP page to collect .NET Passport user IDs and create Active Directory user accounts with the .NET Passport mapping.

```
%
 '
 ' Instantiate Passport Manager.
  '
 Set objPassportManager = Server.CreateObject("Passport.Manager.1")
 '
 ' Get any available information about the user from Passport.
 '
 strCurrentUserEmail = objPassportManager.Profile("PreferredEmail")
 strMemberIDHigh = objPassportManager.Profile("MemberIDHigh")
 strMemberIDLow = objPassportManager.Profile("MemberIDLow")
 strHex = Hex(strMemberIDHigh)
  '
 ' Convert the PUID into the correct form.
 '
 strPUID = String(8 - Len(strHex), "0") & strHex
 strHex = Hex(strMemberIDLow)
 strPUID = strPUID & String(8 - Len(strHex), "0") & strHex
 strLastName = objPassportManager.Profile("LastName")
 strFirstName = objPassportManager.Profile("FirstName")
 '
 ' Connect to Active Directory and find the default naming context for the default
domain.
 '
 set rootDSE = GetObject("LDAP://RootDSE")
 if Err.Number <> 0 then
  Response.Write "GetObject Error = " & Hex(Err.Number) & " (Source: " & Err.Source &
")"
 end if
 Err.Clear
 strDomainDN = rootDSE.Get("defaultNamingContext")
 if Err.Number <> 0 then
  Response.Write "Get Domain DN Error = " & Hex(Err.Number) & " (Source: " & Err.Source
& ")"
 end if
 Err.Clear
 strdnsName = rootDSE.Get("dnsHostName")
      FirstDot = Instr( strdnsName, "." )
      strDomainName = Right( strdnsName, Len( strdnsName ) - FirstDot )
 strContainerDN = "cn=users, " & strDomainDN

 ' Bind to the user's container.
 set cont = GetObject("LDAP://" & strContainerDN )
 if Err.Number <> 0 then
```

```

 '
      '   IMPORTANT!!!
      ' Before going live with a site based on this sample code,
      ' the following must be changed so that a random password
      ' is assigned to each account. A recommended way to do this
      ' is to use the CAPICOM Utilities.GetRandom function.
 '
      user.put "userPassword", "89sd53ET!23kL"
 ' Write the property cache.
 user.SetInfo
 ' Refresh the property cache.
 user.GetInfo
 ' Clear the account disabled flag and set neccessary flags.
 flags = user.get("userAccountControl")
 flags = flags OR "H00010000
 flags = flags AND "HFFFFFFFD
 user.put "userAccountControl", flags
 user.SetInfo
%
```

**Configuring for Preproduction**

Real-world .NET Passport users probably do not have existing e-mail names within the PREP environment. Part of your site's development and testing effort might require that you first create a store of users within the PREP environment and then use these accounts for testing against the .NET Passport authentication and profile-access portions of your site's code. The .NET Passport server code that runs the services in the PREP environment is essentially identical to the code that runs *live* in the Production environment; Production and PREP are released in tandem. This means that *going live* should be a matter of simply stopping the servers on a site currently running against the PREP environment, reconfiguring Passport Manager on those servers to run against the Production environment instead, and then restarting the servers.

For more information about getting a PREP site ID, see "Registering Your .NET Passport Site" in the .NET Passport SDK (starting with version 2.1) Help. For more information about PREP Passports, see "Get a PREP Passport" and "Sign in to PREP Passport" in .NET Passport SDK (starting with version 2.1) Help. Also, see "Going Live: Deploying Passport Manager and Site Code."

Upon completion of the registration process, you will see a confirmation page that indicates your new .NET Passport sign-in name. This is the name you will use while in the development phase.

**Configuring for Production**

All Microsoft .NET Passport users already have an account in this environment. Users of Microsoft MSN Internet Access and MSN Explorer, as well as users who registered directly at the Passport.com Web site, also have passports in this environment. Within the Production environment, sites can expect to handle many real-world .NET Passport users who might already have been authenticated at various other Passport participating sites.

To deploy the .NET Passport code of your site, the Passport Manager server-side object must be reconfigured to work against the Production environment. To deploy against the Production environment, your site must also register for a site ID in the Production environment, and must supply some configuration information about your site that is specific to the Production deployment. Approval of a site ID in the Production environment might require some basic remote checking of your site's .NET Passport implementation by the .NET Passport team, and might also require some additional contracts or agreements.

**Important**

Do not place co-branded URLs in a virtual directory on which .NET Passport authentication is enabled. If a co-branded URL resides in a virtual directory on which .NET Passport authentication is enabled, client requests are challenged to authenticate before the co-branded information is passed to the client. This can result in a situation where a client might not be able to authenticate and view the desired page.

To deploy against the .NET Passport Production environment, see "Registering Your Passport Web Site" in the .NET Passport SDK (starting with version 2.1) Help. To disable the default installation environment and enable normal operation, enter a different site ID in the **Site ID** field and commit changes. Note that if you change the site ID to something other than 1, a matching encryption key must also be installed. The key, as well as the unique site ID assigned to any particular participating site, can be obtained only by registering as a .NET Passport participating site.

**Note**

Be sure to reconfigure your Windows XP clients for .NET Passport production mode as well. For more information, see ".NET Passport SDK: System Requirements" in the .NET Passport SDK (starting with version 2.1) Help. More specifically, read the section titled "Client Computer Requirements."

**Passport Manager Administration Utility**

The Microsoft Passport Manager Administration utility is a graphical user interface (GUI) alternative to editing the registry when changing Passport Manager object settings. The most common use of the Passport Manager Administration utility is to change the default settings. For details about how defaults can be set and affect the behavior of Passport Manager methods, see "Setting Passport Manager Defaults" in .NET Passport SDK Help.

**To access the Passport Manager Administration utility**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **msppcnfg.exe**, and click **OK**.

**Related Information**

- For helpful whitepapers that include information about everything from the benefits of enabling .NET Passport on your Web sites, to the .NET Passport Software Development Kit (SDK), see the Microsoft .NET Passport Web site.
- For more information about IIS and Web site security, see Security in IIS 6.0.

# Enabling .NET Passport Authentication in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When .NET Passport is enabled, requests coming into IIS must contain .NET Passport credentials either on the query string or within a cookie. The credentials also have to be valid, meaning the ticket has not expired. If IIS does not detect .NET Passport credentials, requests are redirected to the .NET Passport sign-in page.

.NET Passport uses cookies, which contain information that can be compromised. However, .NET Passport authentication can be used over a Secure Sockets Layer (SSL) connection, which reduces the potential of replay attacks.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:***MyComputer***\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

**Procedures**

**To enable .NET Passport authentication on a Web site**

1. In IIS Manager, expand the local computer, expand the **Web Sites** folder, right-click the Web site on which you want to enable .NET Passport authentication, and click **Properties**.
2. Click the **Directory Security** tab.
3. In the **Anonymous access and authentication control** section, click **Edit**.
4. Select the **.NET Passport Authentication** check box. There are fundamental differences in the way .NET Passport validates user credentials, so .NET Passport cannot be used with other authentication methods. When .NET Passport authentication is selected, all other authentication methods are unavailable.
5. Click **OK**.

**Related Information**

- For comprehensive developer and technical support resources to help businesses implement .NET Passport services, including information about licensing and implementing .NET Passport, see the Microsoft .NET Passport for Developers Web site.
- For information about configuring .NET Passport authentication programmatically, see AuthFlags Metabase Property in the Metabase Property Reference.
- For more information about SSL, see Configuring SSL on a Web Server or Web Site.
- For more information about secure protocols, see Authentication in IIS 6.0.

# FTP Site Authentication in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure an FTP server to allow anonymous access to FTP resources or to require Basic authentication in the form of a user name and password corresponding to a valid Windows user account.

| **Note** |
| --- |
| Digest and Integrated Windows authentication cannot be used with FTP sites. Available authentication settings must be set at the site level for FTP sites. |

This section includes the following information:

- Configuring Anonymous FTP Authentication: Describes how to enable anonymous FTP authentication for an FTP site.
- Configuring Basic FTP Authentication: Describes how to enable basic FTP authentication for an FTP site.

# Configuring Anonymous FTP Authentication

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure your FTP server to allow anonymous access to FTP resources. If you select Anonymous FTP authentication for a resource, all requests for that resource are accepted without prompting the user for a user name or password. This is possible because IIS automatically creates a Windows user account called IUSR_*computername*, where *computername* is the name of the server on which IIS is running.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**.

**Procedures**

**To enable Anonymous FTP authentication**

1. If the IUSR_*computername* account is not used for Anonymous FTP authentication, you must create a Windows user account appropriate for the authentication method and add the account to a Windows user group.
2. Configure NTFS permissions for the directory or files for which you want to control access, using the user account you selected in step 1.
3. In IIS Manager, double-click the local computer; right-click the **FTP Sites** folder, an individual FTP site folder, a virtual directory, or a file; and then click **Properties**.

   **Note**

   Configuration settings made at the FTP Sites level are inherited by all of the FTP sites on the server. You can override inheritance by configuring the individual site or site element.

4. Click the **Security Accounts** tab.
5. Select the **Allow anonymous connections** check box.
6. To allow your users to gain access by Anonymous authentication only, select the **Allow only anonymous connections** check box.
7. In the **User name** and **Password** boxes, type the anonymous logon user name and password that you want to use, and then click **OK**. The user name is the name of the anonymous user account, which is typically designated as IUSR_*computername*.
8. Set the appropriate NTFS permissions for the anonymous account.

**Important**

If you change the security settings for your Web site or virtual directory, your Web server prompts you for permission to reset the security settings for the child keys of that site or directory. If you choose to accept these settings, the child keys inherit the security settings from the parent site or directory.

**Related Information**

- For information about creating Windows user accounts, see Best Practices for Securing Files with NTFS Permissions.
- For information about setting NTFS permissions for an anonymous account, see Setting NTFS Permissions for Directories or Files.

- For information about setting metabase properties, see Configuring the Metabase.

# Configuring Basic FTP Authentication

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

To establish an FTP connection with your Web server by using the Basic FTP authentication method, users must log on with a user name and password corresponding to a valid Windows user account.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To enable the Basic FTP authentication method**

1. Create a Windows user account appropriate for the authentication method. If appropriate, add the account to a Windows user group.
2. Configure NTFS permissions for the directory or file for which you want to control access.
3. In IIS Manager, right-click the FTP site, directory, virtual directory, or file, and then click **Properties**.
4. Click the **Security Accounts** tab.
5. Clear the **Allow anonymous connections** check box.
6. Click **OK**.
7. Set the appropriate NTFS permissions for the account.

| **Important** |
| --- |
| If you change the security settings for your Web site or virtual directory, your Web server prompts you for permission to reset the security settings for the child nodes of that site or directory. If you choose to accept these settings, the child nodes inherit the security settings from the parent site or directory. |

**Related Information**

- For information about creating Windows user accounts, see Best Practices for Securing Files with NTFS Permissions.
- For information about setting NTFS permissions for an anonymous account, see Setting NTFS Permissions for Directories or Files.
- For information about setting metabase properties, see Configuring the Metabase.

# Access Control with IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can control which users and computers are allowed to access your Web server and its resources. You can use both NTFS and Internet Information Services (IIS) security features, such as Web permissions and IP address restrictions, to specific access rights to Web sites, directories, and files.

This section includes the following information:

- Securing Files with NTFS Permissions: Describes how to use NTFS permissions to secure the files and directories that comprise your Web site.
- Securing Sites with Web Site Permissions: Describes how to set Web permissions to protect your Web content.
- Allowing Anonymous Access to Web Sites: Describes how to set up an account for anonymous access to Web sites.
- Configuring Worker Process Identities: Describes how to configure the worker process identity so an application can run with the appropriate access rights for your Web server.
- Securing Sites with IP Address Restrictions: Describes how to prevent specific computers, groups of computers, or entire networks from accessing your Web content.
- Securing Virtual Directories: Describes how to secure virtual directories.

**Related Information**

- For information about FTP user isolation, which prevents users from viewing or overwriting other users' Web content, see Isolating FTP Users.
- For information about configuring content rating features to warn users about objectionable Web content, see Using Content Ratings.
- For information about configuring your Web server's Secure Sockets Layer (SSL) security features, see Configuring SSL on a Web Server or Web Site.

# Securing Files with NTFS Permissions

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

It is strongly recommended that you use the NTFS file system, instead of the FAT or FAT32 file system, for your application server. With NTFS, you can limit access to your Web server's files and directories. You can also configure the access level granted to a particular user or group for the files and directories on your server.

This section includes the following information:

- Best Practices for Securing Files with NTFS Permissions: Provides best practices for configuring the files and folders that comprise your Web site to use NTFS security features.

- Setting NTFS Permissions for Directories or Files: Provides procedural information about configuring NTFS permissions, which define the level of file or directory access assigned to a Windows user account.

# Best Practices for Securing Files with NTFS Permissions

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Observe the following best practices when you set NTFS permissions:

- Assign permissions to groups rather than to users. Because it is inefficient to maintain user accounts directly, assigning permissions on a user basis should be the exception.
- If possible, avoid changing the default permission entries on file system objects, particularly on system folders and root folders. Changing default permissions can cause unexpected access problems or reduce security.
- Never deny the Everyone group access to an object. If you deny Everyone permission to an object, it includes administrators. A better solution is to remove the Everyone group, as long as you give other users, groups, or computers permissions to that object. You may also need to assign Full Control to the Administrators group and LocalSystem.
- Inherited Deny permissions do not prevent access to an object if the object has an explicit Allow permission entry. Explicit permissions take precedence over inherited permissions, including inherited Deny permissions.
- Deny permissions should be used only for the following special cases:
    - To exclude a subset of a group which has Allowed permissions.
    - To exclude one special permission when you have already assigned Full Control to a user or group.
- Use care when configuring NTFS permissions for your Web site. Inappropriately set permissions can deny valid users access to required files and directories. For example, even though a user has the correct user rights to view and execute a program, the user might not have permission to access a particular dynamic-link library (DLL) that is required to run that program. To guarantee users secure and uninterrupted file access, place related files in the same directory, and then assign the appropriate NTFS permissions to the directory.

**Related Information**

- For more information about NTFS permissions, see "Access Control" in Help and Support Center in Windows Server 2003.
- For more information about converting a volume from the FAT or FAT32 file system to NTFS, see "Convert" in Help and Support Center in Windows Server 2003.

# Setting NTFS Permissions for Directories or Files

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can control access to your Web site's directories and files by setting NTFS access permissions. You can use NTFS permissions to define the level of access that you want to grant to specific users, and groups of users. The appropriate configuration of file and directory permissions is crucial for preventing unauthorized access to your resources.

The procedures in this section explain how to secure Web sites using IIS Manager, which allows setting permissions on Web sites, directories, and virtual directories. Files inherit permissions from directories. To set permissions on individual files, use a programmatic solution, such as Adsutil.vbs IIS Administration Utility.

This section includes the following information:

- Securing a Web Site Using NTFS Permissions: Describes how to set NTFS permissions on a Web site.
- Securing a Web Site Using NTFS Special Permissions: Describes how to set NTFS special permissions on a Web site.

# Securing a Web Site Using NTFS Permissions

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can strengthen the security of a Web site by configuring NTFS permissions for directories, virtual directories, or the Web site itself.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To secure a Web site by using NTFS permissions**

1. In IIS Manager, expand the local computer, right-click a Web site or file, and then click **Permissions**.

   Do one of the following:

| Task | Procedure |
| --- | --- |
| Add a group or user that does not appear in the **Group or user names** list box. | a. Click **Add**.<br>b. In the **Enter the object name to select** box, type the name of the user or group, and then click **OK**. |
| Change or remove permissions from an existing group or user. | In the **Group or user names** list box, click the name of the group or user. |

2. To allow or deny a specific permission, in the **Permissions for** *User or Group* list box, select the **Allow** or **Deny** check box.

| **Important** |
| --- |
| Inherited Deny permissions do not prevent access to an object if the object has an explicit Allow permission entry. Explicit permissions take precedence over inherited permissions, including inherited Deny permissions. |

**Related Information**

- For more information about access control, see "Access Control" in Help and Support Center for Windows Server 2003.

# Securing a Web Site Using NTFS Special Permissions

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

With NTFS permissions, you can assign special permissions to groups or users. Special permissions are permissions on a more detailed level. For better management, you should assign broad-level permissions to users or groups, where it is applicable. For descriptions of permissions, see "Permissions for Files or Folders" in Help and Support Center for Windows Server 2003.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To secure a Web site by using NTFS special permissions**

1. In IIS Manager, expand the local computer, right-click a Web site, directory, or virtual directory, and then click **Permissions**.
2. Click the **Advanced** tab, and then do one of the following:

| To | Do this |
| --- | --- |
| Set special permissions for an additional group or user | Click **Add**, and in the **Enter the object name to select** box, type the name of the user or group, and then click **OK**. |
| View or change special permissions for an existing group or user | Click the name of the group or user and then click **Edit**. |
| Remove an existing group or user and its special permissions | Click the name of the group or user and then click **Remove**. If the **Remove** button is unavailable, clear the **Allow inheritable permissions from the parent to propagate to this object and all child objects. Include these with entries exclusively defined here.** check box, and then click **Remove**. Click **OK** and skip steps 3-6 below. |

3. In the **Permissions** box, select or clear the appropriate **Allow** or **Deny** check boxes.
4. In the **Apply onto** list box, click the folders or subfolders you want these permissions to be applied to.
5. To prevent the subfolders and files from inheriting these permissions, clear the **Apply these permissions to objects and/or containers within this container only** check box.
6. Click **OK** three times.

| **Important** |
| --- |
| You should assign permissions to the highest-level folders possible and then apply inheritance to propagate the settings to lower-level subfolders and files. For more information about inheritance, see "How Inheritance Affects File and Folder Permissions" in Help and Support Center for Windows Server 2003. |

**Related Information**

- For more information about access control, see "Access Control" in Help and Support Center for Windows Server 2003.

# Securing Sites with Web Site Permissions

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Web site permissions are not meant to be used in place of NTFS permissions. Instead, they are used with NTFS permissions to strengthen the security of your Web site content. You can configure your Web site's access permissions for specific sites, directories, and files. Unlike NTFS permissions, Web site permissions affect everyone who tries to access your Web site.

The following conditions apply to setting permissions:

- If Web site permissions conflict with NTFS permissions for a directory or file, the more restrictive settings are applied.
- Disabling permissions restricts all users. For example, disabling the Read permission restricts all users from viewing a file, regardless of the NTFS permissions applied to those users' accounts. However, enabling the Read permission can allow all users to view that file, unless NTFS permissions that restrict access have also been applied.
- If both IIS and NTFS permissions are set, the permissions that explicitly deny access take precedence over permissions that grant access.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set permissions for Web content (including WebDAV)**

1. In IIS Manager, double-click the local computer; right-click the **Web Sites** folder, an individual Web site folder, a virtual directory, or a file; and then click **Properties**.

   | **Note** |
   | --- |
   | Configuration settings made at the Web Sites level are inherited by all of the Web sites on the server. You can override inheritance by configuring the individual site or site element. |

2. On the **Home Directory**, **Virtual Directory**, or **File** property sheet, select or clear any of the following check boxes (if available):

   - **Read** (selected by default) Users can view directory or file content and properties.
   - **Write** Users can change directory or file content and properties.
   - **Script Source Access** Users can access source files. If Read is selected, then source can be read, if Write is selected, then source can be written to. Script Source Access includes the source code for scripts. This option is not available if neither Read nor Write is selected.

     | **Important** |
     | --- |
     | When you select **Script source access**, users might be able to view sensitive information, such as a user name and password. They might also be able to change source code that runs on your server, and thereby significantly affect your server's configuration and performance. |

   - **Directory browsing** Users can view file lists and collections.

- **Log visits** A log entry is created for each visit to the Web site.
- **Index this resource** Allows Indexing Service to index this resource. This allows searches to be performed on the resource.

3. Under **Execute Permissions** select the appropriate level of script execution:
   - **None** Do not run scripts or executables on the server.
   - **Scripts only** Run only scripts on the server.
   - **Scripts and Executables** Run both scripts and executables on the server.
4. Click **OK**.

**Related Information**

- For information about securing WebDAV, see Managing WebDAV Security.
- For information about setting NTFS permissions, see Securing Files with NTFS Permissions.

# Allowing Anonymous Access to Web Sites

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Anonymous access, the most common Web site access control method, allows anyone to visit the public areas of your Web sites. In IIS 6.0, anonymous users are assigned by default to the IUSR_*computername* account, which is a valid Windows account that is a member of the **Guests** group. The IUSR_*computername* account can be defined on a computer or on a domain.

**Procedures**

**To create a new "anonymous logon" user account**

1. Change the account used for anonymous authentication. For more information, see Changing the Account Used for Anonymous Authentication.
2. Assign the following NTFS permissions on the Web site directory for the anonymous account: **Read & Execute**, **List Folder Contents**, and **Read**. When setting permissions on a Web site, be aware that all subfolders and files inherit these permissions by default. For more information about changing NTFS permissions on a Web site directory, see Setting NTFS Permissions for Directories or Files and "Access Control" in Help and Support Center for Windows Server 2003.

For security reasons, in order to run most executables (such as Cmd.exe) in the system folder, you must be a member of the Administrators group, the LocalSystem, Interactive, or Service account. Because this limits remote access to administrators, an anonymous user will not be able to run these executables (such as a CGI program).

| **Note** |
| --- |
| In IIS 6.0, the IUSR_*COMPUTERNAME* account has been denied write access to Web content by default. |

**Related Information**

- For information about creating a user account, see "Creating user and group accounts" in Help and Support Center for Windows Server 2003.
- For information about modifying user rights, see "Edit Local Security Settings" or "Edit a Security Setting on a Group Policy Object" in Help and Support Center for Windows Server 2003.

# Configuring Worker Process Identities

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In previous versions of IIS, the worker processes ran as the LocalSystem account. Because the LocalSystem account has access to almost all resources on the operating system, this had serious security implications. IIS 6.0 offers better security in that the worker process runs under the new built-in Network Service account by default. IIS 6.0 also allows you to configure which account worker processes run as. You have the option of using one of the three predefined accounts, or creating your own account.

This section includes the following information:

- Configuring a Worker Process Identity Using a Predefined Account: Describes how to specify a predefined account as the worker process identity of an application pool.
- Configuring a Worker Process Identity Using a Configurable Account: Describes how to create a new account as the worker process identity of an application pool.
- Configuring Applications to Run Independently of Each Other: Describes how to isolate applications by configuring them in separate application pools that run with different worker process identities.

# Configuring a Worker Process Identity Using a Predefined Account

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure a predefined account, such as Network Service, Local Service, or Local System, as the worker process identity for an application pool.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To configure a worker process identity for an application pool using a predefined account**

1. In IIS Manager, expand the local computer, expand the **Application Pools** folder, right-click the application pool you want to configure, and then click **Properties**.
2. Click the **Identity** tab.
3. Click **Predefined**, and in the list box beside it, click **Network Service**, **Local Service**, or **Local System**.

   | **Note** |
   | --- |
   | Network Service, Local Service and LocalSystem are members of the IIS_WPG group. |

4. Click **OK**.

**Related Information**

- For information about adding user accounts to groups, see "Add a Member to a Local Group" in Help and Support Center for Windows Server 2003.
- For information about application pools, see Configuring Application Pools in IIS 6.0.

# Configuring a Worker Process Identity Using a Configurable Account

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure a custom account to use as the worker process identity for an application pool.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To configure a worker process identity for an application pool using a configurable account**

1. In IIS Manager, expand the local computer, expand the **Application Pools** folder, right-click the application pool you want to configure, and then click **Properties**.
2. Click the **Identity** tab.
3. Click **Configurable**.
4. Click **Browse**, and under **Enter the object name to select**, type the account name in which you want your worker process to run, and then click **OK**.
5. In the **Password** box, type the password associated with this account. If there is no password associated with the account, leave the **Password** box blank.
6. Click **OK**.
7. Add the account you just created to the IIS_WPG group. For information about adding user accounts to groups, see "Add a Member to a Local Group" in Help and Support Center for Windows Server 2003.
8. If the account you just created must be able to start CGI processes, assign the following user rights to this account: **Adjust memory quotas for a process** and **Replace a process level token**. For information about configuring user rights for CGI applications, see Configuring CGI Applications.

**Related Information**

- For information about application pools, see Configuring Application Pools in IIS 6.0.
- For information about configuring NTFS permissions, see Best Practices for Securing Files with NTFS Permissions.

# Configuring Applications to Run Independently of Each Other

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

*Application isolation* is the separation of applications through process boundaries to prevent them from affecting one another.

For worker process isolation mode, you can configure isolation using application pools. You can either place single applications into their own application pool or group multiple applications into a single application pool.

**Procedures**

**To configure applications to run independently of each other**

1. Create a new account and configure a worker process identity for an application pool.
2. Add the account to the IIS_WPG group. The IIS_WPG group has **Read & Execute**, **List Folder Contents**, and **Read** permissions on every Web site directory by default. In a case where the account is not in the IIS_WPG group and does not have the appropriate permissions, the worker process will fail to start.

**Related Information**

- For information about adding user accounts to groups, see "Add a Member to a Local Group" in Help and Support Center for Windows Server 2003.
- For information about application pools, see Configuring Application Pools in IIS 6.0.
- For information about configuring NTFS permissions, see Best Practices for Securing Files with NTFS Permissions.

# Securing Sites with IP Address Restrictions

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure your Web sites and FTP sites to grant or deny specific computers, groups of computers, or domains access to Web sites, FTP sites, directories, or files. For example, if your intranet server is connected to the Internet, you can prevent Internet users from accessing your server by granting access only to members of your intranet, and explicitly denying access to outside users.

| **Note** |
| --- |
| IP address restrictions apply only to IPv4 addresses. |

| **Note** |
| --- |
| In Windows 2003 Server Service Pack 1 (SP1), HTTP.sys will not cache content from a Web site with restricted IP addresses. In this case, you might consider using Internet Protocol Security (IPSec) instead of IP address restriction. For more information about IPSec, see Creating an IPsec Policy to Restrict Ports. |

This section includes the following information:

- Granting or Denying Access to a Computer: Describes how to configure IP address restrictions to grant or deny access to a computer.
- Granting or Denying Access to a Domain: Describes how to configure IP address restrictions to grant or deny access to a domain.
- Granting or Denying Access to a Group of Computers: Describes how to configure IP address restrictions to grant or deny access for a group of computers.

# Granting or Denying Access to a Computer

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use the following procedure to grant or deny access to a specific computer.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To grant or deny access to a computer**

1. In IIS Manager, double-click the local computer; right-click the **Web Sites** or **FTP Sites** folder, an individual Web or FTP site, a virtual directory, or a file; and then click **Properties**.

   | **Note** |
   | --- |
   | Configuration settings made at the Web or FTP Sites level are inherited by all of the Web or FTP sites on the server. You can override inheritance by configuring the individual site or site element. |

2. Click the **Directory Security** or **File Security** tab, and then do one of the following:

   - For Web sites, in the **IP address and domain name restrictions** section, click **Edit**.
   - For FTP sites, continue to the next step.

3. Click **Granted access** or **Denied access**. When you select **Denied access**, you deny access to all computers and domains, except to those that you specifically grant access. When you select **Granted access**, you grant access to all computers and domains, except to those that you specifically deny access.
4. Click **Add**, and then click **Single computer**.
5. Click **DNS Lookup** to search for computers or domains by name, rather than by IP address.
6. Type the DNS name for the computer. IIS searches on the current domain for the computer, and if found, enters its IP address in the **IP address box**.

   The following information is important to remember when using the **DNS Lookup** feature:

   - It causes a performance decrease on your server while it is looking up DNS addresses.
   - A user accessing your Web server through a proxy server appears to have the IP address of the proxy server.
   - Some user server access problems can be corrected by entering the "*.*domainname*.com" syntax, rather than the "*domainname*.com" syntax.

7. Click **OK** three times.

**Related Information**

- For more information about IP address restrictions, see Setting IP Address and Domain Name Restrictions.
- For more information about subnet masks, see "Subnet masks" in the Windows Server 2003 Help and Support Center.

# Granting or Denying Access to a Domain

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use the following procedure to grant or deny access to a specific domain.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To grant or deny access to a domain**

1. In IIS Manager, double-click the local computer; right-click the **Web Sites** or **FTP Sites** folder, an individual Web or FTP site, a virtual directory, or a file; and then click **Properties**.

   | **Note** |
   | --- |
   | Configuration settings made at the Web or FTP Sites level are inherited by all of the Web or FTP sites on the server. You can override inheritance by configuring the individual site or site element. |

2. Click the **Directory Security** or **File Security** tab, and then do one of the following:
   - For Web sites, in the **IP address and domain name restrictions** section, click **Edit**.
   - For FTP sites, continue to the next step.
3. Click **Granted access** or **Denied access**. When you select **Denied access**, you deny access to all computers and domains, except to those that you specifically grant access. When you select **Granted access**, you grant access to all computers and domains, except to those that you specifically deny access.
4. Click **Add**, and then click **Domain name**.
5. In the **Domain name** box, type the domain name, and then click **OK** three times.

**Related Information**

- For more information about IP address restrictions, see Setting IP Address and Domain Name Restrictions.
- For more information about subnet masks, see "Subnet masks" in the Windows Server 2003 Help and Support Center.

# Granting or Denying Access to a Group of Computers

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

A group of computers can be either denied or granted access based upon their network ID and a subnet mask.

For example, if the host computer has an IP address of 172.16.16.1 and a subnet mask of 255.255.0.0, all of the computers in that subnet would have IP addresses that began with 172.16. To select all of the computers in the subnet, enter 172.16.16.1 in the **Network ID** box and 255.255.0.0 in the **Subnet Mask** box.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the runas command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To grant or deny access to a group of computers**

1. In IIS Manager, double-click the local computer; right-click the **Web Sites** or **FTP Sites** folder, an individual Web or FTP site, a virtual directory, or a file; and then click **Properties**.

   | **Note** |
   | --- |
   | Configuration settings made at the Web or FTP Sites level are inherited by all of the Web or FTP sites on the server. You can override inheritance by configuring the individual site or site element. |

2. Click the **Directory Security** or **File Security** tab, and then do one of the following:
   - For Web sites, in the **IP address and domain name restrictions** section, click **Edit**.
   - For FTP sites, continue to the next step.
3. Click **Granted access** or **Denied access**. When you select **Denied access**, you deny access to all computers and domains, except to those that you specifically grant access. When you select **Granted access**, you grant access to all computers and domains, except to those that you specifically deny access.
4. Click **Add**, and then click **Group of computers**.
5. In the **Network ID** box, type the IP address of the host computer.
6. In the **Subnet mask** box, type the subnet ID for the computer you want grant or deny access to, and then click **OK** three times.

**Related Information**

- For more information about IP address restrictions, see Setting IP Address and Domain Name Restrictions.
- For more information about subnet masks, see "Subnet masks" in the Windows Server 2003 Help and Support Center.

# Securing Virtual Directories

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can secure virtual directories by using local user authentication. IIS supports controlling access to directories and files on a local computer using all Windows authentication methods.

This section includes the following information:

- Securing a Virtual Directory: Describes how to create a secure virtual directory on the local computer.
- Changing Security on an Existing Virtual Directory: Describes how to change the security setting for an existing virtual directory.

# Securing a Virtual Directory

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure access permissions when you create a virtual directory.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To create a secure virtual directory mapped to resources on the local computer**

1. In IIS Manager, expand the local computer, expand the **Web Sites** folder, right-click the Web Site or folder within which you want to create the virtual directory, point to **New**, and then click **Virtual Directory**.
2. Click **Next**.
3. In the **Alias** box, type the alias for the new virtual directory, and then click **Next**.
4. In the **Path** box, type the path to the local directory, and then click **Next**.
5. Select the appropriate check boxes for the access permissions you want to allow, and clear the check boxes for the permissions you want to deny.
6. Click **Next** to complete the wizard.

**Related Information**

- For information about changing the security setting on an existing virtual directory, see Changing Security on an Existing Virtual Directory.
- For information about using virtual directories, see Using Virtual Directories.

# Changing Security on an Existing Virtual Directory

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

To protect the contents of an existing virtual directory, you can change the access permissions on the virtual directory.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To change security on an existing virtual directory mapped to resources on the local computer**

1. In IIS Manager, right-click the virtual directory you want to secure, and click **Properties**.
2. On the **Virtual Directory** tab, under **Local Path**, select the check boxes for the access permissions you want to allow, and clear the check boxes for the permissions you want to deny.
3. Click **OK**.

**Related Information**

- For information about creating a secure virtual directory, see Securing a Virtual Directory.
- For information about using virtual directories, see Using Virtual Directories.

# URL Authorization in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

URL authorization helps simplify access management by authorizing user access to the URLs that comprise a Web application. IIS 6.0 works with Authorization Manager, a management tool available with the Windows Server 2003 operating systems, to implement IIS URL authorization. For information about Authorization Manager, see "Authorization Manager" in Help and Support Center for Windows Server 2003.

To use URL authorization in IIS 6.0 you must perform the following configuration tasks, in the order specified below:

- Disabling Anonymous Access for an Application, Virtual Directory, or Web Site Describes how to disable anonymous access for applications, virtual directories, or Web sites that use URL authorization.
- Enabling Wildcard Scriptmapping for an Application, Virtual Directory, or Web Site Describes how to enable the Urlauth.dll ISAPI interceptor.
- Adding Urlauth.dll as a New Web Service Extension Describes how to add Urlauth.dll to the list of Web service extensions.
- Creating an Authorization Policy Store in Authorization Manager Describes how to create a policy store in Authorization Manager for the URL.
- Setting the Scope for the Application Describes how to set the scope for URL authorization.
- Adding the IIS Worker Process to the Readers Role Describes how to configure the Readers role in Authorization Manager to accept the IIS worker process identity.
- Setting Metabase Properties for URL Authorization Describes how to set IIS metabase properties to ensure that URL authorization works correctly.

# Disabling Anonymous Access for an Application, Virtual Directory, or Web Site

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Integrated Windows authentication is the default authentication method for Windows Server 2003 operating systems. It is required for applications, virtual directories, or Web sites that use URL authorization. Anonymous access is not permitted.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc** *%systemroot%***\system32\inetsrv\iis.msc"**. |

**Procedures**

**To disable anonymous access for an application, virtual directory, or Web site**

1. In IIS Manager, expand the local computer and then expand the **Web Sites** folder.
2. Do one of the following:

   Expand the Web site that contains the application for which you want to configure URL authorization, right-click the application directory, and then click **Properties**.

   Or

   Expand the Web site that contains the virtual directory for which you want to configure URL authorization, right-click the virtual directory, and then click **Properties**.

   Or

   Right-click the Web site where you want to configure URL authorization, and then click **Properties**.
3. Click the **Directory Security** tab, and in the **Authentication and access control** section, click **Edit**.
4. Clear **Enable anonymous access**, ensure that **Integrated Windows authentication** is checked in the **Authenticated access** section, and then click **OK**.

**Related Information**

- For more information about Integrated Windows authentication, see Integrated Windows Authentication in IIS 6.0.

# Enabling Wildcard Scriptmapping for an Application, Virtual Directory, or Web Site

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

URL authorization uses *wildcard scriptmapping* as implemented by an ISAPI interceptor, Urlauth.dll. To use Urlauth.dll, you must first enable it for each Web site, application, or virtual directory where you want to configure URL authorization.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc** *%systemroot%***\system32\inetsrv\iis.msc"**. |

**Procedures**

**To configure wildcard scriptmapping for an application, virtual directory, or Web site**

1. In IIS Manager, expand the local computer and then expand the **Web Sites** folder.
2. Do one of the following:

   Expand the Web site that contains the application for which you want to configure URL authorization, right-click the application directory, and then click **Properties**.

   Or

   Expand the Web site that contains the virtual directory for which you want to configure URL authorization, right-click the virtual directory, and then click **Properties**.

   Or

   Right-click the Web site where you want to configure URL authorization, and then click **Properties**.
3. Click the **Directory** tab (for an application), the **Virtual Directory** tab (for a virtual directory), or the **Home Directory** tab (for a Web site), and then in the **Application settings** section, click **Configuration**.
4. Click the **Mappings** tab, and then in the **Wildcard application maps** section, click **Insert**.
5. In the **Add/Edit Application Extension Mapping** box, click **Browse** and browse to the **Windows\system32\inetsrv** directory.
6. Click **urlauth.dll**, click **Open**, and then click **OK** three times.

**Related Information**

- For more information about application mappings, see Installing Wildcard Application Mappings.

# Adding Urlauth.dll as a New Web Service Extension

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you want to use a Web service extension that is not in the default list of extensions, you must add the file to the list, and then enable the Web service extension.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc** *%systemroot%***\system32\inetsrv\iis.msc"**. |

**Procedures**

**To add Urlauth.dll as a new Web service extension**

1. In IIS Manager, expand the local computer, right-click the **Web Service Extensions** node, and then click **Add a new Web service extension**.
2. In **Extension Name**, type the following text exactly as it appears below:

   ```
   URL Authorization
   ```

   and then click **Add**. If you do not type this text exactly as it appears, IIS URL authorization fails without sending a warning message.
3. Click **Browse** on the **Add file** dialog box, browse to *systemroot***\system32\inetsrv**, select urlauth.dll, click **Open**, and then click **OK** twice.
4. Check **Set extension status to Allowed**, and then click **OK**.

**Related Information**

- For more information about application mappings, see Installing Wildcard Application Mappings.
- For more information about web service extensions, see Enabling and Disabling Dynamic Content in IIS 6.0.

# Creating an Authorization Policy Store in Authorization Manager

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

An authorization store is a database that stores Authorization Manager policy.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc** *%systemroot%***\system32\inetsrv\iis.msc"**. |

**Procedures**

**To create an authorization policy store in Authorization Manager**

1. Click **Start**, click **Run**, type

   ```
   Azman.msc
   ```

   and then click **OK**.

2. In the console tree, right-click **Authorization Manager** and then click **Options**.
3. Confirm that **Developer mode** is selected, and then click **OK**.
4. In the console tree, right-click **Authorization Manager** and then click **New Authorization Store**.
5. Click **XML file** and, in **Store name**, type the name of the store, for example, C:\MyStore.xml.
6. Optionally, in **Description**, type information about the new store, and then click **OK**.
7. In the console tree, right-click the store file you just created and then click **New Application**.
8. In **New Application**, in **Name**, type the following text exactly as it appears below:

   ```
   IIS 6.0 URL Authorization
   ```

   If you do not type this text exactly as it appears, IIS URL authorization fails without sending a warning message.

9. Optionally, in **Description**, type information about this usage of IIS URL Authorization, and then click **OK**.
10. In the console tree, double-click **Authorization Manager**, double-click the store name, double-click the application name (IIS 6.0 URL Authorization), double-click **Definitions**, right-click **Operation Definitions**, and then click **New Operation Definition**.
11. In **New Operation Definition**, in **Name**, type the following text exactly as it appears below:

    ```
    AccessURL
    ```

    In **Operation number**, type the numeral **1**, and then click **OK**. If you do not type this text exactly as it appears, IIS URL authorization fails without sending a warning message.

**Related Information**

- For more information about Authorization Manager, see Help and Support Center in Windows Server 2003.

# Setting the Scope for the Application

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

A *scope* is a subdivision within an application that separates selected resources from other resources that are used by the application. Scopes can help to prevent unintended resource sharing, as well as to support auditing and delegation.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc** *%systemroot%***\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set the scope for the application**

1. If Authorization Manager is not already open, click **Start**, click **Run**, type

   ```
   Azman.msc
   ```

   and then click **OK**.

2. In the console tree, right-click **IIS 6.0 URL Authorization** and then click **New Scope**.

3. In **Name**, type the following text exactly as it appears below:

   ```
   WebApp
   ```

   and then click **OK**. If you do not type this text exactly as it appears, IIS URL authorization fails without sending a warning message.

4. In the console tree, double-click **IIS 6.0 URL Authorization**, double-click **Definitions**, right-click **Role Definitions**, and then click **New Role Definition**.

5. In **New Role Definition**, in **Name**, type the following text exactly as it appears below:

   ```
   Viewer
   ```

   and then click **Properties**.

   If you do not type this text exactly as it appears, IIS URL authorization fails without sending a warning message.

6. Click the **Definition** tab, click **Add**, and then click the **Operations** tab.

7. Select the **AccessURL** checkbox and then click **OK** twice.

8. In the console tree, under **IIS 6.0 URL Authorization**, under **WebApp**, right-click **Role Assignments**, and then click **Assign Roles**.

9. Select the **Viewer** checkbox and then click **OK**.

10. In the details pane, right-click the role assignment you created above, and then click **Assign Windows Users and Groups**.

11. In **Enter the object names to select (examples)**, type your user name, and then click **OK**.

**Related Information**

- For more information about Authorization Manager, see Help and Support Center in Windows Server 2003.

# Adding the IIS Worker Process to the Readers Role

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

By default, IIS runs in the Network Service account. You can, however, configure an IIS worker process to run in a different account.

If you use a remote authorization store, such as Active Directory or a remote XML file-based store, and you run IIS in the default Network Service context, you must add the Active Directory account of the Web server running IIS to the store's Readers role.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc** *%systemroot%***\system32\inetsrv\iis.msc"**. |

**Procedures**

### To add the IIS worker process to the Readers role

1. If Authorization Manager is not already open, click **Start**, click **Run**, type

   ```
   Azman.msc
   ```

   and then click **OK**.

2. In the console tree, right-click **Authorization Manager**, click **Open Authorization Store**, click **Browse**, click the name of the authorization store file you want to update, click **Open**, and then click **OK**.

3. In the console tree, right-click the name of the store, and then click **Properties**.

4. Click the **Security** tab, and in the **Authorization manager user role** list, click **Reader**, and then click **Add**.

5. In the **Enter the object names to select (examples)** box, type the name of the IIS worker process, and then click **OK** twice.

**Related Information**

- For more information about application mappings, see Installing Wildcard Application Mappings.

- For more information about configuring a worker process account, see Configuring a Worker Process Identity Using a Configurable Account.

# Setting Metabase Properties for URL Authorization

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

To use URL authorization, you must set the required metabase properties on the application, virtual directory, or Web site where you want to authorize user access. You can either edit the metabase directly or run a script to set metabase properties.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile/User:***MyComputer***\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

**Procedures**

**To set metabase properties for URL authorization by editing the metabase directly**

- Edit the metabase directly to set the following metabase properties:
  - AzEnable Metabase Property: Enables URL authorization for the virtual directory, application, or URL that corresponds to the entry in the metabase.
  - AzStoreName Metabase Property: Associates an Authorization Manager store with the virtual directory, application, or URL.
  - AzScopeName Metabase Property: Associates the virtual directory, application, or URL with a scope. This scope will be the name of a scope in the IIS 6.0 URL authorization application in the Authorization Manager policy store referred to in the **AzStoreName** attribute. If no scope or an empty string is specified, the default scope of the IIS 6.0 URL authorization will be used.
  - AzImpersonationLevel Metabase Property: Determines the impersonation behavior for the application. This allows you to configure the Web application to impersonate the client user, the IIS worker process, or the IUSR_*computername* account for the worker process. Each setting significantly changes the environment and implied design of the Web application.

The sample script, written in Microsoft Visual Basic® Scripting Edition (VBScript), marks the root of the first site as a URL in MyAZScope, which is defined in the MyAZStore.xml file. Users with URLAccess rights in this scope will be able to access the site.

**To set metabase properties for URL authorization by using a script**

- Use the following sample script as a guide to setting the required metabase properties:

```
var objVDir = GetObject("IIS://localhost/w3svc/1/root")

objVDir.AzEnable = true

objVDir.AZStoreName = "MSXML://d:\MyAZStore.xml"

objVDir.AzScopeName = "MyAZScope"

objVDir.AZImpersonationLevel = 0

objVDir.SetInfo()
```

**Related Information**

- For more information about the IIS Metabase, see Working with the Metabase.

# IIS 6.0 Encryption

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use encryption to help protect the private information that clients exchange with your Web server, such as credit card numbers or phone numbers. You can also encrypt data when running WMI-based remote administration scripts. In IIS, the foundation for encryption is the Secure Sockets Layer (SSL) protocol, which establishes an encrypted communication link with users.

This section contains the following information:

- Configuring Secure Sockets Layer: Describes how to configure a Web server or Web site to use SSL for secure connections.
- Setting Encryption Strength: Describes how to configure encryption strength in IIS Manager.
- Encrypting Data When Running WMI–Based Remote Administration Scripts: Describes how to modify WMI-based administration scripts to establish an encrypted remote connection.

# Configuring Secure Sockets Layer

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This section contains the following information:

- Configuring SSL on a Web Server or Web Site: Describes how to configure a Web server or Web site to use SSL for secure connections.
- Redirecting Bookmarked Requests to SSL-Enabled Content: Describes how to prevent 404 errors by redirecting requests from http:// to https:// URLs.
- Enabling Kernel-Mode SSL: Describes how to enable kernel-mode SSL for a Web Server.

# Configuring SSL on a Web Server or Web Site

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure Secure Sockets Layer (SSL) security features on a Web server or a Web site to verify the integrity of your content, verify the identity of users, and encrypt network transmissions.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To configure SSL on a Web server or a Web site**

1. In IIS Manager, double-click the local computer, and then double-click the **Web Sites** folder.
2. Right-click the Web site or file that you want to protect with SSL, and then click **Properties**.
3. Under **Web site identification** click **Advanced**.
4. In the **Advanced Web site identification** box, under **Multiple identities for this Web site**, verify that the Web site IP address is assigned to port 443, the default port for secure communications, and then click **OK**. Optionally, to configure more SSL ports for this Web site, click **Add** under **Multiple identities of this Web site**, and then click **OK**.
5. On the **Directory Security** or **File Security** tab, under **Secure communications**, click **Edit**.
6. In the **Secure Communications** box, select the **Require secure channel (SSL)** check box.
7. To enable SSL client certificate authentication and mapping features, select the **Enable client certificate mapping** check box, click **Edit**, add the 1-to-1 or many-to-1 mappings you need, and then click **OK** three times.

**Note**

If you set your Web site to require SSL, as in step 6 above, and you have not completed setting up SSL for the site, then users browsing your site will receive this error: "HTTP Error 403.4 - Forbidden: SSL is required to view this resource." To avoid this condition, either complete all the steps in the list above, or go back and clear the **Require Secure Channel (SSL)** check box (see step 6).

**Related Information**

- For information about enabling client certificates, see Enabling Client Certificates in IIS 6.0.
- For information about client certificate mapping, see Mapping Client Certificates to User Accounts in IIS 6.0.

# Redirecting Bookmarked Requests to SSL-Enabled Content

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When you update a Web site configuration to require SSL, users who have previously bookmarked pages on the site will receive a 403.4 "Forbidden: SSL required" error message when they request those pages after SSL is configured. You can prevent this situation by creating a custom error page that automatically redirects the http: call to an https: call.

The example in the following procedure uses ASP, but you can use any dynamic content handler. Because dynamic content handlers are not enabled by default when IIS is installed, you should ensure that the appropriate Web service extension is enabled.

**Procedures**

**To redirect bookmarked requests to SSL-enabled content**

1. Create an ASP page called RedirectToSSL.asp and save it in the root directory of your Web site.
2. Include redirection code similar to the following code example. Note that this code example does not include any error-handling code.

```
<%@Language=VBScript %>
<%
strQueryString = Request.QueryString
strAddress = Right(strQueryString, Len(strQueryString) - Instr(1,strQueryString,
";"))
strSecure = Replace(strAddress, "http:", "https:", 1, 1)
Response.Redirect strSecure
%>
```

3. In IIS Manager, right-click the SSL-enabled Web site and then click **Properties**.
4. In the **Secure communications** section on the **Directory Security** tab, click **Edit**.
5. Click **Require secure channel (SSL)** and then click **OK**.
6. On the **Custom Errors** tab, select the 403;4 error message and then click **Edit**.
7. In the **Message Type** field on the **Edit Custom Error Properties** dialog box, choose **File**, click **Browse** and browse to the location of the RedirectToSSL.asp page, and click **OK** twice.
8. Navigate to the location of the RedirectToSSL.asp page, right-click the page, and then click **Properties**.
9. In the **Secure communications** section on the **File Security** tab, click **Edit**.
10. Clear **Require secure channel (SSL)** and then click **OK** twice.

**Related Information**

- For information about enabling web service extensions, see Enabling Web Service Extensions.
- For more information about SSL, see About Secure Sockets Layer.

# Enabling Kernel-Mode SSL

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Enabling kernel-mode Secure Sockets Layer (SSL) improves SSL performance because encryption and decryption operations take place in the faster processing space of the kernel. However, enabling kernel-mode SSL disables user-mode SSL. For more information, see Kernel-Mode SSL.

| **Important** |
| --- |
| Using Registry Editor incorrectly can cause serious problems that require reinstalling the operating system. Because Registry Editor bypasses the standard safeguards that prevent you from entering settings that are conflicting or likely to degrade performance or damage your system, exercise caution when making changes to the registry. Microsoft cannot guarantee that problems resulting from the incorrect use of Registry Editor can be solved. |

Note that you should back up the registry before you edit it. If you are running Microsoft® Windows NT® Server or a newer server operating system from Microsoft, you should also update your Emergency Repair Disk (ERD).

For information about how to edit the registry, see the "Changing Keys and Values", "Add and Delete Information in the Registry", and "Edit Registry Data" topics in Registry Editor Help.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer***\Administrator cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

**Procedures**

**To configure SSL to run in kernel mode**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type Regedit.exe, and click **OK**.
3. Navigate to and double-click the following key in the registry:

   HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\HTTP\Parameters
4. From the **Edit** menu, point to **Add**, click **DWORD Value** and then add the following registry value:

   Name: **EnableKernelSSL**

   Type: **REG_DWORD**

   Data: Set this to 1 to use kernel-mode SSL instead of user-mode SSL.
5. Quit Registry Editor.
6. Restart IIS.

**Related Information**

- For information about restarting an IIS service, see Restarting IIS.
- For information about configuring SSL, see Configuring SSL on a Web Server or Web Site.

# Configuring SSL Host Headers

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Organizations that host multiple Web sites on a single server often use host headers to create multiple Web sites without requiring a unique IP address for each site. For more information about hosting multiple Web sites on a single server, see Hosting Multiple Web Sites.

You can configure Web sites that use host headers to serve protected content over a Secure Sockets Layer (SSL) connection, that is, a connection that uses https:// instead of http://. To use SSL with host headers, you must obtain and install a wildcard server certificate. After you configure SSL host headers for a Web site, protected content is served only over an https:// connection.

| **Important** |
| --- |
| The following conditions apply to the use of SSL host headers: |

- SSL host headers cannot be configured by using the IIS Manager UI.
- Using SSL host headers requires that the wildcard certificate be installed on each Web site from which you want to serve protected content. This adds overhead to site management, because you must manually ensure that multiple sites are kept in sync with each other.
- You must configure secure bindings for each Web site that uses the wildcard server certificate to prevent unauthorized use of that certificate.

This section includes the following information:

- Obtaining and Installing a Wildcard Server Certificate: Describes how to request a wildcard server certificate and install it on a Web site.
- Configuring Server Bindings for SSL Host Headers: Describes how to configure the **SecureBindings** metabase property to create SSL host headers for each Web site that you want to enable to use the wildcard server certificate.
- Ensuring That Secure Content Is Served Over HTTPS Only: Describes how to prevent unauthorized Web sites from using the wildcard certificate.

# Obtaining and Installing a Wildcard Server Certificate

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

A wildcard server certificate works with many SSL sites, because a wildcard (*) is used to stand for the host header name for each of the sites. All SSL-enabled Web sites that use the same IP/port binding and are distinguished only by their host header names must use the same wildcard server certificate.

| **Important** |
| --- |
| Not all Certification Authorities (CAs) issue wildcard certificates. |

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To obtain a wildcard server certificate**

1. In IIS Manager, expand the local computer, and then expand the **Web Sites** folder.
2. Right-click the Web site for which you want to obtain a wildcard server certificate, and then click **Properties**.
3. On the **Directory Security** tab, under **Secure communications**, click **Server Certificate**.
4. In the Web Server Certificate Wizard, click **Create a new certificate**.
5. Follow the Web Server Certificate Wizard, which will guide you through the process of requesting a new server certificate. On the **Your Site's Common Name** page, type a name in the **Common name** box, using the following format:

   *.< *sitename* >

   for example, *.contoso.com.

   By default, the certificate request file is saved as C:\Certreq.txt, but the wizard allows you to specify a different location.
6. Click **Finish** to complete the wizard.

After you receive the wildcard server certificate from the Certification Authority (CA), assign the certificate on all Web sites that have the same IP/port binding and are distinguished only by host header name.

**Related Topics**

- For information about installing a server certificate, see Installing Server Certificates.
- For general information about certificates, see "SSL and Certificates" in Managing a Secure IIS 6.0 Solution.

# Configuring Server Bindings for SSL Host Headers

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In addition to installing a wildcard server certificate on SSL-enabled Web sites, you must also configure the **SecureBindings** metabase property on each site so it contains the host header name of the site. All SSL-enabled sites that use the same IP/port binding and are distinguished only by host header name must use the same wildcard server certificate.

| **Important** |
| --- |
| You must configure secure bindings for all SSL-enabled Web sites that use the wildcard server certificate to prevent unauthorized use of the certificate. |

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

**Procedures**

**To configure the SecureBindings metabase property for SSL host headers**

1. Click **Start**, click **Run**, type

   ```
   cmd
   ```

   in the **Open** box, and then click **OK**.

2. Type the following command at the command prompt:

   `cscript.exe adsutil.vbs set /w3svc/` *<site identifier>* `/SecureBindings ":443:`*<host header>* `"`

   where *host header* is the host header for the Web site, for example, site2.contoso.com or site4.contoso.com.

**Related Topics**

- For information about preventing unauthorized use of a wildcard server certificate, see Ensuring That Secure Content Is Served Over HTTPS Only.
- For information about the **SecureBindings** metabase property, see SecureBindings Metabase Property.
- For information about Adsutil.vbs, see Using the Adsutil.vbs Administration Script.

# Ensuring That Secure Content Is Served Over HTTPS Only

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

After a certificate is installed on a site, it can be served over HTTP or HTTPS. To ensure that only SSL requests are served, you must configure the **AccessSSL** metabase property to force SSL content requests only.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

**Procedures**

**To force SSL content requests only**

1. Click **Start**, click **Run**, type

   ```
   cmd
   ```

   and then click **OK**.

2. Type the following command at the command prompt:

   ```
   cscript.exe adsutil.vbs set /w3svc/< site identifier >/AccessSSL TRUE
   ```

   where <*site identifier*> is the unique number that identifies the site.

**Related Topics**

- For information about configuring server bindings for SSL host headers, see Configuring Server Bindings for SSL Host Headers.
- For information about Adsutil.vbs, see Using the Adsutil.vbs Administration Script.
- For information about **AccessSSL**, see AccessSSLFlags Metabase Property.

# Setting Encryption Strength

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure your Web server to require a 128-bit minimum session-key strength for all Secure Sockets Layer (SSL) communications. This is the default session-key strength for Microsoft Windows Server 2003.

If you set a minimum 128-bit key strength, users attempting to establish a secure communications channel with your server must use a browser capable of communicating with a 128-bit session *key*. The session key is not the same as an SSL *key pair*, which is used to negotiate and establish a secure communication link. For information about upgrading browsers to 128-bit encryption capability, see How to Upgrade Internet Explorer to 128-Bit Encryption on the Windows Support Web site.

To establish encrypted communications, you must have a valid server certificate installed.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**.

**Procedures**

**To set encryption strength**

1. In IIS Manager, double-click the local computer, and then right-click the Web site, directory, or file that you want and click **Properties**.
2. On the **Directory Security** or **File Security** tab, under **Secure Communications**, click **Edit**.
3. In the **Secure Communications** box, select the **Require secure channel (SSL)** check box.
4. If 128-bit encryption is required, select the **Require 128-bit Encryption** check box.
5. Click **OK**.

**Note**

If you open a Server Gated Cryptography (SGC) certificate, you might receive a notice on the **General** tab that reads as follows: "The certificate has failed to verify for all of its intended purposes." This notice is issued because of the way SGC certificates interact with Windows, and does not necessarily indicate that the certificate does not work correctly.

**Related Information**

- For information about server and client certificates, see Certificates_IIS_SP1_Ops.
- For information about Server-Gated Cryptography (SGC), an extension of SSL that allows financial institutions with export versions of IIS to use strong encryption, see Server-Gated Cryptography.
- For information about SSL encryption, see About Secure Sockets Layer.

# Encrypting Data When Running WMI–Based Remote Administration Scripts

Updated: August 22, 2005

Applies To: Windows Server 2003 R2, Windows Server 2003 with SP1

WMI-based administration scripts operating on an IIS server over a remote connection send data over the network in clear text. You can enhance security by modifying WMI-based administration scripts to establish an encrypted remote connection.

| **Important** |
| --- |
| For Windows Server 2003 with Service Pack 1 (SP1), WMI-based remote administration scripts must be modified to encrypt authentication credentials and data as outlined in this topic. If you do not modify the scripts, they will fail. |

Use one of the following two methods to establish an encrypted remote connection:

- Use the **IWbemLocator::ConnectServer** method when an administrator user name and password must be passed to the remote server.
- Use the **GetObject** function when an administrator user name and password do not need to be passed to the remote server. This is the case when the administrator user name and password on the remote server and on the server running the script are the same.

To establish an encrypted connection to a remote server when an administrator user name and password must be provided, use the **ConnectServer** method to connect to the server, and then set the **AuthenticationLevel** property to encrypt the connection. The following code example illustrates this.

| **Note** |
| --- |
| The **ConnectServer** call encrypts the administrator user name and password. |

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

```
var locatorObj=new ActiveXObject("WbemScripting.SWbemLocator");
provObj=locatorObj.ConnectServer(Server_Name,"root/MicrosoftIISv2",
AdministratorUserName, AdministratorPassword);
var wbemAuthenticationLevelPktPrivacy=6;
provObj.Security_.AuthenticationLevel=wbemAuthenticationLevelPktPrivacy;
```

To establish an encrypted connection to a remote server when an administrator user name and password do not need to be provided, use the **GetObject** function, and then set the **AuthenticationLevel** property to **pktPrivacy**. The following code example illustrates this.

```
provObj=GetObject( "winmgmts:
{AuthenticationLevel=pktPrivacy}!//Server_Name/root/MicrosoftIISv2");
```

**Related Information**

- For more information about security settings in WMI scripts, see the Scripting API for WMI on MSDN Online.

# Creating an IPsec Policy to Restrict Ports

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Internet Protocol security (IPsec) is designed to encrypt data as it travels between two computers, protecting it from modification and interpretation. To use IPsec, you must define how computers that attempt to connect will trust each other and how the computers will secure their traffic. To implement these specifications, create and apply an IPsec policy. IPsec policies support policy-based stateful packet filtering rules that can be used with IPsec authentication and encryption to provide robust end-to-end security.

**Example: Creating an IPsec Policy**
This section provides step-by-step instructions for creating an example IPsec policy that allows inbound requests to connect only to ports 80 and 443. Port 80 is the default port for HTTP requests, and port 443 is the default port for HTTPS requests. The policy blocks requests for all other ports on the server.

In contrast with typical firewall or packet filtering rules, there is no way to order the list of rules in an IPsec policy. The rule engine matches traffic with rules according to specificity. If a packet matches more than one rule, the engine will apply the most specific rule to the packet. In the following example, packets that match the filter list that allows connections to port 80 also match the filter list that blocks all incoming traffic. Because the former list is more specific, the rule engine uses that list to make its decision. Therefore, traffic that connects to port 80 or port 443 is passed to the server, while everything else is blocked. You need to create multiple filter lists to make the policy effective.

There are several steps to creating an IPsec policy:

1. Create IPsec filter lists. Filter lists include ports, protocols, and directions and trigger a decision when traffic matches an item in the list. This example requires you to create three filter lists. The first two filter lists apply to inbound traffic that attempts to connect to port 80 or 443, and the third filter list applies to all ports.

2. Set filter actions. Filter actions are the required response when traffic matches a filter list. This example uses only permit and block actions for its IIS IPsec policy.

3. Create the IPsec policy. The IPsec policy is a collection of rules, which are the correlation of a filter list with a filter action. You can have only one active, or assigned, policy at any particular time.

The following steps are for creating IPsec policies using the Local Security Settings snap-in in Windows Server 2003. You can also create IPsec policies using the **Netsh** commands for IPsec. For more information about **Netsh** commands for IPsec, see IPsec.

To create IPsec filter lists, begin by changing the security settings on the local computer.

**To create the IPsec filter lists**

1. From the **Start** menu, point to **All Programs**, point to **Administrative Tools**, and then select **Local Security Policy**.

2. In the **Local Security Settings** dialog box, click **IP Security Policies on Local Computer**. The right pane displays the default Windows Server 2003 policies.

3. Right-click the right pane, and then click **Manage IP filter lists and filter actions**.

4. In the **Manage IP filter lists and filter actions** dialog box, on the **Manage IP Filter Lists** tab, click **Add**.

5. In the **IP Filter List** dialog box, in the **Name** box, type a name for your filter list, such as Inbound HTTP, and type a description if you want one. This is the filter list that applies to all inbound HTTP connections.

6. Click **Add**. The IP Filter Wizard appears. Create a filter list with the following specifications:

    - Description: Optional.

    - Source address: **Any IP Address**.

- Destination address: **My IP Address**. Or click **A specific IP address**, and then type the IP address of the interface that is connected to the Internet.
- Protocol type: **TCP**.
- Protocol Port: **From any port**.
- To this port: **80**.

7. In the **Completing the IP Filter Wizard** screen, clear the **Edit properties** check box, and then click **Finish**.
8. In the **IP Filter List** dialog box, click **OK**.
9. Repeat steps 1 through 8, this time to create a filter list that applies to destination port 443 for HTTPS connections. Name the filter list Inbound HTTPS, or something similar.
10. Repeat steps 1 through 8, this time to create a filter list that applies to all destination ports. This filter list will apply to the policy that blocks all inbound traffic. Name the filter list All Inbound, or something similar.

After you create the IPsec filter list, you must create a filter action that will occur when incoming traffic matches the criteria in your filter lists. For this example, two actions are necessary. The first is a permit action for allowing requests to connect to ports 80 and 443. The action to permit traffic is an existing default, so you do not need to create it. You must create the second action, which is to block traffic to all other ports.

**To set the filter actions**

1. After you create the filter lists, in the **Local Security Settings** dialog box, right-click the right pane, and then click **Manage IP filter lists and filter actions**.
2. In the **Manage IP filter lists and filter actions** dialog box, click the **Manage Filter Actions** tab, and then click **Add**. The Filter Action Wizard appears.
3. Create a filter action with the following specifications:
   - Name: **Block**
   - Description: Optional
   - Filter Action General Options: **Block**
4. In the **Completing the IP Security Filter Action Wizard** screen, clear the **Edit properties** check box, and then click **Finish**.
5. In the **Manage IP filter lists and filter actions** dialog box, click **Close**.

After you create the IPsec filter lists and filter actions, you must create the IPsec policies and define the rules that link the lists to the actions.

**To create the IPsec policies**

1. After you set the filter actions, in the **Local Security Settings** dialog box, right-click the right pane, and then select **Create IP Security Policy**. The IP Security Policy Wizard appears.
2. Create a policy with the following specifications:
   - Name: **Packet Filter**
   - Description: Optional
3. In the **Requests for Secure Communication** screen, clear the **Activate the default response rule** check box, and then click **Next**.

4. In the **Completing the IP Security Policy Wizard** screen, make sure that the **Edit properties** check box is selected, and then click **Finish**. The **New IP Security Policy Properties** dialog box appears. Do not close this dialog box.

After you create the IPsec filter lists, filter actions, and IPsec policies, you must add rules to the policy and associate the IPsec filter lists that you created with the rules.

**To add rules to the policy**

1. After you create the IPsec policies, in the **New IP Security Policy Properties** dialog box, click **Add**. The Security Rule Wizard appears.
2. Create a rule with the following specifications:
   - Tunnel endpoint: **This rule does not specify a tunnel**.
   - Network type: **All network connections**.
   - IP filter lists: **All Inbound** (or the name of your filter list that applies to inbound traffic on any port).
   - Filter Action: **Block**.
3. In the **Completing the Security Rule Wizard** screen, clear the **Edit properties** check box, and then click **Finish**.
4. In the **New IP Security Policy Properties** dialog box, click **Close**.
5. Repeat steps 1 through 4 to create rules that apply to the Inbound HTTP and Inbound HTTPS filter lists. For these rules, choose the **Permit** filter action.

After you create the IPsec filter lists, filter actions, and policies and add rules to the policy and associate the IPsec filter lists with rules, you must assign the IPsec policy to the server. Only one policy can be assigned at any time.

**To assign the IPsec policy**

- In the **Local Security Settings** dialog box, right-click the policy you created, and click **Assign**.

The policy is applied immediately, and IPsec starts processing packets according to the rules in the policy. You do not need to reboot the server. To stop the policy, right-click the policy in the **Local Security Settings** dialog box, and click **Un-assign**.

# Certificates_IIS_SP1_Ops

Updated: August 22, 2005

Applies To: Windows Server 2003 R2, Windows Server 2003 with SP1

Certificates are a form of digital identification for your server, and for clients that are requesting information from your server. Their function is similar to that of a passport, or other official identity card, which identifies the person carrying it. Certificates are part of the Secure Sockets Layer (SSL) features of Internet Information Services (IIS) that establish a secure connection over which sensitive information can be sent.

**This section includes the following information:**

- Server Certificates
    - Obtaining Server Certificates: Describes how to obtain a server certificate.
    - Installing Server Certificates: Describes how to install a server certificate.
    - Backing Up Server Certificates: Describes how to back up a server certificate.
    - Determining the Intermediate Root CA Version on a Web Server: Describes how to determine the intermediate Root CA version on a Web server.
    - Configuring a List of Trusted Certification Authorities: Explains how to add new certification authorities to your server's list of trusted issuing authorities.
    - Managing Server Certificates Programmatically in IIS 6.0: Describes samples that use the certificate component to import, copy, save, and back up server certificates.
- Client Certificates
    - Obtaining Client Certificates in IIS 6.0: Describes how to obtain user digital identifications, called client certificates.
    - Enabling Client Certificates in IIS 6.0: Describes how to enable SSL authentication of client certificates.
    - Backing Up Client Certificates in IIS 6.0: Describes how to create a copy of a client certificate.
    - Checking the Status of Client Certificates in IIS 6.0: Explains how to verify the validity of your users' client certificates.
    - Mapping Client Certificates to User Accounts in IIS 6.0: Describes how to map client certificates in one of three ways.

**Related Information**

- For information about regulating how users access your Web server files and directories, see Access Control with IIS 6.0.
- For information about setting up or changing encryption settings, see IIS 6.0 Encryption.

# Obtaining Server Certificates

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can obtain server certificates from a third-party certification authority (CA), which may require you to provide proof of identity before issuing a certificate. You can also issue your own server certificates by using an online CA, such as Microsoft Certificate Services, which installs the certificate at the time of your request. When you use the Server Certificate Wizard to obtain a server certificate, the process is referred to as creating a server certificate.

This section includes the following information:

- Requesting a New Server Certificate from an Online CA: Describes how to request a server certificate by using the Web Server Certificate Wizard.
- Obtaining a Server Certificate from a Third-party CA: Describes how use a server certificate request to obtain a server certificate from a certification authority.
- Issuing Your Own Server Certificates: Describes how to act as your own certification authority to issue server certificates for the Internet or for corporate intranets.

# Requesting a New Server Certificate from an Online CA

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the Web Server Certificate Wizard, available through IIS Manager, to request a new server certificate that will be installed immediately by an online CA.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**. |

**Procedures**

**To request a new server certificate from an online CA**

1. In IIS Manager, double-click the local computer, and then double-click the **Web Sites** folder.
2. Right-click the Web site or file for which you want to request a certificate, and then click **Properties**.
3. On the **Directory Security** or **File Security** tab, under **Secure communications**, click **Server Certificate**.
4. In the Web Server Certificate Wizard, click **Create a new certificate**.
5. On the **Delayed or Immediate Request** wizard page, select **Send the request immediately to an online certification authority.**
6. Complete the rest of the steps in the Web Server Certificate Wizard and then click **Finish**.

**Related Information**

- For information about other ways to obtain certificates, see Obtaining Server Certificates.
- For general information about certificates, see SSL and Certificates.
- For information about online certification authorities, see "Certificates Services" in Help and Support Center for Windows Server 2003.

# Obtaining a Server Certificate from a Third-party CA

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the Web Server Certificate wizard to obtain a server certificate from a third-party certification authority (CA). The wizard generates a certificate request, which you then send to the CA. Some certification authorities require you to prove your identity before they process your request or issue a certificate.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To obtain a server certificate from a third-party certification authority**

1. In IIS Manager, double-click the local computer, and then double-click the **Web Sites** folder.
2. Right-click the Web site or file for which you want to request a certificate, and then click **Properties**.
3. On the **Directory Security** or **File Security** tab, under **Secure communications**, click **Server Certificate**.
4. In the Web Server Certificate Wizard, on the **Delayed or Immediate Request** page, click **Prepare the request now, but send it later**. By default, the certificate request file is saved as C:\Certreq.txt, but the wizard allows you to specify a different location.
5. Complete the rest of the steps in the Web Server Certificate Wizard and then click **Finish**.
6. Send the request to the certification authority. The CA will process the request and then send you the certificate.

**Related Information**

- For information about other ways to obtain server certificates, see Obtaining Server Certificates.
- For information about installing server certificates, see Installing Server Certificates.
- For general information about certificates, see SSL and Certificates.

# Issuing Your Own Server Certificates

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use Microsoft Certificate Services to create a customizable service for issuing and managing certificates. You can create server certificates for the Internet or for corporate intranets, giving your organization complete control over certificate management policies. For more information, see "Certificate services" in Help and Support Center for Windows Server 2003.

Online requests for server certificates can be made only to local and remote Enterprise Certificate Services and remote standalone Certificate Services. The IIS Web Server Certificate Wizard does not recognize a standalone installation of Certificate Services on the same computer when requesting a certificate. To get around this, use the offline certificate request to save the request to a file and then process as an offline request. For information about standalone certification authorities, see "Standalone certification authorities" in Help and Support Center for Windows Server 2003.

If you are not using an online certification authority, you will need to save the request file generated by the Web Server Certificate Wizard to disk and send it to the CA. When the response is received, you can start the wizard and it will begin where it left off. If you are replacing a certificate, IIS will continue to use the old certificate until the new request is completed. For information about using the Web Server Certificate Wizard to save a request file, see Obtaining a Server Certificate from a Third-party CA.

**Related Information**

- For information about other ways to obtain certificates, see Obtaining Server Certificates.
- For general information about certificates, see SSL and Certificates.

# Installing Server Certificates

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

After you have obtained a server certificate, you can install it. When you use the Server Certificate Wizard to install a server certificate, the process is referred to as *assigning* a server certificate.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To install a server certificate using the Web Server Certificate Wizard**

1. In IIS Manager, expand the local computer, and then expand the **Web Sites** folder.
2. Right-click the Web site or file that you want, and then click **Properties**.
3. On the **Directory Security** or **File Security** tab, under **Secure communications**, click **Server Certificate**.
4. In the Web Server Certificate Wizard, click **Assign an existing certificate**.
5. Follow the Web Server Certificate Wizard, which will guide you through the process of installing a server certificate.

| **Note** |
| --- |
| When you use the Web Server Certificate Wizard to assign a certificate, you must specify a password before the certificate can be assigned to your Web server. |

**Related Information**

- For information about obtaining server certificates, see Obtaining Server Certificates.
- For general information about certificates, see SSL and Certificates.

# Backing Up Server Certificates

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the Certificate Manager MMC snap-in to back up server certificates.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

#### Procedures

### To back up a server certificate by using Certificate Manager

1. If you do not have **Certificate Manager** installed in the MMC, install it.
2. Locate the correct certificate store. This is typically the **Local Computer** store in Certificate Manager.
3. In the **Personal** store, click the certificate that you want to back up.
4. On the **Action** menu, point to **All tasks**, and then click **Export**.
5. In the Certificate Manager Export Wizard, click **Yes, export the private key**.
6. Follow the wizard default settings, and enter a password for the certificate backup file when prompted.

   | **Important** |
   | --- |
   | Do not select **Delete the private key if export is successful**, because this will disable your current server certificate. |

7. Complete the wizard to export a backup copy of your server certificate.

### To add Certificate Manager to the MMC

1. To open an MMC console:
   - From the **Start** menu, click **Run**.
   - In the **Open** box, type the following: **mmc**.
   - Click **OK**.
2. On the **File** menu, click **Add/Remove Snap-in**.
3. In the **Add/Remove Snap-in** box, click **Add**.
4. In the **Available Standalone Snap-ins** list, click **Certificates**, and then click **Add**.
5. In the **Certificates** snap-in box, click **Computer Account**, and then click **Next**.
6. In the **Select Computer** box, click **Local Computer**, and then click **Finish**.

#### Related Information

- For general information about certificates, see Server Certificates.

# Determining the Intermediate Root CA Version on a Web Server

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The VeriSign Global Server ID Intermediate Root certification authority (128-bit SSL) expired on January 7, 2004. Servers running IIS that have not been updated with the new Global Server ID Intermediate Root certification authority may encounter problems when clients try to establish SSL sessions by using the Secure Hypertext Transfer Protocol after January 7, 2004.

| **Note** |
| --- |
| Servers that use VeriSign 40-bit Secure Server ID certificates are not affected by this expiration. |

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To determine the Intermediate Root CA version on a Web server**

1. From the **Start** menu, click **Run**, type **mmc**, and then click **OK**.
2. On the **File** menu, click **Add/Remove Snap-in**.
3. On the **Add/Remove Snap-in** dialog box, click **Add**, select **Certificates** from the snap-in list, and then click **Add**.
4. Choose the **Computer account** option and then click **Next**.
5. Select **Local Computer (the computer this console is running on)**, and then click **OK**.
6. Click **Close**, and then click **OK**.
7. In the console window, expand **Certificates**, and then expand **Intermediate Certificate Authorities**.
8. Click the **Certificates** folder.
9. In the **Issued To** column, locate the certificate with "www.verisign.com/CPS Incorp.by Ref. LIABILITY LTD. ©97 Verisign" as the certificate name.
10. Right-click the certificate, and then click **Open**.

    If the certificate has expired, the following message is displayed on the **General** tab:

    "This certificate has expired or is not yet valid."

    If the certificate is current, the following message is displayed on the **General** tab:

    "This certificate is intended for the following purposes:"

    and lists the purposes for which the certificate is to be used.
11. Note the **Valid from date to date** range, and then click **OK**.
12. If you need to update the Intermediate Root CA on your Web server, follow the instructions on the Verisign Web site.

# Configuring a List of Trusted Certification Authorities

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure computers running a member of the Windows Server 2003 family with IIS 6.0 to accept certificates from a predefined list of certification authorities (CAs). You can then automatically verify client certificates against your CTL. CTLs are especially useful for Internet Service Providers (ISPs) who have several Web sites on one server and need a different list of approved certification authorities for authenticating clients at each site.

Each of your Web sites can be configured to accept certificates from a different list by using different certificate trust lists (CTLs). For example, an intranet administrator creates a different list of trusted certification authorities (CAs) for each department's Web site on an intranet, in the form of a CTL. As a result, IIS only accepts certificates from certification authorities that are on the department's CTL. When members of the department log on with a client certificate from a CA on the department's CTL, they are automatically authenticated.

This section includes the following information:

- Creating a Certificate Trust List on Your Server: Describes how to create a certificate trust list by using the Certificate Trust List Wizard.

- Modifying a Certificate Trust List on Your Server: Describes how to modify a certificate trust list.

# Creating a Certificate Trust List on Your Server

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the Certificate Trust List Wizard to create CTLs and to add new root certificates to your CTLs. By default, IIS installs the most commonly used CA root certificates.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To create a certificate trust list on your server**

1. In IIS Manager, expand the local computer, and then expand the **Web Sites** folder.

   | **Note** |
   | --- |
   | CTLs can be applied only at the Web site level, not at the virtual directory or file level. CTLs are not available on FTP sites. |

2. Right-click the Web site that you want, and then click **Properties**.
3. On the **Directory Security** tab, under **Secure Communications**, click **Edit**.

   | **Note** |
   | --- |
   | The **Edit** button is enabled only if a server certificate has been installed on the site. For information about obtaining and installing a server certificate, see Obtaining Server Certificates and Installing Server Certificates. |

4. In the **Secure Communications** box, select the **Enable certificate trust list** check box, and then click **New**.
5. Follow the steps in the Certificate Trust List Wizard, which will guide you through the process of creating a CTL.

**Related Information**

- For general information about certificates, see SSL and Certificates.

# Modifying a Certificate Trust List on Your Server

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the Certificate Trust List Wizard to edit existing CTLs.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To modify a certificate trust list on your server**

1. In IIS Manager, expand the local computer, and then expand the **Web Sites** folder.
2. Right-click the Web site that you want, and then click **Properties**.
3. On the **Directory Security** tab, under **Secure Communications**, click **Edit**.
4. In the **Secure Communications** box, scroll through the **Current CTL** list, click the CTL that you want to modify, and then click **Edit**.
5. Follow the steps in the Certificate Trust List Wizard, which will guide you through the process of modifying a CTL.

**Related Information**

- For general information about certificates, see SSL and Certificates.

# Managing Server Certificates Programmatically in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use scripts in conjunction with **IISCertObj**, a Component Object Model (COM) object, to manage certificates remotely and programmatically. You can use **IISCertObj** to perform the following tasks:

- Import copies of a certificate from a .pfx file (a file containing a PFX-encrypted certificate and a private key) from a server onto multiple servers.
- Save backup copies of certificates on a central site.
- Copy a certificate from one server onto multiple servers.

To learn about obtaining SSL server certificates, see Obtaining Server Certificates.

**Sample Scripts**

After acquiring an SSL server certificate from a certification authority, distributing copies to all of the servers requires one or more of the following steps:

- Import copies of master certificates onto multiple servers.
- Save backup copies of certificates in a central archive.
- Export certificates across multiple servers.

In IIS, if you use Windows Script Host (WSH) or Active Server Pages (ASP), you can execute scripts that communicate with **IISCertObj** programmatically to import, archive, or export certificates.

**Import Certificates to Multiple Servers (CertImport.vbs)**

Large sites often need to use one SSL certificate for secure user logon to multiple servers. It would be very time-consuming to use the MMC to add copies of the certificate to each server. What you need is a scripted solution that installs copies of the same certificate to all of the targeted servers.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

Save the following script as CertImport.vbs. Modify the command-line statement arguments to match your network resources. Then use the command-line statement to import a certificate from a certificate store on one server to other servers.

```
Option Explicit
Dim iiscertobj, pfxfile, pfxfilepassword, InstanceName, WebFarmServers, IISServer
Set iiscertobj = WScript.CreateObject("IIS.CertObj")
pfxfile = WScript.Arguments(0)
pfxfilepassword = WScript.Arguments(1)
InstanceName = WScript.Arguments(2)
WebFarmServers = split(WScript.Arguments(3), ",")
iiscertobj.UserName = WScript.Arguments(4)
iiscertobj.UserPassword = WScript.Arguments(5)
For Each IISServer in WebFarmServers
  iiscertobj.ServerName = IISServer
  iiscertobj.InstanceName = InstanceName
  iiscertobj.Import pfxfile, pfxfilepassword, true, true
Next
```

Command-line statement:

```
Certimport.vbs cert.pfx pfxpassword w3svc/1 iisserver1,iisserver2,iisserver3 Administrator aal34290
```

**Save Certificates in a Central Archive (Save_all_certs.vbs)**
Using the **IISCertObj** export method, you can archive a backup of each certificate on your server farm to a central site.

Save the following script as Save_all_certs.vbs in your text editor. Modify the command-line statement arguments to match your network resources. Then use the command-line statement to export copies of certificates to the central site.

```
Option Explicit
Dim iiscertobj, targetServer, targetServers, pfxbasename, pfxpassword, InstanceName
Set iiscertobj = WScript.CreateObject("IIS.CertObj")
pfxbasename = WScript.Arguments(0)
pfxpassword = WScript.Arguments(1)
InstanceName = WScript.Arguments(2)
targetServers = split(WScript.Arguments(3), ",")
iiscertobj.UserName = WScript.Arguments(4)
iiscertobj.UserPassword = WScript.Arguments(5)
iiscertobj.InstanceName = InstanceName
For Each targetServer in targetServers
  iiscertobj.ServerName = targetServer
  iiscertobj.Export pfxbasename + targetServer + ".pfx", pfxpassword, true, false,
false
Next
```

Command-line statement:

```
Save_all_certs.vbs C:\certbackup\ adsf-0324 w3svc/1 iisserver2,iisserver3,iisserver4 Administrator aal34290
```

**Copy a Certificate from an Existing Server to a New Server (CertCopy.vbs)**
With the script and command-line statement below you can use the **copy** method of **IISCertObj** to copy a certificate to a new server after you add the server to a server farm.

Save the script below as certcopy.vbs. Modify the command-line statement arguments to match your network resources. Then run the command-line statement.

```
Option Explicit
Dim iiscertobj, targetServer, targetServers, targetInstance
Set iiscertobj = WScript.CreateObject("IIS.CertObj")
iiscertobj.ServerName = WScript.Arguments(0)
iiscertobj.Instancename = WScript.Arguments(1)
targetServers = split(WScript.Arguments(2), ",")
targetInstance = WScript.Arguments(3)
iiscertobj.UserName = WScript.Arguments(4)
iiscertobj.UserPassword = WScript.Arguments(5)
For Each targetServer in targetServers
  iiscertobj.Copy true, true, targetServer, targetInstance
Next
```

Command-line statement:

```
Certcopy.vbs iisServer1 w3svc/1 iisServer2 w3svc/1 Administrator asdf-0324
```

# Obtaining Client Certificates in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can obtain a client certificate from a *certification authority* (CA), which is a trustworthy third-party organization. Before the CA issues a certificate, you may need to verify your identity. The identification information required by the CA varies, depending on the type of certificate that you want to obtain. How these certificates are obtained and implemented depends upon the browser that is being used. The procedures in this topic are for Microsoft Internet Explorer version 3.0 and later only. For client certificate procedures for other browsers, see the browser documentation.

**Procedures**

### To obtain a client certificate

1. Choose a certification authority. For information about choosing a certification authority, see Obtaining and Installing Server Certificates.
2. Refer to the specific ordering instructions that are provided by the certification authority.
3. Order your certificate. Some client certificates are valid only for the computer and Web browser that are used to generate the certificate request. When this is the case, be sure to make the online request from the computer where you intend to install the certificate.
4. When you receive your client certificate, use your Web browser's security features to install the certificate. (Some Web browsers may refer to client certificates as "browser certificates" or "personal certificates.")

**Related Information**

- For information about enabling client certificates, see Enabling Client Certificates in IIS 6.0.
- For information about backing up client certificates, see Backing Up Client Certificates in IIS 6.0.

# Enabling Client Certificates in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can require users attempting to access your Web site to log on with a client certificate. Requiring a client certificate is just one aspect of protecting your server against unauthorized access. Any user with a valid and trusted client certificate can establish a secure connection and access your resource. To protect your Web content from unauthorized access you must do one of the following:

- Use Basic, Digest, or Integrated Windows authentication, in addition to requiring a client certificate.
- Create a Windows account mapping for client certificates. For more information, see Mapping Client Certificates to User Accounts in IIS 6.0.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures, or you must have been delegated the appropriate authority. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc** *systemroot***\system32\inetsrv\iis.msc"**. For information about delegating administrative authority, see "Delegating administration" in Help and Support Center for Windows Server 2003. |

**Procedures**

**To enable client certificates**

1. In IIS Manager, double-click the local computer, and then right-click the Web site, directory, or file that you want and click **Properties**.
2. If you have not previously obtained a server certificate, click the **Directory Security** tab, and then under **Secure Communications**, click **Server Certificate**. For more information, see Obtaining Server Certificates.
3. If you have previously obtained a server certificate, click the **Directory Security** or **File Security** tab, and then under **Secure Communications**, click **Edit**.
4. In the **Secure Communications** box, select the **Require secure channel (SSL)** check box. Requiring a secure channel means that users cannot connect to this site without using a secure link (that is, the link's URL must begin with https://).
5. Under **Client certificates** select one of the following to enable client Certificate authentication:
   - **Accept client certificates** Users can access the resource with a client certificate, but the certificate is not required.
   - **Require client certificates** The server will request a client certificate before connecting the user to the resource. Users without a valid client certificate will be denied access.
   - **Ignore client certificates** Users with or without a client certificate will be granted access.

**Related Information**

- For information about obtaining client certificates, see Obtaining Client Certificates in IIS 6.0.
- For information about backing up client certificates, see Backing Up Client Certificates in IIS 6.0.

# Backing Up Client Certificates in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use the Certificate Export Wizard to create a backup copy of a certificate.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

### To back up a client certificate

1. On the **Tools** menu in Internet Explorer, version 5.0 or later, click **Internet Options**, and then click the **Content** tab.
2. On the **Content** tab, click **Certificates**, and then click the **Personal** tab.
3. On the **Personal** tab, in the list of certificates, click the certificate that you want to back up, and then click **Export**.
4. In the Certificate Export Wizard, click **Next**.
5. On the next page in the wizard, click **No, do not include any private keys in the export**, and then click **Next**.
6. On the next page in the wizard, click **Base64 Encoded X.509 (*.CER)**, and then click **Next**.
7. Follow the remaining steps in the Certificate Export Wizard to complete the procedure.

# Checking the Status of Client Certificates in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Certification authorities (CAs) cannot physically revoke your users' client certificates. However, they may publish Certificate Revocation Lists (CRLs) that are copied onto your computer, where you can search them for client certificates that are in revoked status. For information about retrieving CRLs from a CA and storing them on your computer, see "Retrieve a certificate revocation list" in Help and Support Center for Windows Server 2003.

The metabase properties that control CRL checking can be set or viewed using a COM object, or WMI scripts, or ADSI scripts. For information about configuring the metabase, see Configuring the Metabase.

To use a certificate revocation list to check the status of client certificates, take the following actions:

- Enable CRL checking.
- Optionally, configure the CRL on your computer to refresh at a fixed interval, even when the CRL on your computer is still valid.
