- Optionally, change the default time interval for refreshing the CRL on your computer at a fixed interval.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /User:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

**Procedures**

**To enable and disable CRL checking**

- Set the CertCheckMode Metabase Property. CRL Checking is enabled by default. The CRL will be refreshed by the CA when a new CRL is issued, unless you intervene by setting a CRL refresh interval.

**To set the CRL refresh interval**

- Change the setting of the RevocationFreshnessTime Metabase Property. You can refresh the CRL on your computer with the CRL on the CA server even when the cached CRL on your computer is valid.

**To change the default interval to a custom time**

- Set the RevocationURLRetrievalTimeout Metabase Property to a time in milliseconds.

**Related Information**

# Mapping Client Certificates to User Accounts in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Mapping client certificates allows you to automatically authenticate users who log on with client certificates, without requiring the use of other supported authentication methods such as Basic, Digest, or Integrated Windows authentication.

This section includes the following information:

- Mapping Client Certificates One-to-One: Describes how to map individual client certificates to Windows user accounts.
- Mapping Client Certificates Many-to-One: Describes how to use wildcard-matching rules to map more than one client certificate to a Windows user account.
- Mapping Client Certificates with Directory Service Mapping: Describes using native Windows Active Directory features to authenticate users with client certificates.

| **Note** |
| --- |
| The client certificate mapping programs for both IIS 6.0 and Windows Active Directory Services accept certificates formatted as either binary or Base-64 encoded files. |

# Mapping Client Certificates One-to-One

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

One-to-one mapping maps individual client certificates to Windows user accounts. The server compares the copy of the client certificate it holds with the client certificate that is sent by the browser. The two must be identical for the mapping to proceed. If a client gets another certificate containing all of the same user information, it must be mapped again.

This section includes the following information:

- Exporting a Client Certificate for One-to-One Mapping: Describes how to export a client certificate so it can be used for IIS one-to-one mapping.

- Mapping a Specific Client Certificate to a User Account: Describes how to map a specific client certificate one-to-one to a Windows user account.

# Exporting a Client Certificate for One-to-One Mapping

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Some client certificates need to be *exported* for use in IIS one-to-one mapping. For more information about whether you must export client certificates, contact your certification authority.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To export a client certificate for one-to-one mapping**

1. On the **Tools** menu in Internet Explorer, version 5.0 or later, click **Internet Options**, and then click the **Content** tab.
2. On the **Content** tab, click **Certificates**, and then click the **Personal** tab.
3. On the **Personal** tab, in the list of certificates, click the certificate that you want to export, and then click **Export**.
4. In the Certificate Export Wizard, click **Next**.
5. On the next page in the wizard, click **No, do not include any private keys in the export**, and then click **Next**.
6. On the next page in the wizard, click **Base64 Encoded X.509 (*.CER)**, and then click **Next**.

   | **Note** |
   | --- |
   | The client certificate mapping programs for both IIS 6.0 and Windows Active Directory Services accept certificates formatted as either binary or Base-64 encoded files. |

7. Follow the remaining steps in the Certificate Export Wizard to complete the procedure.
8. Map the exported certificate one-to-one with a Windows user account. For information about mapping a certificate one-to-one with a Windows user account, see Mapping a Specific Client Certificate to a User Account.

**Related Information**

- For information about how to add a client certificate mapping using wildcard rules, see Mapping Client Certificates Many-to-One.
- For information about when to use each type of client certificate mapping, see Mapping Strategies.
- For general information about certificates, see SSL and Certificates.

# Mapping a Specific Client Certificate to a User Account

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use the following procedure to map a specific client certificate to a user account.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To map a specific client certificate to a user account**

1. In IIS Manager, expand the local computer, and then expand the **Web Sites** folder.
2. Right-click the Web site for which you want to configure authentication, and then click **Properties**.
3. Click the **Directory Security** tab, and then, in the **Secure Communications** section, click **Edit**.
4. In the **Secure Communications** box, select the **Enable client certificate mapping** check box, and then click **Edit**.
5. In the **Account Mappings** box, click the **1-to-1** tab.
6. On the **1-to-1** tab, either add a new certificate by clicking **Add**, or edit an existing mapping by selecting the mapping and clicking **Edit Map**.
7. If you are adding a new certificate, browse to the certificate file and open it.

   | **Note** |
   | --- |
   | If you cannot find the certificate file, it might first need to be exported. For information about exporting a certificate for use in one-to-one mapping, see Exporting a Client Certificate for One-to-One Mapping. |

8. In the **Map to Account** box, enter a map name for the mapping. This is the name that will be displayed in the selection list on the **Account Mappings** box.
9. Either type or browse to a Windows user account. Type the password of the account to which the certificate is being mapped.
10. Click **OK**.
11. Repeat these steps to map other certificates, or to map this certificate to other accounts.

**Related Information**

- For information about how to map a client certificate by using wildcard rules, see Mapping Client Certificates Many-to-One.
- For information about when to use each type of client certificate mapping, see Mapping Strategies.
- For general information about certificates, see SSL and Certificates.

# Mapping Client Certificates Many-to-One

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Many-to-one mapping uses *wildcard* matching rules that verify whether a client certificate contains specific information, such as issuer or subject. This mapping does not compare the actual client certificate, but rather accepts all of the client certificates that fulfill the specific criteria. If a client gets another certificate containing all of the same user information, the existing mapping will work.

When using many-to-one mapping, keep the following information in mind:

- Specific client certificate mappings always take precedence over wildcard mappings.
- Some client certificates offer more identifying information and may contain additional custom subfields. For information about certificate formats, contact your certification authority.

This section includes the following information:

- Adding a Client Certificate Mapping Using Wildcard Rules: Describes how to use wildcard rules to map more than one client certificate to a Windows user account.
- Editing Existing Wildcard Rules for Client Certificate Mapping: Describes how to edit existing wildcard rules.

# Adding a Client Certificate Mapping Using Wildcard Rules

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When you create wildcard rules to map client certificates, you should use matching rules that are as specific as possible. A good wildcard rule matches information from several different fields and subfields. For example, the names "Accounting", "Shipping", and "Sales" can appear in the organization unit subfield of more than one company's client certificate. A matching rule that maps certificates based exclusively on this subfield would probably result in unintended mappings.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To add a client certificate mapping using wildcard rules**

1. In IIS Manager, double-click the local computer, and then double-click the **Web Sites** folder.
2. Right-click the Web site for which you want to configure wildcard certificate mapping, and then click **Properties**.
3. Click the **Directory Security** tab, and then in the **Secure Communications** section, click **Edit**.
4. In the **Secure Communications** box, select the **Enable client certificate mapping** check box, and then click **Edit**.
5. In the **Account Mappings** box, click the **Many-to-1** tab, and then click **Add**.
6. In the **General** box, type a name for the rule. This is the name that will be displayed in the selection list on the **Account Mappings** box. You can create rules for future use or disable rules without deleting them by selecting or clearing the **Enable this wildcard rule** check box. Click **Next**.
7. In the **Rules** box, click **New**.
8. In the **Edit Rule Element** box, select the appropriate criteria and click **OK**.

   **Note**

   Steps 6 and 7 can be repeated to define the rule more stringently.

9. When you have finished editing the rule, click **Next**.
10. In the **Mapping** box, either type or browse to a Windows user account. Type the password of the account to which the rule is being mapped.

    **Note**

    If the account you are mapping to is on a computer that is a member of a workgroup, you must specify the computer name and the account name. For example, if you are mapping to the "RegionalSales" account on the computer called "Sales1", the mapping account name would be "Sales1\RegionalSales".

11. Click **OK**.
12. Repeat these steps to create other mapping rules.
13. Use the **Move Up** and **Move Down** buttons to establish the precedence given to the rules. Rules that are higher in the list take precedence.

**Related Information**

- For information about how to map a specific client certificate to a user account, see Mapping Client Certificates One-to-One.
- For information about when to use each type of client certificate mapping, see Mapping Strategies.
- For general information about certificates, see SSL and Certificates.

# Editing Existing Wildcard Rules for Client Certificate Mapping

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use the following procedure to edit existing wildcard rules for client certificate mapping.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To edit an existing wildcard rule for client certificate mapping**

1. In IIS Manager, expand the local computer, and then expand the **Web Sites** folder.
2. Right-click the Web site that you want to configure authentication for, and then click **Properties**.
3. Click the **Directory Security** tab, and then in the **Secure Communications** section, click **Edit**.
4. In the **Secure Communications** box, select the **Enable client certificate mapping** check box, and then click **Edit**.
5. In the **Account Mappings** box, click the **Many-to-1** tab.
6. On the **Many-to-1** tab, in the list of rules, click the rule that you want to modify, and then click **Edit Rule**.
7. Make the necessary changes, and when you are finished editing the rule, click **OK**.

**Related Information**

- For information about how to map a specific client certificate to a user account, see Mapping Client Certificates One-to-One.
- For information about mapping a client certificate to an Active Directory user account, see Mapping Client Certificates with Directory Service Mapping.
- For information about when to use each type of client certificate mapping, see Mapping Strategies.
- For general information about certificates, see SSL and Certificates.

# Mapping Client Certificates with Directory Service Mapping

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| If you use directory service mapping, you cannot use one-to-one or many-to-one mapping for the entire World Wide Web Publishing Service (WWW service). |

Directory service (DS) certificate mapping uses native Windows Active Directory features to authenticate users with client certificates. For information about mapping a certificate to an Active Directory user account, see "Map a certificate to a user account" in Help and Support Center for Windows Server 2003.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

### To enable Directory Service mapping

1. In IIS Manager, right-click the **Web Sites** node, and then click **Properties**.
2. On the **Directory Security** tab, select the **Enable the Windows directory service mapper** check box, and then click **OK**.

**Related Information**

- For information about how to map a specific client certificate to a user account, see Mapping Client Certificates One-to-One.
- For information about how to map many user accounts to a single client certificate, see Mapping Client Certificates Many-to-One.
- For information about when to use each type of client certificate mapping, see Mapping Strategies.
- For general information about certificates, see SSL and Certificates.

# Auditing in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can use security auditing techniques to track the activities of users and to detect unauthorized attempts to access your NTFS file system directories and files. Activities that you can audit include the following:

- User attempts to log on, both successful and unsuccessful.
- User attempts to access restricted accounts.
- User attempts to execute restricted commands.

| **Note** |
| --- |
| In IIS 6.0, successful account logons, including every impersonation of the anonymous account, are audited by default. If your server is hosting busy Web sites, this can cause the security event log to fill quickly with entries. To disable auditing of successful logons in the security event log, see "Auditing security events" in Help and Support Center for Windows Server 2003. |

**Related Information**

- For information about how to log user Web site and FTP site activity, see Logging Site Activity.
- For information about how to control access to your Web site and FTP site, see Access Control with IIS 6.0.

# Performance Tuning

Updated: June 30, 2006

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Web server administrators often monitor their Web servers to create a performance baseline. A performance baseline is a collection of data that indicates how the servers are performing when everything is running smoothly. Before making changes to their servers in a production environment, administrators tune their servers in a test environment to achieve the established performance baseline. By tuning their servers, Web server administrators maximize the Web server's ability to handle HTTP requests and minimize Web application response times, which create a better experience for clients accessing their Web servers.

**In This Section**

This section includes the following information:

- Using HTTP Compression: Describes how to improve performance between client computers and servers by reducing file sizes before the files are sent to the client computer. Reducing the file size as described here is referred to as compression.
- Enabling HTTP Keep-Alives: Describes how to use HTTP Keep-Alive requests to maintain an open connection.
- Limiting Connections: Describes how to set limits on the number of connections to a Web server.
- Setting Connection Timeouts: Describes how to set connection time-out values on a Web server.
- Throttling Bandwidth: Describes how to change the bandwidth used by a Web server and individual Web sites.
- Setting the IIS Object Cache Time Period: Describes how to set the IIS object cache time period.
- Maximizing Data Throughput for Network Applications: Describes how to maximizing data throughput for network applications.
- Setting the SSL Cache Time-out Interval: Describes how to set the SSL cache time-out interval.
- Measuring Load Time for a Web Page: Describes how to measure load time for a Web page.
- Enabling CPU Monitoring in IIS 6.0: Describes how to monitor and stop problematic applications.
- Configuring Application Pool Queue-Length Limits: Describes how to limit the number of requests IIS stores in any application pool queue so the requests do not grow to such a large size as to exhaust server resources.
- Scalability: Provides information and links to detailed resources about scalability.
- Configuring Last-Modified Caching: Describes how to configure last-modified caching.
- Configuring ASP Change-Notification Caching: Describes how to configure ASP change-notification caching.

**Related Sections**

- For more information about each of the performance features described in this section and for a more detailed introduction into what it means to monitor and tune an IIS Web server, see Optimizing IIS 6.0 Performance.
- For more information about performance tuning, how to work with counters, how to create and configure counters, trace logs, or alerts, and a list of best practices; see "Monitoring Performance" in Help and Support Center for Windows Server 2003.

- For information about monitoring the performance of your ASP.NET applications, see Overview of ASP.NET Performance Monitoring.

- For more information about the Web Capacity Analysis Tool for performance testing and monitoring, download the IIS 6.0 Resource Kit Tools and their accompanying documentation.

# Viewing Counter Data in the Performance Console

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In its default view, System Monitor provides a list of active counters, including their object and instance, directly below the graphical display of counter data. Remember that many counters display the last observed value or a cumulative count, not an average value or rate.

If you are new to Windows Server 2003 performance monitoring, open the Performance console and take a look at the data provided by a few counters.

**To select performance objects and counters to view in System Monitor**

1. In Control Panel, double-click **Administrative Tools**, and then double-click **Performance**.
2. On the System Monitor toolbar, click the **Add** button (**+**) to open the **Add Counters** dialog box.
3. Click the **Performance object** list box to view a list of available performance objects, and then select an object to monitor.

   When you select an object, the list box on the left shows the available counters for that object and the list box on the right displays the instances for that object.
4. To select specific counters for the performance object, click **Select counters from list** (the default option), and then select the counters that you want to view.

   After you select a counter, you can click **Explain** to view a description.
5. If you want to monitor one or more specific instances of the counter (when available), select from the list of instances in the box on the right. Windows provides a default selection if you do not select a specific instance.
6. Click **Add** to begin monitoring.

# Using HTTP Compression

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

To more efficiently use available bandwidth, enable IIS HTTP compression. HTTP compression provides faster transmission time between compression-enabled browsers and IIS, regardless of whether your content is served from local storage or a UNC resource. You can compress static files and application response files. Compressing application response files is usually called *dynamic compression*.

This section includes the following information:

- Enabling HTTP Compression: Describes how to enable compression.
- Customizing the File Types IIS Compresses: Describes how to add or remove file types from IIS compression.

**Related Information**

- For a detailed discussion of how HTTP compression works, how to test compression, and detailed compression configuration options, see Using HTTP Compression for Faster Downloads.
- For more information about improving the performance of IIS network resources using related features like bandwidth throttling and connection time-outs, see Administering Network Resources.

# Enabling HTTP Compression

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Introduction to and procedures for enabling HTTP compression using IIS Manager and command-line scripts.

You can enable HTTP compression server-wide or on a specific directory. HTTP compression improves bandwidth utilization and speeds up Web site performance. In addition, you can compress static or dynamic responses.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName***"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To enable global HTTP compression by using IIS Manager**

1. In IIS Manager, double-click the local computer, right-click the **Web Sites** folder, and then click **Properties**.
2. Click the**Service** tab, and in the **HTTP compression** section, select the **Compress application files** check box to enable compression for dynamic files.
3. Select the **Compress static files** check box to enable compression for static files.
4. In the **Temporary directory** box, type the path to a local directory or click **Browse** to locate a directory. Once a static file is compressed, it is cached in this temporary directory until it expires, or the content changes. The directory must be on the local drive of an NTFS–formatted partition. The directory cannot be compressed or shared, and the access control lists (ACLs) for the directory must include Full Control access to the identity of the application pool or to the IIS_WPG group.
5. Under **Maximum temporary directory size**, click a folder size option. If you specify a maximum size under **Limited to (in megabytes)** (the default setting is 95 MB), then when the limit is reached, IIS automatically cleans up the temporary directory by applying the "least recently used" rule.
6. Click **Apply**, and then click **OK**.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator***cmd** to open a command window with administrator rights and then type **cscript.exe***ScriptName* (include the script's full path and any parameters). |

**To enable global HTTP compression by using Adsutil.vbs**

1. Open a command prompt.
2. To enable dynamic compression, type the following at the command prompt and then press ENTER:

   **cscript adsutil.vbs set w3svc/filters/compression/parameters/HcDoDynamicCompression true**

3. To enable static compression, type the following at the command prompt and then press ENTER:

   **cscript adsutil.vbs set w3svc/filters/compression/parameters/HcDoStaticCompression true**

**To enable HTTP Compression for Individual Sites and Site Elements**

1. To enable static compression for only a single directory, first disable global static compression (if it is enabled) and then enable static compression at that directory. For example, to enable static compression for a directory at http://www.contoso.com/Home/StyleSheets, perform the following steps:

a. Disable global static compression by executing the following command at a command prompt:

**adsutil set w3svc/filters/compression/parameters/HcDoStaticCompression false**

a. Enable static compression at this directory by executing the following command at a command prompt:

**adsutil set w3svc/1/root/Home/StyleSheets/DoStaticCompression true**

2. To disable static compression for only a single directory, first enable global static compression (if it is disabled) and then disable static compression at that directory. For example, to enable static compression for a directory at http://www.contoso.com/Home/StyleSheets, perform the following steps:

   a. Disable global static compression by executing the following command at a command prompt:

   **adsutil set w3svc/filters/compression/parameters/HcDoStaticCompression true**

   a. Enable static compression at this directory by executing the following command at a command prompt:

   **adsutil set w3svc/1/root/Home/StyleSheets/DoStaticCompression false**

**Related Information**

- For a detailed discussion of how HTTP compression works, how to test compression, and detailed compression configuration options, see Using HTTP Compression for Faster Downloads.

- For more information about improving the performance of IIS network resources using related features like bandwidth throttling and connection timeouts, e Administering Network Resources.

- For information about configuring the types of files IIS compresses server-wide, see Customizing the File Types IIS Compresses.

# Customizing the File Types IIS Compresses

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can customize the file types IIS compresses. Enabling static file compression compresses .htm, .html, and .txt files. Enabling dynamic compression compresses .asp, .dll, and .exe files.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

**Procedures**

**To add one or more file types to the server-wide static compression configuration**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd**, and click **OK**.
3. Type both of the following commands:
   - **cscript adsutil.vbs SET W3SVC/Filters/Compression/Deflate/HcFileExtensions "htm" "html" "txt" "newext"** where *newext* is a file type you want to compress (for example, Microsoft Word or Excel documents), then press **ENTER**. You can add multiple file types separated by spaces.
   - **cscript adsutil.vbs SET W3SVC/Filters/Compression/gzip/HcFileExtensions "htm" "html" "txt" "newext"** where *newext* is a file type you want to compress, then press **ENTER**. You can add multiple file types separated by spaces.

| **Note** |
| --- |
| To remove one or more file types from the server-wide static compression configuration, repeat the previous two commands, leaving out the file type you want to remove. |

**To add one or more file types to the server-wide dynamic compression configuration**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cmd**, and click **OK**.
3. Type both of the following commands:
   - **cscript adsutil.vbs SET W3SVC/Filters/Compression/Deflate/HcScriptFileExtensions "asp" "dll" "exe" "newext"** where newext is a file type you want to compress (for example, aspx, a commonly used ASP extension), then press **ENTER**. You can add multiple file types separated by spaces.
   - **cscript adsutil.vbs SET W3SVC/Filters/Compression/gzip/HcScriptFileExtensions "asp" "dll" "exe" "newext"** where newext is a file type you want to compress, then press **ENTER**. You can add multiple file types separated by spaces.

| **Note** |
| --- |
| To remove one or more file types from the server-wide dynamic compression configuration, repeat the previous two commands, leaving out the file type you want to remove. |

**Related Information**

For a detailed discussion of how HTTP compression works, how to test compression, and detailed compression configuration options, see Using HTTP Compression for Faster Downloads.

For more information about improving the performance of IIS network resources using related features like bandwidth throttling and connection timeouts, see Administering Network Resources.

# Enabling HTTP Keep-Alives

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Most Web browsers request that the server keep the client connection open while the server sends multiple elements (.htm files and .gif or .jpeg files) to the client. Keeping the client connection open in this way is referred to as an HTTP Keep-Alive. Keep-Alive is an HTTP specification that improves server performance. HTTP Keep-Alives are enabled by default.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To enable HTTP Keep-Alives**

1. In IIS Manager, expand the local computer, expand the **Web Sites** folder, right-click the Web site, and click **Properties**.
2. On the **Web Site** tab, in the **Connections** section, click the **Enable HTTP Keep-Alives** check box.
3. Click **Apply**, and then click **OK**.

**Related Information**

- For information about HTTP Keep-Alives, including security requirements and how disabling keep-alives can impact the server, see Enabling HTTP Keep-Alives to Keep Connections Open.
- For more information about improving the performance of IIS network resources using related features like HTTP Compression, bandwidth throttling, and connection limits, see Administering Network Resources.

# Limiting Connections

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Connection limits restrict the number of simultaneous client connections to your Web sites and your Web server. Limiting connections conserves memory and protects against malicious attacks designed to overload your Web server with thousands of client requests.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set a global WWW or FTP service connection limit**

1. In IIS Manager, expand the local computer, right-click the **Web Sites** or **FTP Sites** folder, and then click **Properties**.
2. Click the **FTP Site** tab to limit connections on the FTP service, or click the **Performance** tab to limit connections on the WWW service.
3. Click the **Connections limited to** option, and in the box next to it, type the maximum number of simultaneous connections you want to allow on your Web or FTP service.
4. Click **Apply**, and then click **OK**.

**To set a Web or FTP site connection limit**

1. In IIS Manager, expand the local computer, expand the **Web Sites** or **FTP Sites** folder, right-click the Web or FTP site on which you want to set the connections limit, and click **Properties**.
2. Click the **FTP Site** tab to limit connections on the FTP site, or click the **Performance** tab to limit connections on the Web site.
3. Click the **Connections limited to** option, and in the box next to it, type the maximum number of simultaneous connections you want to allow on your Web or FTP site.
4. Click **Apply**, and then click **OK**.

**Related Information**

- For more detailed information about IIS connection limits, including the security ramifications of selecting the **Unlimited** option, see Limiting Connections to Manage Resources.
- For more information about improving the performance of IIS network resources using related features like HTTP Compression and bandwidth throttling, see Administering Network Resources.

# Setting Connection Timeouts

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Connection time-outs help reduce the loss of processing resources consumed by idle connections. When you enable connection time-outs, IIS enforces the time-outs at the connection level.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To set a global WWW or FTP service connection time-out value**

1. In IIS Manager, expand the local computer, right-click the **Web Sites** or **FTP Sites** folder, and click Properties.
2. On the **Web Site** or **FTP Site** tab, in the **Connection timeout** box, type the maximum number of seconds that IIS should maintain an idle connection before resetting the connection.
3. For the WWW service, verify that the **Enable HTTP Keep-Alives** box is selected. For more information, see Enabling HTTP Keep-Alives.
4. Click **Apply**, and then click **OK**.

**To set a connection time-out value for a specific Web or FTP site**

1. In IIS Manager, expand the local computer, expand the **Web Sites** or **FTP Sites** folder, right-click a Web or FTP site, and click **Properties**.
2. On the **Web Site** or **FTP Site** tab, in the **Connection timeout** box, type the maximum number of seconds that IIS should maintain an idle connection before resetting the connection.
3. For the WWW service, verify that the **Enable HTTP Keep-Alives** box is selected. For more information, see Enabling HTTP Keep-Alives.
4. Click **Apply**, and then click **OK**.

**Related Information**

- For more information about connection timeouts, including which counters to use to monitor connection timeouts, see Setting Connection Timeouts to Save Resources.
- For more information about improving the performance of IIS network resources using related features like bandwidth throttling, HTTP Compression, and connection limits, see Administering Network Resources.
- For information about setting CGI application timeouts, see Configuring CGI Application Timeouts.

# Throttling Bandwidth

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If the network or Internet connection used by your Web server is also used by other services such as e-mail or news, you may want to limit the bandwidth used by your Web server so it is available for those other services. If your Web server hosts more than one Web site, you can individually throttle the bandwidth used by each site.

This section includes the following information:

- Enabling Packet Scheduler: Describes how to enable Packet Scheduler when configuring a site to use bandwidth throttling without using IIS Manager.
- Enabling Bandwidth Throttling: Describes how to enable bandwidth throttling globally for the WWW service and for individual Web sites.
- Disabling Bandwidth Throttling: Describes how to disable bandwidth throttling for individual Web sites.

**Related Information**

- For more information about when and where to use bandwidth throttling, see Throttling Bandwidth to Manage Service Availability.
- For more information about improving the performance of IIS network resources using related features like HTTP Compression and connection limits, see Administering Network Resources.

# Enabling Packet Scheduler

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Bandwidth throttling uses Packet Scheduler to manage when data packets are sent. When you configure a site to use bandwidth throttling by using IIS Manager, Packet Scheduler is automatically installed, and IIS automatically sets bandwidth throttling to a minimum of 1024 kilobytes per second (KBps). However, if you use another method, such as Active Directory® Service Interfaces (ADSI) or WMI, you must install Packet Scheduler in order for bandwidth throttling to work correctly.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To enable Packet Scheduler**

1. From the **Start** menu, click **Control Panel**, click **Network Connections**, right-click any of the listed connections, and then click **Properties**.
2. On the **General** tab under **This connection uses the following items**, click any of the listed items, and then click **Install**.
3. In the **Select Network Component Type** dialog box, click **Service**, and then click **Add**.
4. In the **Select Network Service** dialog box, click **QoS Packet Scheduler**, and then click **OK** to close all open dialog boxes.

When using ADSI or WMI to configure bandwidth throttling, you must set bandwidth throttling to 1024 KBps or more, because Packet Scheduler cannot enforce bandwidth throttling settings below that level. Also, you need to uninstall Packet Scheduler if it is not in use by individual sites or the WWW service as a whole.

**Related Information**

- For more information about administering IIS with ADSI or with WMI, see ADSI and WMI Providers in IIS in the IIS Platform SDK on MSDN.

# Enabling Bandwidth Throttling

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The following procedures tell how to globally enable bandwidth throttling for the WWW service or to enable bandwidth throttling for a specific Web site.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To globally throttle WWW service bandwidth**

1. In IIS Manager, expand the local computer, right-click the **Web Sites** folder, and click **Properties**.
2. Click the **Performance** tab, and in the **Bandwidth throttling** section, select the **Limit the total network bandwidth available for all Web sites on this server** check box.
3. In the **Maximum bandwidth (in kilobytes per second)** box, type the maximum number of kilobytes per second that you want each site contained in the directory to use. This value must be at least 1024 Kbps.
4. Click the **Connections limited to** option, and in the box next to it, type the maximum number of simultaneous connections that you want to allow on your Web or FTP service.
5. Click **Apply**, and then click **OK**.

**To throttle the bandwidth used by an individual Web site**

1. In IIS Manager, expand the local computer, expand the **Web Sites** folder, right-click the Web site, and click **Properties**.
2. Click the **Performance** tab, and in the **Bandwidth throttling** section, select the **Limit the network bandwidth available to this Web site** check box.
3. In the **Maximum bandwidth (in kilobytes per second)** box, type the maximum number of kilobytes per second that you want this site to use. This value must be at least 1024 Kbps.
4. Click **Apply**, and then click **OK**.

# Disabling Bandwidth Throttling

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The following procedure tells how to disable bandwidth throttling for an individual site. The procedure is slightly different if you are overriding global bandwidth throttling. Either task can also be performed by using ADSI or WMI to update the **MaxBandwidth** metabase property for the site.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To disable bandwidth throttling on an individual site**

1. If global bandwidth throttling is not in effect, on the **Performance** tab, under **Bandwidth throttling**, clear the **Limit the network bandwidth available to this Web site** check box. Alternatively, you can set the **MaxBandwidth** metabase property to **-1** by using ADSI or WMI.
2. If global bandwidth throttling is in effect, but you want an individual site to have virtually unlimited bandwidth, on the Performance tab, under Bandwidth throttling, do not clear the **Limit the network bandwidth available to this Web site** check box (the global setting automatically applies to the individual site when the check box is cleared). Instead, enter a very high number in the **Maximum bandwidth (in kilobytes per second)** box. Alternatively, you can set the **MaxBandwidth** metabase property to **-2** by using ADSI or WMI.

| **Note** |
| --- |
| Bandwidth throttling is not supported for requests that come to a site by means of an IPv6 address. The **MaxBandwidth** metabase property does not affect IPv6 network traffic. |

**Related Information**

- For more information about the **MaxBandwidth** property, see MaxBandwidth Metabase Property.
- For more information about administering IIS with ADSI or with WMI, see ADSI and WMI Providers in IIS in the IIS Platform SDK on MSDN.

# Setting the IIS Object Cache Time Period

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The value of ObjectCacheTTL controls the static file cache by specifying the Time To Live (TTL), which sets the length of time that objects are held in cached memory. If an object in the memory cache has not been referenced for the defined period, that object is phased out of the cache.

| **Caution** |
| --- |
| Do not edit the registry unless you have no alternative. The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see IIS 6.0 Registry Reference. |

Use the following procedure to reset the time that an unused object remains in the object cache by adding the ObjectCacheTLL entry to the registry.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to edit the registry. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to open a command window as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **regedit.exe** to open the registry editor. |

**To reset the period that unused objects remain in the cache**

1. From the **Start** menu, click **Run**, type **regedit.exe**, and then click **OK**.
2. In the registry editor, navigate to the following subkey:

   HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\InetInfo\Parameters
3. Right-click the Parameters subkey, point to **New**, and then click **DWORD Value**.
4. In the **New Value** box, type **ObjectCacheTTL**.
5. Right-click **ObjectCacheTTL**, and then click **Modify**.
6. Under **Base**, click **Decimal**.
7. In the **Value Data** box, type the number of seconds that you want an unused object to remain in the cache, and then click **OK**.

   The default value is 30 (seconds). You can enter any value from zero, to disable caching, through 4,294,967,295 (unlimited), to disable the object-cache scavenger and allow cached objects to remain in the cache until the cached object changes.

# Maximizing Data Throughput for Network Applications

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

By default, servers running Windows Server 2003 are configured to give preference to the file system cache over the working sets of processes when allocating memory (through the server property **Maximize data throughput for file sharing**). Although IIS 6.0–based servers benefit from a large file system cache, giving the file system cache preference often causes the IIS 6.0 pageable code to be written to disk, which results in lengthy processing delays. To avoid these processing delays, set server properties to maximize data throughput for network applications.

**To maximize data throughput on the server for network applications**

1. In Control Panel, double-click **Network Connections**, right-click **Local Area Connection**, and then click **Properties**.
2. Select **File and Printer Sharing for Microsoft Networks**, and then click **Properties**.
3. Under **Optimization**, select **Maximize data throughput for network applications**.

# Setting the SSL Cache Time-out Interval

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you expect thousands of users to connect to your site by using SSL, estimate how long you expect SSL sessions to last, and then set the value of the ServerCacheTime entry to a number slightly higher than your estimate. Do not set the value much higher than your estimate, because the resulting time-out interval might cause your server to retain stale data in the cache.

| **Caution** |
| --- |
| The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see IIS 6.0 Registry Reference. |

Before changing the SSL cache time-out interval, make sure that HTTP Keep-Alives are enabled (HTTP Keep-Alives are enabled by default). SSL sessions do not expire when you use them with HTTP Keep-Alives except when the browser closes the connection.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to edit the registry. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to open a command window as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **regedit.exe** to open the registry editor. |

**To configure the ServerCacheTime registry entry**

1. In the registry editor, navigate to the following subkey:

   HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\SecurityProviders \SCHANNEL.

2. Right-click the SCHANNEL subkey, point to **New**, and then click **DWORD Value**.
3. In the **New Value** box, type the following: **ServerCacheTime**
4. Right-click the **ServerCacheTime** entry and then click **Modify**.
5. Under **Base**, click **Decimal**.
6. In the **Value Data** box, type the value (in milliseconds) that you want to assign for the cache time (1 minute = 60,000 milliseconds), and then click **OK**. See Table 6.28 for commonly used cache times converted to milliseconds.

**Table 6.28 Calculating ServerCacheTime Values for Secure Session Caching**

| **Desired Cache Time (1 minute = 60,000 milliseconds)** | **ServerCacheTime Value (in Milliseconds)** |
| --- | --- |
| No secure session caching | 0 (turns off session caching) |
| 2 minutes (default setting for the Microsoft® Windows NT® version 4.0 operating system) | 120000 |
| 5 minutes (default setting for the Microsoft® Windows® 2000 operating system) | 300000 |
| 10 hours (default setting for Windows Server 2003, Windows 2000 with Service Pack 2 [SP2] or later, and Windows XP) | 36000000 |

For more information about configuring the SSL cache time-out interval, see Configuring ServerCacheTime for SSL Sessions.

# Measuring Load Time for a Web Page

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Measure your first-access and second-access page-load times by using the procedures that follow.

**To measure a Web page's first-access load time**

1. Set up your WAN simulator to represent your 50th percentile domestic user. For example, your settings might be 60 milliseconds roundtrip delay, 50 kilobits per second, and no packet loss.
2. Set the site that you want to test as the default home page for your browser.
3. Browse to a site other than the one you are testing.

   If you are still on the test site when you clear your cache, the site refreshes after you clear the cache, reloading the files that you want to clear.
4. Clear the cache of all files by doing the following:
   a. On the **Tools** menu of Internet Explorer, click **Internet Options**.
   b. On the **General** tab, under **History**, click **Clear History**.
5. Close your browser.

   You must close TCP connections between tests, or your tests will be affected by TCPs slow-start algorithm, which retains the window size from the previous page load, producing inaccurate results.
6. Start your Network Monitor capture.
7. Open your browser to the test site (your new home page).
8. Stop the capture when the page is fully loaded and run Network Monitor. Determine how much total time elapsed while the page was loading.
9. Copy your data into a Microsoft® Excel worksheet for further analysis.

| **Important** |
| --- |
| Do not use CTRL+F5 (refresh the Web page — regardless of time stamp) as a substitute for this procedure. Although using CTRL+F5 is similar to this process in that it forces a full reload, it does not disconnect the TCP connections before the new page load. |

When you test a Web page for its second-access load time, you can use files that are saved in the client's cache.

**To measure a Web page's second-access load time**

1. Use the same WAN parameters and browser default settings that you used to determine first-access load time.
2. Close your browser without clearing the cache.
3. Restart your Network Monitor capture.
4. Open your browser to the test page.
5. Stop the capture when the page is fully loaded, and measure the time from the first TCP SYN from the client to the server, until the last byte is received.
6. Copy the results to a second Excel worksheet for further analysis.

| **Important** |
| --- |

Do not use F5 (refresh the Web page) as a substitute for this procedure because it does not provide the same results as a second page-load. Using F5 forces Internet Explorer to check the date on all cached files regardless of whether the dates will expire in the future.

After obtaining a page-load performance profile, analyze the data and remove obstacles to the pages efficient performance by using the information in Optimizing a Page-Load Performance Profile. For more information about first-access and second-access page-load times, see Obtaining a Page-Load Performance Profile.

# Enabling CPU Monitoring in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The CPU monitoring feature monitors and automatically shuts down worker processes that consume large amounts of CPU time. CPU monitoring is enabled for individual application pools.

Before enabling CPU monitoring, take note of the following:

- IIS must be operating in Worker Worker Process Isolation Mode.
- CPU monitoring is available only for application pools.
- CPU monitoring does not apply to CGI applications.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Enabling CPU Monitoring by Using IIS Manager**

When you enable CPU monitoring by using IIS Manager, IIS allows, by default, a maximum CPU use of 50 percent. To change the default value, follow this procedure.

**To enable CPU monitoring**

1. In IIS Manager, expand the local computer, expand the **Application Pools** folder, right-click the application pool for which you want to enable CPU accounting, and click **Properties**.
2. Click the **Performance** tab, and select the **Enable CPU monitoring** check box.
3. In the **Maximum CPU use** box, click the up and down arrows to set the maximum percentage of the CPU the application pool should use. If the application pool uses more than the designated maximum, IIS generates an error in the Windows Events log.
4. In the **Refresh CPU usage numbers (in minutes)** box, click the up and down arrows to set the refresh rate.
5. In the **Action performed when CPU usage exceeds maximum CPU use** list box, click the appropriate action for the designated application pool.
   - To have IIS write an event to the system log when the application pool reaches the maximum CPU usage, without shutting the application pool down, click **No Action**.
   - To shut down the application pool in addition to logging an event in the system log, click **Shutdown**.

     By default, **No Action** is selected.

     | **Important** |
     | --- |
     | Shutting down the application pool shuts down all worker processes that serve that application pool. |

6. Click **Apply**, and then click **OK**.

**Enabling CPU Monitoring from the Command Line**

Enabling CPU monitoring from the command line can take as many as three steps:

- Set the **CPULimit** metabase property, which limits the worker processes in a specified application pool to a percentage of CPU time.

- Set the **CPUResetInterval** metabase property, which specifies the time interval for CPU monitoring.

- Set the **CPUAction** metabase property, which specifies the type of action you want IIS to take, such as write to the event log or shut down worker processes that exceed the CPU limit.

#### Set the CPU Limit

The**CPULimit**property configures the maximum percentage of CPU time that the worker processes in an application pool are allowed to consume over the period of time set by the **CPUResetInterval** property. If the limit set by the **CPULimit** property is exceeded, an event is written to the event log and an optional set of events can be triggered as determined by the **CPUAction** property. Setting the value of the **CPULimit** property to zero disables CPU monitoring.

To start CPU monitoring for an application pool, set the **CPULimit** property to a value greater than zero. To calculate the value to set, determine the maximum percentage of CPU time that you want the worker processes in an application pool to use — for example, 50 percent (which is the default value). Next multiply that percentage by 1,000 (50  1,000 = 50,000). Hence, to limit CPU use to 50 percent, set a value of 50000 for the CPU limit.

**To set the CPU limit for CPU monitoring by using Adsutil.vbs**

1. In the **Run** dialog box, type **cmd**, and then click **OK**.

2. At the command prompt, type:

   **cscript %Systemroot%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AppPools/** *ApplicationPoolName* **/CPULimit** *n*

   Replace *n* with the maximum percentage of CPU use to allow for the application pool in 1/1,000ths of a percentage.

#### Set the CPU Reset Interval

After turning on CPU monitoring for the application, use Adsutil.vbs to set a value for the **CPUResetInterval** property, which specifies the reset period (in minutes) for CPU monitoring and throttling limits on the application pool. When the number of minutes elapsed since the last CPU monitoring reset equals the number specified by this property, IIS resets the CPU timers for both the logging and limit intervals. The default value is five minutes. Setting the value of this property to zero disables CPU monitoring.

| **Important** |
| --- |
| The value of the **CpuResetInterval** property must be greater than the time between logging operations; otherwise, IIS resets counters before logging has occurred, and CPU monitoring does not occur. |

**To set the CPU monitoring reset interval by using Adsutil.vbs**

1. In the **Run** dialog box, type **cmd**, and then click **OK**.

2. At the command prompt, type:

   **cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AppPools/** *ApplicationPoolName* **/CPUResetInterval** *n*

   Replace *n* with the number of minutes for the reset interval. To disable CPU monitoring, type **0**.

#### Set the CPU Action

Finally, set the **CPUAction** property, which configures the actions that IIS takes when Microsoft® Windows NT® job objects run. Only one Windows NT job object exists per application pool; therefore, you must configure the **CPUAction** property separately for each application pool. If you do not set the **CPUAction** metabase property, IIS assigns the default value, which is zero (event logging only).

**To set the CPUAction value by using Adsutil.vbs**

1. In the **Run** dialog box, type **cmd**, and then click **OK**.

2. At a command prompt, type:

**cscript %SystemDrive%\Inetpub\AdminScripts\adsutil.vbs set W3SVC/AppPools/** *ApplicationPoolName* **/CPUAction** *ActionValue*

Replace *ActionValue* with the appropriate value: **0** logs an error without shutting down the process; **1** logs an error and shuts down the process.

For more information about setting the CPU action, see the CPULimit Metabase Property, the CPUResetInterval Metabase Property, and theCPUAction Metabase Property.

**Related Information**

- For more information about CPU Monitoring, including explanations of the corresponding metabase properties and options for advanced CPU monitoring with Windows System Resource Manager, see Enabling CPU Monitoring.

- For information about related features that help manage and conserve resources when IIS is running in Worker Process Isolation Mode, see Managing Resources in Worker Process Isolation Mode.

# Configuring Application Pool Queue-Length Limits

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

*Application pool queue-length limits* prevent large numbers of requests from queuing up and overloading your server. When application pool queue-length limits are enabled, IIS monitors the number of requests for a designated application pool queue before queuing a new request. If adding the new request to the queue exceeds the queue size, the server rejects the request and sends an uncustomizable 503-error response to the client.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To change an application pool queue-length limit using IIS Manager**

1. In IIS Manager, expand the local computer, expand the **Application Pools** folder, right-click the application, and then click **Properties**.
2. Click the **Performance** tab.
3. In the **Request queue limit** section, select the **Limit the kernel request queue to** check box, and click the up and down arrows in the **requests** box to set the maximum number of queued requests.

   **Note**

   If you clear the **Limit the kernel request queue to** check box, or if you set the **AppPoolQueueLength** metabase property to zero, IIS does not enforce a kernel request limit. Without a kernel request limit, IIS could queue an unlimited number of requests and your server could potentially run out of memory. For this reason, you should set kernel request-queue limits on all production servers.

4. Click **Apply**, and then click **OK**.

**Related Information**

- For more information about application pool queue-length limits, as well as other features and strategies for managing memory resources on your server, see Optimizing Memory Usage.
- For information about application pools, including guidelines for creating application pools, see Creating Application Pools.
- For information about features and strategies to help you monitor the health and performance of your application pools, see Ensuring Application Health in Worker Process Isolation Mode.

# Scalability

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

**Scalability** is the capability of a piece of hardware or software to easily expand to meet future computing needs. Each version of IIS is designed for better performance and scalability than the previous version. However, scalability can be impaired by hardware configurations and bottlenecks in poorly designed or poorly tested Web applications. Administrators can dramatically improve the scalability of their IIS server environment with careful planning and assessment of their infrastructure, which includes hardware, distributed applications, and custom components.

**Related Information**

- For information about scaling IIS, including information about adjusting IIS queue and cache settings and how to scale IIS with UNC centralized content storage, see Web Server Scalability.

- For information about monitoring IIS performance and scalability, including which counters to use, the tools available, and how to collect useful performance data, see Optimizing IIS 6.0 Performance.

# Configuring Last-Modified Caching

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

To allow for greater scalability of UNC-based storage systems, IIS 6.0 implements a new last-modified cache algorithm for static and ASP files. The new caching algorithm does not request change notification for each directory structure; instead, it requests only the last-modified date of the cached file. If the file is new, the cache entry is updated with the new content and served. If the file has not changed, IIS serves the cached version of the file. By default, IIS checks the last-modified date for both ASP and static files if more than five seconds have elapsed since the file was last checked. Otherwise, IIS assumes the file has not changed, and it serves the existing content.

| **Note** |
| --- |
| The server side includes (SSI) file handler (Ssinc.dll) makes use of the static file cache, so this behavior occurs for .stm, .shtml, and any other files that are mapped to this DLL. |

IIS 6.0 uses the last-modified caching algorithm by default. To specify change-notification caching or to change the TTL value of the cached files, you must edit the registry.

| **Caution** |
| --- |
| Do not edit the registry unless you have no alternative. The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the IIS 6.0 Registry Reference. |

**To set change-notification tracking or TTL for static files**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **Regedit.exe**, and then click **OK**.
3. Navigate to the following subkey: HKLM\System\CurrentControlSet\Services\Inetinfo\Parameters
4. Do one or both of the following:
   - To enable change-notification caching, modify the value of the registry entry **DoDirMonitoringForUnc** by setting it to **1**.
   - To change the TTL setting from the default of five seconds, change the value of the registry entry **FileAttributeCheckThreshold** to the number of seconds you want to use.
5. Close the registry editor.

When stale content is being served by the Web Server even though the content has been updated on the remote file server, you can disable the Web Server cache to attempt to isolate the problem.

**To disable the static file cache**

1. Navigate to the following subkey in the registry:

   HKLM\System\CurrentControlSet\Services\Inetinfo\Parameters
2. Add DisableMemoryCache, a DWORD value, and set it to **1**.

Then disable the ASP file cache to complete disabling the Web Server cache. For information about disabling ASP file caching, see Configuring ASP Template Caching.

# Configuring ASP Change-Notification Caching

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS 6.0 provides a scalable change-notification mechanism for ASP pages. Because change notification occurs for unique directory structures, instead of for every directory, the number of work items required for change notification is reduced.

To specify change-notification caching or to change the TTL value of the cached files, you must edit the registry.

| **Caution** |
| --- |
| Do not edit the registry unless you have no alternative. The registry editor bypasses standard safeguards, allowing settings that can damage your system, or even require you to reinstall Windows. If you must edit the registry, back it up first and see the IIS 6.0 Registry Reference. |

**To set change-notification tracking or TTL for ASP files**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **Regedit.exe**, and then click **OK**.
3. Navigate to the following subkey: HKLM\System\CurrentControlSet\Services\ASP\Parameters
4. Do one or both of the following:
   - To enable change-notification caching, change the value of the registry entry **EnableChangeNotificationForUNC** by setting it to **1**.
   - To change the TTL setting from the default of five seconds, change the value of the registry entry **FileMonitoringTimeoutSeconds** to the number of seconds you want to use.
5. Close the registry editor.

# Logging Site Activity

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can collect information about user activity by enabling logging for your Web sites. Logging information in Internet Information Services (IIS) goes beyond the scope of the event logging or performance monitoring features provided by Microsoft® Windows®. The logs can include information such as who has visited your site, what the visitor viewed, and when the information was last viewed. You can use the logs to assess content popularity or to identify information bottlenecks.

**In This Section**

This section includes the following information:

- Enabling Logging: Describes how to enable or disable logging for a Web or FTP site, or for directories.
- Enabling UTF-8 Format for Non-English Languages and Security: Describes how to log data in UTF-8 format.
- Customizing W3C Extended Logging: Describes how to change which fields are logged when using W3C Extended logging.
- Enabling W3C Centralized Logging: Describes how to save all log data for all sites on the server in a single log file.
- Saving Log Files: Describes how to specify the log-file directory and the options for creating new log files.
- Centralized Binary Logging in IIS 6.0: Describes how to save all log files for all Web sites on a specific IIS server in a centralized container, in binary format.
- Remote Logging: Describes how to store log data on a remote share using a UNC path.
- Substatus Error Codes in Log Files: Describes the IIS 6.0 implementation of substatus error codes, how to log these codes in IIS log files, and how to use these codes to debug IIS problems.

Related Information

- For more information about logging, including examples and descriptions of various IIS log file formats and information about HTTP.sys error logging, see Analyzing Log Files section.
- For information about auditing techniques to track the activities of users and to detect unauthorized attempts to access your NTFS file system directories and files, see Auditing in IIS 6.0.
- For an explanation of W3C Extended logging fields, including a detailed technical breakdown of the **time-taken** field, see W3C Extended Log File Format.
- For more information about HTTP status codes (100 - 500) see HTTP Status Codes in IIS 6.0.
- For information about client error codes (400 - 404) and how to troubleshoot common request problems, see HTTP 40x - - Client Error Codes.

# Enabling Logging

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can choose a format and enable logging for individual Web sites and FTP sites. After you enable logging on a Web site or FTP site, all traffic to the site (including virtual directories) is written to the corresponding file for each site.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To enable logging on a Web or FTP site**

1. In IIS Manager, double-click the local computer, double-click the **Web Sites** or **FTP Sites** folder, right-click the Web site or FTP site for which you want to enable logging, and then click **Properties**.
2. On the Web Site or FTP Site tab, select the **Enable logging** check box.
3. In the **Active log format** box, click a format. By default, the format is **W3C Extended Log File Format**.

   | **Note** |
   | --- |
   | If you select ODBC logging, click **Properties** and type the ODBC Data Source Name (DSN) and the name of the table within the database in the text boxes. If a user name and password are required to access the database, type the necessary credentials, and then click **OK**. |

   | **Note** |
   | --- |
   | Logging to a UNC share is not supported by IIS FTP. You must configure the FTP log files location to a path on the local machine. |

4. Click **Apply**, and then click **OK**.

**Related Information**

- For more information about logging, including examples and descriptions of various IIS log file formats and information about HTTP.sys error logging, see the Analyzing Log Files section.
- For an explanation of W3C Extended logging fields, including a detailed technical breakdown of the **time-taken** field, see W3C Extended Log File Format.

# Enabling UTF-8 Format for Non-English Languages and Security

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Note** |
| --- |
| IIS does not support the UTF-8 format for FTP site log files. |

*UTF-8* is a method of character encoding that allows for both single and multibyte characters in one string. If you want to read text-based (W3C Extended, IIS, and NCSA Common) log files in a language other than English, you can enable the UTF-8 format. You also need the UTF-8 format if you serve URLs in a language other than the native server code page, for example, if you serve Chinese URLs on a Japanese system. In addition, because IIS 6.0 tries to serve URLs in code pages other than the server default code page by default, you might want to enable the UTF-8 format for security reasons. It is a good security practice to enable the UTF-8 format in case of an attack based on URLs in UTF-8 that might not translate correctly to the default code page.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

### To enable UTF-8 format

1. In IIS Manager, right-click the local computer, and then click **Properties**.
2. In **UTF-8 Logging**, select the **Encode Web logs in UTF-8** check box, and then click **OK**.

#### Related Information

- For more information about formats of log files in IIS, see Log File Formats in IIS.

# Customizing W3C Extended Logging

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you selected the W3C Extended log file format for a Web or FTP site, you can customize the logged data. You can also limit unnecessary data and reduce the size of the log file by omitting unneeded fields.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To customize W3C Extended logging**

1. In IIS Manager, expand the local computer, expand the **Web** or **FTP Sites** folder, right-click the Web or FTP site, and click **Properties**.
2. On the **Web Site** or **FTP Site** tab, select the **Enable logging** check box (if it is not already selected).
3. In the **Active log format** list box, click **W3C Extended Log File Format**.
4. Click **Properties**.
5. On the **Advanced** tab, select the properties you want to log.
6. Click **OK**.

**Related Information**

- For an explanation of W3C Extended logging fields, including a detailed technical breakdown of the **time-taken** field, see W3C Extended Log File Format.
- For information about the **Protocol Substatus** field, see Substatus Error Codes in Log Files.

# Enabling W3C Centralized Logging

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

W3C centralized logging is a global configuration on the server where all Web sites write data to a single log file. This single log file uses the W3C Extended log file format and can be viewed in a text editor. W3C centralized logging is available in Windows Server 2003 Service Pack 1 or later. For more information about this logging option, see W3C Centralized Logging.

By default, log files are stored in the Windows/system32/logfiles/W3SVC directory. After you enable, W3C centralized logging, IIS creates a new log file and all Web sites begin writing data to that single source.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To enable W3C Centralized Logging**

1. From a command prompt, type
   **Adsutil.vbs set w3svc/CentralW3CLoggingEnabled true**
2. The World Wide Web Publishing Service (WWW service) must be stopped and restarted for changes to take effect. From the command prompt, type **net stop W3SVC**, and press **ENTER**. The WWW service stops.
3. Type **Net start w3svc**

**See Also**

CentralW3CLoggingEnabled Metabase Property

# Saving Log Files

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

By default, IIS creates a new log file for each Web site in the *systemroot*\System32\LogFiles directory. However, you can specify the directory into which log files are saved, and you can determine when new log files are started. To protect logged data, set appropriate Access Control with IIS 6.0 on the log file directory. Consider allowing only the administrator and the IIS_WPG group to have access to the log file directory.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**.

**Procedures**

**To set options for saving log files**

1. In IIS Manager, expand the local computer, expand the Web or FTP Sites directory, right-click the Web or FTP site, and click **Properties**.
2. On the **Web Site** or **FTP Site** tab, click **Properties** next to the **Active log format** list box.
3. Select the log schedule to use when starting a new log file.

   **Note**

   "Midnight" is midnight local time for all log file formats except the W3C Extended format. For W3C Extended log file format, "midnight" is midnight Greenwich Mean Time (GMT), by default, but can be changed to midnight local time. To open new W3C Extended logs using local time, select the **Use local time for file naming and rollover** check box. The new log starts at midnight local time, but the time recorded in the log files is still GMT.

4. Under **Log file directory**, type the directory where log files should be saved. For information about saving log files on a remote share, see Remote Logging.
5. Click **Apply**, and then click **OK** twice.

**Related Information**

- For information about saving log data in raw, binary format to conserve hard-disk space and to reduce memory consumption, see Centralized Binary Logging.
- For more information about IIS and centralized-content storage, see Improving Scalability Through UNC-Based Centralized Content Storage.

# Centralized Binary Logging in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Centralized binary logging is the process by which multiple Web sites write binary, unformatted log data to a single log file. When enabled, all Web sites on your server write log data to a single log file.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to run scripts and executables. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run your script or executable as an administrator. At a command prompt, type **runas /profile /user:***MyComputer******Administrator* **cmd** to open a command window with administrator rights and then type **cscript.exe** *ScriptName* (include the script's full path and any parameters). |

**Procedures**

**To enable centralized binary logging for all Web sites on your server running IIS**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **cscript.exe adsutil.vbs SET W3SVC/CentralBinaryLoggingEnabled true**, and click **OK**.
3. The World Wide Web Publishing Service (WWW service) must be stopped and restarted for changes to take effect. From the command prompt, type **net stop W3SVC**, and press ENTER. The WWW service stops.

From the command prompt, type **net start W3SVC**, and press ENTER. The WWW service starts and centralized binary logging is enabled.

The binary log file is created in the W3SVC folder located at *systemroot*\System32\LogFiles\.

**Related Information**

- For more detailed information about centralized binary logging, including information about how to extract data from the raw log file, see Centralized Binary Logging.
- For more information about W3C centralized logging, see W3C Centralized Logging.
- For more information about logging, including examples and descriptions of various IIS log file formats and information about HTTP.sys error logging, see Analyzing Log Files.

# Remote Logging

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can write log data to a remote share over a network using a full Universal Naming Convention (UNC) path for centralized log file storage and backup. Be aware that remote logging can negatively affect performance because IIS writes the log file and log file data over the network.

| **Note** |
| --- |
| Logging to a UNC share is not supported by IIS FTP. You must configure FTP log files location to a path on the local machine. |

| **Important** |
| --- |
| It is highly recommended that you enable Internet Protocol security (IPSec) between your Web server running IIS and the remote server before configuring remote logging. If IPSec is not enabled between the Web server running IIS and the remote server, data packets containing log data are potentially at risk of being intercepted by malicious individuals and wire-sniffing applications while the data packet travels through the network. |

**Procedures**

**Setting up remote logging requires the following actions:**

1. Configuring IIS to Log Data on a Remote Share
2. Configuring Permissions for Remote Logging
3. Setting Up a Null Session for Cross-Domain Logging (if applicable)

**Related Information**

- For more information about IIS and centralized-content storage, see Improving Scalability Through UNC-Based Centralized Content Storage.

# Configuring IIS to Log Data on a Remote Share

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure IIS to write log file data to a remote share. In the remote share, IIS creates a unique directory for each Web site, for example **W3SVC***X*, where *X* is a random number generated by IIS to represent the specific Web site. IIS also creates the log file with exclusive write access, so that multiple machines cannot write to the same log file.

**Important**

You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc systemroot\system32\inetsrv\iis.msc"**.

**Procedures**

**To log Web site data on a remote share**

1. Create a log file directory on a remote server in the same domain as your Web server running IIS.
2. Change the directory properties so the directory is a share and assign the **Everyone** group **Full Control** permissions. If you want to write log files to a remote server in a different domain, see Setting Up a Null Session for Cross-Domain Logging.
3. Ensure that your server running IIS has **Full Control** access permission on the remote share and read and write permissions on the remote log file directory. For more information, see Configuring Permissions for Remote Logging.
4. In IIS Manager, expand the local computer, right-click the **Web Sites** folder, and click **Properties**.
5. On the **Web Site** tab, ensure that the **Enable logging** check box is selected.
6. In the **Active log format** list box, click a log file format.
7. Click **Properties**.
8. Click the **General** tab, and in the **Log file directory** box, type the full UNC path. For example, type *servername**LogFiles*, where *servername* represents the name of the remote server, and *LogFiles* represents the name of the share where the log files are stored.
9. Click **Apply**, and then click **OK**. All Web sites within the directory begin logging data to the remote share.

**Note**

Logging to a UNC share is not supported by IIS FTP. You must configure the FTP log files location to a path on the local machine.

**Related Information**

- For information about saving log data in raw, binary format to conserve hard-disk space and to reduce memory consumption, see Centralized Binary Logging in IIS 6.0.
- For more information about IIS and centralized-content storage, see Improving Scalability Through UNC-Based Centralized Content Storage.

# Configuring Permissions for Remote Logging

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS can store log files on a remote share as long as the remote computer allows IIS to create log files and write data to the remote share. Use the following procedure to configure permissions on the remote machine so IIS can create log files and write data to the remote share.

**Procedures**

**To configure permissions for remote logging**

1. On the remote computer, navigate to *systemroot**System32*, right-click the **LogFiles** folder, and then click **Sharing and Security**.
2. On the **Sharing** tab, click **Share this folder**, and then click **Permissions**.
3. Click **Add**.
4. Click **Object Types**.
5. Select the **Computers** check box, and click **OK**. If you like, you can deselect all other options.
6. In the **Enter the object name to select** box, type the object name in the form *Domain**WebServer*, and then click **OK**.
7. In the **Group or user names** list, select the *Domain**WebServer* object, and in the **Permissions** section, select the **Allow** check box next to **Full Control**.
8. In the **Group or user names** list, select **Everyone**.
9. In the **Permissions** section, clear all permissions and click **OK**. The remote computer now has the appropriate access permissions.
10. To set the appropriate file permissions, click the **Security** tab.
11. Select the *Domain**WebServer* object and in the **Permissions** section, select the **Allow** check box next to **Full Control**.
12. Click **Apply**, and then click **OK**.

**Related Information**

- For more information about permissions in IIS see, Setting NTFS Permissions for Directories or Files.
- For more information about IIS and centralized-content storage, see Improving Scalability Through UNC-Based Centralized Content Storage.

# Setting Up a Null Session for Cross-Domain Logging

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Remotely logging files to a UNC share in a different domain requires configuring the remote share as a null session share. A null session connection is an unauthenticated connection. When IIS attempts to access a remote Microsoft Windows server resource, such as a file share, using a null session, the operation might fail if the file share is not configured as a null session share, or if there are any registry, group, or policy restrictions set on the server hosting the file share.

| **Important** |
| --- |
| Using Registry Editor incorrectly can cause serious problems that require reinstalling the operating system. Because Registry Editor bypasses the standard safeguards that prevent you from entering settings that are conflicting or likely to degrade performance or damage your system, exercise caution when making changes to the registry. Microsoft cannot guarantee that problems resulting from the incorrect use of Registry Editor can be solved. For information about how to edit the registry, see "Changing Keys and Values" in Registry Editor Help. |

**Procedures**

**To enable null session access**

1. From the **Start** menu, click **Run**.
2. In the **Open** box, type **Regedit.exe**, and click **OK**.
3. Navigate to and double-click the following key in the registry:

   HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\LanmanServer\Parameters\NullSessionShares.

   | **Note** |
   | --- |
   | **NullSessionShares** is a REG_MULTI_SZ value. |

4. On a new line in the **NullSessionShares** key, type the name of the share that you want to access with a null session, for example, **public**.
5. Navigate to and click the following key in the registry:

   HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\LSA.

6. From the **Edit** menu, point to **Add**, click **DWORD Value** and then add the following registry value:

   Name: **RestrictAnonymous**

   Type: **REG_DWORD**

   Data: **0**

7. Quit Registry Editor.
8. Restart the server.

If the remote share does not allow your IIS server to write the log file to the designated share after restarting the server, you might need to adjust the Windows security groups and security policies on the remote machine to enable anonymous access.

**Related Information**

- For more information about security groups and security policies, see "Security" in Help and Support Center for Windows Server 2003.
- For more information about IIS and centralized-content storage, see Improving Scalability Through UNC-Based Centralized Content Storage.

# Substatus Error Codes in Log Files

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When enabled, substatus error codes are written to IIS log files whenever a client request fails.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

### To log substatus error codes

1. In IIS Manager, expand the local computer, expand the **Web Sites** folder, right-click the Web site, and click **Properties**.
2. On the **Web Site** tab, ensure that the **Enable logging** check box is selected.
3. In the **Active log format** list box, click **W3C Extended Log File Format**.
4. Click **Properties**.
5. Click the **Advanced** tab, and under **Extended properties**, select the **Protocol Substatus** check box.
6. Click **OK** twice.

**Related Information**

- For an explanation of W3C Extended logging fields, including a detailed technical breakdown of the **time-taken** field, see W3C Extended Log File Format.
- For more information about HTTP status codes (100 - 500) see HTTP Status Codes in IIS 6.0.
- For information about client error codes (400 - 404) and how to troubleshoot common request problems, see HTTP 40x - - Client Error Codes.

# Error Messages in IIS 6.0

Updated: June 30, 2006

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

You can configure Internet Information Services (IIS) to send default HTTP 1.1 error messages or custom error messages. Custom error messages can be mapped to a file name or to a URL.

This section includes the following information:

- Enabling Standard HTTP 1.1 Error Messages: Describes how to use the detailed (also known as friendly) HTTP 1.1 errors that are included with IIS.

- Configuring Custom Error Messages: Provides information about customizing Microsoft® Active Server Pages (ASP) error files.

- Enabling ASP Error Processing: Describes how to use the 500-100.asp custom error file to process ASP errors.

- Disabling HTTP Friendly Error Messages in Internet Explorer: Describes how to show literal HTTP error codes used with to troubleshooting.

  | **Note** |
  | --- |
  | HTTP.sys, the kernel-mode driver, does not serve custom errors. If a request does not reach user mode, HTTP.sys returns standard HTTP 1.1 error messages to the browser. HTTP.sys might return standard error messages for the following errors, even if you have specified a custom error message: |

  - 400: Cannot resolve the request.

  - 414: Request URL is too large and therefore unacceptable on the Web server.

  - 501: Header values specify a configuration that is not implemented.

  For details about why HTTP.sys returned one of these standard error messages, view the HTTP error logs. By default, HTTP error logs are created in the following location: *systemroot*\System32\LogFiles\HTTPERR.

- Disabling HTTP Friendly Error Messages in Internet Explorer: Describes how to disable HTTP friendly error messages in Internet Explorer for troubleshooting purposes.

**Related Sections**

- For more information about HTTP status codes (100–500) see HTTP Status Codes in IIS 6.0.

- For information about client error codes (400–404) and how to troubleshoot common request problems, see HTTP 40x -- Client Error Codes.

- For information about how to log substatus error codes and what substatus error codes mean, see Substatus Error Codes in Log Files.

# Enabling Standard HTTP 1.1 Error Messages

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

By default, IIS sends custom error messages because these messages contain more information to help users understand why they have received an error. You can, however, configure IIS to send standard, or default, HTTP 1.1 error messages.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To enable standard HTTP 1.1 error messages**

1. In IIS Manager, double-click the local computer; right-click the Web site, virtual directory, directory, or file for which you want to enable standard HTTP 1.1 error messages; and then click **Properties**.
2. Click the **Custom Errors** tab.
3. In the **Error messages for HTTP errors** list, click the HTTP error(s) that you want to change to standard HTTP 1.1 error(s), click **Set to Default**, and then click **OK**.

**Related Information**

- For information about how to configure custom error messages, see Configuring Custom Error Messages.
- For more information about HTTP status codes (100 - 500) see HTTP Status Codes in IIS 6.0.
- For information about client error codes (400 - 404) and how to troubleshoot common request problems, see HTTP 40x - - Client Error Codes.
- For information about logging substatus error codes and what substatus error codes mean, see Substatus Error Codes in Log Files.

# Configuring Custom Error Messages

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS can send standard HTTP 1.1 error messages or custom error messages. Custom error messages provide more informative, or friendly, feedback than standard error messages. By default, IIS is configured to send custom error messages from a file stored in the *systemroot*\Help\IisHelp\Common folder. You can also configure IIS to return a URL to a custom error message.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To configure custom error messages**

1. In IIS Manager, double-click the local computer; right-click the **Web Sites** folder, an individual Web site folder, a virtual directory, or a file; and then click **Properties**.

   | **Note** |
   | --- |
   | Configuration settings made at the Web Sites level are inherited by all of the Web sites on the server. You can override inheritance by configuring the individual site or site element. |

2. Click the **Custom Errors** tab.

3. In the **Error messages for HTTP errors** list, click the HTTP error that you want to change, and then click **Edit**.

   | **Note** |
   | --- |
   | The following errors are not customizable: 400, 403.9, 411, 414, 500, 500.11, 500.14, 500.15, 501, 503, and 505. |

4. In the **Message Type** list box, click either **File** to return a custom error file or **URL** to direct the request to a custom error URL on the local machine.

   | **Important** |
   | --- |
   | If your custom error is an .asp page, you must select **URL**. If you do not select **URL**, you risk returning .asp source code to the client. |

5. If you selected **File**, type the path to the file or click **Browse** to navigate to the file. Custom error messages are installed by default to the *systemroot*\Help\IisHelp\Common folder. The file names are numbers that correspond to the specific HTTP errors; for example, 400.htm, 401-1.htm, and so on.

   or

   If you selected **URL**, type the path to the Web site or virtual directory. The URL must be a Web site or a virtual directory on the local machine. In addition, the custom error URL must exist in the application pool that directs the request to the custom error URL. If you store custom error pages in a virtual directory, that virtual directory must run in the same application pool as the rest of your Web site. Otherwise, the worker process cannot serve the custom error page when it is requested.

6. Click **OK**, and then click **OK** again.

If you upgraded from IIS 4.0, and you previously created your own custom error files or modified the custom error files that IIS 4.0 installed in the *systemroot*\Help\Common folder, your custom error files have been moved to the *systemroot*\Help\IisHelp\Common folder and given a .bak file name extension. You can retrieve your custom errors and reuse

them. For example, the custom error file 400.htm that IIS 4.0 installed is now named 400.bak and is located in the *systemroot*\Help\IisHelp\Common folder (in addition to the new IIS custom error files).

**Related Information**

- For more information about HTTP status codes (100 - 500) see HTTP Status Codes in IIS 6.0.
- For information about client error codes (400 - 404) and how to troubleshoot common request problems, see HTTP 40x -- Client Error Codes.
- For information about logging substatus error codes and what substatus error codes mean, see Substatus Error Codes in Log Files.

# Enabling ASP Error Processing

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The default Web site transfers the processing of Active Server Pages (ASP) errors to the 500-100.asp file (by default). If you create a new Web site, ASP errors return standard HTTP Status Codes (known as **Default** in IIS Manager. If you want to customize ASP errors, you can either map the 500-100 error to the 500-100.asp file or create an error-processing ASP file of your own. If you create an ASP error-processing file of your own, you must enable the custom error file through IIS Manager.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To enable ASP error processing by mapping to a URL**

1. Create a file that contains your custom error message, and save it to a virtual directory.
2. In IIS Manager, double-click the local computer; right-click the Web site, virtual directory, directory, or file for which you want to enable ASP error processing; and then click **Properties**.
3. Click the **Custom Errors** tab.
4. In the **Error messages for HTTP errors** list, click the HTTP error that you want to change, and then click **Edit**.
5. In the **Message Type** list box, click **URL**.
6. In the **URL** box, type the URL that points to your customized error message by typing the path to the URL, beginning with the virtual directory name.
7. Click **OK**, and then click **OK** again.

**Related Information**

- For more information about HTTP status codes (100 - 500) see HTTP Status Codes in IIS 6.0.
- For information about client error codes (400 - 404) and how to troubleshoot common request problems, see HTTP 40x - - Client Error Codes.

# Disabling HTTP Friendly Error Messages in Internet Explorer

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Internet Explorer displays friendly error messages when it encounters a problem during communication with an HTTP server. Friendly error messages are appropriate for the end user. However, they can prevent administrators from seeing the literal HTTP error codes and explanations, which makes troubleshooting difficult, if not impossible. During the discovery phase of troubleshooting, you can gather and record the HTTP errors that have occurred if you have disabled friendly messages.

**To disable friendly HTTP error messages in Internet Explorer**

1. On the **Tools** menu in Internet Explorer, click **Internet Options**.
2. Click the **Advanced** tab.
3. In the list of options under **Browsing**, clear the **Show friendly HTTP error messages** check box.
4. Click **Apply**, and then click **OK**.

# Web Application Guide

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This section includes information about configuring Web applications using Microsoft® ASP.NET. In this section you will find information about configuration, security, and deployment.

**In This Section**

This section includes the following information:

- About the .NET Framework: Provides an introduction to the Microsoft .NET Framework.
- About ASP.NET: Provides information about ASP.NET configuration, deployment, and security.
- About ASP: Provides an overview of what is new in Microsoft Active Server Pages (ASP).

Related Information

- For information about writing server-side scripts with ASP and creating ASP applications, see the Active Server Pages Guide on MSDN® Online or in the Internet Information Services (IIS) Software Development Kit (SDK).
- Redirect Reference: This section explains how to format a server redirection correctly. For reference topics related to ASP, see the IIS Web Application Technology Reference section of the IIS Software Developer Kit (SDK).

# About the .NET Framework

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| This feature is not available on Windows XP 64-Bit Edition and the 64-bit versions of the Windows Server™ 2003 family. For more information, see "Features unavailable on 64-bit versions of the Windows Server family" in Help and Support Center for Windows 2003. |

The Microsoft .NET Framework is a new computing platform that simplifies application development in the distributed environment of the Internet. The .NET Framework is designed to provide an object-oriented programming environment that guarantees the safe execution of code, and to eliminate the performance problems of scripted environments.

The .NET Framework has two main components: the common language runtime and the .NET Framework class library. Microsoft ASP.NET hosts the runtime to provide core services such as memory management, thread management, and remoting while enforcing strict type safety and other forms of code accuracy that ensure security and robustness. Code management is a fundamental principle of the runtime; code that targets the runtime is called *managed code*, while code that does not target the runtime is called *unmanaged code*.

The .NET Framework class library is a comprehensive, object-oriented collection of reusable types that developers can use to create ASP.NET applications.

**Common Language Runtime Features**

The common language runtime (CLR) manages memory, thread execution, code execution, code safety verification, compilation, and other system services. These features are intrinsic to the managed code that runs on the common language runtime hosted by ASP.NET. Managed components are granted varying degrees of trust, depending on a number of factors including their origin (such as the Internet, enterprise network, or local computer). This means that a managed component might or might not be able to perform sensitive functions, even if it is being used in the same active application.

The CLR enforces code access security. Applications can be granted access to specific resources but cannot access any resources outside of those limits.

The CLR also enforces code robustness by implementing a strict type- and code-verification structure called the common type system (CTS). The CTS ensures that all managed code is self-describing, which means that managed code can consume other types and instances regardless of which language compiler was used to develop the software.

In addition, the managed environment of the CLR eliminates many common software issues. For example, the CLR automatically handles object layout and manages references to objects, releasing them when they are no longer in use. This automatic memory management resolves the two most common application errors: memory leaks and invalid memory references. The CLR is designed to enhance performance. Although the CLR provides many standard runtime services, managed code is never interpreted. Just-in-time (JIT) compiling enables all managed code to run in the native machine language of the system on which it is executing. Meanwhile, the memory manager further improves performance.

**.NET Framework Class Library Features**

The .NET Framework class library is a collection of reusable types that tightly integrate with the CLR. The class library is object-oriented, providing types from which applications can derive additional functionality. This object orientation makes the .NET Framework types easy to use and it reduces the time associated with learning new features of the .NET Framework. In addition, third-party components can integrate seamlessly with classes in the .NET Framework.

The .NET Framework types enable you to accomplish a range of common programming tasks such as string management, data collection, database connectivity, and file access. In addition, the class library includes types that support a variety of specialized development scenarios.

**Related Information**

- For information about writing, building, testing, and deploying .NET Framework applications, see the Microsoft .NET Framework Software Development Kit.

# About ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| This feature is not available on Windows XP 64-Bit Edition and the 64-bit versions of the Windows Server™ 2003 family. For more information, see "Features unavailable on 64-bit versions of the Windows Server family" in Help and Support Center for Windows 2003. |

Microsoft ASP.NET is more than just the next generation of Active Server Pages (ASP). It provides an entirely new programming model for creating network applications that take advantage of the Internet. This section includes information about configuration, security, and deployment of ASP.NET applications.

FrontPage Server Extensions does not support unicode content directory names or Web Distributed Authoring and Versioning (WebDAV). New FrontPage Server Extensions virtual servers should be assigned to the MSSharePointPool application pool. Also, do not make changes to the MSSharePointPool application pool configuration.

| **Note** |
| --- |
| If you have a Web site that uses Sharepoint™ Team Services (STS) from Microsoft, the following types of pages do not work without excluding the virtual directory containing the pages from the STS ISAPI filter: |

- ASP pages
- ASP.NET pages
- PHP pages
- PerlScript pages

**Procedures**

**To enable these types of pages to work on your STS Web site**

1. In the **Central Administration** Web site for STS, choose to **Manage** your virtual directory or Web site.
2. Under **Defined Managed Paths**, type the path to the virtual directory that contains your excluded pages (such as \MyASPPages) and select **Exclude**.

This section includes the following information:

- Overview of ASP.NET: Describes the ASP.NET programming model and infrastructure.
- Why Use ASP.NET?: Describes the differences between ASP.NET and ASP.
- Introduction to XML Web Services Created with ASP.NET: Defines XML Web services and describes how to use them.
- ASP.NET Administration: Describes installing, configuring, and deploying ASP.NET applications on a computer running Microsoft Windows Server™ 2003.

**Related Information**

- For more information about creating ASP.NET Web applications, see Creating ASP.NET Web Applications

# Overview of ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

ASP.NET is a unified Web application platform that provides the services necessary to build and deploy enterprise-class Web applications. ASP.NET offers a new programming model and infrastructure for more secure, scalable, and stable applications that can target any browser or device.

ASP.NET is part of the Microsoft .NET Framework, a computing environment that simplifies application development in the highly distributed environment of the Internet. The .NET Framework includes the common language runtime (CLR), which provides core services such as memory management, thread management, and code security. It also includes the .NET Framework class library, which is a comprehensive, object-oriented collection of types that developers can use to create applications.

ASP.NET offers the following benefits:

- Manageability: ASP.NET uses a text-based, hierarchical configuration system that simplifies applying settings to your server environment and Web applications. Because configuration information is stored as plain text, new settings can be applied without the aid of local administration tools. Any changes to the configuration files are automatically detected and applied to the application. For more information, see Overview of ASP.NET Configuration.

- Security: ASP.NET provides default authorization and authentication schemes for Web applications. Developers can easily add to, remove, or replace these schemes depending on the needs of the application. For more information, see Overview of ASP.NET Security.

- Ease of Deployment: An ASP.NET application is deployed to a server by simply copying the necessary files to the server. No server restart is required — not even to deploy or replace running compiled code. For more information, see Overview of ASP.NET Deployment.

- Enhanced Performance: ASP.NET is compiled code running on the server. Unlike traditional Active Server Pages (ASP), ASP.NET can take advantage of early binding, just-in-time (JIT) compilation, native optimization, and caching services right out of the box for improved performance. For more information, see Overview of ASP.NET Performance Monitoring.

- Flexible Output Caching: ASP.NET can cache page data, portions of a page, or whole pages, depending on the needs of the application. Cached items can be dependent on files or other items in the cache, or they can be refreshed based on an expiration policy.

- Internationalization: ASP.NET uses Unicode internally to represent request and response data. Internationalization settings can be configured for each computer, each directory, and each page.

- Mobile Device Support: ASP.NET supports any browser on any device. Developers use the same programming techniques to target new mobile devices that they use for traditional desktop browsers.

- Scalability and Availability: ASP.NET was designed to be scalable, with features specifically tailored to improve performance in clustered and multiprocessor environments. Moreover, processes are closely monitored and managed by Internet Information Services (IIS) and the ASP.NET CLR so that if one misbehaves, a new process can be created in its place, which helps keep your application available to handle requests. For more information, see Overview of ASP.NET Process Isolation.

- Tracing and Debugging: ASP.NET provides tracing services that can be enabled during debugging at both the application level and the page level. You can choose to view the information either in a page or using the application-level trace viewing tool. ASP.NET supports local and remote debugging with .NET Framework debugging tools, both during development and when the application is in production. When an application is put into production, tracing statements can be left in the production code with no impact on performance.

- Integration with the .NET Framework: Because ASP.NET is part of the .NET Framework, the power and flexibility of the

entire platform is available to Web applications. The .NET class library, as well as solutions for messaging and data access, are all seamlessly accessible from the Web. ASP.NET is language-independent, so developers can choose the language that best applies to the application. In addition, CLR interoperability preserves existing investments in COM-based development.

- Compatibility with Existing ASP Applications: ASP and ASP.NET can run side by side on an IIS Web server without interference; there is no chance of corrupting an existing ASP application by installing ASP.NET. Only files with a .aspx file name extension are processed by ASP.NET. Files with an .asp file name extension will continue to be processed by the ASP engine. You should note, however, that session state and application state are not shared between ASP and ASP.NET pages.

ASP.NET enables two features for distributed applications: Web Forms and XML Web services. These two features are supported by the same configuration and debugging infrastructure.

- Web Forms technology enables you to build powerful form-based Web pages. Web Forms pages use reusable built-in or custom components to simplify the code of a page.

- XML Web services that are created using ASP.NET enable you to access servers remotely. Using XML Web services, businesses can provide programmatic interfaces to their data or business logic, which in turn can be obtained and manipulated by client and server applications. XML Web services enable the exchange of data using standards such as XML messaging and HTTP across firewalls in client/server and server/server scenarios. Programs written in any language and running on any operating system can call XML Web services.

**Related Information**

- For more information about how ASP.NET works with IIS 6.0, see How ASP.NET Works with IIS 6.0.

- For more information about deploying ASP.NET applications on IIS 6.0, see Deploying ASP.NET Applications in IIS 6.0.

# Why Use ASP.NET?

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Microsoft ASP.NET is more than just the next generation of Active Server Pages (ASP). It provides an entirely new programming model for creating network applications that take advantage of the Internet.

**Improved Performance and Scalability**

- Compiled Execution: ASP.NET is much faster than classic ASP, while preserving the "just hit save" update model of ASP. No explicit compile step is required. ASP.NET automatically detects any change, dynamically compiles files if needed, and stores the compiled results to reuse for subsequent requests. Dynamic compilation ensures that your application is always up to date, and compiled execution makes it fast. Most applications migrated from classic ASP to ASP.NET see a 3x to 5x increase in pages served.

- Rich Output Caching: ASP.NET output caching can dramatically improve the performance and scalability of your application. When output caching is enabled on a page, ASP.NET executes the page once and saves the result in memory before sending it to the user. When another user requests the same page, ASP.NET serves the cached result from memory without re-executing the page. Output caching is configurable, and it can be used to cache individual regions or an entire page.

- Web Farm Session State: ASP.NET session state lets you share session data across all machines in a Web farm. Now a user can hit different servers in the Web farm over multiple requests and still have full access to session data.

**Enhanced Reliability**

- Memory Leak, Dead Lock, and Crash Protection: ASP.NET automatically detects and recovers from errors such as dead locks and memory leaks to ensure that your application is always available. For example, when a memory leak is detected, ASP.NET automatically starts up a new copy of the ASP.NET worker process and directs all new requests to the new process. After the old process has finished processing pending requests, it is gracefully disposed of and the leaked memory is released.

**Easy Deployment**

- "No Touch" Application Deployment: With ASP.NET you can deploy an entire application by copying it to the server. Configuration settings are stored in an XML file within the application.

- Dynamic Update of Running Application: ASP.NET lets you update compiled components without restarting the Web server. Unlike classic COM components that required the Web server to be manually restarted when an update was deployed, ASP.NET automatically detects the change and starts using the new code.

- Easy Migration Path: ASP.NET runs side by side on IIS with classic ASP applications on Microsoft Windows 2000 and Windows XP, and on members of the Windows Server 2003 family. You can migrate one application at a time, or even single pages. ASP.NET even lets you continue to use your existing classic COM business components.

**New Application Models**

- XML Web Services: XML Web services allow applications to communicate and share data over the Internet, regardless of operating system or programming language. ASP.NET makes exposing and calling XML Web services simple.

- Mobile Web Device Support: ASP.NET mobile controls let you target over 80 mobile Web devices using ASP.NET. You write the application once, and the mobile controls automatically generate pages for the requesting device.

**Developer Productivity**

- Easy Programming Model: ASP.NET makes building real-world Web applications dramatically easier with server controls that let you build great pages with far less code than classic ASP.

- Flexible Language Options. ASP.NET supports not only Microsoft Visual Basic Scripting Edition (VBScript) and Microsoft JScript but also more than 25 .NET languages, including built-in support for Visual Basic .NET, Microsoft C#, and JScript .NET.

- Rich Class Framework: The .NET Framework class library offers over 4,500 classes that encapsulate rich functionality such as XML, data access, file upload, regular expressions, image generation, performance monitoring and logging, transactions, message queuing, and SMTP mail.

# Introduction to XML Web Services Created with ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

An XML Web service is a programmable entity that provides a particular function, such as application logic, and is accessible to systems using Internet standards such as XML, HTTP, and SOAP. Applications written in any language and running on any operating system can call XML Web services.

An XML Web service can be used internally by a single application or exposed externally over the Internet for use by any number of applications. Because it is accessible through a standard interface, an XML Web service allows heterogeneous systems to work together as a single web of computation. One of the core characteristics of an XML Web service is the high degree of abstraction that exists between the implementation and consumption of a service. Because an XML Web service is created and accessed using XML-based messaging, the XML Web service provider and the client need no knowledge of each other beyond inputs, outputs, and location.

The XML Web services infrastructure provides a discovery mechanism to locate XML Web services, a service description for defining how to use those services, and standard wire formats for communication.

*Discovery* is the process of locating one or more documents that describe a particular XML Web service using the Web Services Description Language (WSDL). Once a service is found, the WSDL document provides a description of the interactions that the service supports. XML Web services communicate using open wire formats, which are protocols that can be understood by any system capable of supporting the most common Web standards. SOAP is the key protocol for XML Web service communication.

ASP.NET enables you to build and publish XML Web services using the same programming constructs that are used to build and publish ASP.NET Web pages. XML Web services created with ASP.NET use the industry standards shown in the following table.

| **Industry standard** | **Use in XML Web services created with ASP.NET** |
|---|---|
| XML | The text format used when communicating with XML Web services using SOAP. When communicating with XML Web services using the HTTP-GET and HTTP-POST protocols, XML is used to encode the response. |
| SOAP | An XML-based message exchange protocol used for communication between XML Web services and their clients. |
| Web Services Description Language (WSDL) | Describes the contract of messages that an XML Web service can interpret when communicating with an XML Web service client. |
| XML Schema Definition language (XSD) | Provides a universal type system, allowing data types to be defined and passed across platforms. For an XML Web service, XSD defines the structure and data types for the XML encapsulated within a SOAP message sent to and from an XML Web service. |
| application/x-www-form-url encoded | A MIME type used for encoding parameters on a URL. This encoding is used for encoding request parameters to XML Web services using the HTTP-GET and HTTP-POST protocols. |

# ASP.NET Administration

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

| **Important** |
| --- |
| This feature is not available on Windows XP 64-Bit Edition and the 64-bit versions of the Windows Server™ 2003 family. For more information, see "Features unavailable on 64-bit versions of the Windows Server family" in Help and Support Center for Windows 2003. |

This document is for administrators responsible for establishing and maintaining Microsoft® ASP.NET applications on production servers. It covers common concepts and tasks that administrators need to be familiar with, from setting up ASP.NET on server computers to monitoring ASP.NET applications once they are deployed.

This section includes the following information:

- Overview of ASP.NET Setup: Describes how to install and uninstall ASP.NET on the platforms that support it and how to identify and solve common problems with a new ASP.NET installation.
- Overview of ASP.NET Web Applications: Defines ASP.NET applications and the file types and directories they contain.
- Overview of ASP.NET Configuration: Describes how to configure ASP.NET applications and includes reference information about each of the ASP.NET configuration elements.
- Overview of ASP.NET Security: Describes how to work with authorization and authentication in ASP.NET applications.
- Overview of ASP.NET Deployment: Describes how to distribute ASP.NET applications and components from development and test servers to production servers.
- Overview of ASP.NET Process Isolation: Describes the process models that Internet Information Services (IIS) 6.0 and ASP.NET use.
- Overview of ASP.NET Performance Monitoring: Describes the tools available to monitor the performance of your ASP.NET applications and includes a list of performance counters that are exposed by ASP.NET.
- Additional Resources for ASP.NET: Contains a list of other sources of information about administering ASP.NET applications.

# Overview of ASP.NET Setup

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Microsoft ASP.NET is installed with the Microsoft .NET Framework through Web downloads, Microsoft Visual Studio .NET installations, and as a service on all products in the Microsoft Windows Server™ 2003 family.

| **Note** |
| --- |
| ASP.NET is a part of the .NET Framework. You must install the .NET Framework to install ASP.NET. |

This section describes the necessary steps to install and enable ASP.NET on all platforms that support it. It also explains how to uninstall ASP.NET and includes a troubleshooting section that addresses common problems encountered once ASP.NET is installed.

This section includes the following information:

- Installing ASP.NET: Describes the software requirements for ASP.NET and how to install it on servers running a product in the Windows Server 2003 family.
- Uninstalling ASP.NET: Describes how to remove an ASP.NET installation from a server.
- Troubleshooting an ASP.NET Installation: Explains how to solve common problems encountered once ASP.NET is installed on a server.
- ASP.NET IIS Registration Tool: Explains how to use the ASP.NET IIS Registration tool to create script maps that point from your application to a particular version of ASP.NET and the .NET Framework.

# Installing ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

ASP.NET is supported on the Windows Server™ 2003 family, Windows 2000 (Professional, Server, and Advanced Server), and Windows XP Professional for both client and server applications.

A server running a member of the Microsoft Windows Server 2003 family can be configured as an application server, with ASP.NET as an option that you can enable while configuring the application server role. To deploy ASP.NET Web applications to a production server, you must be sure to enable the ASP.NET and IIS roles on the production server before you distribute the application.

| **Note** |
| --- |
| If you want to install ASP.NET on a domain controller, there are special steps you must take to make the installation work correctly. For more information, see Knowledge Base article Q315158, ASP.NET Does Not Work with the Default ASPNET Account on a Domain Controller. |

ASP.NET, along with the .NET Framework version 1.1, is installed as a part of Windows Server 2003. You simply need to add it as a new program from Control Panel or enable it by using the Configure Your Server wizard.

| **Note** |
| --- |
| When you use the Configure Your Server wizard or the **Add or Remove Programs** dialog box to install ASP.NET on a server running Windows Server 2003, ASP.NET is automatically enabled in IIS Manager. However, if you install ASP.NET from a Web download or as part of an application such as Visual Studio .NET, you must enable ASP.NET manually. For instructions, see the "To enable ASP.NET in IIS Manager on a server running Windows Server 2003" procedure, later in this topic. |

**Procedures**

**To install ASP.NET on a server running Windows Server 2003 using the Configure Your Server wizard**

1. From the **Start** menu, click **Manage Your Server**; in the **Manage Your Server** window, click **Add or remove a role**.
2. In the **Configure Your Server Wizard**, click **Next**, and in the **Server Role** dialog box, check **Application Server (IIS, ASP.NET)** and then click **Next**.
3. In the **Application Server Options** dialog box, select the **Enable ASP.NET** check box, click **Next**, and then click **Next** again.
4. If necessary, insert your Windows Server 2003 installation CD in the CD-ROM drive and then click **Next**.
5. When the installation is complete, click **Finish**.

**To install ASP.NET on a server running Windows Server 2003 using the Add or Remove Programs dialog box**

1. From the **Start** menu, point to **Control Panel**, and then click **Add or Remove Programs**.
2. In the **Add or Remove Programs** dialog box, click **Add/Remove Windows Components**.
3. In the **Components** box in the Windows Components wizard, select the **Application Server** check box, and then click **Next**.
4. When the Windows Components wizard has finished configuring Windows Server 2003, click **Finish**.

**To enable ASP.NET in IIS Manager on a server running Windows Server 2003**

1. From the **Start** menu, click **Run**.
2. In the **Open** box in the **Run** dialog box, type **inetmgr**, and then click **OK**.
3. In IIS Manager, expand the local computer and then click **Web Service Extensions**.

4. In the details pane, right-click **ASP.NET** and then click **Allow**. The status of ASP.NET changes to **Allowed**.

| **Note** |
| --- |
| If your applications require ISAPI, CGI, ASP, WebDAV, or other extensions to operate, you must enable those extensions also. |

# Uninstalling ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

On Windows Server™ 2003, you can use the Configure Your Server wizard or use the Add or Remove Programs dialog box in Control Panel to disable or uninstall ASP.NET.

| **Note** |
| --- |
| There are specific issues that you need to understand if you are uninstalling a version of ASP.NET from a server with multiple versions. For more information, see Managing Multiple Versions of ASP.NET on MSDN. |

The following procedures describe how to remove ASP.NET and the .NET Framework from all server platforms that support them. You might also need to uninstall to troubleshoot an installation of ASP.NET.

**Procedures**

**To uninstall ASP.NET from a computer running Windows Server 2003 using the Configure Your Server wizard**

1. From the **Start** menu, click **Manage Your Server**; in the **Manage Your Server** window, click **Add or remove a role**.
2. In the Configure Your Server wizard, click **Next**, and in the **Server Role** dialog box, clear **Application Server (IIS, ASP.NET)**, and then click **Next**.
3. When the setup program is complete, click **Finish**.

**To uninstall ASP.NET and the .NET Framework from a computer running Windows Server 2003**

1. From the **Start** menu, point to **Control Panel**, and then click **Add or Remove Programs**.
2. In the **Currently installed programs** box, click **Microsoft .NET Framework (***language***)** *version*, and then click the **Change/Remove** button.

| **Note** |
| --- |
| In the program name, *language* is a placeholder that represents the language of the version of the .NET Framework that you want to remove from your server, and *version* represents the version number of the installation you want to remove from your server. |

1. In the **Add or Remove Programs** dialog box, click **Yes**.
2. Answer any questions from the setup program.

**Related Information**

- For general information about ASP.NET setup, see Overview of ASP.NET Setup.
- For information about installing ASP.NET, see Installing ASP.NET.
- For information about troubleshooting an installation of ASP.NET, see Troubleshooting an ASP.NET Installation.

# Troubleshooting an ASP.NET Installation

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

There are a few problems that commonly occur with new ASP.NET installations:

- You have installed ASP.NET and the .NET Framework on the server, but when you request a page from your application, nothing happens and the request does not resolve.

  You need to install and enable IIS on the server before you install the .NET Framework. Either you can uninstall the .NET Framework from the server, install IIS, then reinstall the .NET Framework, or you can install IIS, then use the ASP.NET IIS Registration tool (Aspnet_regiis.exe) to configure the script maps that IIS uses for ASP.NET file name extensions. For more information, see Uninstalling ASP.NET, Setting Application Mappings in IIS 6.0, and the "To repair IIS mappings for ASP.NET using Aspnet_regiis.exe" procedure later in this topic.

- You have installed ASP.NET and the .NET Framework with IIS installed and enabled, then uninstalled and reinstalled IIS. When you request a page from your application, nothing happens and the request does not resolve.

  When you uninstalled and reinstalled IIS, the script maps that IIS uses for ASP.NET were broken. Use Aspnet_regiis.exe to configure the script maps that IIS uses for ASP.NET file name extensions. For more information, see the "To repair IIS mappings for ASP.NET using Aspnet_regiis.exe" procedure later in this topic.

- You have installed and enabled IIS, installed ASP.NET and the .NET Framework, deployed your application, and requested a page, but you receive one of the following error messages:

  - Access denied to 'C:\Inetpub\Wwwroot' directory. Failed to start monitoring directory changes.

  - Server cannot access application directory 'C:\Inetpub\Wwwroot\ *Virtual Directory Name* \'. The directory does not exist or is not accessible because of security settings.

  The proper permissions have not been set for the Web site or virtual directory. ASP.NET requires read, execute, and list access for the ASPNET account (the Aspnet_wp.exe process account) on the root Web site or on any virtual directory. These settings are necessary so that ASP.NET can access the content files and can monitor file changes. To correct this problem, follow the steps in the following procedure.

**Procedures**

**To add read, execute, and list permissions for the ASPNET account on the root Web site or on a virtual directory**

1. In Windows Explorer, browse to the folder that contains the root Web site (which is C:\Inetpub\Wwwroot by default) or the virtual directory.
2. Right-click the folder and then click **Properties**.
3. On the **Security** tab, click **Add**.
4. Type *ComputerName***\ASPNET** (for example, on a computer named Webdev, type **Webdev\ASPNET**) and then click **OK**.
5. Allow the following permissions for the ASPNET account: Read & Execute, List Folder Contents, and Read.
6. Click **OK** to close the **Properties** dialog box and to save the changes.

| **Note** |
| --- |
| You do not need to perform these steps if the Everyone group or the Users group has read access to the root Web site or virtual directory. |

**To repair IIS mappings for ASP.NET using Aspnet_regiis.exe**

1. From the **Start** menu, click **Run**.
2. In the **Open** box in the **Run** dialog box, type **cmd**, and then click **OK**.
3. At the command prompt in the new window, type the following line:

   **"%systemroot%\Microsoft.NET\Framework** *version* **\aspnet_regiis.exe" -i**.

4. In this path, *version* represents the version number of the .NET Framework installed on your server. You must replace this placeholder with the actual version number when you type the command.

   | **Note** |
   | --- |
   | You must include the quotation marks in the command. |

   For more information about Aspnet_regiis.exe, use repeat step 3 with **-?** as an argument, or see ASP.NET IIS Registration Tool (Aspnet_regiis.exe).

Also, on Windows Server 2003, if you have installed the .NET Framework and ASP.NET from a Web download or through Visual Studio .NET, you must enable ASP.NET manually from IIS Manager. For more information, see Installing ASP.NET.

| **Note** |
| --- |
| If you want to install ASP.NET on a domain controller, there are special steps you must take to make the installation work properly. For more information, see Knowledge Base article Q315158, ASP.NET Does Not Work with the Default ASPNET Account on a Domain Controller. |

# ASP.NET IIS Registration Tool

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When multiple versions of the .NET Framework are executing side by side on a single computer, the ASP.NET ISAPI version that is scriptmapped to an ASP.NET application determines which version of the common language runtime is used for the application. The ASP.NET IIS Registration tool (Aspnet_regiis.exe) allows an administrator or installation program to easily update the scriptmaps for an ASP.NET application to point to the ASP.NET ISAPI version associated with the tool. The tool can also be used to display the status of all installed versions of ASP. NET, register the ASP.NET version coupled with the tool, create client-script directories, and perform other configuration operations.

```
Aspnet_regiis [options]
```

You can specify one or more of the following options.

| Option | Description |
|---|---|
| -c | Installs the client-side scripts for ASP.NET, such as client-side validation scripts, to the aspnet_client subdirectory of each IIS site directory.<br>**Note**<br>Only the client-side scripts for the ASP.NET version associated with Aspnet_regiis.exe are installed. |
| -e | Removes the client-side scripts for ASP.NET from the aspnet_client subdirectory of each IIS site directory.<br>**Note**<br>Only the client-side scripts for the ASP.NET version associated with Aspnet_regiis.exe are removed. |
| -ea | Removes the client-side scripts for all versions of ASP.NET from the Aspnet_client subdirectory of each IIS site directory. |
| -i | Installs the version of ASP.NET associated with Aspnet_regiis.exe and updates the scriptmaps at the IIS metabase root and below.<br>**Note**<br>Only the scriptmaps for applications that use an earlier version of the ASP.NET are updated. Applications that use a later version are not affected. |
| -ir | Installs the version of ASP.NET associated with Aspnet_regiis.exe and only registers ASP.NET in IIS.<br>**Note**<br>This option does not update the scriptmaps. To install ASP.NET and update the scriptmaps, use the **-i** option. |
| -k *path* | Removes the scriptmaps to all versions of ASP.NET from all ASP.NET applications at the specified application root path and its subdirectories. |
| -kn *path* | Removes the scriptmaps to all versions of ASP.NET from the ASP.NET application only at the specified application root path.<br>**Note**<br>This option does not affect applications in subdirectories of path. |

| | |
|---|---|
| -lk | Lists the path and version of all IIS metabase keys where ASP.NET is scriptmapped.<br>**Note**<br>The keys that inherit ASP.NET scriptmaps from a parent key are not displayed. |
| -lv | Lists the status and installation path of all versions of ASP.NET installed on the computer. |
| -r | Updates all scriptmaps in the IIS metabase and below to point to the ASP.NET ISAPI version associated with Aspnet_regiis.exe.<br>**Note**<br>All existing scriptmaps are updated to point to the ASP.NET ISAPI version associated with Aspnet_regiis.exe, regardless of the current version. |
| -s *path* | Installs the scriptmap pointing to the ASP.NET ISAPI version associated with Aspnet_regiis.exe to all ASP.NET application at the specified application root path and its subdirectories. All existing scriptmaps in the specified path and below that use an earlier version of the ASP.NET ISAPI are updated. |
| -sn *path* | Installs the scriptmap pointing to the ASP.NET ISAPI version associated with Aspnet_regiis.exe to the ASP.NET application at the specified application root path. All existing scriptmaps in the specified path that use an earlier version of the ASP.NET ISAPI are updated. [[LEFT]] Note<br>**Note**<br>This option does not affect applications in subdirectories of *path*. |
| -u | Uninstalls the version of ASP.NET associated with Aspnet_regiis.exe from the computer. Existing scriptmaps to this version of the ASP.NET ISAPI are automatically remapped to the highest remaining ASP.NET ISAPI version installed. |
| -ua | Uninstalls all versions of ASP.NET from the computer. |
| -? | Displays the command syntax and options for the tool. |

**Remarks**

When multiple versions of ASP.NET are installed on a computer, ASP.NET is said to be running *side-by-side*. In this setup, Internet Information Services (IIS) needs to know which version of the ASP.NET ISAPI (aspnet_isapi.dll) should process a page in an ASP.NET application. The ASP.NET ISAPI version associated with an ASP.NET application determines which version of the common language runtime is used for the application. An ASP.NET application is associated with an ASP.NET ISAPI version through a scriptmap in IIS. To simplify the configuration process for an ASP.NET application, each version of ASP.NET comes with a linked version of Aspnet_regiis.exe.

**Note**

A unique version of Aspnet_regiis.exe is included with each version of the .NET Framework. Because each version of the tool is applicable only to its associated version of the .NET Framework, be sure to use the appropriate version of the tool to configure an ASP.NET application.

Aspnet_regiis.exe is commonly used with the **-s** or **-sn** option to remap an ASP.NET application to the version of the .NET Framework that is associated with the tool. Use the **-s** option to update the applications at the specified root path and in all its subdirectories. If you don't want applications in subdirectories to be updated, use the **-sn** option. To update the scriptmaps of all existing ASP.NET applications on the computer at once, use the **-r** option.

**Note**

The *path* parameter refers to the root path of the application, not the physical path. For example, `W3SVC/1/ROOT/SampleApp1`.

Conversely, you can use the tool to remove the scriptmaps to any version of ASP.NET from an application using the **-k** or **-kn** option and specifying the root path of the application.

| **Note** |
| --- |
| If the root path specified inherits its scriptmap from a parent root path, the **-k** and **-kn** options will have no effect. |

The tool can also be used to install and uninstall the linked version of ASP.NET. Use the **-i** option to install ASP.NET and to update the scriptmaps of all existing ASP.NET applications. Use the **-ir** option to install ASP.NET without updating the scriptmaps. To uninstall the ASP.NET version associated with the tool, use the **-u** option. If you want to uninstall all versions of ASP.NET from the computer, use the **-ua** option.

You can use Aspnet_regiis.exe to view information about ASP.NET. To list the status and installation path of all installed versions of ASP.NET, use the **-lv** option. If you would like to see the paths to all IIS metabase keys where ASP.NET is scriptmapped, use the **-lk** option.

Client-side scripts, such as client-side validation, can be installed and removed using Aspnet_regiis.exe. To install the client-side script for the version of ASP.NET associated with the tool to the aspnet_client subdirectory of each IIS site directory, use the **-c** option. To remove the client-side script for just the ASP.NET version associated with the tool, use the **-e** option. To remove the client-side script for all installed versions of ASP.NET, use the **-ea** option.

For more information about side-by-side execution in ASP.NET, see Side-by-Side Support in ASP.NET on MSDN. For more information about script maps and application root path, see Setting Application Mappings in IIS 6.0.

**Examples**

The following command installs the scriptmaps pointing to the ASP.NET version associated with Aspnet_regiis.exe to the SampleApp1 application and all its sub-applications.

```
Aspnet_regiis -s W3SVC/1/ROOT/SampleApp1
```

The following command only updates the scriptmaps for the SampleApp1 application, without affecting applications in subdirectories.

```
Aspnet_regiis -sn W3SVC/1/ROOT/SampleApp1
```

The following command installs the ASP.NET version associated with the tool and updates the scriptmaps of all existing ASP.NET applications. Note that only applications that are currently scriptmapped to an earlier version of ASP.NET are affected.

```
Aspnet_regiis -i
```

The following command installs the ASP.NET version associated with the tool, but does not update the scriptmaps of existing ASP.NET applications

```
Aspnet_regiis -ir
```

The following command displays the status and installation path of all versions of ASP.NET installed on the computer.

```
Aspnet_regiis -lv
```

# Overview of ASP.NET Web Applications

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

A Microsoft ASP.NET application is defined as all the files and executable code that can be invoked from a virtual directory and its subdirectories on a Web server. These can include Web pages (.html files), Web Forms pages (.aspx files), Web Forms user controls (.ascx files), XML Web Services (.asmx files), HTTP handlers, HTTP modules, and other files (such as image and configuration files). Any script maps that are associated with the version of the Microsoft .NET Framework that you are using are also a part of an ASP.NET application.

If an ASP.NET application has been developed using Microsoft Visual Studio .NET, a project DLL is stored in the \Bin directory under the application's root directory. Any other DLLs that provide functionality that the application uses, whether it has been developed using Visual Studio or not, must reside in the \Bin directory as well. These can include compiled ASP.NET custom server controls, business logic, and database access logic.

The relationship between an ASP.NET application and Internet Information Services (IIS) is this: IIS serves all requests for publishable ASP.NET files through aspnet_isapi.dll (the process model for ASP.NET). IIS does not process the server-side code; the ASP.NET engine does that and then returns the output to IIS (or another Web server, possibly) to be served from that software.

This section includes the following information

- Layout of ASP.NET Web Applications: Describes the guidelines for creating a file structure for an ASP.NET application.
- Viewing the ASP.NET Version: Describes how to determine which version of the .NET Framework, and ASP.NET, an application is using.

**Related Information**

- ASP.NET Administration
- Overview of ASP.NET Deployment
- Overview of ASP.NET Configuration

# Layout of ASP.NET Web Applications

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

An ASP.NET application must reside in an IIS virtual directory, known as the application root. ASP.NET applications can contain compiled assemblies (usually DLL files that contain business logic); a well-known directory, always named \Bin, where precompiled code is stored; configuration settings stored in a text-based, human-readable Web.config file; pages; server controls; and XML Web services.

Any precompiled code that is not shared with other applications on the server must be stored in the application's \Bin directory. This is the local assembly cache for the application.

| **Note** |
| --- |
| If you intend to use the same assembly in multiple applications on your Web server, you should deploy that assembly to the global assembly cache. For more information, see Deploying Shared Components to the Global Assembly Cache. |

Web.config files store application-wide configuration settings in an XML-based text file. This means that you can use any standard text editor or XML parser to create them, and that they are readable. If you do not include a Web.config file in the application root, configuration settings are determined by those set in the Machine.config file, the configuration file for the entire server. A version of the Machine.config file is installed when you install the .NET Framework. For more information about configuration files, see Overview of ASP.NET Configuration.

The following illustration shows a sample file system layout for an ASP.NET application.

The application in this illustration includes two DLL files in the \Bin directory, a Default.aspx page, a user control named Menu.ascx, an XML Web service named MyWebService.asmx, and a Global.asax file. In addition, the application is configured using three configuration files: the machine-level Machine.config file in the system root directory, the site-level Web.config file in the C:\Inetpub\Wwwroot directory, and the application-level Web.config file in the application root directory. Configuration settings stored in the application root override the settings in the site's Web.config file and the Machine.config file, while the site's Web.config file overrides settings in the Machine.config file.

| **Note** |
| --- |
| ASP.NET applications are composed of virtual directory structures, not physical directory structures. Configuration settings are applied to virtual paths. |

# Viewing the ASP.NET Version

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The version of the Framework used by an ASP.NET application is determined by the version of the aspnet_isapi.dll file that is registered under the IIS script maps for that application. A script map is a three-way association of a file name extension, such as .aspx; an HTTP verb associated with a request, such as GET; and the DLL that contains instructions for what the Web server should do when it receives an HTTP request for a file with the specified file name extension. You can set these script maps to the application root directory itself, which is an IIS virtual directory, or allow them to be inherited from a parent application or site.

**Procedures**

**To view script maps for file name extensions in your application**

1. From the **Start** menu, click **Run**, type **inetmgr** in the **Open** box, and then click **OK**.
2. In IIS Manager, expand the **local computer**, expand **Web Sites**, expand **Default Web Site**, and then click the name of your application.
3. Right-click the application name, and then click **Properties**.
4. On the **Directory** tab, click **Configuration**. All the script maps associated with your application appear alphabetically by file name extension in the **Application Mappings** box.

**Configuring Script Maps**

ASP.NET provides a command-line tool, called the ASP.NET IIS Registration tool (Aspnet_regiis.exe), to make it easy to configure script maps for your applications. If you have multiple versions of ASP.NET installed on your Web server, a version of this tool is provided with each. You can use the tool associated with a particular version of ASP.NET to register your application with that version.

The **-s** and **-sn** commands included in Aspnet_regiis.exe install the current version to the specified path, included as an argument on the command line. The **-s** command installs the specified version of ASP.NET to the specified application root and all its virtual subdirectories. This command updates all existing script maps in the specified path and below that use an earlier version of the ASP.NET ISAPI. The **-sn** command installs the specified version of ASP.NET to the directory specified in the path argument only; it does not install the version to subdirectories. For example, the following entry on the command line creates a script map between the version of ASP.NET associated with the tool version and the `SampleApp1` directory, along with all its subdirectories:

```
aspnet_regiis.exe -s W3SVC/1/ROOT/SampleApp1
```

Aspnet_regiis.exe has other utility purposes as well, such as registering a version of ASP.NET (which includes registering the Aspnet_isapi.dll, setting up the state server, setting up the worker process account, and so on) and creating client script directories for that version of ASP.NET. It can also list all installed versions of ASP.NET and which applications use each version. For more information about this tool, see ASP.NET IIS Registration Tool.

For more information about running multiple ASP.NET applications on a server using different versions of the .NET Framework, see Side-by-Side Support in ASP.NET on MSDN.

# Overview of ASP.NET Configuration

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The Microsoft® ASP.NET configuration system features an extensible infrastructure that enables you to define configuration settings when your ASP.NET applications are first deployed so that you can add or revise configuration settings at any time with minimal impact on operational Web applications and servers.

The ASP.NET configuration system provides the following benefits:

- Configuration information is stored in XML-based text files. You can use any standard text editor or XML parser to create and edit ASP.NET configuration files.

- Multiple configuration files, all named Web.config, can appear in multiple directories on an ASP.NET Application server. Each Web.config file applies configuration settings to its own directory and all child directories below it. Configuration files in child directories can supply configuration information in addition to that inherited from parent directories, and the child directory configuration settings can override or modify settings defined in parent directories. The root configuration file named *systemroot*\Microsoft.NET\Framework*versionNumber*\CONFIG\Machine.config provides ASP.NET configuration settings for the entire Web server.

- At run time, ASP.NET uses the configuration information provided by the Web.config files in a hierarchical virtual directory structure to compute a collection of configuration settings for each unique URL resource. The resulting configuration settings are then cached for all subsequent requests to a resource. Note that inheritance is defined by the incoming request path (the URL), not the file system paths to the resources on disk (the physical paths).

- ASP.NET detects changes to configuration files and automatically applies new configuration settings to Web resources affected by the changes. The server does not have to be rebooted for the changes to take effect. Hierarchical configuration settings are automatically recalculated and recached whenever a configuration file in the hierarchy is changed. The <processModel> section is an exception.

- The ASP.NET configuration system is extensible. You can define new configuration parameters and write configuration section handlers to process them.

- ASP.NET helps protect configuration files from outside access by configuring Internet Information Services (IIS) to help prevent direct browser access to configuration files. HTTP access error 403 (forbidden) is returned to any browser attempting to request a configuration file directly.

This section includes the following information:

- ASP.NET Configuration Files Format: Explains how ASP.NET configuration files are organized.

- Hierarchical Configuration Architecture in ASP.NET: Explains configuration setting inheritance.

**Related Information**

- ASP.NET Administration

# ASP.NET Configuration Files Format

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Configuration information for ASP.NET resources is contained in a collection of configuration files, each named Web.config. Each configuration file contains a nested hierarchy of XML tags and subtags with attributes that specify the configuration settings. Because the tags must be well-formed XML, the tags, subtags, and attributes are case-sensitive. Tag names and attribute names are camel-cased, which means that the first character of a tag name is lowercase and the first letter of any subsequent concatenated words is uppercase. Attribute values are Pascal-case, which means that the first character is uppercase and the first letter of any subsequent concatenated words is uppercase. Exceptions are **true** and **false**, which are always lowercase.

All configuration information resides between the <configuration> and </configuration> root XML tags. Configuration information between the tags is grouped into two main areas: the configuration section handler declaration area and the configuration section settings area.

Configuration section handler declarations appear at the top of the configuration file between <configSections> and </configSections> tags. Each declaration contained in a <section> tag specifies the name of a section that provides a specific set of configuration data and the name of the .NET Framework class that processes configuration data in that section.

The configuration section settings area follows the <configSections> area and contains the actual configuration settings. There is one configuration section for each declaration in the <configSections> area. Each configuration section contains subtags with attributes that contain the settings for that section.

The following Web.config file example declares two configuration <section> handlers. One manages application settings and the other manages session state.

```
<configuration>
<configSections>
<section name="appSettings"
type="System.Configuration.NameValueFileSectionHandler,
System, Version=1.0.3300.0,
Culture=neutral, PublicKeyToken=b77a5c561934e089"/>
<section name="sessionState"
type="System.Web.SessionState.SessionStateSectionHandler,
System.Web, Version=1.0.3300.0, Culture=neutral,
PublicKeyToken=b03f5f7f11d50a3a"
allowDefinition="MachineToApplication"/>
</configSections>
<appSettings>
<add key="dsn" value="localhost;uid=MyUserName;pwd=;"/>
<add key="msmqserver" value="server\myqueue"/>
</appSettings>
<sessionState cookieless="true" timeout="10"/>
</configuration>
```

You need to declare a configuration section handler only once. You can place it in the server's root Machine.config file or in a Web.config file in the virtual directory containing the Web application files. Configuration files in subdirectories automatically inherit configuration handlers declared in parent directories. For more information, see Configuration Inheritance in ASP.NET.

Configuration settings are often nested together under section grouping tags. These top-level section tags typically represent the namespace to which the configuration settings apply. For example, the top-level <system.net> tag represents the settings for network classes, and the <system.web> tag represents the settings for the ASP.NET classes.

The following example shows tag nesting.

```
<configuration>
```

```
<configSections>
<sectionGroup name="system.net">
<section name="authenticationModules"
type="System.Net.Configuration.NetAuthenticationModuleHandler,
System, Version=1.0.3300.0, Culture=neutral,
PublicKeyToken=b77a5c561934e089"/>
<section name="webRequestModules"
type="System.Net.Configuration.WebRequestModuleHandler,
System, Version=1.0.3300.0, Culture=neutral,
PublicKeyToken=b77a5c561934e089"/>
</sectionGroup>
<sectionGroup name="system.web">
<section name="authorization"
type="System.Web.Configuration.AuthorizationConfigHandler,
System.Web, Version=1.0.3300.0, Culture=neutral,

```

The ASP.NET configuration infrastructure makes no assumptions about the types of configuration data that the infrastructure supports. Configuration section handler classes process all Web.config data. You can use the predefined configuration section handlers that are supplied with the .NET Framework or you can create your own handlers to process your own custom

configuration data.

# Hierarchical Configuration Architecture in ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

ASP.NET applies configuration settings to resources in a hierarchical manner. Site-wide Web.config configuration files supply configuration information to the directories in which they are located and to all child directories. The configuration settings for a Web resource are supplied by the configuration file located in the same directory as the resource and by all configuration files in all parent directories.

Configurations settings are inherited from file to file in a virtual path, with the Machine.config file, which helps control configuration settings for the entire server, at the root. Web.config files that are stored in the virtual path help control their sites and virtual roots.

**In This Section**

Configuration Inheritance in ASP.NET: Describes how to design virtual paths so that configuration problems will not arise in your ASP.NET applications.

Configuration <location> Settings in ASP.NET: Describes how to customize configurations settings to apply to a specific directory or resource in that directory.

Locking Configuration Settings in ASP.NET: Describes how to make configuration settings on a site unchangeable, particularly for administrators who host Web applications.

**Related Sections**

- For general information about ASP.NET configuration, see Overview of ASP.NET Configuration.
- For guidelines on creating a file structure for an ASP.NET application, see Layout of ASP.NET Web Applications.

# Configuration Inheritance in ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When the server receives a request for a particular Web resource, ASP.NET computes the configuration settings for that resource hierarchically, using all the configuration files located in the virtual directory path for the requested URL. For example, you could have a Web site with the following file structure, where the application root directory is the application virtual directory (Vdir).

Normally, the last configuration setting overwrites settings for the same section provided in parent directories, but the section handler might implement a different inheritance scheme.

For example, as the administrator, you could configure the application settings to allow all users access to the ASP.NET resources in the application root directory (the physical directory mapped by the application virtual directory) but allow only selected users access to the ASP.NET resources in the two subdirectories.

Assume that there is a Web.config file in the SubDir1 directory and none in the application root or SubDir2 directories. In this case, ASP.NET is using two configuration files. The highest-level file is the one located in the *systemroot*\Microsoft .NET \Framework*versionNumber*\CONFIG directory. This file, named Machine.config, is at the machine level, and all ASP.NET directories and subdirectories inherit its settings. Machine.config is shipped with the .NET Framework and contains many default ASP.NET settings. The default setting for the security configuration section of this file allows all users to access all URL resources. There is no configuration file in the example's application root directory that modifies security, so all users have access to the ASP.NET resources in it (because that directory inherits from the machine-level configuration file). If the Web.config file in the SubDir1 directory contains a security configuration section that allows access only to certain users, then SubDir2 inherits that setting. So, all users have access to the ASP.NET resources in the application root directory, but only certain users have access to the ASP.NET resources in SubDir1 and SubDir2.

Configuration settings for virtual directories are independent of physical directory structure, and virtual directories must be organized carefully to avoid configuration problems. For example, you could have an application named MyResource.aspx with the following physical directory structure: C:\Subdir1\Subdir2\MyResource.aspx.

Assume that a configuration file is located in Subdir1 and a virtual directory named Vdir1 is mapped to c:\Subdir1 and a virtual directory named Vdir2 is mapped to c:\Subdir1\Subdir2. If a client accesses the resource physically located at c:\Subdir1\Subdir2\MyResource.aspx using the URL http://localhost/vdir1/subdir2/MyResource.aspx, the resource inherits configuration settings from Vdir1. However, if the client accesses the same resource using the URL http://localhost/vdir2/MyResource.aspx, it does not inherit settings from Vdir1. Therefore, creating virtual directories in this manner could cause unexpected results or even an application failure and is not recommended.

| **Note** |
| --- |
| The ASP.NET configuration system applies only to ASP.NET resources (those registered to be handled by ASP.NET using the Aspnet_isapi.dll). The configuration system does not provide authorization for non-ASP.NET resources by default. ASP, HTML, TXT, GIF, and JPEG files, for example, are accessible by all users. In the preceding example, if directory browsing is enabled and no other restrictions are in place, all users can view non-ASP.NET files located in the application root directory, SubDir1, and SubDir2. For more information about ASP.NET security, see Overview of ASP.NET Security. |

# Configuration <location> Settings in ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Configuration settings can be applied to specific resources by using a **<location>** tag with an appropriate **path** attribute. The **path** attribute can be used to identify a specific file or child directory to which unique configuration settings apply.

For example, the following configuration file specifies settings at three levels:

- Settings that apply to the current directory and all child directories (everything contained within the top <configuration> tag).
- Settings that apply to the Sub1 child directory (everything contained within the <location> tag with a path attribute set to Sub1).
- Settings that apply to the Sub2 child directory (everything contained within the <location> tag with a path attribute set to Sub2).

```
<configuration>
<system.web>
<sessionState cookieless="true" timeout="10"/>
</system.web>
<!-- Configuration for the "Sub1" subdirectory. -->
<location path="sub1">
<system.web>
<httpHandlers>
<add verb="*" path="Sub1.Scott" type="Sub1.Scott"/>
<add verb="*" path="Sub1.David" type="Sub1.David"/>
</httpHandlers>
</system.web>
</location>
<!-- Configuration for the "Sub2" subdirectory. -->
<location path="sub2">
<system.web>
<httpHandlers>
<add verb="*" path="Sub2.Scott" type="Sub2.Scott"/>
<add verb="*" path="Sub2.David" type="Sub2.David"/>
</httpHandlers>
</system.web>
</location>
</configuration>
```

Hierarchical Configuration Architecture in ASP.NET

# Locking Configuration Settings in ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

By default, configuration files located in subdirectories override and extend all configuration settings defined in parent configuration files. In application hosting scenarios, administrators often want to lock or make some settings on a site unchangeable to prevent modification. For example, an administrator might want to lock the sandbox security settings for hosted applications to help prevent Web users from attacking the system.

Administrators can lock configuration settings by adding an **allowOverride="false"** attribute to a **<location>** directive. This tells the configuration system to throw an error if a lower-level configuration file attempts to override any configuration section defined within this locked **<location>** directive.

The following configuration file example (which could be stored at either the main system level or at the site level) locks the trust level of two different ASP.NET applications (`application1` and `application2`).

```
<configuration>
<location path="application1" allowOverride="false">
<system.web>
<trust level="High"/>
</system.web>
</location>
<location path="application2" allowOverride="false">
<system.web>
<trust level="Medium"/>
</system.web>
</location>
</configuration>
```

Any attempt to override the configuration settings in the preceding example by the configuration settings in the following example would generate a configuration system error.

```
<configuration>
<system.web>
<trust level="Full"/>
</system.web>
</configuration>
```

# ASP.NET Settings Schema Reference

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The ASP.NET configuration section schema contains elements that help control how ASP.NET Web applications behave. Where a default value is specified for an attribute, the default value is set in the Machine.config file that is located at *systemroot*\Microsoft.NET\Framework*versionNumber*\Config\Machine.config.

For detailed information about the ASP.NET settings schema elements, see ASP.NET Settings Schema.

**Related Information**

For more information about ASP.NET settings, see Overview of ASP.NET Configuration.

# Overview of ASP.NET Security

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Most Web sites need to selectively restrict access to some portions of the site. You can think of a Web site as somewhat analogous to an art gallery. The gallery is open for the public to come in and browse, but there are certain parts of the facility, such as the business offices, that are accessible only to people with certain credentials, such as employees. When a Web site stores its customers' credit card information in a database, for example, ASP.NET helps protect the database from public access. ASP.NET security addresses this and many other security issues.

ASP.NET, in conjunction with Internet Information Services (IIS), can authenticate user credentials such as names and passwords using any of the following authentication methods:

- Windows: Basic, digest, or Integrated Windows Authentication (NTLM or Kerberos).
- Microsoft Passport authentication
- Forms authentication
- Client Certificate authentication

ASP.NET helps control access to site information by comparing authenticated credentials, or representations of them, to NTFS file system permissions or to an XML file that lists authorized users, authorized roles (groups), or authorized HTTP verbs.

The topics in this section describe the specifics of ASP.NET security.

This section includes the following information:

- How Security Works in ASP.NET: Provides an overview of ASP.NET security.
- Architecture in ASP.NET: Provides an overview of ASP.NET infrastructure and subsystem relationships, as related to security.
- Data Flow in ASP.NET: Describes the security data flow for two common scenarios.
- Authentication in ASP.NET: Describes ASP.NET authentication providers.
- Authorization in ASP.NET: Describes two fundamental ways to authorize access to a resource.
- Impersonation in ASP.NET: Describes how and when to use ASP.NET Impersonation.
- Authentication and ASP.NET Impersonation: Describes how to create ASP.NET application with incorporated security.
- Security of ASP.NET Applications in Hosted Environments: Describes ASP.NET security features for multi-application Web servers.

# How Security Works in ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Helping protect Web sites against unauthorized access is a critical, complex issue for Web developers. A successful system requires careful planning, and Web site administrators and programmers must have a clear understanding of the options for securing their site.

ASP.NET works in concert with the Microsoft .NET Framework and Internet Information Services (IIS) to help provide Web application protection. To help protect an ASP.NET application, you must perform the two fundamental functions described in the following table.

| Security function | Description |
|---|---|
| Authentication in ASP.NET | Assures that the user is, in fact, who the user claims to be. The application obtains credentials (various forms of identification, such as name and password) from a user and validates those credentials against some authority. If the credentials are valid, the entity that submitted the credentials is considered an authenticated identity. |
| Authorization in ASP.NET | Limits access rights by granting or denying specific permissions to an authenticated identity. |

IIS can also grant or deny access based on a user's host name or IP address. Any further access authorization is performed by NTFS file access permission's URL authorization.

It is helpful to understand how all the various security subsystems interact. Since ASP.NET is built on the Microsoft .NET Framework, the ASP.NET application developer also has access to all the built-in security features of the .NET Framework, such as code access security and role-based user-access security. For details about the security capabilities of ASP.NET, see ASP.NET Code Access Security.

# Architecture in ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This section provides an overview of the ASP.NET infrastructure and subsystem relationships, as they relate to the subject of security. The following illustration shows the relationships among the security systems in ASP.NET.

As the illustration shows, all Web clients communicate with ASP.NET applications through Internet Information Services (IIS). IIS deciphers and optionally authenticates the request. If Allow Anonymous is set to **true**, no authentication occurs. IIS also finds the requested resource (such as an ASP.NET application), and, if the client is authorized, returns the appropriate resource.

In addition to the built-in ASP.NET features, an ASP.NET application can use the low-level security features of the .NET Framework. For more information, see the "Key Security Concepts" topic in .NET Framework Help.

**Integrating with IIS**

When considering ASP.NET authentication, you should understand the interaction with IIS authentication services.

IIS always assumes that a set of credentials maps to a Microsoft Windows NT account and uses them to authenticate a user. There are three different kinds of authentication available in IIS 5.0 through IIS 6.0: basic, digest, and Integrated Windows Authentication (NTLM or Kerberos). You can select the type of authentication to use in IIS administrative services. For more information about IIS authentication, see Authentication in IIS 6.0.

If you request a URL containing an ASP.NET application, the request and authentication information are handed off to the application. ASP.NET provides the two additional types of authentication described in the following table.

| ASP.NET authentication provider | Description |
|---|---|
| Forms authentication | A system by which unauthenticated requests are redirected to an HTML form using HTTP client side redirection. The user provides credentials and submits the form. If the application authenticates the request, the system issues an authentication ticket in a cookie that contains the credentials or a key for reacquiring the identity. Subsequent requests are issued with the cookie in the request headers; they are authenticated and authorized by an ASP.NET handler using whatever validation method the application developer specifies. |
| Passport authentication | Centralized authentication service provided by Microsoft that offers a single logon and core profile services for member sites. |

**Using ASP.NET Configuration Files**

ASP.NET configuration, of which security is a part, has a hierarchical architecture. All configuration information for ASP.NET is contained in files named Web.config and Machine.config. Web.config can be placed in the same directories as the application files. The Machine.config file is in the Config directory of the install root. Subdirectories inherit a directory's settings unless overridden by a Web.config file in the subdirectory. In a Web.config file, there are sections for each major category of ASP.NET functionality. To see an example of the way in which the hierarchical configuration system works for security, see Hierarchical Configuration Architecture in ASP.NET.

The security section of a Web.config file is organized as follows.

```
<authentication mode="[Windows|Forms|Passport|None]">

<forms name="[name]"
```

```
loginUrl="[url]"
protection="[All|None|Encryption|Validation]"
path="[path]" timeout="[minutes]"
requireSSL="[true|false]"
slidingExpiration="[true|false]">
<credentials passwordFormat="[Clear|MD5|SHA1]">
<user name="[UserName]"
password="[password]"/>
</credentials>
</forms>
<passport redirectUrl="internal"/>
</authentication>
<authorization>
<allow users="[comma separated list of users]"
roles="[comma separated list of roles]"/>
<deny users="[comma separated list of users]"
roles="[comma separated list of roles]"/>
</authorization>
<identity impersonate ="[true|false]"
userName="[domain\user_name]"
password="[user_password]"/>
<trust level="[Full|High|Medium|Low|Minimal]"
originUrl=""/>
<securityPolicy>
<trustLevel name="Full" policyFile="internal"/>
<trustLevel name="High" policyFile="web_hightrust.config"/>
<trustLevel name="Medium" policyFile="web_mediumtrust.config"/>
<trustLevel name="Low" policyFile="web_lowtrust.config"/>
<trustLevel name="Minimal" policyFile="web_minimaltrust.config"/>
</securityPolicy>
```

The default settings for these elements are shown in the following table.

| **Default value** | **Description** |
|---|---|
| <allow roles= > | No default value. |
| <allow users="*"> | All |
| <authentication mode="Windows"> | The authentication mode cannot be set at a level below the application root directory. |
| <credentials passwordFormat="SHA1"> | The hashing algorithm to be used on passwords. |
| <deny roles=""> | Empty |
| <deny users=""> | Empty |

| | |
|---|---|
| <forms loginUrl="login.aspx"> | If you set the mode to **Forms**, and if the request does not have a valid ticket (cookie), this is the URL to which the request is directed for a forms-based logon. |
| <forms name=".ASPXAUTH"> | Default cookie name. |
| <forms path="/"> | Path |
| <forms protection="All"> | Type=[All\|None\|Encryption\|Validation]. |
| <forms requireSSL="false"> | Specifies that an encrypted connection is not required to transmit the authentication cookie. |
| <forms slidingExpiration="true"> | Specifies that sliding expiration is enabled. |
| <forms timeout="30"> | Time-out in minutes. 30 minutes is the default. |
| <identity impersonate="false"> | Impersonation is disabled by default. |
| <identity userName=""> | Empty |
| <identity password=""> | Empty |
| <passport redirectUrl="internal"> | If you set the mode to **Passport**, and if the requested page requires authentication (anonymous users are denied access) but the user has not logged on with Passport, then the user will be redirected to this URL. |
| <trustLevel name="Full" policyFile="internal"/> | Default policy file for Full trust level. |
| <trustLevel name="High" policyFile="web_hightrust.config"/> | Default policy file for High trust level. |
| <trustLevel name="Medium" policyFile="web_mediumtrust.config"/> | Default policy file for Medium trust level. |
| <trustLevel name="Low" policyFile="web_lowtrust.config"/> | Default policy file for Low trust level. |
| <trustLevel name="Minimal" policyFile="web_minimaltrust.config"/> | Default policy file for Minimal trust level. |
| <user name=""> | Empty |
| <user password=""> | Empty |

There are three major subsections to a Web.config file: authentication, authorization, and identity. The values for each of the security elements are usually set by overriding a section of the computer-level configuration file with a similar section in an application configuration file placed in the application root directory. All subdirectories automatically inherit those settings. However, subdirectories can have their own configuration files that override other settings.

| **Note** |
|---|
| ASP.NET configuration applies only to ASP.NET resources (those registered to be handled by Aspnet_isapi.dll). Unfortunately, ASP.NET configuration cannot provide authorization for non-Aspnet_isapi.dll resources, so TXT, HTML, GIF, JPEG, ASP, and other types of files are still accessible by all users, subject to IIS permissions. For example, although the ASP.NET resources in a directory might be restricted by a Web.config file, all users can still view the files located in that directory if directory browsing is turned on and no other restrictions are in place. |

You can avoid this situation by explicitly mapping such files, but not directories, to Aspnet_isapi.dll using the IIS administration tool. However, there could be a performance impact if you do this.

You can use the <**location**></**location**> tags to specify a particular file or directory to which settings should apply. For more information about how to use the <**location**> tag, see Configuration <location> Settings in ASP.NET and <location> Element.

**Related Information**

# Data Flow in ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

There are a number of different ways to design security into ASP.NET applications. This section describes the data flow for two common scenarios: impersonation and forms authentication using cookies.

**Scenario 1: Impersonation**
This scenario relies on Internet Information Services (IIS) authentication and Microsoft Windows NT® file access security to minimize security programming in the ASP.NET application itself. The data flow is shown in the following illustration.

The illustration shows the following sequence of events:

1. A request for access comes to IIS from a network client.

2. IIS authenticates the client using basic, digest, or Integrated Windows Authentication (NTLM or Kerberos).

3. If the client is authenticated, IIS hands the authenticated request over to ASP.NET.

4. The ASP.NET application impersonates the requesting client using the access token passed from IIS, and relies on NTFS file permissions for granting access. The ASP.NET application needs only to verify that in the ASP.NET configuration file, the impersonation-enable directive is set to **true**; no ASP.NET security code needs to be written.

   Notice that if impersonation is not enabled, the application runs with the IIS process identity. For Microsoft Windows® 2000 Server and Windows XP, the default identity is a User account named ASPNET that is created automatically when ASP.NET is installed. For products in the Microsoft Windows Server 2003 family, the default identity is the Network Service account. If you want to restrict access, you must use some other means of authorization, such as URL authorization.

   For more details about using impersonation in ASP.NET applications, see Impersonation in ASP.NET and Using IIS Authentication with ASP.NET Impersonation.

5. If access is granted, the ASP.NET application returns the requested page through IIS.

**Scenario 2 - Forms Authentication**
In this scenario an application uses ASP.NET forms authentication, a process that enables the application to collect credentials such as name and password directly from the client requestor and make its own determination about their authenticity. IIS authentication is not used by the application, but IIS authentication settings are important to the ASP.NET forms authentication process. Unless you decide to reject all requests that do not meet the criteria for the enabled method of IIS authentication, you must enable the IIS **Anonymous Access** setting.

| **Note** |
| --- |
| If you do not enable anonymous access in IIS, requests not meeting the criteria for IIS authentication will be rejected and never reach the ASP.NET application. |

The data flow in this scenario is shown in the following illustration.

This illustration shows the following sequence of events:

1. A client generates a request for a protected resource.

2. IIS receives the request, and if the requestor is authenticated by IIS, or if IIS anonymous access is enabled, the request gets passed on to the ASP.NET application. Because the authentication mode in the ASP.NET application is set to forms in this case, IIS authentication is not used.

3. If there is no cookie attached to the request, ASP.NET redirects the request to a logon page, the path of which resides in the application's configuration file. On the logon page, the client user enters the required credentials (usually a name and password).

4. The application code checks the credentials to confirm their authenticity, usually in an event handler. If the credentials are authenticated, the application code attaches a ticket (as a cookie) containing the user name, but not the password. If authentication fails, the request is usually returned with an Access Denied message or the logon form is presented again.

5. After a ticket is issued by the application, ASP.NET just checks the ticket for validity using a message authentication check. Applications do not need the credentials in the *.config files. In fact, ASP.NET does not check them after the cookie is issued, even if they are present.

6. If the user is authenticated, ASP.NET checks authorization and can either allow access to the originally requested, protected resource or redirect the request to some other page, depending on the design of the application. It can also direct the request to a custom authorization module where the credentials are tested for authorization to access the protected resource. If authorization fails, ASP.NET always redirects to the logon page.

7. If the user is authorized, access is granted to the protected resource; or the application might require an additional test of the credentials before authorizing access to the protected resource, depending on the design of the application.

- Overview of ASP.NET Security

# Authentication in ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003 R2, Windows Server 2003 with SP1

Authentication is the process of obtaining identification credentials such as name and password from a user and validating those credentials against some authority. If the credentials are valid, the entity that submitted the credentials is considered an authenticated identity. Once an identity has been authenticated, the authorization process determines whether that identity has access to a given resource.

ASP.NET implements authentication through authentication providers, the code modules that contain the code necessary to authenticate the requestor's credentials. ASP.NET supports the authentication providers described in the following table.

| **ASP.NET authentication provider** | **Description** |
|---|---|
| Forms authentication | A system by which unauthenticated requests are redirected to an HTML form using HTTP client-side redirection. The user provides credentials and submits the form. If the application authenticates the request, the system issues a cookie that contains the credentials or a key for reacquiring the identity. Subsequent requests are issued with the cookie in the request headers; they are authenticated and authorized by an ASP.NET event handler using whatever validation method the application developer specifies. |
| Passport authentication | Centralized authentication service provided by Microsoft that offers a single logon and core profile services for member sites. |
| Windows authentication | ASP.NET uses Windows authentication in conjunction with Internet Information Services (IIS) authentication. Authentication is performed by IIS in one of three ways: basic, digest, or Integrated Windows Authentication. When IIS authentication is complete, ASP.NET uses the authenticated identity to authorize access. |

**Important**

Integrated Windows authentication is disabled by default if you install Windows Server 2003 Service Pack 1 (SP1) as part of a slipstream installation of a Windows Server 2003 operating system. If you install Windows Server 2003 SP1 by itself as an upgrade to a Windows Server 2003 operating system, the setting for Integrated Windows authentication is unchanged from its Windows Server 2003 setting. Integrated Windows authentication is enabled by default for Windows Server 2003 operating systems.

To enable an authentication provider for an ASP.NET application, create an entry for the application configuration file as follows.

```
// Web.config file

<authentication mode= "[Windows|Forms|Passport|None]"/>
```

The mode is set to one of the authentication modes: **Windows**, **Forms**, **Passport**, or **None**. The default is Windows. If the mode is **None**, ASP.NET does not apply any additional authentication to the request - this can be useful when you want to implement a custom authentication scheme, or if you are solely using anonymous authentication and want the highest possible level of performance.

The authentication mode cannot be set at a level below the application root directory. As is the case with other ASP.NET modules, subdirectories in the URL space inherit authentication modules unless explicitly overridden.

**Related Information**

- Windows Authentication Provider in ASP.NET
- Passport Authentication Provider in ASP.NET
- Forms Authentication Provider in ASP.NET

# Windows Authentication Provider in ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003 R2, Windows Server 2003 with SP1

The **WindowsAuthenticationModule** provider relies on Internet Information Services (IIS) to provide authenticated users, using any of the mechanisms that IIS supports. If you want to help protect site security with a minimum of ASP.NET coding, this is the provider configuration you should use. The provider module constructs a **WindowsIdentity** object. The default implementation constructs a **WindowsPrincipal** object and attaches it to the application context. The **WindowsPrincipal** object maps identities to Windows groups.

If you use IIS authentication, the provider module uses the authenticated identity passed in from IIS. IIS authenticates the identity using basic, digest, or Integrated Windows authentication, or some combination of them. You can use impersonation and NTFS ACL permissions to restrict or allow access to protected resources.

| **Important** |
| --- |
| Integrated Windows authentication is disabled by default if you install Windows Server 2003 Service Pack 1 (SP1) as part of a slipstream installation of a Windows Server 2003 operating system. If you install Windows Server 2003 SP1 by itself as an upgrade to a Windows Server 2003 operating system, the setting for Integrated Windows authentication is unchanged from its Windows Server 2003 setting. Integrated Windows authentication is enabled by default for Windows Server 2003 operating systems. |

An important reason to use the **WindowsAuthenticationModule** provider is to implement an impersonation scheme that can use any of the authentication methods that might have already been performed by IIS before passing the request to the ASP.NET application. To do this, set the authentication mode to Windows, and confirm that the **impersonate** element is set to **true**, as shown in the following example:

```
<authentication mode="Windows"/>
<identity impersonate="true"/>
```

Note that configuring an ASP.NET application has no effect on the IIS Directory Security settings. The systems are completely independent and are applied in sequence. In addition to selecting an authentication mode for an ASP.NET application, it is also important to configure IIS authentication appropriately.

Next, you must set the NTFS ACLs to allow access only to the proper identities.

# Passport Authentication Provider in ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Passport authentication is a centralized authentication service provided by Microsoft that offers a single logon and core profile services for member sites. This benefits the user because it is no longer necessary to log on to access new encrypted resources or sites. If you want your site to be compatible with Passport authentication and authorization, this is the provider you should use. This topic provides some introductory material about Microsoft .NET Passport and the ASP.NET support for it. For more information, see the Passport documentation located at http://www.passport.com. In order to access the documentation, you must get a Passport and register.

Passport is a cookies-based authentication service. A sample transaction conversation using Passport authentication might look similar to the following:

1. A client issues an **HTTP GET** request for a protected resource, such as http://www.contoso.com/default.aspx.
2. The client's cookies are examined for an existing Passport authentication ticket. If the site finds valid credentials, the site authenticates the client. If the request does not include a valid authentication ticket, the server returns status code 302 and redirects the client to the Passport Logon Service. The response includes a URL in the query string that is sent to the Passport logon service to direct the client back to the original site.
3. The client follows the redirect and requests the original resource again, this time with the Passport cookie.
4. The Passport logon server presents the client with a logon form.
5. The client fills out the form and does a **POST** back to the logon server, using Secure Sockets Layer (SSL).
6. The logon server authenticates the user and redirects the client back to the original URL (http://www.contoso.com/default.aspx). The response contains an encrypted Passport cookie in the query string.
7. The client follows the redirect and requests the original protected resource again, this time with the Passport cookie.
8. Back on the originating server, the **PassportAuthenticationModule** detects the presence of the Passport cookie and tests for authentication. If successful, the request is then authenticated.

Subsequent requests for protected resources at the site are authenticated at the originating server using the supplied ticket. Passport also makes provisions for ticket expiration and reusing tickets on other member sites.

Passport uses the Triple DES encryption scheme. When member sites register with Passport, they are granted a site-specific key. The Passport logon server uses this key to encrypt and decrypt the query strings passed between sites.

| **Note** |
| --- |
| To use Passport authentication, you must register your site with the Passport service, accept the license agreement, and install the .NET Passport SDK prior to use. |

The ASP.NET **PassportAuthenticationModule** provides a wrapper around the .NET Passport SDK for ASP.NET applications, and provides Passport authentication services and profile information from an **IIdentity**-derived class called **PassportIdentity**.

As is the case with **WindowsIdentity**, the primary purpose of handling the **PassportAuthentication_OnAuthenticate** event is to attach a custom **IPrincipal** object to the context. A special **IIdentity**-derived class called **PassportIdentity** provides an interface to the Passport profile information and methods to encrypt and decrypt Passport authentication tickets.

**Procedures**

**To implement Passport authentication in an ASP.NET application**

1. Download, install, and configure the .NET Passport SDK from http://www.passport.com/business. You must complete a

registration form to obtain the SDK. Windows Server 2003 includes the .NET Passport SDK and does not require this step.

2. Set up Passport as the authentication mode in the application configuration file as follows.

```
<authentication mode= "Passport"/>
```

3. Using the Passport documentation and the .NET Passport SDK functionality, implement Passport authentication and authorization.

# Forms Authentication Provider in ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Forms authentication generally refers to a system in which unauthenticated requests are redirected to an HTML form, using HTTP client-side redirection. Forms authentication is a good choice if your application needs to collect its own user credentials at logon time through HTML forms. The user provides credentials and submits the form. If the application authenticates the request, the system issues a cookie that contains the credentials or a key for reacquiring the identity. Subsequent requests are issued with the cookie in the request headers. The requests are authenticated and authorized by an ASP.NET event handler using whatever validation method the application specifies.

Note that forms authentication is often used for personalization, where content is customized for a known user. In some of these cases, identification is the issue rather than authentication, so it is enough merely to store the user name in a durable cookie and use that cookie to access the user's personalization information.

For detailed information about how to develop ASP.NET applications that use forms authentication, see documentation on the forms authentication provider in the MSDN Library.

**Forms Authentication Across Applications**

ASP.NET supports forms authentication in a distributed environment, either across applications on a single server or in a Web farm. Several configuration attributes in the <forms> element configuration section must match for all applications participating in shared forms authentication. The directives **name**, **protection**, **path**, **validationKey**, **descriptionKey**, and **validation** in the following example must be identical (unless otherwise noted) across the applications.

```
<configuration>

<system.web>

<authentication>

<forms name=".ASPXAUTH"

loginUrl="logon.aspx"

protection="all" <!-- Protection must be identical.-->

timeout="30"

path="/" > <!-- Path must have a compatible scope.-->

</authentication>

<!-- Validation and decryption keys must exactly match and cannot

be set to "AutoGenerate". The validation algorithm must also

be the same. -->

<machineKey>

validationKey=
"C50B3C89CB21F4F1422FF158A5B42D0E8DB8CB5CDA1742572A487D9401E3400267682B202B746511891C1BAF47F8D25C07F6C39A104696DB51F17C529AD3CABE"

decryptionKey= "8A9BE8FD67AF6979E7D20198CFEA50DD3D3799C77AF2B72F"

validation="SHA1"

isolateApplications="false"

</machineKey>

</system.web>

</configuration>
```

The encryption and validation keys and the encryption scheme used for cookie data must be exactly the same. If the settings do not match, cookies cannot be shared.

After a cookie has been issued, expiration of the cookie is tracked based on the **Expires** property value in the cookie itself. This means that if two applications have different **timeout** attributes, the expiration date and time that was set when each cookie was originally issued is retained throughout the lifetime of the cookie. When a cookie is updated, the cookie's original expiration is used to compute the new expiration. The only time the configuration **timeout** value is used is when the cookie is initially created.

# Authorization in ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The purpose of authorization is to determine whether an identity should be granted the requested type of access to a given resource. There are two fundamental ways to authorize access to a given resource:

- File authorization

  File authorization is performed by the **FileAuthorizationModule**, and is active when you use Windows authentication. It does an access control list (ACL) check of the .aspx or .asmx handler file to determine if a user should have access. Applications can further use impersonation to get resource checks on resources that they are accessing. For more information about impersonation, see Authentication and ASP.NET Impersonation.

- URL authorization

  URL authorization is performed by the **URLAuthorizationModule** class, which maps users and roles to pieces of the URL namespace. This module implements both positive and negative authorization assertions. That is, the module can be used to selectively allow or deny access to arbitrary parts of the URL namespace for certain sets, users, or roles.

The **URLAuthorizationModule** is available for use at any time. You only need to place a list of users and/or roles in the <**allow**> or <**deny**> elements of the <**authorization**> section of a configuration file.

To establish the conditions for access to a particular directory, you must place a configuration file that contains an <**authorization**> section in that directory. The conditions set for that directory also apply to its subdirectories, unless configuration files in a subdirectory override them. The general syntax for this section is as follows.

```
<[element] [users] [roles] [verbs]/>
```

An element is required. Either the *users* or the *roles* attribute must be included. Both can be included, but both are not required. The verbs attribute is optional.

The permissible elements are <**allow**> and <**deny**>, which grant and revoke access, respectively. Each element supports three attributes, which are defined in the following table.

| Attribute | Description |
|---|---|
| roles | Identifies a targeted role for this element. The associated **IPrincipal** object for the request determines the role membership. You can attach arbitrary **IPrincipal** objects to the context for a given request and they can determine role membership in whatever way you like. For example, the default **WindowsPrincipal** class uses Microsoft Windows NT groups to determine role membership. |
| users | Identifies the targeted identities for this element. |
| verbs | Defines the HTTP verbs to which the action applies, such as **GET**, **HEAD**, and **POST**. |

Anonymous users are also denied.

The following example grants access to Kim and members of the Admins role, while denying it to John and all anonymous users:

```
<authorization>
<allow users="Kim"/>
<allow roles="Admins"/>
<deny users="John"/>
<deny users="?"/>
</authorization>
```

Both users and roles can refer to multiple entities by using a comma-separated list, as shown in the following example.

```
<allow users="John, Kim, contoso\Jane"/>
```

Notice that the domain account, `contoso\Jane`, must include both the domain and user name combination.

In addition to identity names, there are two special identities, as shown in the following table.

| Identity | Description |
|---|---|
| * | Refers to all identities |
| ? | Refers to the anonymous identity |

To allow John and deny everyone else, one might construct the following configuration section.

```
<authorization>
<allow users="John"/>
<deny users="*"/>
</authorization>
```

The following example lets everyone do a **GET**, but only Kim can use **POST**.

```
<authorization>
<allow verb="GET" users="*"/>
<allow verb="POST" users="Kim"/>
<deny verb="POST" users="*"/>
</authorization>
```

Rules are applied using the following heuristics:

- Rules contained in configuration files at lower directory levels take precedence over rules at higher directory levels. The system determines which rule takes precedence by constructing a merged list of all rules for a URL, with the most recent (nearest in the hierarchy) rules at the head of the list.

- Given a set of merged rules for a URL, the system starts at the head of the list and checks rules until the first match is found. Note that the default configuration for ASP.NET contains an <**allow users="*"**> element, which authorizes all users. If no rules match, the request is allowed unless otherwise denied. If a match is found and the match is a <**deny**> element, it returns the 401 status code. Applications or sites can easily configure a <**deny users="*"**> element at the top level of their site or application to prevent this behavior.

  If an <**allow**> matches, the module does nothing and lets the request be processed further.

There is also a <**location**> tag that you can use to specify a particular file or directory to which settings wrapped by that tag (between <**location**> and <**/location**> tags) should apply.

# Impersonation in ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When using impersonation, ASP.NET applications can optionally execute with the identity of the client on whose behalf they are operating. The usual reason for doing this is to avoid dealing with authentication and authorization issues in the ASP.NET application code. Instead, you rely on Internet Information Services (IIS) to authenticate the user and either pass an authenticated token to the ASP.NET application or, if unable to authenticate the user, pass an unauthenticated token. In either case, the ASP.NET application impersonates whichever token is received if impersonation is enabled. The ASP.NET application, now impersonating the client, then relies on the settings in the NTFS directories and files to allow it to gain access, or not. Be sure to format the server file space as NTFS, so that access permissions can be set.

Impersonation is disabled by default. For ASP compatibility, the user must explicitly enable impersonation. If impersonation is enabled for a given application, ASP.NET always impersonates the access token that IIS provides to ISAPI extensions. That token can be either an authenticated user token, or the token for the anonymous user (such as IUSR_*ComputerName*). The impersonation occurs regardless of the type of authentication being used in the application.

Only application code is impersonated; compilation and configuration are read as the process token. The result of the compilation is put in the Temporary ASP.NET files directory. The account that is being impersonated needs to have read/write access to this directory. If an application is on a universal naming convention (UNC) share, ASP.NET will always impersonate the token provided to IIS to access that share unless a configured account is used. If an explicit configured account is provided, ASP.NET will use that account in preference to the IIS UNC token. Applications that require per-request impersonation can simply be configured to impersonate the user making the request.

Impersonation is disabled at the computer level by default and, unless overridden, all the application domains inherit this setting. You can enable impersonation by putting a configuration file in the application root directory. For more information about the ASP.NET configuration system, see Overview of ASP.NET Configuration.

As is the case with other configuration directives, this directive applies hierarchically. It is respected by nested applications in the hierarchy, unless explicitly overridden. The default value for this setting is as follows.

```
<impersonation enable="false"/>
```

A minimal configuration file to enable impersonation for an application might look similar to the following example.

```
<!-- Web.config file. -->
<identity impersonate="true"/>
```

There is also name support for running an application as a configurable identity. For example:

```
<identity impersonate="true" userName="contoso\Jane" password="pass"/>
```

This enables the entire application to run as `contoso\Jane`, regardless of the identity of the request, as long as the password is correct. This type of impersonation can be delegated to another computer.

You can programmatically read the identity of the impersonated user, as shown in the following example.

```
[Visual Basic]
Dim username As String = System.Security.Principal.WindowsIdentity.GetCurrent().Name
[C#]
String username = System.Security.Principal.WindowsIdentity.GetCurrent().Name;
```

In the preceding example, **userName** and **password** are stored in clear text in the configuration file. Although IIS will not transmit .config files in response to a user agent request, configuration files can be read by other means, for instance by an authenticated user with proper credentials on the domain that contains the server. To help maintain security, the identity section supports storage of encrypted **userName** and **password** attributes in the registry as shown in the following example.

```
userName="registry:HKLM\Software\AspNetIdentity,Name"
password="registry:HKLM\Software\AspNetIdentity,Password"
```

The portion of the string after the keyword **registry** and up to the first comma indicates the **registry** key that ASP.NET must

open. The portion after the comma contains a single string value name from which ASP.NET will read the credentials. The comma is required and the credentials must be stored in the HKLM hive. If the configuration format is incorrect, ASP.NET will not launch the worker process and the current account creation failure code path will be followed.

The portion of the string after the keyword registry and before the comma indicates the name of the registry key that ASP.NET opens. The portion after the comma contains a single string value name from which ASP.NET will read the credentials. The comma is required, and the credentials must be stored in the HKLM hive. If the configuration format is incorrect, ASP.NET will not launch the worker process and the current account creation failure code path will be followed.

The credentials must be in REG_BINARY format, containing the output of a call to the Windows API function **CryptProtectData**. You can create the encrypted credentials and store them in the registry with the ASP.NET Set Registry console application (Aspnet_setreg.exe), which uses CryptProtectData to accomplish the encryption. To download Aspnet_setreg.exe, along with the Visual C++ source code and Help, visit the Web site www.asp.net and search for **aspnet_setreg**.

You should configure access to the key storing the encrypted credentials so that access is provided only to Administrators and SYSTEM. Because the key will be read by the ASP.NET process running as SYSTEM, you should set the following permissions:

Administrators:F

SYSTEM:F

CREATOR OWNER:F

ProcessAccount:R

This provides two lines of defense to protect the data.

The ACL permissions require the identity accessing the data to be an Administrator. An attacker must run code on the server (**CryptUnprotectData**) to recover the credentials for the account.

# Authentication and ASP.NET Impersonation

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The examples in this section show how to create ASP.NET applications that incorporate various kinds of industry-standard security technologies. For examples of how to create applications that use forms authentication, see information about Forms Authentication Provider on MSDN.

**Using IIS Authentication with ASP.NET Impersonation**

In this scenario, you are setting up an application on an intranet Web site for posting employee information. However, some of the information is for managers only. The manager information can be posted to a subdirectory of the general employee information, so that access to it can be limited. The scenario also assumes that:

- You are using a Microsoft Windows NT or Microsoft Windows 2000 server.
- The hard disk is formatted for NTFS.
- Internet Information Services (IIS) 6.0 is the Web server.
- All employees needing access are using Windows platforms.

You, as administrator:

1. Create the files and directories shown in the following illustration.

2. Create a Windows group called Managers that contains all users who should have access to the ManagerInfo.aspx file.
3. Set up Windows authentication using the IIS administration tool.
4. Set the **impersonate** attribute in the <identity> element in the ASP.NET configuration file to **true**.
5. Set the NTFS access control list (ACL) for the ManagerInformation directory to allow access to only those identities that are in the Windows Manager group. Note that the local system still needs access as well so that the ASP.NET process itself can read the files. Settings in this directory typically resemble the following:
    a. Remove access from the Everyone group, if it has access.
    b. Deny anonymous users.
    c. Add accounts that are to have access privileges.
    d. Give the system account access.

This helps provide the necessary security without the necessity of writing any code.

# Security of ASP.NET Applications in Hosted Environments

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

ASP.NET offers an excellent environment for hosting multiple applications on a single Web server. Application Service Providers (ASPs) and Internet Service Providers (ISPs) are able to host multiple applications from different outside sources on a shared server and keep the applications isolated from each other and from critical resources on the server. ASP.NET's configuration system is designed to make it easy to isolate Web applications and to grant code access security permissions to individual applications.

**In This Section**

Configuring Process Identity for ASP.NET: Describes the trust level and policy settings that you can use to help protect the configuration of the server that hosts your ASP.NET applications.

Required Access Control Lists (ACLs) for ASP.NET: Lists the permissions that ASP.NET needs to access specific server resources.

Code Access Security for ASP.NET: Describes the importance of configuring your Web applications so that they will accept code only from trusted sources.

Trust Levels and Policy Files for ASP.NET: Describes the trust level and policy settings that you can use to securely configure the server that hosts your ASP.NET applications.

**Related Sections**

Overview of ASP.NET Security:Describes how to work with authorization and authentication in ASP.NET applications.

Overview of ASP.NET Configuration: Describes how to configure ASP.NET applications and includes reference information about each of the ASP.NET configuration elements.

# Configuring Process Identity for ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The ASP.NET worker process (Aspnet_wp.exe) should run with a different and less privileged identity than the Windows default System identity. This allows the process to run as a relatively untrusted user so that hosted Web applications do not have administrative privileges and cannot compromise the integrity of the server. If the security of the ASP.NET worker process were breached, only a relatively weak account would be compromised and the intruder would not have administrative access to the entire server.

To run the ASP.NET worker process with its own account under Windows 2000 and Windows Server, you can apply the following two attributes to the **<processModel>** configuration element:

- **userName**

  The name of the account under which the process will run.

- **password**

  The clear-text password for the account. There are risks associated with storing clear-text passwords in a configuration file. For applications published on the Internet, you should use alternative means of running the application with a specific identity, or you should store encrypted credentials in the registry. For more information about storing credentials in the registry, see "<processModel>" on MSDN.

The following example shows how to set these attributes in the <**processModel**> section of a configuration file to run the worker process under a local user account.

```
<system.web>
    <processModel enable="true"
                  userName="LOCALMACHINE\IUSR_SomeUser"
                  password="password"/>
</system.web>
```

System and Machine are two predefined **userName** identity settings. The System account runs the worker process with the same identity as Internet Information Services (IIS) itself (typically System). The Machine account runs the worker process with a special unprivileged account named ASPNET. With either identity, the password is **AutoGenerate**, which means that the process does not have to supply credentials to the operating system.

To enable running the worker process with the special ASPNET account, add the following lines to the Machine.config file. If you change the process account in Machine.config, you must reset IIS or stop the Aspnet_wp.exe process.

```
<system.web>
    <processModel enable="true"
                  userName="Machine"
                  password="AutoGenerate"/>
</system.web>
```

With the new process model enabled on Internet Information Services version 6, ASP.NET does not use its own process model. Its identity is inherited from the IIS worker process.

The following example is supported only if you explicitly add the appropriate account rights to the account under which the worker process runs. There are risks associated with storing clear-text passwords in a configuration file. For applications published on the Internet, you should use alternative means of running the application with a specific identity, or you should store encrypted credentials in the registry. For more information, see "<processModel>"on MSDN.

```
<system.web>
    <identity impersonate="true"
              userName="LOCAL\SomeUser"
              password="password"/>
</system.web>
```

The technique described in the following paragraphs is commonly used by administrators hosting ASP sites and it will work in an ASP.NET environment with a weaker process identity.

The application grants access to an anonymous user (this assumes that the authentication scheme allows anonymous users), and the anonymous account is configured to be the desired account for the application. Also, the application uses per-request impersonation and the application code executes as the impersonated account. The process account still compiles and reads configuration because impersonation is used only with the request handler.

If you alternate between running the worker process with an account that has administrator privileges and a weaker account, the weaker account will not be able to read the Local Security Authority (LSA) secret used for Forms authentication, so all Forms authentication users must be reauthenticated. This does not apply when going from an account without administrative privileges to an account with administrative privileges. It does apply to applications with the following configuration.

```
<system.web>
    <authentication mode="Forms"/>
    <machineKey validationKey="AutoGenerate"
                decryptionKey="AutoGenerate"/>
</system.web>
```

# Required Access Control Lists (ACLs) for ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The following table shows which type of access permissions ASP.NET must have in order to access the listed locations.

| Location | Access type | Account | Comments |
|---|---|---|---|
| *installroot*\ASP.NET Temporary Files | Read/Write/Execute | Process or configured impersonation. | This is the location for dynamically compiled files. Beneath this location, application code generation takes place in a discrete directory for each application. The root location itself can be configured using the **tempDir** attribute of the **<compilation>** section. |
| **systemroot**\assembly | Read/Execute | Process or configured impersonation. | This is the location of the global assembly cache. |
| **systemroot**\system32 | Read/Execute | Process | Contains system DLLs loaded by the .NET Framework. |
| **systemroot**\temp | Read/write/delete | Process | Used for XML Web services support. |
| *userprofile* directory | Read/write | Process | Used by the global assembly cache lock files and the common language runtime security configuration caching mechanism. If the user profile directory for the account does not exist, ASP.NET will use the default *userprofile* directory. |
| *application* directory | Read | Process or configured impersonation. | This is the location for application files. |
| *installroot* hierarchy | Read/Execute | Process or configured impersonation | ASP.NET must be able to access the system assemblies referenced in the Machine.config file in the config subdirectory under *installroot*. |
| Default Web Site monitoring | Read | Process | Used for file change notification monitoring. |

# Code Access Security for ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

One of the major benefits of using ASP.NET to host multiple Web sites is the common language runtime's support for code access security to help provide an execution platform for server applications. Code is assigned to a security zone classification based on evidence about the code's origin (evidence such as a strongly named assembly or the URL of origin, for example). Without the ability to configure security for individual, unrelated applications installed on a common server, code in an ASP.NET page belonging to one application would be able to read the files, for example, the Web.config file, in another application. Applications that run with full trust are constrained only by the operating system account under which they are executing.

Code access security can be easily handled for an individual assembly by strongly naming it and adding policy for that assembly. However, many ASP.NET assemblies are dynamically generated as a result of dynamic page compilation and therefore are not strongly named, so an additional facility is required.

ASP.NET lets you assign to an application a configurable level of trust that corresponds to a predefined set of permissions. By default (unless you explicitly alter the configuration), applications receive a level of trust commensurate to the evidence they present. For example, local applications must run in the MyComputer zone with the **Full** trust permission set, and applications located on a Universal Naming Convention (UNC) share must run in the Intranet zone with the **LocalIntranet** restricted permission set. If you want to run a Web application with less than **Full** trust, you must use one of the predefined trust levels defined in ASP.NET Trust Levels and Policy Files to enforce a partial trust policy.

You can use the following configuration settings to override the default behavior and associate an application with a given security policy.

```
<location path="MyApp" allowOverride="false">
<trust level="High"
originUrl="http://www.contoso.com"/>
</location>
```

The <**trust**> configuration tag can apply to the machine level or to any application root directory in the hierarchy.

If you want to set policy for the entire site, you can do so by specifying the root of the site as the path location, as follows.

```
<location path="ContosoSite" allowOverride="false">
<trust level="High"
originUrl="http://www.contoso.com"/>
</location>
```

You should take care to specify the <location> directive using the **allowOverride** attribute if you do not want applications to be able to specify their own trust level (this is the case in most shared server installations).

The following table lists the default supported attributes for the <**trust**> element.

| Attribute | Description | Default supported values |
|---|---|---|
| level | Specifies the security zone under which the application will run. | Full, High, Medium, Low, and Minimal. |
| originUrl | Allows an administrator to set the application's URL of origin.<br>This allows the permissions that rely on the notion of host to function correctly | Well-formed HTTP URLs. |

By default, the policies associated with the various security levels are granted the permissions shown in the following table.

| | **Level** | | | | |
|---|---|---|---|---|---|
| Permission | Full | High | Medium | Low | Minimal |

| AspNetHostingPermission | Full | High | Medium | Low | Minimal |
|---|---|---|---|---|---|
| Environment | Un | Un | Read: TEMP, TMP, OS, USERNAME, COMPUTERNAME | | |
| FileIO | Un | Un | Read, Write, Append, PathDiscovery:Application Directory | Read, Path Discovery: Application Directory | |
| IsolatedStorage | Un | Un | AssemblyIsolationByUser, Unrestricted UserQuota | 1 MB quota (can be varied for individual sites), AssemblyIsolationByUser" | |
| Reflection | Un | ReflectionEmit | | | |
| Registry | Un | | | | |
| Security | Un | Execution, Assertion, ControlPrincipal, ControlThread, RemotingConfiguration | Execution, Assertion, ControlPrincipal, ControlThread, RemotingConfiguration | Execution | Execution |
| Socket | Un | Un | | | |
| WebPermission | Un | Un | Connect to origin host (if configured) | | |
| DNS | Un | Un | Un | | |
| Printing | Un | Default Printing | Default Printing | | |
| OleDBPermission | Un | | | | |
| SqlClientPermission | Un | Un | AllowBlankPassword=false | | |
| EventLog | Un | | | | |
| Message Queue | Un | | | | |
| Service Controller | Un | | | | |
| Performance Counters | Un | | | | |
| Directory Service | Un | | | | |

Un = Unrestricted

Blank = No Permission

When a permission level is available but is not explicitly mentioned in security policy, applications running with the **Full** level of trust can use it (since they have the **Full** trust permission set). Applications running with lower trust levels will not be able to use resources protected by nonexplicit permissions unless you specifically alter policy to allow it.

As the table shows, **High** trust applications have read/write permission for files in their application directories, and **Low** trust applications have read-only permission for files in their application directories. Because **FileIO** permission relies on a physical path (for example, `c:\MyAppPath`), ASP.NET uses a tokenized statement in the policy files that is replaced at run time with

relevant path information for the application.

Note that **WebPermission** allows the application to connect to the origin host. This mechanism works from ASP.NET by providing an optional **OriginUrl** attribute on the <**trust**> section for a given application. The **OriginUrl** attribute is used to replace the **$OriginHost$**variable in policy files, as demonstrated in the following code from Web_hightrust.config.

```
<IPermission class="WebPermission" version="1">
<ConnectAccess>
<URI uri="$OriginHost$"/>
</ConnectAccess>
</IPermission>
```

**SocketPermission** takes a host name or a dotted IP string (possibly with wildcard characters) and **WebPermission** takes a regular expression that includes the protocol (for example, `http://backendmachine/.*`). If you want to change this, you can alter the policy files (or create new ones by copying the defaults) with the desired permissions. For example, you can alter the **SocketPermission** section from the ASP.NET named permission set to grant TCP socket connectivity to "backend1" and "backend2" on port 8080, as follows.

```
<IPermission class="SocketPermission" version="1">
<ConnectAccess>
<ENDPOINT host="backend1" transport="Tcp" port="8080"/>
<ENDPOINT host="backend2" transport="Tcp" port="8080"/>
</ConnectAccess>
</IPermission>
```

# Trust Levels and Policy Files for ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Trust levels are associated with policy files using the <securityPolicy> configuration element, which is only valid in a site level (Web.config) configuration file.

```
<system.web>
<securityPolicy>
<trustLevel name="Full" policyFile="internal"/>
<trustLevel name="High" policyFile="web_hightrust.config"/>
<trustLevel name="Medium" policyFile="web_mediumtrust.config"/>
<trustLevel name="Low" policyFile="web_lowtrust.config"/>
<trustLevel name="Minimal" policyFile="web_minimaltrust.config"/>
</securityPolicy>
</system.web>
```

You should take care to specify a <location> directive using the **allowOverride=False** attribute if you do not want applications to be able to specify their own trust level (as is the case in most shared server scenarios). You can remove or add trust levels by adding a new entry to the configuration section specifying the trust level name and the policy file to be used. The default trust files will be installed in the config directory under the location where the aspnet_isapi.dll file is stored. This is the same location as the Machine.config configuration file and the runtime security policy file.

The **Full** trust Level is a special case. Because it is exactly equivalent to having full trust in the local machine zone, the ASP.NET host does not apply any additional policy to these applications. Therefore, it is mapped to an internal handler and the host does not add additional policy to the application domain for **Full** trust applications.

In order to preserve the default settings, ASP.NET will ship two copies of each default file. One copy will be as described above in the configuration section, the second will have a .default.config extension and will not be consumed directly by the system.

**ASP.NET Policy Mechanics**

The application domain policy for the various trust levels consists of a policy level (for example, an instance of the **System.Security.Policy.PolicyLevel** class that is loaded and applied to the application domain as an application domain policy. The policy tree itself is the same for **High**, **Medium**, **Low**, and **Minimal** trust levels (no policy is applied for **Full**), except for the set of granted permissions in the ASP.NET permission set. The policy tree with the permissions granted to the **High** trust level is shown in the table below.

To find the location of the global assembly cache, check for "`CacheLocation`" in the following registry key: HKLM\Software\Microsoft\Fusion. If this key does not exist, the location defaults to `%windir%\assembly`.

The three code groups that use a **UrlMembershipCondition** object rely on paths that are dynamically computed at run time; ASP.NET loads the policy files and replaces the specially delimited arguments (for example, it replaces `$AppDirUrl$` with the proper path before performing the policy resolution).

After computing the application domain policy for a given application (**Full** trust applications are exempt from this step), the policy is applied to the application domain. Application domain policy is intersected with the various other policy levels (Enterprise, Machine, and User) so that it can only further restrict, not expand, the existing policy.

To see how application domain policy is used to restrict granted permissions, consider the fictitious permission sets and policy levels shown in the following table.

| Level | Name | Permissions |
|---|---|---|
| Enterprise | P1 | {A, B, C, D} |
| Machine | P2 | {A, B, C} |
| User | P3 | {A, B, C} |
| Application Domain | P4 | {A, B} |

The simplified application permission (ignoring permission requests) of these policy sets would be the intersection of the permissions granted at the various levels. Thus, the intersection of P1, P2, P3, and P4 is {A, B}.

**Managing Policy Files**

Policy files can be hand-edited. You can use the .NET Framework Configuration Tool or the Code Access Security Policy Tool to administer security policy for the enterprise, machine, or user levels. For more information about using these tools, see the "Administering Security Policy" topic in .NET Framework Help.

# Overview of ASP.NET Deployment

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Deployment is the process of distributing a completed application or component to be installed on other computers. Microsoft ASP.NET is designed to make Web application deployment easy. To that purpose, it includes the following features:

- When a newer version of a Web.config, .aspx, .asmx, or any other ASP.NET file is copied to an existing Web application, ASP.NET detects that the file has been updated. It then loads a new version of the Web application to handle all new requests, while allowing the original instance of the Web application to finish responding to any current requests. When all requests have been satisfied for the original application, it is automatically removed This feature eliminates downtime while Web applications are being updated.

- All ASP.NET application configuration settings are stored in a Web.config file, an XML-based text file stored in the application root directory, for easy deployment of application settings. If you modify these settings when the application is running, ASP.NET automatically detects the changes, reapplies all the settings, and recompiles the application for you. For more information, see Overview of ASP.NET Configuration.

| **Note** |
| --- |
| This does not apply to Internet Information Services (IIS) or COM configuration settings. ASP.NET application settings also can be made in IIS, such as security or process model configuration. Configuration changes made in IIS are not automatically detected and updated by ASP.NET. For more information, see IIS Metabase. |

- No registration is required for local application components. To include any precompiled managed code in your application, you simply need to place it in the local assembly cache. The local assembly cache is the \Bin directory, which is a subdirectory of the application root directory. In addition, any assembly stored in the \Bin directory can be replaced while the application is running.

- All ASP.NET pages are dynamically compiled when they are first requested. The application then uses the compiled class to satisfy requests until a change is made to the page. This allows you to make changes to a page and replace it in a running application.

To deploy application files and local component files, you can simply copy them to the directory structure on the production server. To do this on a network you can use either the XCOPY command-line tool or Microsoft Windows Explorer. To deploy files over the Internet, you can use the FTP tool of your choice. If you are developing your ASP.NET application using Microsoft Visual Studio .NET, use Visual Studio to deploy any Microsoft FrontPage Server Extensions associated with your application. For more information, see Visual Studio .NET Help.

This section describes how to deploy ASP.NET applications and individual application files to a production server. In addition, it explains how to support multiple versions of ASP.NET on a single server and how to ensure that individual applications on that server reference the correct version of ASP.NET. Also, this section describes how to send a redistributable version of the Microsoft .NET Framework to a production server in an application setup program.

This section includes the following information:

- Overview of Deploying ASP.NET Applications: Describes the options for distributing ASP.NET applications and components from a development or test server to a production environment.

- Side-By-Side Support for ASP.NET: Describes how you can run multiple applications that use different versions of the .NET Framework.

- .NET Framework Redistribution: Describes how you can use the redistributable version of the .NET Framework to support applications on a production server.

**Related Information**

- ASP.NET Administration

# Overview of Deploying ASP.NET Applications

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When you are ready to deploy your ASP.NET Web application to a production server, you have many options. Your choice depends on the complexity of your application, whether it uses local-only or shared assemblies, and what tools you used to develop the application.

For ASP.NET applications that do not require modifications to IIS settings or registration of COM objects, you can simply copy the application's files to the directory structure on the production server, using one of the following tools:

- The XCOPY command-line tool can copy files from one computer to another on an intranet or internal network.
- Windows Explorer can copy files from one computer to another on an intranet or internal network.
- You can use the FTP tool of your choice to copy application files from one computer to another over the Internet.
- If your application has been developed using Visual Studio .NET, you can use the **Copy Project** command to copy files from one computer to another on an intranet or internal network. For more information, see Visual Studio .NET Help .

| **Note** |
| --- |
| Front Page Server Extensions must be installed on the target server to use the **Copy Project** command. |

These choices have limitations, however. None performs any IIS configuration that your application might require, and if your application uses COM objects, they will not be registered on the target server. Also, if your application uses shared assemblies stored in the server's global assembly cache, you cannot use any of these methods. For more information, see Deploying Shared Components to the Global Assembly Cache and the "Global Assembly Cache" topic in .NET Framework Help.

| **Note** |
| --- |
| You should deploy components that are used only by your application to the \Bin directory. |

If your application is complex -- for example, if it includes shared assemblies or relies on specific IIS settings -- deploying your application to production servers using Windows Installer 2.0 is recommended. For more information, see the "Deploying Applications and Components" topic in Visual Studio .NET Help.

**In This Section**

Creating an ASP.NET Application Root Directory with IIS

Describes how to use IIS to create a virtual directory or to mark a directory in the C:\Inetpub\Wwwroot directory as an application.

Creating a Directory Structure for an ASP.NET Application

Describes how to create a directory structure for your ASP.NET applications.

Deploying ASP.NET Application Files and Local Components

Describes how to distribute all files associated with your ASP.NET application to a production server.

Deploying Local Application Components

Describes how to compile and distribute component assemblies to your ASP.NET application's \Bin directory.

Deploying Shared Components to the Global Assembly Cache

Describes the global assembly cache and how to distribute shared component assemblies to it.

Deploying HTTP Handlers and HTTP Modules

Describes how to distribute compiled assemblies that contain classes that implement the **IHttpHandler** and **IHttpModule** interfaces. This includes required configuration settings for including new HTTP handlers and HTTP modules in your application.

# Creating an ASP.NET Application Root Directory with IIS

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

All ASP.NET applications use IIS virtual directories as their application root directories. The procedures in this topic show you how to create a virtual directory in IIS.

**Procedures**

**To prepare for this procedure**

1. Create a new directory. This walkthrough uses the directory C:\myWebApp.
2. Next, open IIS Manager and create a virtual directory using one of the following procedures.

**To create a virtual directory on a computer running Windows Server 2003**

1. From the **Start** menu, point to **Administrative Tools**, and then click **Internet Information Services (IIS) Manager**.
2. Expand the **local computer**, and then expand **Web Sites**.
3. Right click **Default Web Site**, point to **New**, and then click **Virtual Directory**.
4. In the Virtual Directory Creation wizard, click **Next**.
5. Enter the name of your application in the **Alias** box, and then click **Next**.
6. Enter the path to the physical directory that you created to prepare for this walkthrough, C:\myWebApp, and then click **Next**.
7. In the **Access Permissions** page, select the access permissions that you want for your application, and then click **Next**.
8. Click **Finish**.

# Creating a Directory Structure for an ASP.NET Application

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

How you organize the directories that your applications contain affects any virtual or relative paths that are included in the files that your application contains. In addition, if your application uses local compiled code, you must include a \Bin directory directly beneath your application root. ASP.NET automatically resolves any references to components stored there.

The procedures in this topic explain which directories to include in the root directory of your ASP.NET Web application. A short discussion of possible directory structures follows, and a sample directory structure with potential file names is included at the end of the topic.

**Procedures**

**To prepare for this walkthrough**

- Create a root directory for your application and mark it as an application, as described in Creating an ASP.NET Application Root Directory with IIS.

**To create a directory structure for your ASP.NET Web application**

1. At the command prompt or in Windows Explorer, open the root directory you created.
2. Create a new directory and name it **Bin**.
3. Create any other directories that your application requires. For example, you could create a directory to contain all the images that your application contains.

The \Bin directory is the default assembly cache for your Web application. Unless your Web application shares DLLs with another application, place all DLLs that your application uses in the \Bin directory to ensure that references to the objects contained in them resolve correctly. These assemblies can include business logic or compiled custom server controls. If your application shares assemblies with other applications, place the shared DLLs in the global assembly cache. For more information, see Deploying Shared Components to the Global Assembly Cache.

| **Note** |
| --- |
| These instructions do not apply to assemblies compiled by Visual Studio .NET when you create an ASP.NET Web application in that environment. For information about how to deploy Web applications developed using Visual Studio .NET, see Visual Studio Help. |

If you want to modify the default configuration for your Web application, create a Web.config file, make the modifications you want, and save it in the root directory. For more information, see Overview of ASP.NET Configuration.

In addition, if you write any application-wide functions, including handlers for Application_Error events, place those in a Global.asax file and save the file in the application root directory. For more information, see the "ASP.NET Applications" topic in .NET Framework Help .

In the following sample directory structure, C:\myWebApp is the application root directory. For the application to function properly, the myWebApp directory must be an IIS virtual directory.

| **Note** |
| --- |
| This simple application includes the \Bin directory and an |Img directory, which stores the image associated with the application. Your directory structure might be more complex than this. |

```
c:\myWebApp

Default.aspx

Menu.ascx

Service.asmx

Web.config
```

```
Global.asax

\Bin

myBizLogic.dll

\Img

myImage.gif
```

# Deploying Local Application Components

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

ASP.NET application components are all of the DLL files that the application uses to perform a variety of tasks. They can include business logic and database access logic for three-tier applications, as well as custom ASP.NET server controls that you have developed. To work for an application, each of the DLLs associated with these components must be deployed to your application's \Bin directory.

**Procedures**

**To deploy ASP.NET application components from the command line**

1. From the **Start** menu, click **Run**.
2. In the **Open** box in the **Run** dialog box, type **cmd**, and then click **OK**.
3. At the command prompt, type the following command:

   **xcopy** < *source path* > < *destination path* >

| **Note** |
| --- |
| In this command, <*source path*> is a placeholder that represents the full path to the compiled component files that you want to deploy, including the drive and directory names. You can omit the file names if you want all files in the directory to be copied. The <*destination path*> placeholder represents the full path to the directory where the files should be placed. |

The following example command copies all compiled components from the `C:\devApp\bin` directory to the `D:\liveApp\bin` directory.

```
xcopy c:\devApp\bin d:\liveApp\bin
```

1. Answer any questions about the files or directory you are copying.

The following example copies a single DLL from a \Bin directory on one drive to a \Bin directory on another.

```
xcopy c:\devApp\bin\myAssembly.dll d:\liveApp\bin\
```

**To compile and deploy an assembly to an application's \Bin directory from the command line**

1. From the **Start** menu, click **Run**.
2. In the **Open** box in the **Run** dialog box, type **cmd**, and then click **OK**.
3. Use the **cd** command to navigate to the directory that you want. This command uses relative paths to navigate through the directories and drives on a computer or network.

   The root location of any path that this command uses is the local drive, often C:\. The examples shown in this procedure assume that you have navigated to the directory where the source files are located. The following use of the **cd** command moves the command prompt from a directory two directories beneath the local drive root to a myApp directory directly beneath the root.

   ```
   cd..\..\myApp
   ```

4. At the command prompt, type the following command:

   `csc /t:library /out:` < *destination path* > < *source path* >

   `vbc /t:library /out:` < *destination path* > < *source path* >

| **Note** |
| --- |

In this command, <*destination path*> is a placeholder that represents the path to the .dll file that is compiled by this command, and <*source path*> represents the path to the source file. Each <*destination path*> should include \Bin and the full name you assign to the .dll file. Both <*destination path*> and <*source path*> are relative paths.

The following example compiles `HelloObj.dll` from the command line from a `HelloObj.cs` or `HelloObj.vb` source file. The destination path is a relative path from the directory where the command line currently is to the \Bin directory of the ASP.NET application where the .dll is used. The source file is in the same directory as the command line.

```
csc /t:library /out:..\..\..\..\bin\HelloObj.dll HelloObj.cs
```

```
vbc /t:library /out:..\..\..\..\bin\HelloObjVB.dll HelloObj.vb
```

# Deploying ASP.NET Application Files and Local Components

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

To deploy an ASP.NET application, simply copy the application files you have created from your development computer to the production Web server that will host your application. You can use the XCOPY command-line tool or any FTP application to copy the files from one location to another.

To deploy assemblies that you want to share across Web applications, such as assemblies that contain custom ASP.NET server controls, you must deploy them to the global assembly cache. For more information, see the "Global Assembly Cache" topic in .NET Framework Help.

**Procedures**

**To deploy ASP.NET application files from the command line**

1. From the **Start** menu, click **Run**.
2. In the **Open** box in the **Run** dialog box, type **cmd**, and then click **OK**.
3. At the command prompt, type the following command:

   **xcopy** < *source path* > < *destination path* >

| **Note** |
| --- |
| In this command, <*source path*> is a placeholder that represents the full path to the source files you want to copy, including the drive, the directory, and the file names. You can omit the file names if you want all files in the directory to be copied. The <*destination path*> placeholder represents the full path to the directory where the copied files should be placed. |

The following example command copies all files from the `C:\myWebApp` directory to the `D:\liveApp` directory.

```
xcopy c:\myWebApp d:\liveApp
```

1. Answer any questions about the files or directory you are copying.

You can use this procedure when you want to update a DLL stored in your application's \Bin directory, or if you want to update any of your other application files. The following example copies a single DLL from a \Bin directory on one drive to a \Bin directory on another.

```
xcopy c:\devApp\bin\myAssembly.dll d:\liveApp\bin\
```

You can also use this command to update files in your application once you have deployed it. Although you can copy an entire directory at once, individual files must be copied one at a time. You can exclude subdirectories, files with a specific file name extension, or specific file names from being copied by using the XCOPY **/exclude** option. For more information about how to use the XCOPY tool, open Help for your operating system and search for XCOPY.

| **Note** |
| --- |
| You must use physical directory names with the XCOPY tool. You cannot use virtual directory names. |

# Deploying Shared Components to the Global Assembly Cache

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you plan to share a component between two or more applications on your Web server, you must deploy the component to the server's computer-wide code cache, called the global assembly cache. Each computer on which the common language runtime is installed has a global assembly cache. The global assembly cache stores assemblies that are shared by several applications on the computer. For more information, see the "Global Assembly Cache" topic in .NET Framework Help.

You should share assemblies by installing them into the global assembly cache only when you need to. As a general guideline, keep assembly dependencies private and locate assemblies in the application directory unless sharing an assembly is explicitly required. Assemblies do not have to be in the global assembly cache to be accessible to COM interop or unmanaged code.

| **Note** |
| --- |
| There are scenarios in which you should not install an assembly into the global assembly cache. If you place one of the assemblies that make up an application in the global assembly cache, you can no longer replicate or install the application by using the XCOPY tool to copy the application directory. You must move the assembly in the global assembly cache as well. |

There are two ways to install an assembly into the global assembly cache:

- Using Microsoft Windows Installer 2.0.

  This is the recommended and most common way to add assemblies to the global assembly cache. The installer provides reference counting of assemblies in the global assembly cache, plus other benefits. The only time you should not use the installer is when you are installing to a development or test server.

- Using the Global Assembly Cache tool (Gacutil.exe).

  You can use Gacutil.exe to add strong-named assemblies to the global assembly cache and to view the contents of the global assembly cache.

| **Note** |
| --- |
| Gacutil.exe is only for development purposes and should not be used to install production assemblies into the global assembly cache. |

For more information, see the "Global Assembly Cache Tool (Gacutil.exe)" topic in .NET Framework Help.

**Procedures**

**To install a strong-named assembly into the global assembly cache**

1. From the **Start** menu, click **Run**, type **cmd**, and then click **OK**.
2. At the command prompt, type the following command:

   **gacutil -i** < *assemblyname* >

| **Note** |
| --- |
| In this command, *assembly name* is the name of the assembly to install in the global assembly cache. |

The following example installs an assembly with the file name Hello.dll into the global assembly cache.

```
gacutil -i Hello.dll
```

The .NET Framework SDK also provides a Windows shell extension called the Assembly Cache Viewer (Shfusion.dll), which you can use to drag and drop assemblies into the global assembly cache.

# Deploying HTTP Handlers and HTTP Modules

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

ASP.NET provides **IHttpHandler** and **IHttpModule** interfaces that allow you to use APIs that are as powerful as the Internet Server API (ISAPI) programming interfaces available with IIS but with a simpler programming model. HTTP handler objects are functionally similar to IIS ISAPI extensions, and HTTP module objects are functionally similar to IIS ISAPI filters.

ASP.NET maps HTTP requests to HTTP handlers. Each HTTP handler enables processing of individual HTTP URLs or groups of URL extensions within an application. HTTP handlers have the same functionality as ISAPI extensions with a much simpler programming model.

An HTTP module is an assembly that handles events. ASP.NET includes a set of HTTP modules that can be used by your application. For example, the **SessionStateModule** is provided by ASP.NET to supply session-state services to an application. You can also create custom HTTP modules to respond to either ASP.NET events or user events.

**Procedures**

**To compile, deploy, and register HTTP handlers**

1. Compile and deploy the .NET class for the HTTP handler in the \Bin directory under the application's virtual root. For more information, see Deploying Local Application Components.

2. Register the HTTP handler, synchronous or asynchronous, in the application's Web.config configuration file. The following example maps all HTTP requests to the classes **MyHandler.New** and **MyHandler.Fin** in the assembly **MyHandler** that is in the file **MyHandler.dll**.

```
<configuration>

<system.web>

<httpHandlers>

<add verb="*" path="MyHandler.New"

type="MyHandler.New, MyHandlerAssembly" />

<add verb="*" path="*.myNewFileExtension"

type="MyHandler.Fin, MyHandlerAssembly" />

</httpHandlers>

<system.web>

</configuration>
```

3. The <**add**> elements within the <**httpHandlers**> configuration section have three attributes: **path**, **type**, and **verb**. For more information, see <add> Element for <httpHandlers>.

4. Register the HTTP handler extension as a script map in IIS. For more information, see Setting Application Mappings in IIS 6.0.

**To compile, register, and deploy HTTP modules**

1. Compile and deploy the .NET class for the HTTP module in the \Bin directory under the application's virtual root. For more information, see Deploying Local Application Components.

2. Register the HTTP module in the application's Web.config configuration file. The following example registers an **OutputCache** module to an application.

```
<configuration>

<system.web>

<httpModules>
```

```
<add name="OutputCache"

type="System.Web.Caching.OutputCacheModule, System.Web,

Version=1.0.2800.0, Culture=neutral,

PublicKeyToken=b03f5f7f11d50a3a"/>

</httpModules>

<system.web>

</configuration>
```

For more information about working with and registering HTTP handlers and HTTP modules, see information about HTTP handlers or HTTP modules in the MSDN Library.

# Side-By-Side Support for ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Traditionally, when a component or application is updated on a computer, the older version is removed and replaced with the newer version. If the new version is not compatible with the previous version, this usually breaks other applications that use the component or application. The .NET Framework provides support for side-by-side execution, which allows multiple versions of an assembly or application to be installed on the same computer, at the same time. Since multiple versions can be installed simultaneously, managed applications can select which version to use without affecting other applications that use a different version.

In ASP.NET, applications are said to be running side by side when they are installed on the same computer but use different versions of the .NET Framework. The following topics describe side-by-side support in ASP.NET and how to configure ASP.NET applications for side-by-side execution.

**In This Section**

Overview of ASP.NET Side-By-Side Support

Describes side-by-side support in ASP.NET and how it relates to side-by-side support in the .NET Framework.

Managing Multiple ASP.NET Versions

Describes how to upgrade, uninstall, and redistribute multiple versions of ASP.NET.

Configuring an ASP.NET Application for an ASP.NET Version

Describes how to configure an ASP.NET application to use a specific version of ASP.NET when multiple versions of the .NET Framework are installed on a computer.

Assembly Unification in the .NET Framework

Describes how an ASP.NET application determines which version of the .NET Framework to use if the application and the components it uses were built on different versions of the runtime.

**Related Sections**

Overview of ASP.NET Deployment

Describes how to distribute ASP.NET applications and components from development and test servers to production servers.

# Overview of ASP.NET Side-By-Side Support

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The .NET Framework allows you to install multiple versions of the runtime on the same computer. By default, when the .NET Framework is installed on a computer with an existing installation, all ASP.NET applications are automatically updated to use this version of the .NET Framework. The only exceptions are applications that are bound to an incompatible version of the runtime or to a later version of the runtime. Although later versions of the .NET Framework are designed to be backwards compatible, you might want to configure an ASP.NET application to use an earlier version.

**Script Maps for ASP.NET Applications**

When multiple versions of the .NET Framework are installed on the same computer, each installation contains an associated version of the ASP.NET ISAPI. An ASP.NET application uses the ASP.NET ISAPI to determine which version of the .NET Framework to use for the application. An ASP.NET application can be configured to use any of the installed ASP.NET ISAPI versions. To specify the ASP.NET ISAPI version to use for an ASP.NET application, a script map is registered in Internet Information Services (IIS) for the application.

A script map associates a file name extension and HTTP verb with the appropriate ISAPI for script handling. For example, when IIS receives a request for an .aspx file, the script map for the application directs IIS to forward the requested file to the appropriate version of the ASP.NET ISAPI for processing. The script map for each ASP.NET application is normally set in the Internet Information Services management console and can be applied directly to an application, or inherited from a parent application. By default, when the .NET Framework is installed, the script maps for all existing ASP.NET applications on the computer are automatically updated to use the ASP.NET ISAPI version associated with the installation, unless the application uses a later or an incompatible version.

To make it easier to reconfigure the script map for an ASP.NET application, each installation of the .NET Framework comes with an associated version of the ASP.NET IIS Registration tool (Aspnet_regiis.exe). By default, this tool is installed in the following directory:

**%systemroot%**\Microsoft.NET\Framework*versionNumber*

Administrators can use this tool to remap an ASP.NET application to the ASP.NET ISAPI version associated with the tool.

| **Note** |
| --- |
| Because Aspnet_regiis.exe is associated with a specific version of the .NET Framework, administrators must use the appropriate version of Aspnet_regiis.exe to reconfigure the script map for an ASP.NET application. Aspnet_regiis.exe only reconfigures the script map of an ASP.NET application to the ASP.NET ISAPI version associated with the tool. |

The tool can also be used to display the status of all installed versions of ASP.NET, register the associated version of ASP.NET, create client-script directories, and perform other configuration operations.

For more information about script maps and IIS configuration, see IIS 6.0 Operations Guide. For more information about updating script maps for an ASP.NET application, see ASP.NET IIS Registration Tool (Aspnet_regiis.exe).

**ASP.NET Performance Counters**

Performance counters allow you to monitor the operation of ASP.NET from the Performance console. Each installation of ASP.NET installs performance counters that apply to each individual version of ASP.NET, as well as to all installed versions.

Each version of ASP.NET installs a separate set of performance counter objects to monitor the ASP.NET system and ASP.NET applications. These objects use the naming conventions "ASP.NET v.X.X.XXXX.X" and "ASP.NET Apps v.X.X.XXXX.X", respectively, where v.X.X.XXXX.X denotes the ASP.NET version and build numbers.

In addition, ASP.NET also installs ASP.NET system and ASP.NET applications performance counters that apply to all installed versions of ASP.NET. Since these counters are shared between all versions of ASP.NET, they always correspond to the latest installed version on the machine. If the latest version of ASP.NET is uninstalled, these counters are automatically re-associated with the latest remaining version of ASP.NET.

**ASP.NET State Service**

ASP.NET state service is used to manage session state on a computer. All compatible versions of ASP.NET that are installed on the same computer share the same state service. The state service version that is used is always the one that is installed with the latest version of ASP.NET. This version is registered under aspnet_state. Therefore, when this version of ASP.NET is

uninstalled, the latest remaining version on the computer is then registered and used in its place.

**ASP.NET SQL State Server**
ASP.NET SQL state server is used to manage session state in SQL on a computer. All compatible versions of ASP.NET that are installed on the same computer share the same SQL state server. The SQL state server version that is used is always the one that is installed with the latest version of ASP.NET. When this version of ASP.NET is uninstalled, the latest remaining version on the computer is then registered and used in its place.

**ASPNET User Account and Filter**
All installed versions of ASP.NET share the same ASPNET user account (for the worker process) and Aspnet_filter.dll (for storing and removing the session ID from cookie-less session-state requests). The ASPNET user account and Aspnet_filter.dll always corresponds to the latest installed version of ASP.NET. When this version of ASP.NET is uninstalled from a computer, the latest remaining version on the computer is then registered and used in its place.

# Managing Multiple ASP.NET Versions

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The .NET Framework allows you to install multiple versions of the runtime on the same computer. This allows an ASP.NET application to use the version it needs to run without affecting other applications. The following sections describe how to install, uninstall, and redistribute multiple versions of ASP.NET on the same computer.

**Installing Multiple Versions of ASP.NET**

To add a version of ASP.NET to a computer, run the .NET Framework redistributable package setup program (Dotnetfx.exe) for the version you want to install. By default, all existing ASP.NET applications are automatically reconfigured during installation to use the installing version of the runtime if the following conditions are met:

- The installing .NET Framework version is later than the version that is currently mapped to the application.
- The installing .NET Framework version is compatible with the version mapped to the application. In general, the version number determines compatibility. Minor revision and build number changes are usually compatible, whereas major revision numbers are not.

| **Caution** |
| --- |
| Although ASP.NET applications are automatically updated to use the installing version of ASP.NET if the preceding conditions are met, custom configuration settings in the current Machine.config file are not transferred to the installing Machine.config file. If your application uses custom configuration settings, be sure to either manually update the new Machine.config file or use the ASP.NET IIS Registration tool (Aspnet_regiis.exe) to remap the application to the previous version of ASP.NET. For more information about remapping an application, see Configuring an ASP.NET Application for an ASP.NET Version. |

To prevent the automatic remapping of all existing applications to the installing version of the .NET Framework, use the **/noaspupgrade** command-line option with the Dotnetfx.exe setup program. The following shows the entire command line:

**Dotnetfx.exe /c:"install /noaspupgrade"**

For more information about the .NET Framework redistributable package, see Redistributing the .NET Framework 1.1 on MSDN.

**Web Service Extensions in IIS 6.0**

If you're using Internet Information Services 6.0, you might need to enable ASP.NET in the Internet Information Services management console after installing ASP.NET. IIS 6.0 introduces a new Web Service Extensions folder, which allows an administrator to selectively enable and disable functionality in IIS. When ASP.NET version 1.1 or later is installed on a computer that uses IIS 6.0, the installation script creates a metabase key for that version of ASP.NET. This metabase key allows ASP.NET to appear in the console as a configurable component. A separate key is created for each installed version of ASP.NET, allowing each version to be separately configurable in the console. When a version of ASP.NET is uninstalled from a computer, the respective key is also removed.

| **Note** |
| --- |
| When ASP.NET is installed through the Add or Remove Programs item in Control Panel, or the Configure Your Server wizard, ASP.NET is enabled in the Web Service Extensions by default. However, if it is installed through Microsoft Visual Studio .NET, Windows Update, or the .NET Framework redistributable package (Dotnetfx.exe), ASP.NET is disabled by default. |

**To manage items in the Web Service Extensions folder**

1. Open IIS Manager, expand **local computer**, and then click the **Web Service Extensions** folder.
2. Click the **Extended** tab, and then click the Web Service Extension item you want to configure.
3. Click the **Allow** or **Prohibit** button to enable or disable the item.
4. Click the **Add a new Web service extension** link to add a new item to the console.

**Uninstalling a Version of ASP.NET**

If you have multiple versions of ASP.NET installed on a machine, you can uninstall a version on an individual basis. Uninstalling ASP.NET is usually accomplished by uninstalling the .NET Framework through the **Add or Remove Programs** Control Panel item. During the uninstall process, the setup program calls the ASP.NET IIS Registration tool (Aspnet_regiis.exe) with the **-u** option (uninstall flag).

| **Note** |
| --- |
| If you just want to uninstall a version of ASP.NET without uninstalling the associated .NET Framework, you can use Aspnet_regiis.exe directly. Each installation of the .NET Framework contains an associated version of the tool. To uninstall only ASP.NET, use the **-u** option of the tool version associated with the ASP.NET version you want to uninstall. For more information, see the ASP.NET IIS Registration Tool. |

The **-u** option of Aspnet_regiis.exe performs the following actions:

- All ASP.NET applications currently mapped to the ASP.NET version being uninstalled are remapped to the next-latest compatible version on the computer. If no compatible version exists, the script map for the application is removed completely.

  | **Caution** |
  | --- |
  | Removing the script maps will cause IIS to serve ASP.NET pages as literal text. This could potentially expose source code to the client. |

- The ASP.NET state service is shared across all compatible versions of ASP.NET and is always mapped to the latest installed version of ASP.NET. If the ASP.NET version you are uninstalling is currently the latest version, the next-highest compatible version on the computer is then registered to replace it. If no compatible version exists, the ASP.NET State Service is uninstalled.

- Performance objects and their associated performance counters specific to the version being uninstalled are removed. The generic performance objects and counters that apply to all installed versions of ASP.NET, ASP.NET and ASP.NET Applications, are directed to the latest installed version remaining on the computer.

- The ASPNET user account is shared across all compatible versions of ASP.NET. If no additional ASP.NET installations remain on the computer, the ASPNET user account and the associated access control lists are removed.

For information about other effects of installing multiple versions of ASP.NET, see "Overview of ASP.NET Side-By-Side Support" on MSDN.

**Third-Party Redistribution of the .NET Framework**

Third-party applications can package and install the .NET Framework as part of their setup under a special redistribution license. This allows an application to install the specific version of the .NET Framework it needs to run. The .NET Framework redistributable package (Dotnetfx.exe) is provided for an application to deploy with the runtime. The default installation script of Dotnetfx.exe might not suit the needs of your application. It is up to the third-party application developer to use the options described below when installing the .NET Framework as part of an application's setup.

For more information about the .NET Framework redistributable package, see "Redistributing the .NET Framework 1.1" on MSDN. For more information about the EULA of the redistributable package, see the Where to Obtain the **.NET Framework Redistributable Package** topic in .NET Framework Help.

**Disabling Automatic Script Map Updates**

By default, when the .NET Framework is installed on a computer with an existing installation, all ASP.NET applications are automatically updated to use this version of the .NET Framework, unless the applications are bound to an incompatible version of the runtime or to a later version of the runtime. Usually, only a system administrator performs this type of installation. When the .NET Framework is installed as part of an application's setup, it should not force other applications on the computer to use that version of the runtime.

As part of the setup script, Dotnetfx.exe normally calls the ASP.NET IIS Registration tool (Aspnet_regiis.exe) with the **-i** option to install ASP.NET. This option attempts to update the script maps of all existing ASP.NET applications. To prevent the installation from automatically updating other applications on the computer, the **/noaspnetupgrade** option is provided as part of Dotnetfx.exe. This option causes the setup program to use the **-ir** option of Aspnet_regiis.exe instead, which skips the automatic

script map updates, default documentation, and MIME swapping steps. The following shows the entire command line.

**Dotnetfx.exe /c:"install /noaspupgrade"**

**Manually Updating Script Maps**

Sometimes, it is necessary to manually set up the script maps for an application. If the application needs its own virtual directory that targets the installing version of the .NET Framework, make sure the application's setup program also explicitly calls Aspnet_regiis.exe with the **-s** or **-sn** option to set up the script maps.

The following shows a sample command line that updates the script maps for an application called `SampleApp1`.

```
Aspnet_regiis.exe -s W3SVC/1/ROOT/SampleApp1.
```

For more information, see the ASP.NET IIS Registration Tool.

# Configuring an ASP.NET Application for an ASP.NET Version

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

By default, when the .NET Framework is installed on a computer with an existing installation, all ASP.NET applications are automatically updated to use this version of the .NET Framework. The only exceptions are applications that are bound to an incompatible version of the runtime or to a later version of the runtime. Although later versions of the .NET Framework are designed to be backward compatible, you might want to configure an ASP.NET application to use an earlier version. The following sections describe the process to configure an ASP.NET application to target a specific version of the .NET Framework.

**Viewing the Script Map for an ASP.NET Application**

When managing a computer with multiple versions of the .NET Framework installed, it is often useful to view the script map for an ASP.NET application to determine which version is used by the application. You can view the script map for an ASP.NET application using the Internet Information Services management console.

### To view the script map for an ASP.NET application

1. Open IIS Manager, expand the local computer by clicking the plus sign, and navigate to the folder that contains the ASP.NET application.
2. Right-click the folder and click **Properties**. The application's **Properties** dialog box appears.
3. On the **Directory** tab, click the **Configuration** button. The **Application Configuration** dialog box appears.
4. On the **Mappings** tab, select an ASP.NET application extension, such as .asmx or .aspx.

The Executable Path column of the dialog box will list the path to the ASP.NET ISAPI version used by the application. By default, the ASP.NET ISAPI is installed in the following location:

*systemroot*\Microsoft.NET\Framework*versionNumber*

The version number shown in the path indicates the version number of the ASP.NET ISAPI used by the application. The ASP.NET ISAPI version determines which version of the runtime is used by the application.

**Updating Script Maps Using Aspnet_regiis.exe**

To make it easier to reconfigure the script map for an ASP.NET application, each installation of the .NET Framework comes with an associated version of the ASP.NET IIS Registration tool (Aspnet_regiis.exe). Administrators can use this tool to remap an ASP.NET application to the ASP.NET ISAPI version associated with the tool.

| **Note** |
| --- |
| Because Aspnet_regiis.exe is linked to a specific version of the .NET Framework, administrators must use the appropriate version of Aspnet_regiis.exe to reconfigure the script map for an ASP.NET application. Aspnet_regiis.exe only reconfigures the script map of an ASP.NET application to the ASP.NET ISAPI version associated with the tool. |

The tool can also be used to display the status of all installed versions of ASP.NET, register the associated version of ASP.NET, create client-script directories, and perform other configuration operations.

### To use Aspnet_regiis.exe to update a script map for an ASP.NET application

1. Open a command window. (Click **Start**, click **Run**, type **cmd**, and then click **OK**.)
2. Navigate to the directory of the Aspnet_regiis.exe version you want to use. Remember that each version of the .NET Framework comes with its own version. The file is usually located in the following directory:

   *systemroot*\Microsoft.NET\Framework*versionNumber*

3. Use the **-s** or **-sn** option of Aspnet_regiis.exe along with the path to the application to setup the script maps. The following shows a sample command line that updates the script maps for an application called `SampleApp1`.

   ```
   Aspnet_regiis.exe -s W3SVC/1/ROOT/SampleApp1
   ```

**Application Pooling in IIS 6.0**

IIS versions earlier than 6.0 use the ASP.NET process model (Aspnet_wp.exe). Under the ASP.NET process model, each unique application version automatically runs in a separate process at run time. All applications that target the same version of the runtime share the same process (or processes in Web garden mode). However, IIS 6.0 uses the IIS 6.0 process model (W3wp.exe) and introduces a new isolation feature called application pooling. Application pooling allows applications to run together in one or more processes, as long as they share the same pool designation. Applications that are assigned different application pools never run in the same process.

When multiple versions of the .NET Framework are installed on a computer that uses IIS 6.0, you might encounter the following error message in the Application Event log.

It is not possible to run different versions of ASP.NET in the same IIS process. Please use the IIS Administration Tool to reconfigure your server to run the application in a separate process.

This error occurs when more than one version of ASP.NET is configured to run in the same process. Different versions of the .NET Framework and runtime cannot coexist side-by-side in the same process. Therefore, an ASP.NET application that uses a particular version of the runtime must not share a process with an application that uses a different version. This error commonly occurs when two or more applications are mapped to different versions of ASP.NET, but share the same application pool.

To use application pooling, first make sure IIS 5.0 isolation mode is disabled. Next, navigate to the desired application in the Internet Information Services management console and assign it an application pool. If you want to isolate your application from the existing application pools, create a new pool designation.

| **Note** |
| --- |
| The process isolation for each application is configured manually. |

**To disable IIS 5.0 isolation mode in IIS 6.0**

1. Open IIS Manager and expand **local computer**.
2. Right-click the **Web Sites** folder and click **Properties**.
3. On the **Service** tab, clear the **Run Web service in IIS 5.0 isolation mode** check box.

**To assign a pool designation to an ASP.NET application in IIS 6.0**

1. Open IIS Manager and expand **local computer**, and then navigate to the folder that contains the ASP.NET application.
2. Right-click the folder and click **Properties**. The application's **Properties** dialog box appears.
3. On the **Directory** tab, select the desired pool designation from the **Application Pool** drop down list.

**To create a pool designation in IIS 6.0**

1. Open IIS Manager and expand **local computer**.
2. Right-click the **Application Pools** folder, point to **New**, and then click **Application Pool**. The **Add New Application Pool** dialog box appears.
3. Enter the new pool designation in the **Application** pool text box, and then click **OK**.

# Assembly Unification in the .NET Framework

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In side-by-side execution, it is possible for an application to be composed of components that are built using different versions of the .NET Framework. This can create conflicts between the dependencies of the components. For example, suppose component A is built using the .NET Framework version 1.0 and needs to use version 1.0 of the System.Data assembly. Component B is built using the .NET Framework version 1.1 and needs to use version 1.1 of the System.Data assembly. If the assembly versions are incompatible, but are loaded at the same time, this could lead to unintended type casting exceptions, or even worse problems.

**How an Application Determines Which .NET Framework Version to Use**

To solve this problem, when an application uses components that are built on different versions of the .NET Framework, the runtime version that is associated with an application determines which version of the .NET Framework assemblies are used by the application and all its components. In the previous example, if the application is associated with version 1.1 of the .NET Framework, version 1.1 of the System.Data assembly is then loaded and shared across all components used by the application. The reference from component A to version 1.0 of the System.Data assembly is promoted at run time to reference version 1.1.

You can override this behavior by adding <**bindingRedirect**> elements to the Machine.config or Web.config files. This allows an application to use an updated assembly version that was designed to replace an existing assembly for certain types of applications. For example, if an updated version of System.Web.Service.dll is released in the future that supports SOAP version 1.2, you might want your application to use that version, instead of the version that was installed with the runtime originally.

| **Note** |
| --- |
| For more information, see the <bindingRedirect> topic in .NET Framework Help. |

This behavior can also be overridden in the ASP.NET host configuration file (Aspnet.config). ASP.NET uses this file to ensure that the version of System.Web.dll and System.Web.RegularExpressions.dll always matches the runtime version associated with an application, regardless of any overrides in the Web.config file.

Sometimes you might want to use a component that was built using a later version of ASP.NET in an application built with an earlier version. Remember that the ASPNET ISAPI version associated with an application always determines the version of the runtime used for an application. If the application is configured to use the earlier version of the runtime, the component will be automatically redirected at runtime to use that version, as well. When using a component built with a later version of the .NET Framework in an application built on an earlier version, consider the following:

- Make sure the component does not use any features or depend on any behaviors specific to the later version of the .NET Framework. These features might not be available in the earlier version of the runtime.

- ASP.NET uses script maps in IIS to bind an application to a version of the runtime. <**supportedRuntime**> and <**requiredRuntime**> configuration elements are not applicable to ASP.NET applications.

Alternatively, if the runtime version used to build the component is installed on the computer, you could also reconfigure the application to use the later runtime version. Since later versions of the .NET Framework are designed to be backward compatible, the application should work without any modifications. For information about configuring an ASP.NET application to use a specific version of the runtime, see Configuring an ASP.NET Application for an ASP.NET Version.

# .NET Framework Redistribution

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When you deploy an ASP.NET application to a production server, you also need to install the .NET Framework redistributable package (Dotnetfx.exe) to support the ASP.NET server controls and other portions of the application that run on the server. However, your application can use one version of the redistributable package while other applications on the server uses another.

When you include the .NET Framework redistributable package with an application that you are installing to a production server, ASP.NET is automatically updated. If the server hosts other applications that use a different version of ASP.NET, you need to incorporate the following command in your application's setup program:

**Dotnetfx.exe /c:"install /NOASPUPGRADE"**

Once the application is installed, you must create a script map between the application's virtual directory to the version of the .NET Framework that you installed. For more information about how to create custom script maps, see Setting Application Mappings in IIS 6.0.

For more information about the Microsoft .NET Framework redistributable package, see information in Dotnetfx.exe in the MSDN Library.

# Overview of ASP.NET Process Isolation

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When Microsoft ASP.NET is enabled on a server running Microsoft Windows Server-TM- 2003, by default it runs in the Internet Information Services (IIS) 6.0 worker process isolation mode. Using worker process isolation mode enables application pooling, recycling, and various application health detection. However, if your application has compatibility problems in this mode, you can switch to run IIS 6.0 to IIS 5.0 isolation mode.

If you install ASP.NET and the Microsoft .NET Framework on a server running Windows XP Professional or Windows 2000 Server, ASP.NET automatically provides its own process model to run in.

This section outlines the process model, and discusses how to use the ASP.NET process model.

This section includes the following information:

- Process Model Modes: Describes the differences between the IIS 6.0 worker process isolation process model and the ASP.NET process model.
- Using the ASP.NET Process Model: Describes how to enable and configure the ASP.NET process model in IIS 6.0.

**Related Information**

- ASP.NET Administration

# Process Model Modes

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When you install ASP.NET on a server running Windows Server 2003, ASP.NET applications are executed by IIS 6.0. IIS 6.0 runs in one of two distinct modes of operation, called application isolation modes. These are worker process isolation mode, the default, and IIS 5.0 isolation mode. IIS functions differently in the two isolation modes.

When ASP.NET runs in the worker process isolation mode, it runs in the W3wp.exe worker process and picks up the IIS 6.0 application pool process properties for its operation.

When running on IIS 6.0 in worker process isolation mode, ASP.NET uses the IIS 6.0 process model settings. For information about how to migrate ASP.NET process model configuration settings to IIS 6.0 application pool settings, see "Configuring IIS 6.0 to Host ASP.NET Applications" in Migrating IIS Web Sites to IIS 6.0.

When you configure IIS 6.0 to run in IIS 5.0 isolation mode, ASP.NET runs in its own process model, Aspnet_wp.exe, and uses its own configuration settings. These settings are stored in the computer-wide Machine.config configuration file.

In almost all situations, ASP.NET applications running on Windows Server 2003 should be run in worker process isolation mode. If your application uses read raw data filters, you should use IIS 5.0 isolation mode instead.

When installed on servers running Windows XP or Windows 2000 Server, ASP.NET runs in IIS 5.1 or IIS 5.0, respectively, and runs in the Aspnet_wp.exe process by default. The ASP.NET process model provides process recycling, health detection, and support for affinities between worker processes and particular CPUs on a server with multiple CPUs. For more information, see Using the ASP.NET Process Model.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**Procedures**

**To configure IIS 6.0 for IIS 5.0 isolation mode**

1. In IIS Manager, double-click the local computer, right-click **Web Sites**, and then click **Properties**.
2. On the **Service** tab, select the **Run WWW service in IIS 5.0 isolation mode** check box, and then click **OK**. The **Internet Services Manager** dialog box appears.
3. To start the Web service, click **Yes.**

| **Note** |
| --- |
| When you have completed this procedure, you must restart the Web service, which will temporarily interrupt the service. |

- Using the ASP.NET Process Model

# Using the ASP.NET Process Model

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

One of the most important requirements for .NET Framework applications is reliability. An architecture in which applications run inside the server process (in IIS, Inetinfo.exe) does not produce a solid foundation for building reliable applications that can continue to run over a long period of time. Too many resources are shared on the process level, and it is too easy for an error to bring down the entire server process.

To solve this problem, ASP.NET provides an out-of-process execution model, Aspnet_wp.exe, which helps protect the server process from user code. It also enables you to apply heuristics to the lifetime of the process to improve the availability of your Web applications. Using asynchronous interprocess communication helps provide a balance between performance, scalability, and reliability.

Process model settings are exposed in the root configuration file for the computer, Machine.config. The configuration section is named <processModel> Element and is shown in the following example. On computers running Windows 2000 and Windows XP, the process model is enabled by default (`enable="true"`).

**Note**

On computers running Windows Server 2003, ASP.NET runs in IIS 6.0 worker process isolation mode by default. If your application is designed with specific ASP.NET process model settings, to be able to use them on Windows Server 2003 you must configure the server to run in IIS 5.0 isolation mode. For more information, see Configuring Isolation Modes.

```
<processModel
enable="true"
timeout="Infinite"
idleTimeout="Infinite"
shutdownTimeout="0:00:05"
requestLimit="Infinite"
requestQueueLimit="5000"
restartQueueLimit="10"
memoryLimit="60"
webGarden="false"
cpuMask="0xffffffff"
userName="machine"
password="AutoGenerate"
logLevel="Errors"
clientConnectedCheck="0:00:05"
comAuthenticationLevel="Connect"
comImpersonationLevel="Impersonate"
responseRestartDeadlockInterval="00:09:00"
responseDeadlockInterval="00:03:00"
maxWorkerThreads="20"
maxIoThreads="20"
/>
```

Most of configuration settings in this example help control when a new worker process begins to serve requests (gracefully taking the place of an old worker process). The **userName** and **password** attributes define the account under which the ASP.NET worker process runs. These default to the values **machine** and **autogenerate**, respectively. These values tell ASP.NET to use the built-in ASPNET account and to use a cryptographically strong random password stored in the Local Security Authority (LSA) for that account.

**Note**

| |
|---|
| On computers running Windows Server 2003, by default ASP.NET runs as part of the IIS 6.0 (W3wp.exe) process using the default identity NETWORK SERVICE. If IIS5 isolation mode is configured on a computer running Windows Server 2003, the ASP.NET worker process runs in the ASPNET account. |

If you want a more privileged process, you can set the **userName** attribute to **System**, which causes the ASP.NET worker process to run with the same identity as the Inetinfo.exe process. This process runs by default as the System identity. When so configured, the ASP.NET worker process will have the right to access nearly all resources on the local server. In Windows 2000, Windows XP, and Windows Server 2003 family systems, the System account also has network credentials and can access network resources as the machine account.

| **Caution** |
|---|
| Caution |

Changing the **userName** attribute to **System** enables access to and the ability to alter nearly all the resources on the computer, creating a significant security risk to your server.

The following example changes the **userName** attribute in the <**processModel**> section of the Machine.config file to run the process as System.

```
<processModel userName="system" password="autogenerate" />
```

The process model supports two types of recycling: reactive and proactive.

**Reactive Process Recycling**
Reactive process recycling occurs when a process is not functioning properly or is unable to serve requests. The process typically displays detectable symptoms, such as deadlocks, access violations, memory leaks, and so on, in order to trigger a process recycle. You can help control the conditions that cause a process restart by using the **requestQueueLimit**, **memoryLimit**, and **shutdownTimeout** configuration attributes. For more information about these attributes, see the <processModel> Element configuration section.

**Proactive Process Recycling**
Proactive process recycling restarts the worker process periodically even if the process is healthy. This can be a useful way to prevent denials of service due to conditions the process model is unable to detect. A process can be restarted after a specific number of requests or after a time-out period has elapsed. You can enable proactive process recycling using the **timeout**, **idleTimeout**, and **requestLimit** configuration attributes. For more information, see the <processModel> Element configuration section.

**Logging Process Model Events**
The process model can write events to the Windows event log when process cycling occurs. This is controlled by the **logLevel** configuration attribute. For more information, see the <processModel> Element configuration section.

When a cycling event occurs, if logging is enabled for that event, the following entries are written to the application event log.

| **Shutdown reason** | **Event Log Type** | **Description** |
|---|---|---|
| Unexpected | Error | The ASP.NET worker process shut down unexpectedly. |
| RequestQueueLimit | Error | The ASP.NET worker process restarted because the request queue limit was exceeded. |
| RequestLimit | Information | The ASP.NET worker process restarted because the request limit was exceeded. |
| Timeout | Information | The ASP.NET worker process restarted because the time-out interval was met. |
| IdleTimeout | Information | The ASP.NET worker process shut down because the idle time-out interval was met. |
| MemoryLimitExceeded | Error | The ASP.NET worker process restarted because the process memory limit was exceeded. |

**Enabling Web Gardens on Multiprocessor Computers**
The process model helps enable scalability on multiprocessor computers by distributing the work to several processes, one per

CPU, each with the processor affinity set to its own CPU. This eliminates cross-processor lock contention and is ideal for large symmetric multiprocessing (SMP) systems. This technique is called Web gardening. To enable Web gardening, you need to set the **cpuMask** and **webGarden** configuration settings in the <**processModel**> element. The following example enables Web gardening on a server running ASP.NET.

```
<configuration>

<system.web>

<processModel

enable="true"

timeout="15"

webGarden="true"

maxWorkerThreads="25"

maxIoThreads="25"/>

</system.web>

</configuration>
```

Web gardening has some side effects that you should be aware of:

- If your application uses session state, it must choose an out-of-process provider (NT Service or SQL).
- Application state and application statistics are per process, not per computer.
- Caching is per process, not per computer.

# Overview of ASP.NET Performance Monitoring

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

There are a number of tools available to help you test and monitor the performance of your Web application. Microsoft Visual Studio .NET provides Application Center Test 1.0 (ACT), which simulates a large group of users by opening multiple connections to a Web server and rapidly sending HTTP requests. ASP.NET includes a number of performance counters that you can use to track the execution of your application. You can also use the built-in ASP.NET tracing feature to track code execution for a page or an application.

ACT is designed to stress-test Web servers and to analyze performance and scalability problems with Web applications. For more information about ACT, either install Visual Studio .NET and open ACT Help, or see information located in the MSDN Library.

When you are doing steady-state running analysis, it is often best to ignore the first request and any one-time initialization costs for objects. For example, when requesting an ASP.NET page for the first time, there is always the cost of compiling an instance of then **Page** class. Once that has occurred, performance will improve for subsequent requests.

This section includes the following information:

- Using the System Monitor (PerfMon) with ASP.NET Applications: Describes the System Monitor tool and how to use it to monitor the performance of ASP.NET applications.
- System and Application Performance Counters for ASP.NET: Lists the performance counters included with ASP.NET.
- Related Performance Counters: Provides guidelines for monitoring an ASP.NET application's performance using the System Monitor tool (PerfMon).

**Related Information**

- ASP.NET Administration

# Using the System Monitor (PerfMon) with ASP.NET Applications

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Unlike traditional Active Server Pages (ASP), which exposed performance counters globally for the entire server computer, most of the ASP.NET performance counters are exposed per application. In the System Monitor tool (PerfMon), per-application counters are available under the **ASP.NET Applications** performance object. If there are multiple applications on the server, you need to specify a particular application instance when selecting a counter to monitor. However, there is a special __Total__ application instance in PerfMon that aggregates the counter values for all applications on a server. The value of __Total__ is usually a sum of the counter values.

ASP.NET also exposes global-only counters that are not bound to a particular application instance. These counters are located under the ASP.NET performance object.

**Procedures**

**To view the available ASP.NET counters on a computer running Windows Server 2003**

1. From the **Start** menu, point to **Administrative Tools**, and then click **Performance**.
2. Right-click the System Monitor details pane and click **Add Counters**.
3. To monitor any computer on which the monitoring console is run, click **Use local computer counters**.

   Or, to monitor a specific computer, regardless of where the monitoring console is run, click **Select counters from computer** and specify a computer name or IP address.
4. In **Performance object**, click an object to monitor.
5. To monitor all counters, click **All counters**.

   Or, to monitor only selected counters, click **Select counters from list** and select the counters you want to monitor.
6. To monitor all instances of the selected counters, click **All instances**.

   Or, to monitor only selected instances, click **Select instances from list** and select the instances you want to monitor.
7. Click **Add**, and then click **OK**.

For information about each of the ASP.NET system and ASP.NET application performance counters, see System and Application Performance Counters for ASP.NET.

# System and Application Performance Counters for ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

ASP.NET supports two groups of performance counters: system and application. The former is exposed in PerfMon in the ASP.NET performance counter object; the latter is exposed in the ASP.NET Applications performance object. There is a significant difference between the State Server Sessions counters found in the ASP.NET performance object, which apply only to the server computer on which the state server is running, and the Sessions counters found in the ASP.NET Applications performance object, which apply only to user sessions that occur in process.

| **Note** |
| --- |
| The value associated with each performance counter is updated every 400 milliseconds. |

When monitoring the performance of your ASP.NET Web applications, you should always track the performance counters listed in the following table.

| Performance object | Performance counter |
| --- | --- |
| ASP.NET | Application Restarts |
| ASP.NET | Requests Queued |
| ASP.NET | Worker Process Restarts |
| ASP.NET Applications | Errors Total |
| ASP.NET Applications | Requests/Sec |
| Processor | % CPU Utilization |

The % CPU Utilization counter monitors CPU utilization on the Web server computer. Low CPU utilization or the inability to maximize CPU utilization regardless of client load can signify contention for resource or a lock in your Web application.

In addition, the performance counters listed in the following table can be valuable in determining problems with your Web applications' performance.

| Performance object | Performance counter |
| --- | --- |
| ASP.NET Applications | Pipeline Instance Count |
| .NET CLR Exceptions | # of Exceps Thrown |
| System | Context Switches/sec |

The # of Exceps Thrown counter displays the number of exceptions thrown in an application, since these can have performance implications. Some code paths, however, rely on exceptions for their proper functioning. For example, the HttpResponse.Redirect method always throws an uncatchable exception, ThreadAbortException. Therefore, it can be more useful to track the number of exceptions thrown using the Errors Total counter to see if the exception generated an error on the application.

The Context Switches/sec counter measures the rate at which thread contexts are switched by all CPUs in the Web server computer. A high number for this counter usually indicates either high contention in locks or many switches between user and kernel mode by the thread. Further investigation with sampling profilers and other tools might be warranted.

The counters in the ASP.NET and ASP.NET Applications performance objects are detailed in the following lists.

**ASP.NET System Performance Counters**

ASP.NET supports the following ASP.NET system performance counters. These aggregate information for all ASP.NET applications on a Web server computer, or they apply generally to a system of ASP.NET servers running the same applications. These can include Web farms and Web gardens.

| Performance Counter | Description |
|---|---|
| Application Restarts | The number of times that an application has been restarted during the Web server's lifetime. Application restarts are incremented with each Application_OnEnd event. An application restart can occur because of changes to the Web.config file, changes to assemblies stored in the application's \Bin directory, or too many changes in Web Forms pages. Unexpected increases in this counter can mean that unforeseen problems are causing your Web application to shut down. In such circumstances you should investigate as soon as possible.<br>**Note**<br>This value is reset every time the Internet Information Services (IIS) host is restarted. |
| Application Running | The number of applications running on the server computer. |
| Requests Disconnected | The number of requests that have been disconnected due to a communication failure. |
| Requests Queued | The number of requests waiting for service from the queue. When this number starts to increment linearly with respect to client load, the Web server computer has reached the limit of concurrent requests that it can process. The default maximum for this counter is 5,000. You can change this setting in the computer's Machine.config file. |
| Requests Rejected | The total number of requests not executed because of insufficient server resources to process them. This counter represents the number of requests that return a 503 HTTP status code, indicating that the server is too busy. |
| Request Wait Time | The number of milliseconds that the most recent request waited for processing in the queue. |
| Session State Server Connections Total | The total number of session-state connections to the computer on which out-of-process session-state data is stored. |
| Session SQL Server Connections Total | The total number of session-state connections to the Microsoft SQL Server-TM- database in which session-state data is stored. |
| State Server Sessions Abandoned | The number of user sessions that have been explicitly abandoned. These are sessions that are ended by specific user actions, such as closing the browser or navigating to another site. This counter is available only on the computer where the state server service (aspnet_state) is running. |
| State Server Sessions Active | The number of currently active user sessions. This counter is available only on the computer where the state server service (aspnet_state) is running. |
| State Server Sessions Timed Out | The number of user sessions that have become inactive through user inaction. This counter is available only on the computer where the state server service (aspnet_state) is running. |
| State Server Sessions Total | The number of sessions created during the lifetime of the process. This counter is the cumulative value of State Server Sessions Active, State Server Sessions Abandoned, and State Server Sessions Timed Out. This counter is available only on the computer where the state server service (aspnet_state) is running. |

| | |
|---|---|
| Worker Process Restarts | The number of times a worker process has been restarted on the server computer. A worker process can be restarted if it fails unexpectedly or when it is intentionally recycled. In the case of unexpected increases in this counter you should investigate as soon as possible. |
| Worker Process Running | The number of worker processes running on the server computer. |

**ASP.NET Application Performance Counters**

ASP.NET supports the following application performance counters, which you can use to monitor the performance of a single instance of an ASP.NET application. A unique instance appears for these counters, named __Total__, which aggregates counters for all applications on a Web server (similar to the global counters described in the first section of this topic). The __Total__ instance is always available. The counters will display zero when no applications are present on the server.

| **Performance Counter** | **Description** |
|---|---|
| Anonymous Requests | The number of requests that are using anonymous authentication. |
| Anonymous Requests/Sec | The number of requests per second that are using anonymous authentication. |
| Cache Total Entries | The total number of entries in the cache. This counter includes both internal use of the cache by the ASP.NET page framework and external use of the cache through exposed APIs. |
| Cache Total Hits | The total number of hits from the cache. This counter includes both internal use of the cache by the ASP.NET page framework and external use of the cache through exposed APIs. |
| Cache Total Misses | The number of failed cache requests per application. This counter includes both internal use of the cache by ASP.NET and external use of the cache through exposed APIs. |
| Cache Total Hit Ratio | The ratio of hits to misses for the cache. This counter includes both internal use of the cache by ASP.NET and external use of the cache through exposed APIs. |
| Cache Total Turnover Rate | The number of additions and removals to the total cache per second. It is useful in helping determine how effectively the cache is being used. If the turnover is large, the cache is not being used efficiently. |
| Cache API Entries | The total number of entries in the application cache. |
| Cache API Hits | The total number of hits from the cache when it is accessed through only the external cache APIs. This counter does not track any use of the cache internally by ASP.NET. |
| Cache API Misses | The total number of failed requests to the cache when accessed through the external cache APIs. This counter does not track any use of the cache internally by ASP.NET. |
| Cache API Hit Ratio | The cache hit-to-miss ratio when accessed through the external cache APIs. This counter does not track any use of the cache internally by ASP.NET. |
| Cache API Turnover Rate | The number of additions and removals to the cache per second, when used through the external APIs (excluding internal use by the ASP.NET page framework). It is useful in helping determine how effectively the cache is being used. If the turnover is large, then the cache is not being used effectively. |

| | |
|---|---|
| Compilations Total | The total number of compilations that have taken place during the lifetime of the current Web server process. This occurs when a file with an .aspx, .asmx, .ascx, or .ashx extension, or a code-behind source file, is dynamically compiled on the server.<br><br>**Note**<br>This number will initially climb to a peak value as requests are made to all parts of an application. Once a compilation occurs, however, the resulting binary is saved to disk, where it is reused until its source file changes. This means that, even in the event of a process restart, the counter can remain at zero (inactive) until the application is modified or redeployed. |
| Debugging Requests | The number of requests that occur while debugging is enabled. |
| Errors During Preprocessing | The number of errors that occurred during parsing. Excludes compilation and run-time errors. |
| Errors During Compilation | The number of errors that occur during dynamic compilation. Excludes parser and run-time errors. |
| Errors During Execution | The total number of errors that occur during the execution of an HTTP request. Excludes parser and compilation errors. |
| Errors Unhandled During Execution | The total number of unhandled errors that occur during the execution of HTTP requests.<br><br>**Note**<br>An unhandled error is any uncaught run-time exception that escapes user code on the page and enters the ASP.NET internal error-handling logic. Exceptions to this rule occur when:<br><br>• Custom errors are enabled, an error page is defined, or both.<br>• The Page_Error event is defined in user code and either the error is cleared (using the HttpServerUtility.ClearError method) or a redirect is performed. |
| Errors Unhandled During Execution/Sec | The number of unhandled exceptions per second that occur during the execution of HTTP requests. |
| Errors Total | The total number of errors that occur during the execution of HTTP requests. Includes any parser, compilation, or run-time errors. This counter is the sum of the Errors During Compilation, Errors During Preprocessing, and Errors During Execution counters. A well-functioning Web server should not generate errors. If errors occur in your ASP.NET Web application, they may skew any throughput results because of very different code paths for error recovery. Investigate and fix any bugs in your application before performance testing. |
| Errors Total/Sec | The number of errors per second that occur during the execution of HTTP requests. Includes any parser, compilation, or run-time errors. |
| Output Cache Entries | The total number of entries in the output cache. |
| Output Cache Hits | The total number of requests serviced from the output cache. |

| | |
|---|---|
| Output Cache Misses | The number of failed output-cache requests per application. |
| Output Cache Hit Ratio | The percentage of total requests serviced from the output cache. |
| Output Cache Turnover Rate | The number of additions and removals to the output cache per second. If the turnover is large, the cache is not being used effectively. |
| Pipeline Instance Count | The number of active request pipeline instances for the specified ASP.NET application. Since only one execution thread can run within a pipeline instance, this number gives the maximum number of concurrent requests that are being processed for a given application. In most circumstances it is better for this number be low when under load, which signifies that the CPU is well utilized. |
| Request Bytes In Total | The total size, in bytes, of all requests. |
| Request Bytes Out Total | The total size, in bytes, of responses sent to a client. This does not include standard HTTP response headers. |
| Requests Executing | The number of requests currently executing. |
| Requests Failed | The total number of failed requests. Any and all status codes greater than or equal to 400 will increment this counter.<br>**Note**<br>Requests that cause a 401 status code will increment this counter and the Requests Not Authorized counter. Requests that cause a 404 or 414 status code will increment this counter and the Requests Not Found counter. Requests that cause a 500 status code will increment this counter and the Requests Timed Out counter.<br>**Note**<br>The equivalent ASP counter would also increment on requests rejected, which cannot be done (because the rejection is done by IIS and not the process model). |
| Requests Not Found | The number of requests that failed because resources were not found (status code 404, 414). |
| Requests Not Authorized | The number of requests that failed due to no authorization (status code 401). |
| Requests Succeeded | The number of requests that executed successfully (status code 200). |
| Requests Timed Out | The number of requests that timed out (status code 500). |
| Requests Total | The total number of requests since the service was started. |
| Requests/Sec | The number of requests executed per second. This represents the current throughput of the application. Under constant load, this number should remain within a certain range, barring other server work (such as garbage collection, cache cleanup thread, external server tools, and so on). |
| Sessions Active | The number of sessions currently active. This counter is supported only with in-memory session state. |
| Sessions Abandoned | The number of sessions that have been explicitly abandoned. This counter is supported only with in-memory session state. |

| | |
|---|---|
| Sessions Timed Out | The number of sessions that timed out. This counter is supported only with in-memory session state. |
| Sessions Total | The number of sessions timed out. This counter is supported only with in-memory session state. |
| Transactions Aborted | The number of transactions aborted. |
| Transactions Committed | The number of transactions committed. |
| Transactions Pending | The number of transactions in progress. |
| Transactions Total | The total number of transactions since the service was started. |
| Transactions/Sec | The number of transactions started per second. |

# Related Performance Counters

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The following sections list other performance objects and counters that can be useful when monitoring your ASP.NET applications. The list is alphabetical by performance object, then by counter.

For a full list of performance counters on a computer running a version of the .NET Framework, see the "Performance Counters" topic in .NET Framework Help . For objects and counters associated specifically with ASP.NET, see System and Application Performance Counters for ASP.NET.

**.NET CLR Exceptions**
### # of Exceptions Thrown/Sec

The total number of managed exceptions thrown per second. As this number increases, performance degrades.

**.NET CLR Loading**
### Bytes in loader Heap

The number of bytes committed by the class loader across all application domains.

### Current App Domains

The current number of application domains loaded in the process. The value of this counter should be the same as the number of virtual directories, plus 1 (to account for the default application domain).

### Current Assemblies

The current number of assemblies loaded in the process. Note that assemblies cannot be unloaded from an application domain; the entire application domain must be unloaded. This is an issue for sites with a large number of pages.

**.NET CLR Memory**
### # Bytes in all heaps

Displays the sum of the **Gen 0 Heap Size**, **Gen 1 Heap Size**, **Gen 2 Heap Size**, and the **Large Object Heap Size** counters. This counter indicates, in bytes, the current memory allocated on the garbage collection heaps.

### # Gen 0 Collections

Displays the number of times that generation 0 objects (that is, the youngest, most recently allocated objects) have been reclaimed by garbage collection since the application started.

Generation 0 garbage collection occurs when the available memory in generation 0 is not sufficient to satisfy an allocation request. This counter is incremented at the end of a generation 0 garbage collection. Higher-generation garbage collections include all lower-generation collections. This counter is explicitly incremented when a higher-generation (generation 1 or 2) garbage collection occurs.

This counter displays the last observed value. The **_Global_** counter value is not accurate and should be ignored.

### # Gen 1 Collections

Displays the number of times that generation 1 objects have been reclaimed by garbage collection since the application started.

The counter is incremented at the end of a generation 1 garbage collection. Higher-generation garbage collections include all lower generation collections. This counter is explicitly incremented when a higher-generation (generation 2) garbage collection occurs.

This counter displays the last observed value. The **_Global_** counter value is not accurate and should be ignored.

### # Gen 2 Collections

Displays the number of times that generation 2 objects have been reclaimed by garbage collection since the application started. The counter is incremented at the end of a generation 2 garbage collection (also called a full garbage collection).

This counter displays the last observed value. The _**Global**_ counter value is not accurate and should be ignored.

**Memory**
### Available Mbytes

The amount of physical memory available to processes running on the computer, in megabytes. It is calculated by adding the amount of space on the zeroed, free, and standby memory lists. Free memory is ready for use; zeroed memory is filled with zeros to prevent later processes from seeing data used by a previous process; standby memory is removed from a process's working set (its physical memory) to be stored on the server's hard drive but is still available to be recalled. This counter displays the last observed value only; it is not an average.

**Process**
### % Processor Time

The percentage of the elapsed time on the processor that it took all threads associated with a single process to perform execution instructions. An instruction is the basic unit of execution in a computer; a thread is the object that executes instructions; and a process is the object created when a program is run. Code executed to handle some hardware interrupts and trap conditions are included in this count.

### Handle Count

The total number of handles currently open that are associated with this process. This number is equal to the sum of the handles currently open for each thread in this process.

### Private Bytes

The current amount of memory, in bytes, that this process has allocated that cannot be shared with other processes.

### Thread Count

The number of threads currently active in this process. An instruction is the basic unit of execution in a processor, and a thread is the object that executes instructions. Every running process has at least one thread.

**Processor**
### % Processor Time

The percentage of sampled time that the processor spends to execute a non-Idle thread. It is calculated by measuring how long the idle thread is active in the sample interval and subtracting that time from the interval duration. (Each processor has an idle thread that consumes cycles when no other threads are ready to run). This counter is the primary indicator of processor activity, and displays the average percentage of busy time observed during the sample interval.

**Web Service**
### Bytes Received/Sec

The number of bytes per second received by the Web service.

### Bytes Sent/Sec

The number of bytes per second sent by the Web service.

### Current Connections

The current number of connections established with the Web service.

### ISAPI Extension Requests/Sec

The number of ISAPI Extension requests per second that are being processed by the Web service.

### Total Method Requests/Sec

The number of HTTP requests per second received by the Web service.

# Additional Resources for ASP.NET

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

There are a number of other useful sources of information about ASP.NET, including Microsoft ASP.NET Help found in the **Creating ASP.NET Applications** section of Microsoft .NET Framework Help.

In addition, the following resources contain a great deal of information about ASP.NET:

- The official ASP.NET Web site contains links to tools, forums, articles, sample applications, a gallery of ASP.NET server controls, links to third-party Web sites, and more.

- The official .NET Framework Community Website Web site contains links to tools, white papers, sample applications and third-party Web sites. This site can help you understand how to access other portions of the .NET Framework from your ASP.NET applications.

- The MSDN Library contains technical articles and columns about ASP.NET, as well as links to other resources. Go to the ASP .Net Developer Center, expand the **.NET Development** node in the Table of Contents, and then click **ASP.NET**.

- The ASP.NET QuickStart, included when you install the .NET Framework, contains overview information and samples of how to develop and administer ASP.NET applications.

**Related Information**

- ASP.NET Administration

# About ASP

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Microsoft Active Server Pages (ASP) is a server-side scripting environment that you can use to create dynamic and interactive Web pages, and to build powerful Web applications. When the server receives a request for an ASP file, it processes server-side script code contained in the file to build the HTML Web page that is sent to the browser. In addition to server-side script code, ASP files can contain HTML (including related client-side scripts) as well as calls to COM components that perform a variety of tasks, such as connecting to a database or processing business logic.

FrontPage Server Extensions does not support unicode content directory names or WebDAV. New FrontPage Server Extensions virtual servers should be assigned to the MSSharePointPool application pool. Also, do not make changes to the MSSharePointPool application pool configuration.

| **Note** |
| --- |
| If you have a Web site that uses Sharepoint™ Team Services (STS) from Microsoft, the following types of pages do not work without excluding the virtual directory containing the pages from the STS ISAPI filter: |

- ASP pages
- ASP.NET pages
- PHP pages
- PerlScript pages

**Procedures**

**To enable these types of pages to work on your STS Web site**

1. In the **Central Administration** Web site for STS, choose to **Manage** your virtual directory or Web site.
2. Under **Defined Managed Paths**, type the path to the virtual directory that contains your excluded pages (such as <code>\MyASPPages</code>) and select **Exclude**.

The topics in this section introduce ASP, explain the basic concepts of scripting with ASP, and discuss more complex application issues such as how to maintain state.

| **Important** |
| --- |
| To help minimize the attack surface of the server, IIS 6.0 is not installed on Windows Server 2003 by default. When you first install IIS 6.0, it is locked down -- which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable these features, IIS returns a 404 error. You can enable these features through the Web Service Extensions node in IIS Manager. For more information about how to troubleshoot 404 errors and other issues, see Troubleshooting in IIS 6.0. |

This section includes the following information:

- Checklist: ASP Security: Provides a checklist of issues to monitor when developing ASP applications that include user input or database access.
- What's New in ASP: Describes new features added in this release.
- Important Changes in ASP: Describes functionality and behavior that has changed for this release.

**Related Information**

- For information about writing server-side scripts with ASP and creating ASP applications, see the Active Server Pages Guide on MSDN Online or in the Internet Information Services (IIS) Software Development Kit (SDK).

- Redirect Reference: This section explains how to format a server redirection correctly. For reference topics related to ASP, see the IIS Web Application Technology Reference section of the IIS Software Developer Kit (SDK).

# Checklist: ASP Security

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The following is a list of issues to keep in mind when you are developing Web pages using ASP.

| | Step | Reference |
|---|---|---|
| | Never trust user input to be of an appropriate size or contain appropriate characters. Always verify user input before using it to make decisions. The best option is to create a COM+ component which you can call from an ASP page to verify user input. You can also use the Server. HTMLEncode method, the Server. URLEncode method, or one of the code examples at the bottom of this page. | Writing Secure Code |
| | Do not create database connection strings in an ASP page by concatenating strings of user input together. Malicious users can inject code in their input to gain access to your database. If you are using an SQL database, use stored procedures for creating database connection strings. | Writing Secure Code |
| | Do not use the default SQL administrator account name, *sa*. Everyone who uses SQL knows that the sa account exists. Create a different SQL administrative account with a strong password and delete the sa account. | "Passwords" in Help and Support Center for Windows 2003. |
| | Before you store client user passwords, hash them, base64encode them, or use **Server.HTMLEncode** or **Server.URLEncode** to encode them. You can also use one of the code examples at the bottom of this page to verify the characters in the client's password. | "Encrypting File System" in Help and Support Center for Windows 2003. |
| | Do not put administrative account names or passwords in administration scripts or ASP pages. | Writing Secure Code |
| | Do not make decisions in your code based on request headers because header data can be fabricated by a malicious user. Before using request data, always encode it or use one of the code examples below to verify the characters it contains. | Writing Secure Code |
| | Do not store secure data in cookies or hidden input fields in your Web pages. | Writing Secure Code |
| | When writing ISAPI applications, filters, or COM+ objects, watch out for buffer over-runs caused by assuming sizes of variables and data. Also watch out for canonicalization issues that can be caused by interpreting things, like absolute path names, as relative path names or URLs. | Writing Secure Code |
| | When you switch an ASP application from running in Single Threaded Apartment (STA) to Multi-Threaded Apartment (MTA), the impersonation token becomes obsolete. This can cause the application to run with no impersonation, effectively letting it run with the identity of the process which might allow access to other resources. If you must switch threading models, disable the application and unload it before you make the change. | Configuring Applications to Use COM+ Services; "COM+ Services" in the IIS Software Development Kit (SDK) |

**Code Example**

This code example includes a function that removes potentially harmful characters from a string that is sent to the function. In both examples above, the code page is specified to ensure proper encoding. The example below is in Microsoft Visual Basic Scripting Edition (VBScript):

```
<%@ LANGUAGE="VBScript" %>

<%

Response.CodePage = 1252

Response.Write("Hello, " & RemoveBadCharacters(Request.Form("UserName")))

Response.Write("<BR>This is why you received an error:")
```

```
Function RemoveBadCharacters(strTemp)

Dim regEx

Set regEx = New RegExp

regEx.Pattern = "[^\s\w]"

regEx.Global = True

RemoveBadCharacters = regEx.Replace(strTemp, "")

End Function

%>
```

The example below is in Microsoft JScript:

```
<%@ LANGUAGE="JScript" %>

<%

Response.CodePage = 1252;

Response.Write("Hello, " + RemoveBadCharacters(Request.Form("UserName")));

Response.Write("<BR>This is why you received an error:");

function RemoveBadCharacters(strTemp) {

strTemp = strTemp.replace(/[^\s\w]/g,"");

return strTemp;

}

%>
```

- IIS 6.0 Security Best Practices

# What's New in ASP

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In addition to internal performance enhancements and optimizations, this version of Active Server Pages (ASP) has the following new features:

- Better International and UTF-8 Support
- Improved POST Support
- ASP Hang Detection
- Caching of Popular Files
- UNC Enhancements
- COM+ Services in ASP
    - **Apartment Model Selection**
    - **Side-by-side Assemblies**
    - **COM+ Partitions**
    - **Tracker**
    - **Transactions**
- New Metabase Properties for ASP
- ASP Debugging

**Better International and UTF-8 Support**
UTF-8 support has been expanded to all ASP built-in object properties and methods. The last version of ASP supported UTF-8 only for Response.Write.

**Improved POST Support**
ASP can now read chunked-encoded POST data from a client.

**ASP Hang Detection**
When an IIS Web site is busy there may be instances when the maximum number of ASP threads has been spawned and some of the ASP threads are hung, resulting in degraded performance. HSE_REQ_REPORT_UNHEALTHY, and the World Wide Web Publishing Service (WWW service) will recycle the worker process hosting ASP.dll and make an entry in the event log.

| **Note** |
| --- |
| Threads are considered *hung* if they do not respond to a timeout. |

**Caching of Popular Files**
ASP now caches some of the most-recently used files on disk, in addition to keeping a memory cache. The default location of the disk cache is **%systemroot%\System32\inetsrv\ASP** Compiled Templates. You can change the location of the disk cache by setting the AspDiskTemplateCacheDirectory Metabase Property.

**UNC Enhancements**

ASP can now handle UNC paths in ASP scripts.

**COM+ Services in ASP**

If you wanted to use COM+ services from an ASP application in previous versions of IIS, you had to create a COM component that would call the methods of those services. Now, you can configure your ASP application to use the following COM+ services without having to create a COM component:

- Apartment Model Selection:

  ASP is now capable of running all of its threads in a multi-threaded apartment (MTA). If your COM components are primarily free-threaded or both-threaded, running the ASP threads as MTA can improve performance significantly.

  To enable an ASP application to run in an MTA, you can use the metabase setting, AspExecuteInMTA Metabase Property, at the application level. This means that you can have one application running on ASP MTA threads and a second application running on ASP STA (single-threaded apartment) threads. The default for ASP threads continues to be STA.

  | **Important** |
  | --- |
  | When you switch an ASP application from running in STA to MTA (or from MTA to STA), the impersonation token becomes obsolete. This can cause the application to run with no impersonation, effectively letting it run with the identity of the process which might allow access to other resources. If you must switch threading models, disable the application and unload it before you make the change. |

  The following example sets the Default Web Site application (*W3SVC/1/ROOT*) to execute in MTA:

```
    On Error Resume Next
    set providerObj = GetObject("winmgmts://MyMachine/root/MicrosoftIISv2")
    ' Get a reference to the ASP application called Default Web Site
    set IIsWebVirtualDirSettingObj =
providerObj.get("IIsWebVirtualDirSetting='W3SVC/1/ROOT'")
    WScript.Echo "Before: AspExecuteInMTA = " &
IIsWebVirtualDirSettingObj.AspExecuteInMTA
    ' Set the ASP application to execute in MTA
    IIsWebVirtualDirSettingObj.AspExecuteInMTA = 1
    IIsWebVirtualDirSettingObj.Put_()
    WScript.Echo "After: AspExecuteInMTA = " &
IIsWebVirtualDirSettingObj.AspExecuteInMTA
```

- Side-by-side Assemblies:

  Side-by-side (SxS) assemblies allow ASP applications to specify which version of a system DLL or classic COM component to use, such as WinHTTP 5.1, Shell Common Controls version 6.0 (Comctl32.dll), GDI Plus version 1.0 (GDIplus.dll), and Visual C++ Run-time Libraries version 6.0. For example, if your ASP application relies on MSXML version 2.0, you can ensure that your application still uses MSXML version 2.0 even after service packs are applied to the server. Any new version of MSXML is still installed on the computer, but version 2.0 remains and is used by your application. Configuring SxS assemblies requires that you know the path to the DLL, and that the COM+ manifest file exists in every virtual directory that needs to use the DLL. The COM+ manifest is an XML file that has information about where a DLL is installed. IIS does not verify that the manifest exists. A manifest looks like the following file excerpt:

```
    <?xml version="1.0" encoding="UTF-8" standalone="yes"?>
    <assembly xmlns="urn:schemas-microsoft-com:asm.v1" manifestVersion="1.0">
    <assemblyIdentity publicKeyToken="75e377300ab7b886" type="win32"
name="Test4Dir" version="1.0.0.0" processorArchitecture="x86"/>
    <file name="DirComp.dll" hash="35ca6f27b11ed948ac6e50b75566355f0991d5d9"
hashalg="SHA1">
    <comClass clsid="{6C6CC20E-0F85-49C0-A14D-D09102BD7CDC}"
progid="DirComp.PathInfo" threadingModel="apartment"/>
    <typelib tlbid="{AA56D6B8-9ADB-415D-9E10-16DD68447319}" version="1.0"
```

```
    helpdir=""/>
        </file>
        </assembly>
```

You can enable side-by-side assemblies on the IIS side programmatically or by using IIS Manager.

**To enable side-by-side assemblies on the IIS side using IIS Manager**

1. In IIS Manager, right-click a Web site or virtual directory and click **Properties**.
2. Click the **Virtual Directory** tab, and click **Configuration**.
3. If the configuration button is not available, it is because you have not created an application for this virtual directory. Click **Create** to create an application.
4. In the **Application Configuration** dialog box, click the **Options** tab.
5. Select the **Enable Side by Side assemblies** check box.
6. In the **Manifest file name** box, type the name of the COM+ manifest file.
7. Click **OK** twice.

To enable side-by-side assemblies programmatically, set the **AspEnableSxs** flag of the AspAppServiceFlags Metabase Property. Also set the AspSxsName Metabase Property to the name of the COM+ manifest name. Set both metabase properties at the application level.

| **Important** |
| --- |
| Only one version of a system DLL can be used in any application pool, even though this feature is configurable at the application level. For example, if application App1 uses MDAC, version 2.5 and application App2 uses MDAC, version 2.4, then App1 and App2 should not be in the same application pool. If they are, the application that is loaded first has its version of MDAC loaded, and the other application is forced to use it until the applications are unloaded. |

The following example enables side-by-side assemblies on the Default Web Site application (*W3SVC/1/ROOT*). Notice that after setting only the **AspEnableTracker** property, the **AspAppServiceFlags** property changes as well:

```
On Error Resume Next
    set providerObj = GetObject("winmgmts://MyMachine/root/MicrosoftIISv2")
    ' Get a reference to the ASP application called Default Web Site
    set IIsWebVirtualDirSettingObj =
providerObj.get("IIsWebVirtualDirSetting='W3SVC/1/ROOT'")
    WScript.Echo "Before: AspEnableSxs = " & IIsWebVirtualDirSettingObj.AspEnableSxs
    WScript.Echo "        AspSxsName = " & IIsWebVirtualDirSettingObj.AspSxsName
    WScript.Echo "        AspAppServiceFlags = " &
IIsWebVirtualDirSettingObj.AspAppServiceFlags
    ' Set the ASP application to enable COM+ side-by-side assemblies
    IIsWebVirtualDirSettingObj.AspEnableSxs = 1
    ' Set the AspSxsName property
    IIsWebVirtualDirSettingObj.AspSxsName = "VersionInfo"
    ' Save the values to the IIS metabase
    IIsWebVirtualDirSettingObj.Put_()
    ' Get the reference again in order to refresh the AspAppServiceFlags property.
    set IIsWebVirtualDirSettingObj = Nothing
    set IIsWebVirtualDirSettingObj =
providerObj.get("IIsWebVirtualDirSetting='W3SVC/1/ROOT'")
    WScript.Echo "After: AspEnableSxs = " & IIsWebVirtualDirSettingObj.AspEnableSxs
    WScript.Echo "       AspSxsName = " & IIsWebVirtualDirSettingObj.AspSxsName
    WScript.Echo "       AspAppServiceFlags = " &
IIsWebVirtualDirSettingObj.AspAppServiceFlags
```

- COM+ Partitions:

  COM+ Partitions can be used to isolate Web applications into their own COM+ partitions. This is useful to prevent one Web application from accessing the private COM+ applications, configuration information, and data of another Web

application. COM+ partitions can hold different versions of your own custom COM components. For example, if you host Web sites for two competing companies that both use COM+ in their Web applications, you can use COM+ partitions to ensure that one company's Web application cannot access the COM+ components in the other company's Web applications. If one of those companies asks you to change certain features in a COM+ application that they both use, you can isolate the new version of that COM+ application in the partition that is linked to their Web application.

To enable COM+ partitions on the IIS side, set the **AspUsePartition** flag of the AspAppServiceFlags Metabase Property at the application level. The partition is identified by a GUID (created using the Component Services Manager snap-in), which can be set at the AspPartitionID Metabase Property. If no partition is specified, the default system partition is used. For more information, please see "Creating and Configuring COM+ Partitions" in the COM+ SDK or online at COM+ (Component Services).

| **Important** |
| --- |
| Only one version of a COM+ component can be used in any application pool, even though this feature is configurable at the application level. For example, if application App1 uses version 1.0 of a custom COM+ application called Shop.dll, and application App2 uses version 2.0 of Shop.dll, then App1 and App2 should not be in the same application pool. If they are, the application that is loaded first has its version of Shop.dll loaded, and the other application is forced to use it until the applications are unloaded. |

The following example enables partitions on the Default Web Site application (*W3SVC/1/ROOT*). Notice that after setting only the **AspEnableTracker** property, the **AspAppServiceFlags** property changes as well.

```
    On Error Resume Next
    set providerObj = GetObject("winmgmts://MyMachine/root/MicrosoftIISv2")
    ' Get a reference to the ASP application called Default Web Site
    set IIsWebVirtualDirSettingObj =
providerObj.get("IIsWebVirtualDirSetting='W3SVC/1/ROOT'")
    WScript.Echo "Before: AspUsePartition = " &
IIsWebVirtualDirSettingObj.AspUsePartition
    WScript.Echo "        AspPartitionID = " &
IIsWebVirtualDirSettingObj.AspPartitionID
    WScript.Echo "        AspAppServiceFlags = " &
IIsWebVirtualDirSettingObj.AspAppServiceFlags
    ' Set the ASP application to enable COM+ partitioning
    IIsWebVirtualDirSettingObj.AspUsePartition = 1
    ' Set the AspPartitionID property to the GUID configured in Component Services
Manager
    ' when you created the COM+ partition
    IIsWebVirtualDirSettingObj.AspPartitionID = "{00000000-0000-0000-0000-
000000000000}"
    ' Save the values to the IIS metabase
    IIsWebVirtualDirSettingObj.Put_()
    ' Get the reference again in order to refresh the AspAppServiceFlags property.
    set IIsWebVirtualDirSettingObj = Nothing
    set IIsWebVirtualDirSettingObj =
providerObj.get("IIsWebVirtualDirSetting='W3SVC/1/ROOT'")
    WScript.Echo "After: AspUsePartition = " &
IIsWebVirtualDirSettingObj.AspUsePartition
    WScript.Echo "       AspPartitionID = " & IIsWebVirtualDirSettingObj.AspPartitionID
    WScript.Echo "       AspAppServiceFlags = " &
IIsWebVirtualDirSettingObj.AspAppServiceFlags
```

- Tracker:

  COM+ tracker allows administrators or developers to debug ASP applications. For example, if a Web application is causing problems on your server, you can enable COM+ tracker to determine when ASP pages are being loaded, when COM components are loaded, and when threads leave a page. After you have debugged your application, you can disable COM+ tracker to return your application to normal performance speed.

  To enable COM+ tracker on the IIS side, set the **AspEnableTracker** flag of the AspAppServiceFlags Metabase Property at the application level.

The following example enables tracking on the Default Web Site application (*W3SVC/1/ROOT*). Notice that after setting only the **AspEnableTracker** property, the **AspAppServiceFlags** property changes as well:

```
    On Error Resume Next
    set providerObj = GetObject("winmgmts://MyMachine/root/MicrosoftIISv2")
    ' Get a reference to the ASP application called Default Web Site
    set IIsWebVirtualDirSettingObj =
providerObj.get("IIsWebVirtualDirSetting='W3SVC/1/ROOT'")
    WScript.Echo "Before: AspEnableTracker = " &
IIsWebVirtualDirSettingObj.AspEnableTracker
    WScript.Echo "        AspAppServiceFlags = " &
IIsWebVirtualDirSettingObj.AspAppServiceFlags
    ' Set the ASP application to enable COM+ tracking
    IIsWebVirtualDirSettingObj.AspEnableTracker = 1
    IIsWebVirtualDirSettingObj.Put_()
    ' Get the reference again in order to refresh the AspAppServiceFlags property.
    set IIsWebVirtualDirSettingObj = Nothing
    set IIsWebVirtualDirSettingObj =
providerObj.get("IIsWebVirtualDirSetting='W3SVC/1/ROOT'")
    WScript.Echo "After: AspEnableTracker = " &
IIsWebVirtualDirSettingObj.AspEnableTracker
    WScript.Echo "       AspAppServiceFlags = " &
IIsWebVirtualDirSettingObj.AspAppServiceFlags
```

- Transactions: Transaction support in ASP pages has been available since IIS version 4.0. However, IIS has changed its internal implementation of transactions to take advantage of COM+ services. IIS no longer creates a COM component to house a transaction but accesses the COM+ transaction service directly, thus greatly improving the speed of transaction processing. As always, transactions can only be configured at the page level using the @TRANSACTION directive and the events of the ASP built-in object called ObjectContext.

**New Metabase Properties for ASP**

The following metabase settings have been added for this release of ASP.

| Metabase Property Name | Purpose |
|---|---|
| AspAppServiceFlags Metabase Property | Enables features like COM+ side-by-side assembly (formerly known as Fusion), partitioning, and so on. |
| AspDiskTemplateCacheDirectory Metabase Property | Specifies the location of the ASP disk cache. |
| AspExecuteInMTA Metabase Property | Enables ASP threads to execute in a multi-threaded apartment. |
| AspKeepSessionIDSecure Metabase Property | Sends the ASP session cookie to a browser securely. |
| AspMaxDiskTemplateCacheFiles Metabase Property | Specifies the ASP Disk cache maximum. |
| AspPartitionID Metabase Property | Specifies the COM+ partition to use for the application. |
| AspRunOnEndAnonymously Metabase Property | Enables ASP to run the global.asa Application_OnEnd and Session_OnEnd events anonymously. |
| AspBufferingLimit Metabase Property | Specifies the limit of the buffer size. |
| AspMaxRequestEntityAllowed Metabase Property | Specifies the maximum number of bytes allowed in the entity body of an ASP request. |

| | |
|---|---|
| AspSxsName Metabase Property | Allows ASP applications to specify which version of a system DLL or classic COM component to use. |

**ASP Debugging**

Because the worker process, W3wp.exe, runs as the Network Service account in IIS 6.0 worker process isolation mode, you must configure Launch and Access permissions to enable ASP debugging for Script Debugger and Visual InterDev. For more information, see Enabling ASP Debugging.

# Important Changes in ASP

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

ASP has undergone several important changes and enhancements to improve security and performance:

| Note |
| --- |
| To learn about new ASP features, see What's New in ASP. |

- ASP Pages are Disabled by Default
- Using Parent Paths
- The "Templates Cached" Performance Counter
- Global.asa Events
- ASP Metabase Properties Removed
- ASP Debugging

**ASP Pages are Disabled by Default**

| Important |
| --- |
| To help minimize the attack surface of the server, IIS 6.0 is not installed on Windows Server 2003 by default. When you first install IIS 6.0, it is locked down -- which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable these features, IIS returns a 404 error. You can enable these features through the Web Service Extensions node in IIS Manager. For more information about how to troubleshoot 404 errors and other issues, see Troubleshooting in IIS 6.0. |

**Using Parent Paths**

As a security precaution, the AspEnableParentPaths Metabase Property setting is now set to 0 by default. This affects your application if it has a Web page that contains the #include server-side include directive and uses ".." notation to refer to a parent directory.

**The "Templates Cached" Performance Counter**

The **AspTemplatesCached**performance counter now counts the number of cached ASP files, both on disk and in memory. In previous versions, because there was no disk-based caching, this counter referred only to the in-memory cache. There is also a new counter called **AspInMemoryTemplatesCached** that reflects the number of ASP pages in the memory cache; it's the number of templates cached in total memory.

**Global.asa Events**

Earlier versions of ASP executed events in the security context (or user identity) of the host process because during these events there is no user context. This caused problems such as access denied errors when writing to a file in the Session_OnEnd event. ASP, by default, now runs the global.asa events, Application_OnEnd, and Session_OnEnd, anonymously. This can be controlled by the metabase setting, **AspRunOnEndAnonymously**.

**ASP Metabase Properties Removed**

The following metabase settings are no longer used by ASP, even though they are still in the metabase for compatibility with existing administration scripts

| Metabase Property Name |
| --- |
| AspAllowOutOfProcComponents Metabase Property |

| |
|---|
| AspTrackThreadingModel Metabase Property |
| AspExceptionCatchEnable Metabase Property |

**ASP Debugging**

Because the worker process, W3WP, runs as the Network Service account in IIS 6.0 worker process isolation mode, you must configure Launch and Access permissions to enable ASP debugging for Script Debugger and Visual InterDev. For more information, see Enabling ASP Debugging.

# Troubleshooting in IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Many of the design changes in Internet Information Services (IIS) 6.0 directly address the need to secure the World Wide Web Publishing Service (WWW service) as a whole, and Web and FTP sites in particular. You might experience errors if you have not enabled certain features or services that are locked, or disabled, by default. This topic describes some of the symptoms of these errors and the processes to remedy them (or a link to a topic that describes how to remedy the error). For a comprehensive list of changes in IIS 6.0, including a list of security changes and a brief explanation of the new process model, see What's Changed in IIS 6.0.

- Connection Errors
- Miscellaneous Errors

# Dynamic or Static Content Errors

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This section includes troubleshooting information about issues with dynamic content and static content.

**In This Section**

- Applications are denied access to resources
- Requests for dynamic content return 404 error
- All requests with /bin in the URL are rejected and return a 404 error
- Requests for static files return 404 error
- Worker process recycling drops application session state
- Server-side include directives (#include) return 404 error (for .stm files) or 0131 error (for .asp files)
- ASP generates Permission Denied errors in event log for global.asa
- CGI processes do not start
- ASP.NET pages are returned as static files
- Collaboration Data Objects for Windows NT Server fail

# Applications are denied access to resources

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

After a clean install, IIS 6.0 runs in Worker Process Isolation Mode in IIS 6.0. Applications running in this mode use the Network Service identity, by default. Network Service is an account with few user rights and therefore provides better security by restricting access to resources on the Web server. If you migrate applications to IIS 6.0 while the server is in worker process isolation mode, and if your applications previously ran in-process (in Inetinfo.exe) as LocalSystem, the applications may fail to access resources because of the restrictions set forth by the Network Service identity. The LocalSystem account has access to almost all resources on the operating system, and therefore creates serious security implications. You should avoid using the LocalSystem account when possible. If it is absolutely necessary to use the LocalSystem account on an application, run that application in a new application pool in its own virtual directory so you can reduce the attack surface by isolating the application. As an alternative, and if your application needs permission to use the Trusted Computing Base (TCB), run the application as a configurable identity and assign the TCB permission to the configurable identity. This alternative, however, still presents a security risk because the TCB permission is very powerful.

| **Note** |
| --- |
| By default IIS 6.0 worker processes run under the low-privileged Network Service user account. This account does not have the appropriate permissions to write to the System event log, so application events, including CGI events, are written to the Application event log. |

For more information, see Configuring Worker Process Identities and IIS and Built-in Accounts.

# Requests for dynamic content return 404 error

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

To help minimize the attack surface of the server, IIS 6.0 is not installed on Windows Server 2003 by default. When you first install IIS 6.0, it is locked down — which means that only request handling for static Web pages is enabled, and only the World Wide Web Publishing Service (WWW service) is installed. None of the features that sit on top of IIS are turned on, including ASP, ASP.NET, CGI scripting, FrontPage® 2002 Server Extensions from Microsoft, and WebDAV publishing. If you do not enable this functionality after installing IIS, by default on this denial, IIS returns a generic 404 custom error page to prevent disclosure of configuration information. IIS also writes the 404 error with the substatus code of 2 (404.2) in the W3C Extended log files, by default.

**Procedures**

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /User:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To enable or disable a Web service extension**

1. In IIS Manager, expand the local computer, and then click **Web Service Extensions**.
2. In the details pane, click the Web service extension that you want to enable or disable, and then do one of the following:
   - To enable a disabled Web service extension, click **Allow**, and then click **OK**.
   - To disable an enabled Web service extension, click **Prohibit**, and then click **OK**.

To enable or disable Web service extensions programmatically, see WebSvcExtRestrictionList Metabase Property.

# All requests with /bin in the URL are rejected and return a 404 error

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This occurs when IIS 6.0 and ASP.NET are both installed. In order to take a more proactive stance against malicious users and attackers, the ASP.NET ISAPI filter, aspnet_filter.dll, blocks incoming request containing /bin in the URL. This behavior occurs server-wide, regardless whether the request is for static or dynamic content.

The preferred solution to this issue is to modify the path to content on the server so that /bin is not necessary in any request.

If the content URL cannot be modified, an alternative solution is to set a registry key that stops the ASP .NET ISAPI filter from filtering requests containing /bin in the URL. This is a server-wide setting.

**Procedures**

| **Important** |
| --- |
| Setting the HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\ASP.NET\ registry key can allow a malicious user access to programs and content in the /bin directory. |

**To disable /bin filtering**

1. Start Registry Editor and navigate to the HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\ASP.NET\ key.
2. In the details pane, right-click, point to **New**, and click **DWORD Value**.
3. In the **Name** box, type the following: **StopBinFiltering**.
4. Double-click the **StopBinFiltering** value, and in the Value data box type **1**.
5. Click **OK**, and then close Registry Editor.
6. To reenable /bin filtering, set the **StopBinFiltering** value to 0.

# Requests for static files return 404 error

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

For requests to static content, this version of IIS serves requests for files with known file name extensions only, a feature called Known Extensions. If a request is made for a resource whose file name extension is not mapped to a known extension in the MimeMap Metabase Property, IIS denies the request and logs a 404 error with the substatus code of 3 (404.3) in the W3C Extended log files (by default). To prevent disclosure of configuration information, IIS is configured to return the generic 404 custom error page by default on this denial. To resolve this error, use IIS manager to add the file name extension to the Multipurpose Internet Mail Exchange (MIME) map on a specific directory or Web site.

If adding the specific file name extension to the MIME map does not remedy the problem, turn off the Known Extensions feature on a specific directory or a Web site. To turn off the Known Extensions feature and thereby allow IIS to serve files with any extension for a specific site or directory, add the ***,application/octet-stream** value to the list of MIME maps (enter the asterisk in the **Extension** text box and **application/octet-stream** in the **MIME Type** text box on the **MIME Type** dialog box). For more information about how to add this value to the MIME map, see Working with MIME Types.

If you are still experiencing problems, you can turn off the Known Extensions feature on the Web server and allow IIS to serve files with any extension for all sites and directories. Turn off the Known Extensions feature by adding the ***,application/octet-stream** to the global MIME map. You must wait until the worker process has recycled or restart the World Wide Web Publishing Service (WWW service) before changes take effect.

| **Important** |
| --- |
| Turning off Known Extensions on the Web server means IIS will serve files with any extension. Malicious users could potentially exploit this configuration to download sensitive information from your Web server. An IIS server that serves files with any extension is not secure. |

| **Note** |
| --- |
| Tools like UrlScan can be configured to block the processing of certain file name extensions. Check your UrlScan settings. |

For more information about adding or editing the MIME map, see Working with MIME Types.

# Worker process recycling drops application session state

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

By default, Worker Processes recycle after a preconfigured amount of time. If your ASP applications are not designed to store session state while a worker process is recycled, then session state in that ASP application can be lost. To remedy this problem, you can either store session state in a database or disable worker process recycling.

**Procedures**

**To disable worker process recycling**

1. In IIS Manager, expand the local computer, expand **Application Pools**, right-click the application pool, and then click **Properties**.
2. On the **Recycling** tab, clear the **Recycle worker processes (in minutes)** check box.
3. Click **OK**.

# Server-side include directives (#include) return 404 error (for .stm files) or 0131 error (for .asp files)

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If your ASP page uses the **#include** server-side include directive and the ".." notation to refer to a parent directory, the directive will return an error unless you have reconfigured the AspEnableParentPaths Metabase Property. This property is set to **false** by default.

| **Important** |
| --- |
| If you set the **AspEnableParentPaths** property to **true**, a potential security risk is introduced because an include path might access critical or confidential files outside of the application root directory. |

**Procedures**

**To enable parent paths through IIS Manager**

1. In IIS Manager, expand the local computer, right-click the starting-point directory of the application you want to configure, and then click **Properties**.
2. Click the **Directory** tab, and then click **Configuration**.
3. Click the **Options** tab.
4. In the **Application configuration** section, select the **Enable parent paths** check box.
5. Click **OK**.

# ASP generates Permission Denied errors in event log for global.asa

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Earlier versions of ASP executed events in the security context (or user identity) of the host process because there is no user context during these events. This caused problems, such as access denied errors when writing to a file in the Session_OnEnd event. ASP, by default, now runs the global.asa events, Application_OnEnd and Session_OnEnd, anonymously (the default value is **true**).

To change this setting programmatically, see AspRunOnEndAnonymously Metabase Property.

# CGI processes do not start

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If your CGI processes do not run, ensure that the CGI Web service extension has been enabled. See Requests for dynamic content return 404 error. Also, CGIs will not start unless the account on which the CGI processes run are assigned certain user rights. You can add the account as a member of the IIS_WPG group and assign the account the following two user rights:

- Adjust memory quotas for a process.
- Replace a process level token.

If you use anonymous authentication and you call external programs, including PHP programs, from CGI code, the operation may fail. The failure occurs because in IIS 6.0 the default anonymous user account, IUSR_*Computername*, is explicitly denied access to all executable programs in the %windir%\System32 folder for security reasons. To resolve this problem, remove the IUSR denial access control list (ACL) on the appropriate command-line tools that reside in the %windir%\System32 folder, and grant the IUSR_*Computername* account **Read & Execute** access.

**Procedures**

**To assign user rights to an account on the local computer**

1. From the **Start** menu, point to **Administrative Tools**, and then click **Local Security Policy**.
2. Expand **Security Settings**, double-click **Local Policies**, and then double-click **User Rights Assignment**.
3. In the details pane, double-click the policy you want to change.
4. Click **Add User or Group**.
5. In the **Enter the object names to select** box, type the user or group name.
6. Click **OK**.

# ASP.NET pages are returned as static files

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you installed IIS 6.0 without installing ASP.NET, ASP.NET files can be returned as static files. This error can also occur if you reinstalled IIS 6.0 without reregistering ASP.NET. To learn how to remedy this error, see ASP.NET IIS Registration Tool and use the **i** option.

# Collaboration Data Objects for Windows NT Server fail

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Collaboration Data Objects for Microsoft Windows NT Server (CDONTS) has been removed from the Microsoft Windows Server-TM- 2003 family. If your Web applications use CDONTS, you can convert them to Microsoft Collaboration Data Objects (CDO). Most methods in CDONTS have matching methods in CDO, but might be named differently.

For reference material for CDO in the Platform Software Developer Kit (PSDK), see Overview of CDO at MSDN Online.

# Connection Errors

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This section includes troubleshooting information about connection errors.

**In This Section**

- Client requests receive a "503: Service Unavailable" error
- Anonymous accounts (IUSR_computername) attempting subauthentication logon receive 401 error
- Clients cannot connect to server
- UNC connections are denied access
- Access denied to console applications in System32 directory
- Client requests time out or error out
- Client cannot renegotiate request and returns an HTTP 413 error
- Clients receive 403.16 when logging on to a Web server over an SSL connection
- Clients browsing to a Web site receive HTTP 403.4 - Forbidden: SSL is required to view this resource error, but the Web site is not configured to use SSL
- UPN logons not accepted by IIS 6.0 server in Windows 2000 domain

# Client requests receive a "503: Service Unavailable" error

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The 503: Service Unavailable error is a noncustomizable error that means the server is currently unable to process the request. There are many reasons why the server might not be able to process a request. For example, the administrator might have shut down an application pool to perform maintenance. Another possible cause of the 503 error is that the application pool queue was already full when the request arrived.

If the error was generated because the application pool queue was full at the time of the request, you will see error code 503 along with the message "QueueFull" when viewing the Httperr.log file. The Httperr.log file is located in the **%Systemroot%**\System32\LogFiles directory.

To remedy this problem, increase the application pool queue length limit as detailed in Configuring Application Pool Queue-Length Limits.

# Anonymous accounts (IUSR_computername) attempting subauthentication logon receive 401 error

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The subauthentication component, Iissuba.dll, is not enabled by default in IIS 6.0. In earlier versions, Iissuba.dll allowed IIS to manage passwords on anonymous accounts, which created a potential security risk. In IIS 6.0, you can use subauthentication to manage passwords for anonymous accounts by meeting the following requirements:

- For applications which you assign anonymous access, the worker process runs as LocalSystem.
- The subauthentication component, Iissuba.dll, is registered.
- The AnonymousPasswordSync Metabase Property is enabled (set to **true**).

The actions taken to meet the above requirements differ between clean installs of IIS 6.0 and upgrades to IIS 6.0 from installations of IIS with subauthentication configured.

For information about the procedures to configure sub-authentication, see Anonymous Authentication in IIS 6.0.

# Clients cannot connect to server

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The Windows Server 2003 family provides a software-based firewall to prevent unauthorized connections to your server from remote computers. The Internet Connection Firewall (ICF) is disabled by default. However, if you have enabled the firewall in its default configuration after installing a member of the Windows Server 2003 family and before installing IIS, clients will not be able to connect to your server. The following procedure configures ICF to allow clients to initiate Web and other IIS-related connections to your server.

**Procedures**

**To configure Internet Connection Firewall for IIS**

1. From the **Start** menu, click **Control Panel**.
2. Double-click **Network Connections**.
3. Right-click **Local Area Connection**, and click **Properties**.
4. Click the **Advanced** tab.
5. If you do not want to use the ICF, make sure the **Protect my computer and network by limiting or preventing access to this computer from the Internet** check box isn't available, and click **OK**.
6. If you do want to use the ICF, make sure the **Protect my computer and network by limiting or preventing access to this computer from the Internet** check box is enabled, and click **Settings**.
7. On the **Services** tab, enable a service to which you want to allow access to clients.
8. In the **Service Settings** dialog box that appears after enabling a service, do one of the following:
   - If you are enabling a service on the same computer you are working, the correct computer name is already filled in. Click **OK**.
   - If you are enabling a service on a different computer on your network, type the name or IP address of the computer hosting the service you are enabling, and click **OK**.
9. Repeat steps 7 and 8 until all the services you want accessible to clients are enabled.

# UNC connections are denied access

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The **Universal Naming Convention (UNC) authentication** method, also called **UNC Passthrough authentication**, determines the credentials to be used for gaining access to a UNC share on a remote computer. Beginning with IIS 6.0, the UNC authentication looks at the request user and the credentials stored in the UNCUserName Metabase Property and UNCPassword Metabase Property properties of the metabase to determine the credentials to pass through to the computer with the UNC share, in the following way:

1. **If UNCUserName** is specified (not empty) and **UNCPassword** is valid, the metabase user credentials are sent as the user identity for access to the remote share. If **UNCUserName** is specified (not empty) and **UNCPassword** is not valid, a 500 Internal Server Error: Invalid Username or Password message is sent to the client.

2. If **UNCUserName** is empty, then the credentials of the request user (either an authenticated set of credentials for authenticated requests or IUSR_*computername* credentials for anonymous requests) are sent as the user identity for access to the remote share.

| **Note** |
| --- |
| The **UNCAuthenticationPassthrough** metabase key is no longer used for UNC authentication. |

# Access denied to console applications in System32 directory

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Requests that use console applications in the Windows System32 directory, such as Cmd.exe, are denied access unless the remote user making the request is an authenticated member of the Administrators group. The denial is the result of special access control lists (ACLs) on all console application programs in the Windows System32 directory to restrict access to only administrators, LocalSystem, interactive users, and services. The ACL restriction does not affect local logon users that should have access, nor does the restriction affect your own custom CGI executable programs.

# Client requests time out or error out

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In IIS 6.0, settings are set to aggressive and secure defaults to minimize attacks due to time-outs and limits that were previously too generous. IIS enforces the following time-outs at the connection level:

- Limits on Response Buffering: The default value for the AspBufferingLimit Metabase Property is 4 MB. If ASP scripts buffer more than this, they error-out. There was no limit to buffering prior to IIS 6.0.

- Limits on posts: The AspMaxRequestEntityAllowed Metabase Property enforces a maximum ASP post size of 204,800 bytes, with each individual field limited to 100 KB. There was no limit to posts prior to IIS 6.0.

- The **ServerListenTimeout** metabase property is not used used by the WWW service in IIS 6.0, but remains available for the FTP, SMTP, and NNTP services. For the WWW service, **ServerListenTimeout** has been replaced by the following metabase properties:

    - ConnectionTimeout Metabase Property: This property specifies the amount of time, in seconds, the server waits before disconnecting an inactive connection.

    - MinFileBytesPerSec Metabase Property: When IIS responds to a client request, the **MinFileBytesPerSec** property determines the length of time the client has to receive the entire response. If the client machine takes too long to receive the entire response, the kernel-mode driver, HTTP.sys, terminates the connection according to the time-out value.

    - HeaderWaitTimeout Metabase Property: When a client connects to the Web server, the client computer is given a time limit to send in all headers for the request (demarked by a final double \r\n). If the complete header set for the request is not received within the time period indicated by **HeaderWaitTimeout**, HTTP.sys resets the connection. You can configure the value of **HeaderWaitTimeout**.

- Header size limitation: By default, HTTP.sys only accepts requests where the request header is less than 16 KB. This means that if HTTP.sys does not receive the terminating <CRLF><CRLF> sequence within 16 KB, HTTP.sys considers the request malicious and terminates the connection. You can change the header size limitation by adjusting the value in the MaxRequestBytes registry key.

# Client cannot renegotiate request and returns an HTTP 413 error

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If client certificates are enabled on a Web server, Web site, or on individual directories or files on the site, clients might see an HTTP 413 error when uploading large files.

If a client sends a long HTTP request, for example, a POST request, to a Web server running IIS 6.0, the IIS worker process might receive enough data to parse request headers, but not receive the entire request entity body. When the IIS worker process detects that client certificates are required to return data to the client, IIS attempts to renegotiate the client connection. However, the client cannot renegotiate the connection because it is waiting to send the remaining request data to IIS.

If client renegotiation is requested, the request entity body must be preloaded using SSL preload. SSL preload will use the value of the **UploadReadAheadSize** metabase property, which is used for ISAPI extensions. However, if **UploadReadAheadSize** is smaller than the content length, an HTTP 413 error is returned, and the connection is closed to prevent deadlock. (Deadlock occurs because a client is waiting to complete sending a request entity, while the server is waiting for renegotiation to complete, but renegotiation requires that the client to be able to send data, which it cannot do).

The solution is to ensure that client is not blocked from sending the entire entity body. To do so, change the value of **UploadReadAheadSize** to a value larger than the content length.

The following example shows how to set the value for **UploadReadAheadSize** to 64 KB on the Web server.

```
cscript adsutil.vbs set w3svc/1/uploadreadaheadsize 65536
```

**Note:** Setting the UploadReadAheadSize property above 64KB is not recommended for web sites that do not require client certificate authentication, otherwise you run the risk of allowing an anonymous Denial of Service (DOS) attack. When UploadReadAheadSize needs to be set at a value higher than 64KB, it is recommended that you set the SSLAlwaysNegoClientCert property to True, which will require that the client has a valid client certificate installed.

For more information about **UploadReadAheadSize**, see UploadReadAheadSize Metabase Property.

For more information see SSLAlwaysNegoClientCert Metabase Property.

# Clients receive 403.16 when logging on to a Web server over an SSL connection

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The VeriSign Global Server ID Intermediate Root certification authority (128-bit SSL) expired on January 7, 2004. Servers running IIS that have not been updated with the new Global Server ID Intermediate Root certification authority may encounter problems when clients try to establish SSL sessions by using the Secure Hypertext Transfer Protocol after January 7, 2004. Clients may see the following error message:

```
403.16 -- Client certificate is untrusted or invalid.

The client certificate has expired or is not yet valid.
```

| **Note** |
| --- |
| Servers that use VeriSign 40-bit Secure Server ID certificates are not affected by this expiration. |

**Procedures**

**To resolve this issue, take the following steps:**

1. Determine the version of the Intermediate Root CA that is currently active on your Web server. For more information, see Determining the Intermediate Root CA Version on a Web Server.
2. If necessary, obtain the current Intermediate CA certificate from the VeriSign Web site. On the VeriSign Web site, search for the Microsoft IIS 5.0 heading, and then click **Get Intermediate CA Here (If Required)** in Step 1.
3. Follow the instructions at the VeriSign Web site to perform the following tasks:
   a. Remove the expired Intermediate Root CA from your Web server.
   b. Install the current Intermediate Root CA on your Web server.
   c. Reboot your Web server and test the SSL connection.

# Client receives 403.16 error when IIS cannot process a complete certificate chain

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When IIS receives an incoming Secure Sockets Layer (SSL) request from a client, it attempts to build its certificate chain before sending its certificate information back to the client. Beginning with IIS 6.0, IIS does not automatically download intermediate certificates by default, which was the behavior in previous versions of IIS. Instead, IIS 6.0 fails the Certificate Revocation List (CRL) check for the certificate because it cannot find the HTTP location for the CRL Distribution Point (CDP). The user then sees an HTTP 403.16 error message.

To rectify this error, add the certificate to the Intermediate Certification Authorities folder on the local computer.

**To add an intermediate certificate to Intermediate Certification Authorities**

1. Download the intermediate certificate to the desktop of the computer where you want to install the certificate.
2. Right-click the certificate, click **Install Certificate** to open the Certificate Import wizard, and then click **Next**.
3. On the **File to Import** page, click **Next**.
4. On the **Password** page, type a password, if available, in the **Password** field, and then click **Next**.
5. On the **Certificate Store** page, click **Place all certificates in the following store** and then click **Browse**.
6. On the **Select Certificate Store** dialog box, check **Show physical stores**.
7. Expand the **Intermediate Certification Authorities** folder, select the **Local Computer** folder, and then click **OK**.
8. Click **Next** and then click **Finish**.

# Clients browsing to a Web site receive HTTP 403.4 - Forbidden: SSL is required to view this resource error, but the Web site is not configured to use SSL

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

It is possible that the Web site configuration has been altered to require SSL, although no certificate has been associated with the Web site. This might happen because the **Edit** button on the **Directory Security** tab is available although no certificate is associated with the Web site. The **Edit** button allows changes to be made to the site's SSL configuration even if a certificate has been removed.

To correct this problem, change the Web site configuration to not require SSL.

**Procedures**

**To remove SSL from a Web site by using IIS Manager**

1. In IIS Manager, right-click the Web site whose SSL configuration you want to change, and then click **Properties**.
2. On the **Directory Security** tab, in the **Secure Communications** area, click **Edit**.
3. Clear the **Require Secure Channel (SSL)** check box, and then click **OK**.

**To remove SSL from a Web site by using adsutil.vbs**

1. Click **Start**, click **Run**, type **cmd**, and then click **OK**.
2. Change to the inetpub\adminscripts directory.
3. At the command prompt, type the following command for the Web site whose SSL configuration you want to change, substituting # with the Web site identifier:

   **cscript adsutil.vbs set w3svc/** # **/AccessSSL False**

# UPN logons not accepted by IIS 6.0 server in Windows 2000 domain

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Although your IIS 6.0 server is a member of a Windows 2000 domain and is correctly configured for Digest authentication as well as subauthentication, logging on with a user principal name (UPN) in the form *username@domain.com* fails. This failure occurs because Digest authentication accepts domain logons in two formats only. If a user logs on to a server in the same domain where the user's account resides, *username* alone is sufficient for authentication. For logons with a user account from another domain, use the *domain**username* format.

# FTP server terminates user connections and returns MSFTPSVC event message 8

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you host a high-load FTP site with the FTP anonymous home directory on an UNC share, you may encounter the following event message in the Event Log: "FTP Server could not create a client worker thread for user at host *ip_address*. The connection to this user is terminated. The data is the error."

This happens when a large number of clients (approximately 1000) attempt to access the same UNC path at the same time and all of the redirector connections are in use. To remedy this problem, enable caching of the anonymous home directory with the registry key CacheAnonymousHomeDirInfo, and set the related timeout values in the registry keys AnonymousHomeDirInfoInterval and AnonymousHomeDirInfoGrace.

**Related Information**

- For more information about the registry keys CacheAnonymousHomeDirInfo, AnonymousHomeDirInfoInterval, and AnonymousHomeDirInfoGrace, see FTP Service Registry Entries.

- For more information about MSFTPSVC event messages, see FTP Service-Related Events.

# Miscellaneous Errors

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This section includes troubleshooting information about miscellaneous errors.

**In This Section**

- File requests to UNIX or Linux server return wrong file or error
- Cannot locate /Scripts or /Msadc directory
- ISAPI filter does not show up as "loaded" in UI
- During an upgrade to Windows Advanced Server, Limited Edition or to Windows Server 2003, Datacenter Edition, clustered IIS resources fail
- When attempting to download a file from an FTP site that is hosted on IIS 6.0, a "File not found" or similar error is returned, and the file name in the error message contains a caret (^) character
- Cannot make immediate request for a Web server certificate
- When adding a new Web site, the Web site is not added, and the error message "No more memory is available for security information updates" is displayed (also, error 1131 might appear in the system Event Log)
- Remote Desktop Connection shortcut does not appear on START menu and Remote tab does not appear on System Properties after upgrade from Windows 2000 with IIS
- Warnings received on upgrade
- Client certificate warnings on upgrade
- Install certificate after deleting the pending certificate request
- User receives ERROR_BAD_EXE_FORMAT on 64-bit Windows

# File requests to UNIX or Linux server return wrong file or error

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If IIS must access files on a UNIX or Linux system, file name case sensitivity can be an issue unless Network File System (NFS) support is enabled in IIS.

UNIX and Linux both support mixed-case file names, and IIS fully supports requesting static files in a case-sensitive manner. An issue arises, however, when IIS makes a subsequent request for a file from its static file cache. Because all file names are converted to uppercase letters in the IIS cache, any request after the first request from the IIS static file cache might fail or return the wrong file.

To remedy this problem, disable the IIS static file cache so that all file requests are issued fresh, thereby retaining correct file name case. The static file cache can be disabled for individual virtual directories on Web sites, or globally for all sites.

| **Note** |
| --- |
| Changing this setting has no effect on how ASP files and templates are cached. |

**Procedures**

**To disable the static file cache for a particular Web site virtual directory**

- Edit the metabase and set the **MD_VR_NO_CACHE** property to **1**.

**To disable the static file cache for all sites**

- Edit the registry and add the binary value **DisableStaticFileCache**=**1** to the HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\InetInfo\Parameters key.

# Cannot locate /Scripts or /Msadc directory

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

By default, the **/scripts** and **/msadc** directories in IIS 5.0 allowed scripts and executables to run. These directories were removed from IIS 6.0 because, if a malicious user gained access to one of these directories, the user could run a script or executable and potentially gain control of the Web server. If your server configuration requires a directory of this nature, you will need to create the directory and establish the appropriate NTFS Permissions.

# ISAPI filter does not show up as "loaded" in UI

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In an effort to optimize resources in IIS 6.0, an ISAPI filter is not loaded until a request is made to a Web site that requires the ISAPI filter. Until this request is made, IIS Manager does not display the status of the ISAPI filter. Also, if the ISAPI filter requires the SF_NOTIFY_READ_RAW_DATA filter notification, the filter will not load while IIS is running in worker process isolation mode. Review the Application Event Log for events from W3SVC-WP to verify that the filter did not load. To remedy this problem, run IIS in IIS 5.0 isolation mode or contact the vendor of the ISAPI filter for compatibility updates.

| **Important** |
| --- |
| If the ISAPI filter is restricted by an access control list (ACL) in such a way that the IIS worker process identity cannot load it, requests receive a 503 error. To remedy this, set the ACLs on the ISAPI filter DLL to allow access for the IIS_WPG group. |

**Procedures**

**To configure IIS for IIS 5.0 isolation mode**

1. In IIS Manager, expand the local computer, right-click **Web Sites**, and then click **Properties**.
2. Click the **Service** tab, select the **Run WWW service in IIS 5.0 isolation mode** check box, and then click **OK**.
3. To start the WWW service, click **Yes**.

# During an upgrade to Windows Advanced Server, Limited Edition or to Windows Server 2003, Datacenter Edition, clustered IIS resources fail

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS 6.0 is not supported during rolling upgrades of server clusters. To upgrade a clustered IIS resource, you must replace the existing IIS resource with a Generic Script Resource. For instructions on how to do this, search for "generic script resource" in Help and Support Center for Windows Server 2003.

# When attempting to download a file from an FTP site that is hosted on IIS 6.0, a "File not found" or similar error is returned, and the file name in the error message contains a caret (^) character

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This error occurs when the requested file contains one or more Unicode characters in its file name. For security reasons, certain characters are disallowed in file names. When Unicode characters are used, they are converted to the closest ANSI equivalent that is available in the code page of the server operating system. Unicode characters that do not have exact ANSI equivalents might be replaced with a disallowed ANSI character. To prevent a disallowed character from appearing in the file name, it is converted to a caret (^).

To avoid this issue, do not use Unicode characters in file names that are used on an FTP site. If Unicode characters must be permitted, only use those that have a direct equivalent (one-to-one mapping) to the server code page.

# Cannot make immediate request for a Web server certificate

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

After installing Certificate Services on a server and configuring it to be either an Enterprise Root certification authority (CA) or a standalone certification authority on a server, you cannot immediately request a Web server certificate by using the Web Server Certificate Wizard on that same server. The **Send the request immediately to an online certification authority** option is grayed and cannot be selected.

It takes a few hours for IIS to recognize that a new CA has come onine. After IIS recognizes the new CA, re-run the Web Server Certificate Wizard to generate the certificate request. The **Send the request immediately to an online certification authority** option will then be available.

If you must have a certificate immediately, run the Web Server Certificate Wizard and select **Prepare the request now, but send it later**. The wizard will generate a certificate request file that can be processed immediately by the new CA.

# When adding a new Web site, the Web site is not added, and the error message "No more memory is available for security information updates" is displayed (also, error 1131 might appear in the system Event Log)

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This problem occurs because insufficient non-paged pool memory has not been allocated for HTTP.sys. By default, IIS automatically determines the number of Web sites that can be created based on the amount of physical memory available. For example, on a computer that has 64 megabytes (MB), the non-paged pool memory value is set to 16. On a computer that has 256 MB, the non-paged pool memory value is set to 64.

To resolve this issue, create a MaxEndPoints registry value, and set it to a number that is at least 1 greater than the number of Web sites you want to host with IIS. To do so, follow these steps:

1. Start Registry Editor and navigate to the HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\HTTP\Parameters key.

2. In the details pane, right-click, point to **New**, and and select **DWORD Value**.

3. In the **Name** box, type the following: **MaxEndPoints**

4. Double-click the MaxEndPoints value, and in the **Value data** box type a number that is at least 1 greater than the number of Web sites that you want to host, but no larger than 1024, then click **OK**, and close Registry Editor.

# Remote Desktop Connection shortcut does not appear on START menu and Remote tab does not appear on System Properties after upgrade from Windows 2000 with IIS

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Although the Start menu shortcut and the Remote tab have not been installed, the Remote Desktop Connection application itself is installed. The user interface elements may be hidden if the permissions on the \Inetpub directory or the \Inetpub\Adminscripts directory deny full control to the Local System account.

There are several ways to address this issue.

- Work around the issue by running Remote Desktop Connection from the command line.
- Restore the Remote tab on the System Properties page.
- Restore the Start menu shortcut.

**Procedures**

**To run Remote Desktop Connection from the command line**

1. Click **Start** and then click **Run**.
2. In the **Open** box, type

```
mstsc.exe
```

and then click **OK**.

**To restore the Remote tab on the System Properties page**

1. In Windows Explorer, right-click %windir%\System32\remotepg.dll, and then click **Open With**.
2. Click **Open With**, click **Select the program from a list**, and then click **OK**.
3. Click **Browse**, navigate to %windir%\System32\regsvr32.exe, and select this file.
4. Click **Open**, click **OK**, and then click **OK** again.

**To restore the Start menu shortcut for Remote Desktop Connection**

1. In Windows Explorer, right-click \Inetpub\Adminscripts and then click **Sharing and Security**.
2. On the **Security** tab, click **Add**, type

```
System
```

and then click **OK**.

1. Grant the account full control, and then click **OK**.
2. Insert the Windows Server 2003 CD, click **Perform Additional Tasks**, and then click **Set up Remote Desktop Connection**.
3. Accept the license agreement, click **Next**, click **Next** again, and then click **Install**.
4. Click **Finish** when installation is complete, and then click to exit the CD.

# Warnings received on upgrade

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When you upgrade a server with IIS installed to Windows Server 2003 with IIS 6.0, you may receive the following warning messages:

The following items are not compatible with Windows. If you continue, you may not be able to use these items, even after Setup is complete.

- IIS World Wide Web Publishing Service (W3SVC) will be disabled during upgrade.
- IIS is being installed on a FAT volume. This will disable IIS security features.

The first message occurs when you upgrade a server without previously running the IIS Lockdown Tool or configuring the RetainW3SVCStatus registry entry. By default, because of increased security measures, the World Wide Web Publishing Service (WWW service) is not enabled after you upgrade from the Windows 2000 Server family with IIS 5.0 unless you take one of the following actions on a manual or unattended upgrade:

- Run the IIS Lockdown Tool on the computer that is running Windows 2000 Server before you start the upgrade process. The IIS Lockdown Tool reduces the attack surface of your server by disabling unnecessary features, and the tool provides the option to enable and customize features for your site. For more information about the IIS Lockdown Tool, see IIS Lockdown Tool 2.1.

  | **Important** |
  | --- |
  | If you do not run the IIS Lockdown Tool, after the upgrade is complete, you must ensure that all unnecessary IIS features have been removed or disabled. You must also ensure that the enabled features are configured with the highest security settings that your organization can support. |

- Add the RetainW3SVCStatus registry entry to the registry prior to upgrading.
- Add the ?DisableWebServiceOnUpgrade = False? entry to the [InternetServer] section of an unattended installation script that you plan to run for the upgrade.
- Enable the WWW service after the upgrade is completed.

  | **Caution** |
  | --- |
  | Incorrectly editing the registry might severely damage your system. Before making changes to the registry, you should back up any valued data on the computer. |

**Procedures**

**To use regedit.exe to add the RetainW3SVCStatus registry entry to the registry**

1. Click **Start**, click **Run**, type

```
regedit
```

in the **Run** box, and then click **OK**.

1. Navigate to the HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\W3SVC registry entry.
2. Click to select the registry entry, point to **New** on the **Edit** menu, and then click **Key**.
3. Type

```
RetainW3SVCStatus
```

and then click **Enter**.

1. On the **Edit** menu, point to **New**, and then click **DWORD Value**.

2. Type

```
do_not_disable
```

and then click **Enter**.

1. On the **Edit** menu, click **Modify**.

2. Type

```
1
```

and then click **Enter**.

**To enable the WWW service after upgrading**

1. Click **Start**, click **Administrative Tools**, and then click **Services**.
2. Right-click **World Wide Web Publishing** and then click **Properties**.
3. Click the **General** tab, set **Startup type** to Automatic, and then click **Apply**.
4. Click **Start** to start the service, and then click **OK** after the service has started.

The second message occurs when the partition on which you are installing IIS 6.0 is formatted as FAT. Installing IIS on a FAT volume disables Windows Server 2003 security features that require the NTFS file system. For example, NTFS supports Active Directory, which is necessary for domains, user accounts, and other important security features. You should convert the partition from FAT to NTFS before continuing the upgrade.

# Client certificate warnings on upgrade

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you have a Web site on Internet Information Services (IIS) 5.0 that requires client certificates, when you upgrade the server to Microsoft Windows Server 2003 with IIS 6.0, clients that connect to the site may receive one of the following error messages even if the client certificates are not controlled by a certificate trust list (CTL):

```
HTTP 403.16 Forbidden: Client certificate untrusted or invalid.

-or-

HTTP 403.16 Forbidden: Client certificate is ill-formed or is not

trusted by the web server.

-or-

HTTP Error 403.7: Forbidden: SSL client certificate is required.
```

In addition, when the client accesses the Web site, one of two things may happen:

- The client may not receive the Client Authentication dialog box in the browser, and therefore cannot choose a client certificate that allows access to the Web site.
- If the client receives the Client Authentication dialog box, the certificate list in the **Client Authentication** dialog box may not display the required client certificate.

These issues may occur if the client certificate was created by a certification authority that the IIS computer does not trust. In IIS 5.0, you could specify a CTL that contained certification authorities whose root certification authority (CA) certificates were installed in the personal certificate store on the local computer. However, in IIS 6.0, the root CA certificates must be installed in the Trusted Root Certification Authorities certificate store on the local computer. This is because IIS 6.0 verifies certificates based on the rules specified in the CryptoAPI. The CryptoAPI rejects certificates if the root CA certificates are not installed in the Trusted Root Certification Authorities certificate store on the local computer.

To resolve the error and display the certificate in the browser, you must install the root CA certificate in the Trusted Root Certification Authorities certificate store on the local computer.

**Procedures**

**To install the root CA certificate in the Trusted Root Certification Authorities certificate store on the local computer**

1. Add a Certificates snap-in for the local computer. For more information about adding a Certificates snap-in, see "To manage certificates for a computer" in Windows Server 2003 Help and Support Center.
2. Export the certificate from the Personal Certificate store on the local computer. For more information about exporting a certificate, see "To export a certificate" in Windows Server 2003 Help and Support Center.
3. Import the certificate to the Trusted Root Certification Authorities certificate store on the local computer. For more information about importing a certificate, see "To import a certificate" in Windows Server 2003 Help and Support Center.

# Install certificate after deleting the pending certificate request

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS stores the private key for a certificate as the pending request. Deleting the pending request deletes the association of the private key with IIS, but the private key still exists in the certificate store. To install the certificate without having the pending request available, you can use version 5.2.3718.0 of the Certutil.exe command-line tool that is available through the Certificate Services MMC snap-in in Windows Server 2003. For more information about Certutil.exe, see Certutil.exe.

**Procedures**

**To install a Web server certificate that lacks a pending certificate request**

1. Click **Start**, point to **Run**, type **cmd**, and then click **OK**.
2. Navigate to the directory where Certutil.exe is stored; by default, this is %windir%\system32.
3. Type the following command at the command prompt: **certutil -addstore my** *certnew.cer*

   where *certnew.cer* is the name of the certificate you received from the certification authority (CA). You should see the following message: **CertUtil: -addstore command completed successfully**.
4. Navigate to the directory where you stored the certificate you received from the CA. Right-click the certificate and then point to **Properties**.
5. Click the **Details** tab and select <All> in the **Show** drop-down list.
6. In the **Field** list, select **Thumbprint** to display its value in the view pane.
7. Select the **Thumbprint** value in the view pane and then click CTRL+C.
8. Return to the command prompt window and type the following command: **certutil -repairstore my "***thumbprint***"**

   where *thumbprint* is the value of the **Thumbprint** field. Be sure to type the double quotes as part of the command. If the command is successful, the following message is displayed: "Encryption test passed CertUtil: = repairstore command completed successfully."
9. Install the server certificate on your Web server.

**Important**

If the certutil command does not complete successfully, the following error message is displayed: "Certutil: -repairstore command FAILED: 0x80090011 (-2146893807) Certutil: Object was not found." This message indicates that the private key for the certificate does not exist in the certificate store. You cannot install the certificate you obtained from the CA. Instead, you must generate a new certificate request, obtain the new certificate, and install that new certificate on your Web server.

Installing Server Certificates

# Cannot launch COM objects with IUSR_computername or IWAM_computername accounts

Updated: August 22, 2005

Applies To: Windows Server 2003 R2, Windows Server 2003 with SP1

For Windows Server 2003, the IUSR_*computername* and IWAM_*computername* accounts are created and granted launch permissions to DCOM components by default when installing IIS. For Windows Server 2003 Service Pack 1 (SP1), the accounts are still created, but are no longer granted launch permissions to DCOM components by default when installing IIS.

If you had installed IIS prior to upgrading to SP1, the permissions will not be changed. However, if you install IIS after upgrading to SP1, Component Object Model (COM) objects will fail to launch under the IUSR_*computername* and IWAM_*computername* accounts if your application uses default launch permissions for those accounts. In this situation you will receive an "Access denied" error message, because COM+ is passing credentials that are not valid to Windows Server 2003. To remedy this problem, grant explicit launch permissions to specific user(s) or group(s) to launch COM objects instead of using default launch permissions. You should also ensure that IIS, COM+, and Windows all have the same password for the IWAM_*computername* account. For more information about configuring launch permissions, see Configuring Launch Permissions for COM+ Server Objects.

# Computer runs slowly when scripts using ADSI scripts to query IIS 6.0

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

When you run a program that uses multiple threads and Active Directory Service Interfaces (ADSI) scripts to query Internet Information Services (IIS), memory usage on your computer might greatly increase, causing the program to stop responding.

This problem occurs on computers that are running one of the following operating systems:

- Microsoft Windows Server 2003
- Microsoft Windows XP Professional
- Microsoft Windows 2000

When you use multiple threads to query IIS using ADSI, memory is used by each of these threads. This problem occurs because the information in the IIS ADSI provider per-thread cache is not cleared when a thread is terminated. Because this memory is not released, the program might run out of memory.

There is a hotfix available to correct this problem. See Knowledge Base article 823700, FIX: Your computer may run slowly when you use Active Directory Service Interfaces scripts in a program to administer IIS on a computer that is running Windows Server 2003, Windows 2000, or Windows XP, for information about how to obtain the hotfix.

# User receives "The system cannot find the path specified" message when clicking on a Web site in IIS Manager

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

This occurs when a user deletes a physical directory for a Web site with virtual directories from a location other than IIS Manager, such as in Windows Explorer or through the command line. When physical directories are deleted this way, the virtual directories continue to exist in the IIS metabase and to serve content. When the user expands or clicks on the Web site in IIS Manager, they receive the message "The system cannot find the path specified" because the folder containing the content for that Web site was deleted; however, IIS Manager will continue to display the Web site with the deleted physical directory as long as virtual directories still exist and serve content under that Web site. To fix this issue, you must correct the path to the home directory for the Web site.

| **Important** |
| --- |
| You must be a member of the Administrators group on the local computer to perform the following procedure or procedures. As a security best practice, log on to your computer by using an account that is not in the Administrators group, and then use the **runas** command to run IIS Manager as an administrator. At a command prompt, type **runas /user:***Administrative_AccountName* **"mmc %systemroot%\system32\inetsrv\iis.msc"**. |

**To set the location of the home directory for a Web site by using IIS Manager**

1. In IIS Manager, expand the local computer, expand **Web Sites**, right-click the Web site with the deleted physical directory, and then click **Properties**.
2. On the **Home Directory** tab of the Web site **Properties** dialog, click **Browse**.
3. In the **Browse For Folder** dialog box, locate a folder with content for the Web site or click **Make New Folder** to create a folder where you will put the content, and click **OK**.
4. Click **Apply** and then **OK**.

# User receives ERROR_BAD_EXE_FORMAT on 64-bit Windows

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The most common problems with 32-bit applications on 64-bit Windows involve image mismatch. An image mismatch occurs when a 64-bit process tries to load a 32-bit DLL or a 32-bit process tries to load a 64-bit DLL. Image mismatch errors that cause a worker process to fail during startup are logged in the Windows Events log as 0xC1: ERROR_BAD_EXE_FORMAT. Image mismatch errors that do not cause the worker process to fail during startup are logged in the IIS log files as Win32 error 0xC1: ERROR_BAD_EXE_FORMAT. To remedy these errors, configure IIS to launch worker processes that are the same bitness as your applications. For information about how to configure IIS to run 32-bit applications on 64-bit Windows, see Configuring IIS to Run 32-bit Applications on 64-Bit Windows. For more information about running 32-bit applications on 64-bit Windows, see Running 32-bit Applications on 64-bit Windows.

# Advanced Troubleshooting with IIS Tracing

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Event Tracing for Windows (ETW) is a feature of the Windows operating system that allows you to troubleshoot issues with HTTP requests in IIS components like Active Server Pages (ASP), Internet Server Application Programming Interface (ISAPI) extensions, and the Secure Sockets Layer (SSL) Filter service. If an HTTP request in IIS fails or becomes unresponsive while ETW is enabled, you can view ETW trace data, called events, to determine which component caused the failure.

This section includes the following information:

Tracing Requests: Describes the various procedures for tracing different components in IIS.

Tracing Startup and Shutdown Issues in the IIS Admin Service: Describes how to trace the IIS Admin Service when IIS is having trouble starting up or shutting down.

**See Also**
**Other Resources**
Troubleshooting IIS 6.0 with Tracing

# Tracing Requests

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

In Windows Server 2003 (Service Pack 1 or later) IIS includes the following tracing features. These features leverage the Event Tracing for Windows (ETW) infrastructure.

- IIS Currently-Executing Requests Tracing: This tracing feature provides general statistics and details about all requests executing on the server at the moment tracing was started. If the CPU on your server is spiking or if requests become unresponsive, currently-executing requests tracing can help you understand which URL is being requested, which application pool the URL resides in, and other similar details. This feature does not include the option to specify which components or URLs to trace. For more detailed information, see Currently Executing Requests Tracing.

- IIS Request-Based Tracing: This tracing feature tracks HTTP requests in IIS components. Request-based tracing can help you target the IIS component processing a request when the request failed or became unresponsive. Request-based tracing allows you to define either a specific URL or a group of URLs to trace. Request-based tracing events can be viewed in real time, but the feature can return a substantial amount of data (depending on server traffic), so it is much more practical to view the data in a trace log. For more detailed information about request-based tracing, see IIS Request-Based Tracing.

This section includes the following information:

- How to Create a Provider File for Request-Based Tracing: Describes how to create a simple text file that defines which IIS components to trace and how much data tracing should return.

- How to Trace Requests in IIS: Describes how to trace various IIS components, called providers, using IIS request-based tracing.

- How to Trace Requests for a Specific URL or Set of URLs: Describes how to trace requests for a specific URL or set of URLs using request-based tracing.

- How to Trace All Requests Currently Executing in IIS Worker Processes: Describes how to trace requests that are executing inside an IIS worker process using the currently-executing requests tracing command-line feature.

- How to Trace Requests Using the Performance Logs and Alerts MMC: Describes how to use the Performance Logs and Alerts MMC to trace IIS providers on demand or according to a schedule.

- How to Process and View Trace Log Files: Describes how to process and view trace log data using Log Parser 2.2 and the DumpTraceReqs.js sample script.

# How to Create a Provider File for Request-Based Tracing

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS components are called **providers** in the context of Event Tracing for Windows (ETW) because they provide trace data. When you start request-based tracing in IIS, you need to tell ETW which provider(s) to trace. You also need to tell ETW how much data each provider should report. The verbosity level is the name of the setting that indicates the amount of data requested. You define provider(s) and verbosity levels in a simple text file called a provider file. When you execute the command to start tracing, you specify the name of the provider file (and path, if necessary). ETW reads the provider file and begins tracing the provider(s) at the verbosity levels defined in that file.

In Windows Server 2003 (Service Pack 1 or later) the following IIS providers report trace data to ETW:

- IIS: WWW Server
- IIS: SSL Filter
- IIS: ISAPI Extension
- IIS: ASP
- IIS: IISAdmin

The IIS: WWW Server provider includes the following flags to enable various functional areas or subcomponents in the WWW server provider. You can define one or more functional areas in your provider file by specifying the flag number or the friendly flag name.

| Functional Area | Flag | Friendly Flag Name |
|---|---|---|
| UrlFilter | 1 | UseURLfilter |
| Authentication | 2 | IISAuthentication |
| Security | 4 | IISSecurity |
| ISAPI Filter | 8 | IISFilter |
| Static File | 10 | IISStaticFile |
| CGI | 20 | IISCGI |
| Compression | 40 | IISCompression |
| Cache | 80 | IISCache |
| WWW Server All | 0xFFFFFFFE | IISAll |

Verbosity levels include the following:

| Level | Name | Description |
|---|---|---|
| 0 | General | IIS providers log only those few events required to provide some context to the request activity. These events include a **General_Request_Start** event that logs the URL and verb for the request and a **General_Request_End** event. |

| | | |
|---|---|---|
| 1 | Fatal Error | IIS providers report events for actions that can cause a process to exit or actions that are about to cause a process to exit. |
| 2 | Error | IIS providers report events when components cannot continue processing a request. The request is immediately rejected.<br>**Note**<br>These events typically indicate a problem on the server side rather than a client-induced problem. |
| 3 | Warning | IIS providers report events when components experience an unexpected result/error but can continue processing the request. |
| 4 | Information | IIS providers report general information about requests. |
| 5 | Verbose | IIS providers report detailed information about requests. |

**To create a provider file**

1. Create a new file in a text editor like Notepad.
2. Enter a provider name in double quotes, flags (if any) or zero (0), and the verbosity level.

   For example:

   "IIS: WWW Server" 0xFFFFFFFE 5

   "IIS: Active Server Pages (ASP)" 0 5

   "IIS: WWW Isapi Extension" 0 5
3. Start a new line for each provider, if you plan to trace more than one provider.
4. Save and close the provider file.

Configuring the IIS Request-Based Tracing Session

# How to Trace Requests in IIS

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you are actively troubleshooting a problem in IIS and you believe the problem exists in a specific component like ASP or the SSL Filter service, you can trace requests in that component to locate the source of the problem. If you are uncertain where the problem exists, you can trace requests in multiple components and view the resulting trace data to locate the source of the problem.

Request-based tracing uses the following commands or switches:

| | |
|---|---|
| **logman start** | Starts the trace session using Logman.exe as the controller. |
| **logman stop** | Stops the trace session. |
| *session name* | Any name you want to give this trace session. |
| **-pf** *provider file name* | Identifies the name of the provider file. This can also be a path to the file. For more information, see How to Create a Provider File for Request-Based Tracing. |
| **-ets** | Tells Logman.exe to start the trace session immediately. |

**To trace requests in IIS components**

1. From a command prompt, type **logman start** *session name* **-pf** *provider file name* **-ets** and press ENTER.

   For example: **logman start ASPtrace -pf ASPproviders -ets**

2. Event Tracing for Windows prints to the screen details about the trace session you just started, including the name of the session, the file name where the trace data will be collected (*session name*.etl by default), the providers listed in the provider file, and whether or not the command was successful.

3. Allow the trace session to run until you have reproduced the problem or until your sites have processed enough requests to produce a manageable data set.

4. From the command prompt, type **logman stop** *session name* **-ets** and press ENTER.

Troubleshooting IIS 6.0 with Tracing

# How to Trace Requests for a Specific URL or Set of URLs

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

If you are actively troubleshooting a problem and you know the URL where the problem exists, you can trace that specific URL. If you do not know which URL is causing the problem, but you suspect it may be an Active Server Page (ASP) or Microsoft ASP.NET page, you can trace a set of URLs.

Request-based tracing for a specific URL or set of URLs uses the following commands or switches:

| | |
|---|---|
| **logman start** | Starts the trace session using Logman.exe as the controller. |
| **logman stop** | Stops the trace session. |
| *session name* | Any name you want to give this trace session. |
| **-pf** *provider file name* | Identifies the name of the provider file. This can also be a path to the file. For more information, see How to Create a Provider File for Request-Based Tracing. |
| **-ets** | Tells Logman.exe to start the trace session immediately. |

**To trace requests for a specific URL**

1. Configure the TraceUriPrefix Metabase Property for the URL you want to trace.

   a. Open a command prompt and navigate to the %windir%\Inetpub\AdminScripts directory.

   b. Type **adsutil.vbs set w3svc/***n***/TraceUriPrefix=***path to URL* and press ENTER. *N* is the number of the site as it is listed in the metabase, e.g. w3svc/1 is the default Web site (by default). *Path to URL* is the physical path to the file you want to trace, e.g. %windir%\Inetpub\wwwroot\asp\default.asp

2. Set the **UseUrlFilter** flag.

   a. Create a new provider file or open an existing provider file. See How to Create a Provider File for Request-Based Tracing.

   b. Enter one of the following items in your provider file:

      **"IIS: WWW Server" UseUrlFilter 5**

      The **UseUrlFilter** flag enables tracing for the URL specified in the **TraceUriPrefix** metabase property.

      -or-

      **"IIS: WWW Server" 0xFFFFFFFE 5**

      The 0xFFFFFFFE flag enables all the WWW server tracing flags, including the **UseUrlFilter** flag.

3. Save and close the provider file.

4. From a command prompt, type **logman start** *session name* **-pf** *provider file name* **-ets** and press ENTER.

   For example: **logman start AllAspTrace -pf AllAspUrls -ets**

5. Event Tracing for Windows prints to the screen details about the trace session you just started, including the name of the session, the file name where the trace data will be collected (*session name*.etl by default), the providers listed in the

provider file, and whether or not the command was successful.

6. Allow the trace session to run until you have reproduced the problem or until your sites have processed enough requests to produce a manageable data set.

7. From the command prompt, type **logman stop** *session name* **-ets** and press ENTER.

   To view the trace data, see How to Process and View Trace Log Files.

**To trace requests for a set of URLs**

1. Configure the TraceUriPrefix Metabase Property for the URLs you want to trace.

   a. Open a command prompt and navigate to the %windir%\Inetpub\AdminScripts directory.

   b. Type **adsutil.vbs set w3svc/***n***/TraceUriPrefix=***path to URL*extension* and press ENTER. *N* is the number of the site as it is listed in the metabase, e.g. w3svc/1 is the default Web site (by default). *Path to URL*extension* is the physical path to the group of files you want to trace, e.g. %windir%\Inetpub\wwwroot\asp*.asp or %windir%\Inetpub\wwroot\aspnet*.aspx

2. Set the **UseUrlFilter** flag.

   a. Create a new provider file or open an existing provider file. See How to Create a Provider File for Request-Based Tracing.

   b. Enter the ASP provider, if you are going to trace a group of .asp files, for example: "IIS: Active Server Pages (ASP)" 0 5

   c. Type one of the following items in your provider file:

      **"IIS: WWW Server" UseUrlFilter 5**

      The **UseUrlFilter** flag enables tracing for the URL specified in the **TraceUriPrefix** metabase property.

      **-or-**

      **"IIS: WWW Server" 0xFFFFFFFE 5**

      The 0xFFFFFFFE flag enables all the WWW server tracing flags, including the **UseUrlFilter** flag.

3. Save and close the provider file.

4. From a command prompt, type **logman start** *session name* **-pf** *provider file name* **-ets** and press ENTER.

   For example: **logman start AllAspTrace -pf AllAspUrls -ets**

5. Event Tracing for Windows prints to the screen details about the trace session you just started, including the name of the session, the file name where the trace data will be collected (*session name*.etl by default), the providers listed in the provider file, and whether or not the command was successful.

6. Allow the trace session to run until you have reproduced the problem or until your sites have processed enough requests to produce a manageable data set.

7. From the command prompt, type **logman stop** *session name* **-ets** and press ENTER.

   To view the trace data, see How to Process and View Trace Log Files.

# How to Trace All Requests Currently Executing in IIS Worker Processes

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use currently-executing requests tracing to find out which requests are executing in a worker process when the worker process has become slow or unresponsive. When enabled, currently-executing requests tracing prompts worker processes to report statistics and details about each request in each worker process.

Currently-executing requests tracing does not require a provider file. Instead, currently-executing requests tracing uses the following commands or switches:

| | |
|---|---|
| **logman start** | Starts the trace session using Logman.exe as the controller. |
| **logman stop** | Stops the trace session. |
| *session name* | Any name you want to give this trace session. |
| **-p "IIS: Request Monitor"** | Identifies which provider (-p) should be traced. |
| **-ets** | Tells Logman.exe to start the trace session immediately. |

**To trace all requests currently executing in IIS worker processes**

1. Open a command window and type **logman start** *session name* **–p "IIS: Request Monitor" -ets** and press ENTER.
2. Event Tracing for Windows prints to the screen details about the trace session you just started, including the name of the session, the file name where the trace data will be collected (*session name*.etl by default), and whether or not the command was successful.
3. Allow the trace session to run until you have reproduced the problem or until your sites have processed enough requests to produce a manageable data set.
4. From the command prompt, type **logman stop** *session name* **-ets** and press ENTER.

   To view the trace data, see How to Process and View Trace Log Files.

# How to Trace Requests Using the Performance Logs and Alerts MMC

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The Performance Logs and Alerts snap-in to the Microsoft Management Console (MMC) allows you to trace IIS providers. You can manually start a trace or you can configure Event Tracing for Windows to trace IIS providers according to a schedule. You cannot, however, configure verbosity levels (the amount of data returned by IIS providers) when using the Performance Logs and Alerts MMC. For more information about verbosity levels, see Verbosity levels.

**To trace IIS providers using the Performance Logs and Alerts MMC**

1. From the Start menu, right-click **My Computer**, and click **Manage**.
2. In the Computer Management MMC, expand the **Performance Logs and Alerts** node, right-click **Trace Logs**, and click **New Log Settings**.
3. Type a name for the new trace session.
4. In the trace session dialog box, click **Nonsystem Providers**.
5. Click the **Add** button.
6. In the **Add Nonsystem Providers** dialog box, select the providers you want to trace. Hold the CTRL key to select multiple providers.
7. Click **OK**.
8. If you want to start the trace immediately, click **OK**. If you want to configure other tracing options, including an automatic tracing schedule or the location and naming of log files, click the other tabs on this dialog box.
9. To stop tracing, right-click the trace session you just created and click **Stop** in the drop-down menu.

   To view the trace data, see How to Process and View Trace Log Files.

# How to Process and View Trace Log Files

Updated: August 22, 2005

Applies To: Windows Server 2003 R2, Windows Server 2003 with SP1

Trace data is written in binary format to a trace log (*filename*.etl). To view the trace data, the log file must be processed by a tool like LogParser. LogParser version 2.2 or later includes a sample script called DumpTraceReqs.js. DumpTraceReqs.js was specifically designed to format trace log files for easy viewing. You do not need to be familiar with LogParser to process trace logs.

| **Note** |
| --- |
| The following procedure does not apply to IIS Admin trace logs. To process and view IIS Admin trace logs, see How to Process IIS Admin Trace Log Files Using Trace Report. |

**To process and view trace log files**

1. Download Logparser, version 2.2 or later from the Microsoft Download Center.
2. Register Logparser.dll on your copy of Windows Server 2003 (version SP1 or later).
3. From a command prompt, navigate to the directory where you installed LogParser.
4. Type **regsvr32 logparser.dll** and press ENTER.
5. Open a command prompt and navigate to the directory where DumpTraceReqs.js is stored (%systemroom%\LogParser\Samples\Scripts, by default).
6. Type **dumptracereqs** *tracelogname* **>***newfilename*.txt and press ENTER.
7. *Tracelogname* is the name of the trace log .etl file and *newfilename*.txt is the name of a new file where the post-processed data will be saved. LogParser and DumpTraceReqs.js process the trace log file and store the post-processed data in the *newfilename*.txt file display the results to the screen.
8. To view the data, type **notepad** *newfilename*.txt and press ENTER.

# Tracing Startup and Shutdown Issues in the IIS Admin Service

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

The IIS Admin service reads the IIS metabase.xml file and the related in-memory configuration services. Use this provider if you notice that the IIS Admin service has trouble starting up or appears to be unresponsive at any time.

This section includes the following information:

- How to Trace the IIS Admin Service
- How to Process IIS Admin Trace Log Files Using Trace Report

Tracing Startup and Shutdown Problems in the IIS Admin Service

# How to Trace the IIS Admin Service

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

Use the following procedure to trace the IIS Admin service if the service fails to startup or shutdown. IIS Admin tracing uses the following parameters:

| | |
|---|---|
| **logman start** | Starts the trace session using Logman.exe as the controller. |
| **logman stop** | Stops the trace session. |
| *session name* | Any name you want to give this trace session. |
| **-p "IIS: IISADMIN Global"** | Identifies which provider (-p) should be traced. |
| **(startup,shutdown)** | Tells Logman.exe to trace the IIS Admin service for startup and shutdown events. You can specify one or both flags, as needed. |
| **-ets** | Tells Logman.exe to start the trace session immediately. |

**To trace the IIS Admin service**

1. From a command prompt, type **logman start** *session name* **-p "IIS: IISADMIN Global"(startup,shutdown) -ets** and press ENTER.

   For example: **logman start IISAdminTrace -p "IIS: IISADMIN Global" (startup,shutdown) -ets**

2. Event Tracing for Windows prints to the screen details about the trace session you just started, including the name of the session, the file name where the trace data will be collected (*session name*.etl by default), and whether or not the command was successful.

3. If necessary, start or stop the IIS Admin service (depending on the nature of the problem you are trying to troubleshoot). Type **net stop IIS Admin** or **net start IIS Admin** and press ENTER.

4. Allow the trace session to run until you have reproduced the problem.

5. From the command prompt, type **logman stop** *session name* **-ets** and press ENTER.

   To view the trace data, see How to Process IIS Admin Trace Log Files Using Trace Report.

# How to Process IIS Admin Trace Log Files Using Trace Report

Updated: August 22, 2005

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1

IIS Admin trace data is written in binary format to a trace log (*filename*.etl). To view the trace data, the log file must be processed using the Trace Report tool that ships with Windows Server 2003.

**To process and view an IIS Admin trace log**

1. Open a command prompt and navigate to the directory where your IIS Admin trace log .etl file is stored.
2. Type **tracerpt** *filename*.etl and press ENTER. Trace Report processes the .etl file and creates two new files in the directory where you executed this command: summary.txt and dump.csv.
3. To view the file, type **notepad dump.csv** and press ENTER.

# Windows Server 2003 Technical Reference

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

**Windows Server 2003 Technical Reference**
Windows Server 2003 Technical Reference documentation provides comprehensive information about the technologies included in the Microsoft Windows Server 2003 operating systems, including Active Directory, Group Policy, and core operating system, high availability and scalability, networking, storage, and security technologies. This set of Technical Reference documentation is designed to assist IT planners and administrators by providing the foundational information about the technology components of the operating system. Windows Server 2003 Technical Reference documentation is not designed to provide prescriptive guidance about how to deploy, operate, or maintain Windows Server 2003 technologies.

**Structure**
Windows Server 2003 Technical Reference includes a number of collections covering each of the core technology areas for Windows Server 2003. Each collection is organized into subjects that provide detailed information about components of the technology, including a basic description of the component, a discussion of how the technology works, and information about tools and settings related to the technology.

In addition, an A-Z list of the technologies documented allows you to quickly find information about a specific feature or technology.

**Coverage**
Windows Server 2003 Technical Reference is a dynamic documentation set. Technical Reference documentation will continue to expand to cover additional technologies and tools. In addition, the content will be updated to reflect product upgrades, service packs, and critical updates. Please let us know if you do not find what you are looking for.

# Technologies Collections

Updated: March 28, 2003

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2

Technical Reference documentation for the Microsoft Windows Server 2003 family of operating systems includes the following technology collections:

### Active Directory Collection

This collection provides in-depth technical reference information about the Windows Server 2003 Active Directory directory service and its components. These components include logical structure, physical structure, data storage, replication, and service publication. In addition, this collection includes technical reference information about the tools that are used to install, upgrade, and migrate an Active Directory environment.

### Core Operating System Collection

This collection describes the core Windows Server 2003 operating system technologies. These technologies provide basic functionality such as printing services, data recovery, and troubleshooting.

### Group Policy Collection

This collection provides in-depth technical information about Windows Server 2003 Group Policy and its supporting technologies, including core Group Policy, Group Policy components, and Group Policy administrative tools. These technologies enable you to deliver, apply, and centrally manage one or more configurations, including Administrative Templates (registry-based policy), folder redirection, scripts, security, and software installation settings, to a set of targeted users and computers within an Active Directory environment.

### High Availability and Scalability Collection

This collection describes the Windows Server 2003 high availability technologies that are designed to reduce unscheduled outages and mitigate the impact of scheduled downtime for servers. This collection also describes the Windows Server 2003 scalability technologies used to increase or decrease computing capacity in order to address the capacity needs of an organization.

### Networking Collection

This collection provides in-depth technical reference information about Windows Server 2003 technologies that make up a networking infrastructure based on the TCP/IP suite of protocols, services, and other industry-standard networking protocols and technologies.

### Storage Technologies Collection

This collection describes the Windows Server 2003 storage technologies that are designed to help you store, access, and manage data on servers.

### Windows Security Collection

This collection describes Windows Server 2003 security technologies, including authentication, authorization, and public key infrastructure (PKI), and provides detailed information about security policy settings.

# Active Directory Collection

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**Active Directory Domain Services Collection**
Active Directory Domain Services (AD DS) directory service is the distributed directory service that is included with Microsoft Windows Server operating systems. AD DS enables centralized, secure management of an entire network, which might span a building, a city, or multiple locations throughout the world.

AD DS includes the following:

- AD DS on a Windows Server Network
- Active Directory Lightweight Directory Services (AD LDS)
- Structure and Storage Technologies
- Domain Controller Roles
- Replication Technologies
- Search and Publication Technologies
- Installation, Upgrade, and Migration Technologies

In distributed computing environments, networked computers and other devices communicate over remote connections to accomplish tasks through client/server applications. Distributed environments require a central repository of information and integrated services that provide the means to manage network users, services, devices, and additional information that administrators want to store.

Organizations operating a distributed environment need to have a way to manage network resources and services. As the organization grows, the need for a secure and centralized management system becomes more critical.

A directory service provides a centralized location to store information in a distributed environment about networked devices and services and the people who use them. A directory service also implements the services that make this information available to users, computers, and applications. A directory service is both a database storage system (directory store) and a set of services that provide the means to securely add, modify, delete, and locate data in the directory store.

AD DS is typically used for one of three purposes:

- Internal directory. Used within the corporate network for publishing information about users and resources within the enterprise. A company's internal directory may be accessible to employees when they are outside the company network using a secure connection such as a virtual private network (VPN) connection, but it is not accessible to non-employees.

- External directory. These are directories typically located on servers in the perimeter network or demilitarized zone (DMZ) at the boundary between the corporate local area network (LAN) and the public Internet. External directories are typically used to store information about customers, clients, and business partners who access external applications or services. They are also made available to customers, clients, and business partners to provide them with selected business information such as catalogs and so on.

- Application directory. Application directories store "private" directory data that is relevant only to the application in a local directory, perhaps on the same server as the application, without requiring any additional configuration to Active Directory. The personalization data, which is only interesting to the portal application and does not need to be widely replicated, can be stored solely in the directory associated with the application. This solution reduces replication traffic on the network between domain controllers.

**AD DS on a Windows Server Network**

AD DS is the information hub of the operating system. The following figure shows AD DS as the focal point of the Windows Server network used to manage identities and broker relationships between distributed resources so they can work together.

**Active Directory on a Windows Server Network**

Active Directory provides:

- A central location for network administration and delegation of administrative authority. You have access to objects representing all network users, devices, and resources and the ability to group objects for ease of management and application of security and Group Policy.

- Information security and single sign-on for user access to network resources. Tight integration with security eliminates costly tracking of accounts for authentication and authorization between systems. A single user name and password combination can identify each network user, and this identity follows the user throughout the network.

- Scalability. AD DS includes one or more domains, each with one or more domain controllers, enabling you to scale the directory to meet any network requirements.

- Flexible and global searching. Users and administrators can use desktop tools to search AD DS. By default, searches are directed to the global catalog, which provides forest-wide search capabilities.

- Storage for application data. AD DS provides a central location to store data that is shared between applications and with applications that need to distribute their data across entire Windows networks.

- Systematic synchronization of directory updates. Updates are distributed throughout the network through secure and cost-efficient replication between domain controllers.

- Remote administration. You can connect to any domain controller remotely from any Windows-based computer that has administrative tools installed.

- Single, modifiable, and extensible schema. The schema is a set of objects and rules that provide the structure requirements for AD DS objects. You can modify the schema to implement new types of objects or object properties.

- Integration of object names with Domain Name System (DNS), the Internet-standard computer location system. AD DS uses DNS to implement an IP-based naming system so that AD DS services and domain controllers are locatable over standard IP both on intranets and the Internet.

- Lightweight Directory Access Protocol (LDAP) support. LDAP is the industry standard directory access protocol, making AD DS widely accessible to management and query applications. AD DS supports LDAPv3 and LDAPv2.

**Active Directory Lightweight Directory Services (AD LDS)**
Active Directory Lightweight Directory Services (AD LDS) is a directory service designed to meet the needs of organizations that cannot rely solely on AD DS to provide directory services for directory-enabled applications. While AD DS offers many benefits for managing network infrastructure, organizations often need a more flexible directory service to support directory-enabled applications. AD LDS is a Lightweight Directory Access Protocol (LDAP) directory service designed specifically for directory-enabled applications.

**Structure and Storage Technologies**
AD DS uses domains and forests to represent the logical structure of the directory hierarchy. Domains are used to manage the various populations of users, computers, and network resources in your enterprise. The forest represents the security boundary for AD DS. Within domains you can create organizational units to subdivide the various divisions of administration.

The logical structure of AD DS includes a two-dimensional definition that can be viewed as a hierarchy, even though the objects themselves are stored in a flat database file. In addition to its own name, each object stores the name of the container directly above it in the hierarchy. That container object stores the name of its superior container, and so on, up to the root container. In this way, a logical structure is imposed that can be viewed by using AD DS tools as a tree of containers. By virtue of a hierarchical naming system, the objects in the tree appear to be nested inside (contained by) other objects.

The AD DS schema defines the types of objects that are available to the directory service. The schema is stored in the schema partition, which is also defined as an object in the directory. The attributes and classes in AD DS are stored in the schema partition as directory objects called schema objects. It is possible for Administrators to add their own classes or attributes to an existing object type. However, the default schema provides all of the classes and attributes that AD DS needs to function.

AD DS uses objects to store and reference data in the directory. The AD DS database file (Ntds.dit) provides the physical storage of all AD DS objects for a single forest. Although there is a single directory, some directory data is stored within domains while other data is distributed throughout the forest, without regard for domain boundaries. Beginning with Windows Server 2003, data can also be distributed to domain controllers according to applications that use the data, where the scope of distribution can be set according to the needs of the application.

Any updates made to data in the directory are automatically distributed to the appropriate domain controllers by means of AD DS replication. By replicating data according to directory partitions, AD DS provides a data repository that is logically centralized (maintains a single point of administration) but physically distributed (is synchronized on multiple domain controllers throughout the network).

**Replication Technologies**
Objects in the directory are distributed among the domain controllers in a forest, and all domain controllers can be updated directly. AD DS replication is the process by which the changes that are made on one domain controller are automatically synchronized with other domain controllers. Data integrity is maintained by tracking changes on each domain controller and updating other domain controllers in a systematic way. By default, AD DS replication uses a connection topology that is created automatically. This replication topology makes optimal use of physical network connections and frees administrators from having to determine which domain controllers replicate with one another. The replication topology can also be created manually. AD DS replication is designed to maximize directory consistency and minimize the impact to network traffic.

**Domain Controller Roles**
A domain controller is a server that has the AD DS server role installed.

### Note

- Implementations of Microsoft Windows NT 3.51 and Microsoft Windows NT 4.0 operating systems also have domain controllers, but they do not support AD DS.

When you install Windows Server on a computer, you can choose to configure a server role for that computer. When you want to create a new forest, a new domain, or an additional domain controller in an existing domain, you configure the server as a domain controller by installing AD DS.

By default, a domain controller stores one domain directory partition consisting of information about the domain in which it is located, plus the schema and configuration directory partitions for the entire forest. A domain controller can also store one or more application directory partitions.

Whereas every domain controller stores the objects for only one domain, a domain controller that is designated as a global

catalog server stores the objects from all domains in the forest. For each object that is not in the domain for which the global catalog server is authoritative as a domain controller, a limited set of attributes is stored in a partial replica of a corresponding domain. The partial replicas on a global catalog server are not writable — you cannot update an object in a partial replica on a global catalog server, but only on a domain controller that stores a full replica. Thus a global catalog server stores its own full, writable domain replica (all objects and all attributes) plus a partial, read-only replica of every other domain in the forest. The attributes that are replicated to the global catalog servers are the attributes that are most likely to be used to search for the object in AD DS. These attributes are identified by default in the schema as being included in the partial attribute set of the global catalog.

The global catalog makes it possible for clients to search AD DS without having to be referred from server to server until the domain controller that has the domain that stores the requested object is found. By default, AD DS searches are directed to global catalog servers. The first domain controller in a forest is automatically created as a global catalog server. Thereafter, you can designate other domain controllers to be global catalog servers if they are needed.

All domain controllers can receive updates to any writable object that they store (with the exception of schema updates, which can be made only on the one domain controller in the forest that has the role of schema master). The day-to-day operations that are associated with managing users, groups, and computers are typically multimaster operations — that is, changes to these objects can be made on any domain controller. When a client application updates an object on a domain controller, the domain controller automatically replicates the change to all other domain controllers in the same domain if the change is a domain change or to all other domain controllers in the forest if the change is a configuration or schema change.

There are some operations, however, that are not performed as multimaster operations because they must occur at only one place and time. For these operations, there are specially designated domain controllers that manage the operations singly. Some master operations, required at the forest level, include the schema master and the domain naming master. Others, required at the domain level, include the PDC emulator, RID master and infrastructure master. Domain controllers that hold these special roles are called operations masters.

**Search and Publication Technologies**

Successful operation of an AD DS forest depends on clients and services being able to locate domain controllers. The success of domain controller location depends on the registration of information in DNS and the availability of that information. AD DS uses DNS to locate networked computers by resolving computer names to IP addresses. The Net Logon service on domain clients and domain controllers interacts with Windows server application programming interfaces (APIs) and DNS to provide a domain controller locator service (Locator). Locator finds requested service-specific and site-specific domain controllers.

After a domain controller has been located, LDAP is used to retrieve information from the directory. AD DS stores objects that provide information about the real objects that exist in an organization's network and that are associated with one or more domains, such as users, specific groups of users, computers, applications, services, files, and distribution lists. AD DS makes this information available to administrators, network users, and applications throughout the organization through LDAP. LDAP enables clients to query, create, update, and delete information stored in a directory service. The LDAP protocol is the AD DS core protocol, and is the preferred and most common way of interacting with AD DS.

The creation, storage, and maintenance of information in AD DS is called service publication. Directory-enabled services and applications can publish globally useful information, such as service availability and properties, in AD DS. This allows client processes to find and connect to any directory-enabled service as needed, and network clients and administrators to find, connect to, and manage services.

**Installation, Upgrade, and Migration Technologies**

The installation or removal of AD DS is performed by the Active Directory Installation Wizard. Before installing AD DS on a server, the wizard will verify that the server is eligible to run AD DS. After the prerequisites have been met, a user interface is used to gather information specific to the environment in which AD DS will be installed. Finally, the wizard configures the directory service, making the server a domain controller.

Part of the directory configuration process includes configuring the AD DS schema. The schema contains a master list of all classes (object types) and attributes that can be used in the directory. The Active Directory Preparation Tool (ADPrep) is used to prepare an AD DS forest and domain for a newer version of the directory service. One of several tasks accomplished by ADPrep is updating the AD DS schema. If you do not prepare your AD DS infrastructure, the upgrade will fail.

After installing or upgrading AD DS, you can enable the appropriate domain or forest functional level based on an assessment of your current environment. The functional level of a domain or forest defines the set of advanced AD DS features that are available in that domain or forest. The functional level of a domain or forest also defines the set of Windows operating systems that can run on the domain controllers in that domain or forest. Functional levels provide configuration support for the AD DS features and ensure compatibility with domain controllers running earlier operating systems.

Depending on the design of your environment, you might opt to restructure it instead of upgrading. For example, if your Windows NT 4.0 environment consists of multiple domains, rather than upgrading each domain it might be more productive

to restructure the environment by consolidating some of those domains. Or if your Windows 2000 environment was poorly designed and you are upgrading your environment to Windows Server 2003, it might benefit you to restructure your existing environment before or after the upgrade takes place. You can perform either of these tasks by using the Active Directory Migration Tool (ADMT). ADMT includes wizards that automate migration tasks such as copying users, groups, and service accounts; moving computers; migrating trusts; and performing security translation. When you use ADMT to restructure Windows NT 4.0 domains, ADMT copies the accounts that are migrated, so that when the accounts are created in the target domain, they continue to exist in the source domain. The primary security identifiers (SIDs) for the accounts can be migrated to the SID history in the target domain. SID history maintains resource permissions when you migrate accounts, thus enabling access to resources in the source domain.

Another method for restructuring an AD DS environment is to rename a domain. You can use the domain rename process to change the names of your domains, and you can also use it to change the structure of the domain trees in your forest. This process involves updating the Domain Name System (DNS) and trust infrastructures as well as Group Policy and service principal names (SPNs).

The ability to rename domains provides you with the flexibility to make important name changes and forest structural changes as the needs of your organization change. Using domain rename, you can not only change the name of a domain, but you can change the structure of the domain hierarchy and change the parent of a domain or move a domain located in one domain tree to another domain tree.

# Active Directory Application Mode

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2012, Windows Server 2012 R2

Active Directory Application Mode (ADAM) is a new mode of the Active Directory directory service that is designed to meet the specific needs of organizations that use directory-enabled applications. While Active Directory supports directory-enabled applications, as well as the server operating system, some directory-enabled applications have requirements that Active Directory does not meet. For example, some directory-enabled applications require schema changes that administrators may not want to make to Active Directory.

In addition, organizations may want to:

- Support directory-enabled applications but not implement Active Directory domains and forests.
- Support directory-enabled applications outside their existing domains and forests.
- Use X.500 naming conventions for top-level directory partitions.
- Run multiple directory service instances on a single server.

ADAM is designed to support these and other directory service scenarios. ADAM runs completely independently from Active Directory, and ADAM has its own schema. You can make changes to the ADAM schema with no impact to the Active Directory schema. ADAM does not require the presence of Active Directory domain controllers, domains, or forests. Therefore, organizations that have not implemented Active Directory can install and run ADAM. ADAM supports X.500 naming conventions for top-level directory partitions, and you can run multiple instances of ADAM on a single server.

ADAM runs on the following:

- Domain controllers running operating systems in the Microsoft Windows Server 2003 family (Note that Microsoft Windows Server 2003, Web Edition cannot be a domain controller.)
- Member servers running operating systems in the Windows Server 2003 family (except for Windows Server 2003, Web Edition)
- Client computers running Microsoft Windows XP Professional

# Active Directory Application Mode Technical Reference

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2012, Windows Server 2012 R2

Active Directory Application Mode (ADAM) is a new mode of the Active Directory directory service that is designed specifically for directory-enabled applications. ADAM is a Lightweight Directory Access Protocol (LDAP) directory service that runs as a user service, rather than as a system service. You can run ADAM on servers and domain controllers running operating systems in the Microsoft Windows Server 2003 family (except for Windows Server 2003, Web Edition) and also on client computers running Microsoft Windows XP Professional. ADAM does not require the deployment of domains or domain controllers. You can run multiple instances of ADAM concurrently on a single computer, with an independently managed schema for each ADAM instance.

# What Is Active Directory Application Mode?

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- The Business Need
- The ADAM Solution
- LDAP Directories Compared to Relational Databases
- ADAM Compared to Active Directory
- ADAM Scenarios
- Related Information

Active Directory Application Mode (ADAM) is a new mode of Active Directory that is designed specifically for directory-enabled applications. ADAM is a Lightweight Directory Access Protocol (LDAP) directory service that runs as a user service, rather than as a system service. You can run ADAM on servers and domain controllers running operating systems in the Windows Server 2003 family (except for Windows Server 2003, Web Edition) and also on client computers running Windows XP Professional.

ADAM contains many Active Directory components and features, but ADAM differs from Active Directory in several key ways, as described in "ADAM Compared to Active Directory" later in this section. Some of the scenarios for which ADAM is designed are described in "ADAM Scenarios" later in this section.

**The Business Need**

ADAM is a directory service that is designed to meet the needs of organizations that cannot rely solely on Active Directory for providing directory services for directory-enabled applications. While Active Directory offers many benefits for managing network infrastructure, organizations often need a more flexible directory service to support directory-enabled applications.

For example, most directory-enabled applications require the directory service to be extended with application-specific schema extensions. Such schema extensions are supported in Active Directory. However, because Active Directory is mission critical for overall network operations, many administrators consider Active Directory to be "off limits" with respect to application-specific schema changes. In addition, many LDAP directory usage scenarios, including development, portal, and legacy application scenarios, are hindered by the forest and domain requirements of Active Directory.

**The ADAM Solution**

ADAM is a new mode of Active Directory that is designed for organizations that require flexible support for directory-enabled applications. ADAM provides data storage and retrieval for directory-enabled applications, without the dependencies that are required for Active Directory. ADAM provides much of the same functionality as Active Directory, including multimaster replication, but ADAM does not require the deployment of domains or domain controllers. You can run multiple instances of ADAM concurrently on a single computer, with an independently managed schema for each ADAM instance. You can run ADAM on servers and domain controllers running operating systems in the Windows Server 2003 family (except for Windows Server 2003, Web Edition) and on computers running Windows XP Professional.

The following figure illustrates the ADAM solution. In the figure, the computer running ADAM is hosting three separate ADAM instances, each with independently managed schema and data. Each ADAM instance is supporting a different directory-enabled application. The computers in this figure can reside within or outside an Active Directory forest.

**Active Directory Application Mode Solution**

**LDAP Directories Compared to Relational Databases**

Both LDAP directories (such as ADAM and Active Directory) and relational databases (such as Microsoft SQL Server 2000) can be used to support applications. However, LDAP directories and relational databases are designed for different purposes. Understanding the basic differences between these two technologies can help you choose the right technology for your application.

The following table summarizes the basic design differences between LDAP directories and relational databases.

**Design Differences Between LDAP Directories and Relational Databases**

| **Directories** | **Databases** |
|---|---|
| Optimized for search and read operations. | Optimized for write operations. |
| Object-oriented, hierarchical data design. Data objects in the directory represent entities such as users, computers, and shared resources. These data objects can be organized hierarchically in containers. | Relational data design. Data is organized in tables of rows and columns. Data from one table can be linked to data in another table. |
| Uses standardized, extensible schemas. | Does not use schemas. |
| Designed for replication and distributed management. | Designed for central storage and administration of data. |
| Precise security, down to the object and attribute level. | Less precise security, only down to the row and column level. |
| Loose data consistency between replication partners. | Transactional — guaranteed data consistency. Referential integrity across relational tables and concurrency control with file and record locking. |

Given these design differences, LDAP directories and relational databases are each particularly suited to certain types of applications.

LDAP directories are well suited for:

- Applications that manage data that is needed by clients throughout the network. Because LDAP directories can replicate data throughout a network easily and efficiently, LDAP directories are well suited to applications that require wide data distribution.

- Applications with a high ratio of search and read operations to write operations. Because LDAP directories are optimized for search and read operations, they are best suited to applications in which data changes infrequently.

- Applications that benefit from hierarchical storage and security models. LDAP directory services are particularly useful

when the data that they store benefits from container-style storage and inheritance-based security. For example, data that is related to enterprise "white pages" usually maps well to a hierarchical model. In other cases in which data corresponds to large business-to-consumer (B2C) e-commerce sites — where users are stored as huge, flat lists, LDAP directories may not be as well suited.

Good candidate applications for LDAP directories include the following:

- White pages applications that store contact and location information about people
- User, security, and resource management applications
- Applications that store network configuration and service policies

Relational databases are well suited for:

- Applications that require complex transactional updates. Directory services do not support complex transactions across multiple object types or tables. Therefore, applications that must observe atomicity, consistency, isolation, and durability (ACID), such as inventory databases, are best suited to relational databases.
- Applications that require change history information. With LDAP directories, it is not practical to create a centralized log that reflects all the updates that have been applied on all replicas throughout the network. Therefore, applications that require a log of changes that are made to data (for example, for auditing reasons) are best suited to relational databases.
- Applications that do not tolerate replication latency and inconsistency. Because of the store-and-forward style of replication that is used by directory services and the fact that directory service replicas are frequently connected by unreliable network connections, directory-enabled applications cannot be designed to rely on updates that propagate between replicas on any particular schedule or on updates that arrive in a particular order.

Good candidate applications for relational databases include the following:

- Airline reservation systems
- Banking systems
- Accounting applications that require transactional update protections and updates that typically occur quickly
- Centralized data collection
- Hardware inventory applications. Most data about the hardware configuration of client and server computers is not relevant to applications throughout the network.
- Process control. Any application that depends on the timing of data propagation between replicas is not well suited for a directory service.

**ADAM Compared to Active Directory**

ADAM is a special mode of Active Directory that is based on the same source code as Active Directory. To a large extent, ADAM operates just like Active Directory. However, because ADAM is designed specifically to support directory-enabled applications, rather than server operating system operations, there are some key differences between ADAM and Active Directory. These differences are related to:

- Supported operating systems
- Schema
- Partition naming

- Directory server consolidation
- Replication
- Dependencies
- Performance and scalability

**Supported Operating Systems**
**The following table lists the operating systems that are supported by Active Directory and ADAM.**
**Operating Systems Supported by Active Directory and ADAM**

| Directory Service | Platforms Supported |
|---|---|
| Active Directory | • Domain controllers running Windows 2000 Server<br>• Domain controllers running Windows 2000 Advanced Server<br>• Domain controllers running Windows 2000 Datacenter Server<br>• Domain controllers running Windows Server 2003, Standard Edition<br>• Domain controllers running Windows Server 2003, Enterprise Edition<br>• Domain controllers running Windows Server 2003, Datacenter Edition |
| ADAM | • Computers running Windows XP Professional<br>• Domain controllers and servers running Windows Server 2003, Standard Edition<br>• Domain controllers and servers running Windows Server 2003, Enterprise Edition<br>• Domain controllers and servers running Windows Server 2003, Datacenter Edition |

When you run ADAM on Windows XP Professional, there are certain considerations to keep in mind. For more information, see "ADAM Servers" in "How Active Directory Application Mode Works."

**Schema**
The schema defines what kind of information the directory can hold. With Active Directory, a single schema applies to the entire forest; that is, all domain controllers must use the same schema. With ADAM, each stand-alone ADAM instance or ADAM configuration set can have its own schema. In addition, the schema of each ADAM instance is fully independent from the Active Directory schema.

Another difference between ADAM and Active Directory is the size of the base schema. The base schema of Active Directory is designed to support overall server operating system operations, and it is therefore very large. The base schema of ADAM is very small — just large enough to bootstrap the ADAM instance. The ADAM schema is designed to be extended with the schema elements that are required for the applications that the ADAM instance supports.

Finally, while only certain object classes in Active Directory can be used to bind to (or authenticate against) Active Directory, you can give any object class in ADAM the ability to bind to ADAM by adding the **msDS-bindableobject** auxiliary class and the **unicodePwd** attribute to the schema definition of an object class. For more information about bindable object classes, see "ADAM Security Principals" in "How Active Directory Application Mode Works."

**Partition Naming**
A directory partition is a logical portion of the directory data store. Each ADAM directory partition has its own unique distinguished name. ADAM partition naming is more flexible than partition naming in Active Directory. Active Directory supports only Domain Name System (DNS)–style (DC=) names for top-level directory partitions. Such names can contain only DC= naming components. For example, Active Directory can have a partition named DC=Microsoft,DC=COM, but it cannot have a partition named DC=Microsoft,C=US. In contrast to Active Directory, ADAM can have a directory partition named

DC=Microsoft,C=US.

ADAM also supports both DNS-style and X.500-style names for top-level directory partitions. ADAM supports all the distinguished name components that are listed in the following table.

**ADAM Directory Partition Distinguished Name Components**

| Distinguished Name Component | Description |
|---|---|
| C= | Country/region |
| CN= | Common name |
| DC= | Domain component |
| L= | Location |
| O= | Organization |
| OU= | Organizational unit |

For more information about directory partitions, see "Directory Partitions" in "How Active Directory Application Mode Works."

**Directory Server Consolidation**
Because of the limitations that are placed on Active Directory by forests and domains, each domain controller can run only one instance of Active Directory. However, with ADAM you can run multiple directory service instances on each computer. Running multiple instances of ADAM on a single computer helps you lower your total cost of ownership (TCO) by consolidating directory operations onto a single server or just a few servers.

**Replication**
Active Directory domain controllers replicate with each other based on membership in a domain or forest. ADAM instances replicate with each other based on membership in a configuration set. A configuration set is a group of ADAM instances that share and replicate a common configuration partition and schema partition. ADAM instances cannot replicate with Active Directory. Furthermore, ADAM instances replicate on a schedule that is completely independent of the Active Directory replication schedule, even when ADAM is running in an Active Directory forest.

**Dependencies**
One key difference between ADAM and Active Directory is that ADAM is free of some of the underlying dependencies that are required by Active Directory. For example, ADAM does not require or rely on forests or domains. In addition, ADAM does not rely on the File Replication service (FRS) or DNS, both of which are required for Active Directory to function properly.

**Performance and Scalability**
Because ADAM is based on the same code as Active Directory, ADAM has the same scalability and performance characteristics as Active Directory. In other words, ADAM supports a comparable number of users, sites, and objects as Active Directory. In addition, ADAM LDAP and replication performance is comparable to that of Active Directory.

**ADAM Scenarios**
ADAM is designed to support a number of usage scenarios, including scenarios that are related to the following:

- Application-specific directories
- Application development
- Support for legacy applications
- Programmatic access to Microsoft Identity Integration Server (MIIS) 3.0
- Extranet access management

**Application-specific Directories**
In the application-specific directory scenario, a directory-enabled application (such as a portal application) requires an LDAP data store for application-specific data that is associated with application users that reside in Active Directory. Because this application-specific data requires schema extensions that the organization does not want to make to Active Directory, this application-specific data store must reside outside Active Directory. In this scenario, the directory-enabled application can use

Active Directory for authentication of users and for service publication while it uses ADAM as a store for the application-specific data that is associated with each user. If the application requires other application-specific data, such as policy and management information, this data can also be stored in ADAM. By using the user principals in Active Directory for authentication and for controlling access to objects in ADAM, the organization can achieve single sign-on (SSO). This design helps avoid the need for each ADAM directory to have its own user database, which prevents a proliferation of user IDs and passwords for end users every time that a new directory-enabled application is introduced on the network. The following figure illustrates an ADAM application-specific directory scenario.

**ADAM Application-specific Directory Scenario**

The ADAM features that are described in the following sections play an important role in application-specific directory scenarios.

**Storage of Application-specific Data**

An application can use ADAM to store "private" directory data, which is relevant only to the application, in an application-specific directory service — perhaps on the same server as the application — without requiring any additional configuration to Active Directory. The application-specific data, which does not need to be widely replicated, is stored solely in the ADAM directory that is associated with the application. This design has an added benefit of reducing replication traffic on the network between domain controllers. In addition, because ADAM is based on the same database engine as Active Directory — the Extensible Storage Engine (ESE), the ADAM data store scales to millions of objects and gigabytes of storage.

**Tailored Schema**

Business data is often organized uniquely for a particular application. ADAM is useful when an organization must use a directory-enabled application that is based on a unique business logic or schema. For example, an application developer may want to expose application data through LDAP in a way that is specific to the clients of the application. The application requires a different schema than the existing Active Directory installation for the server operating system. Without altering the configuration of the Active Directory, the organization is able to provide a directory-enabled application with a tailored schema that meets the organization's business needs, data requirements, and workflow processes. The workflow and associated data that is represented by the application directory can then be stored in the most intuitive way possible, independent of the existing directory structure. In addition, ADAM helps avoid schema conflicts by providing organizations with a separate and independent directory service for each directory-enabled application.

**Local Management in the Organization**

In many organizations, departments implement applications that are relevant to their operations. Because these applications are specific to a department, the information that is stored by each application may not be relevant to the rest of the organization. Each department may need to manage its own local directory service independently. For example, a department may require replication schedules that differ from the replication schedules that are offered by the enterprise directory. ADAM supports this requirement by enabling each department to manage its own directory service independently.

**Optional Centralized Management**

An ADAM instance can be deployed on a locally administered, departmental server or on a centrally managed server, offering a choice of distributed or centralized management. A centrally administered server can host multiple, independently configured instances of ADAM on the same computer, which provides greater efficiency through server consolidation and ease of management. Each separate instance of ADAM can be used by a different directory-enabled application.

**Windows NT 4.0 Domains**

You can install ADAM on a computer running Windows Server 2003 or Windows XP Professional that is joined to a Windows NT 4.0 domain. Any directory-enabled application that can run on ADAM can also run in a Windows NT 4.0 domain. Because ADAM works with any Windows-integrated security infrastructure, the Windows NT 4.0 domain can be used to authenticate domain users for ADAM.

**Application Development**

Developers can use ADAM to prototype an application for Active Directory. ADAM uses the same programming model as Active Directory and provides a similar administration experience. Developers can work with a local instance of ADAM on a developer workstation and then move the application to Active Directory.

**Active Directory Application Mode Setup Wizard**

One feature that enhances the use of ADAM for application development scenarios is the Active Directory Application Mode

Setup Wizard. ADAM provides a simple setup wizard that requires little manual input. The setup can easily be scripted, which is beneficial for unattended and silent installations as part of application installation. Developers can install and uninstall ADAM or use multiple instances of ADAM during the development phase. No reboot is required during setup.

**Locally Installed, Locally Managed**

Consider a scenario in which an application developer is developing a directory-enabled application. Having the directory on a server or domain controller requires the organization to provide a server-class development server. This server must be managed, and installing or uninstalling the directory can affect other users. ADAM does not have to be installed on a server or domain controller; it runs effectively on client computers. Therefore, you can deploy an application without using the resources of a dedicated information technology (IT) professional. ADAM runs on the following:

- Computers running Windows XP Professional
- Domain controllers and servers running:
    - Windows Server 2003, Standard Edition
    - Windows Server 2003, Enterprise Edition
    - Windows Server 2003, Datacenter Edition

**Support for Legacy Applications**

In a legacy application scenario, suppose that your organization has an established directory using the X.500-style attribute value assertions of o=<organization> and c=<country>, and the organization relies on this directory to serve legacy applications. In addition, the organization wants to migrate to Active Directory. In this scenario, to enable migration to Active Directory, you can deploy ADAM to service the applications that rely on X.500-style naming, which Active Directory does not support. You can deploy Active Directory in the organization to provide a shared security infrastructure, while ADAM provides direct support for the legacy applications. As applications are rewritten to avoid the use of o= and c=, the applications can be migrated to Active Directory. You can use a metadirectory application, such as MIIS 3.0, to synchronize data from ADAM to Active Directory automatically for a seamless migration experience. The following figure illustrates an ADAM legacy application scenario.

**ADAM Legacy Application Scenario**

**Programmatic Access to MIIS 3.0**

In a scenario of programmatic access to MIIS 3.0, ADAM provides a read/write interface to MIIS 3.0. MIIS 3.0 synchronizes data between multiple data stores, including LDAP directory services, SQL databases, and other data stores. MIIS 3.0 stores its data in SQL Server 2000. By design, the data that is held by MIIS 3.0 is not available for modification; the data can only be updated when synchronization with one of the connected data sources occurs. You can use ADAM to enable LDAP programmatic access to MIIS 3.0 data. First, the data from an installation of MIIS 3.0 is synchronized to an existing ADAM instance. The data in ADAM can then be modified programmatically through one of the LDAP programmatic interfaces to ADAM. After the data has been updated in ADAM, the data can be resynchronized with MIIS 3.0, updating the data that is held by MIIS 3.0. The following figure illustrates an ADAM scenario of programmatic access to MIIS 3.0.

**ADAM Scenario Featuring Programmatic Access to MIIS 3.0**

**Extranet Access Management**

In an extranet access management scenario, an organization uses a Web portal application (such as OpenNetwork DirectorySmart or Netegrity SiteMinder) to handle extranet access management. The Web portal application stores the authorization information as data in an LDAP directory and uses the directory for authentication purposes only. In such a scenario, ADAM can be used as the LDAP directory store to provide simple authentication support for the Web portal application. Because ADAM can host user objects that are not Windows security principals but are authenticated with LDAP simple binds, all the user information, as well as authorization data for these applications, can be stored in ADAM. This configuration works equally well in heterogeneous environments, where Active Directory is not present as the infrastructure provider. In this case, the Web clients are serviced by the portal application, which can be running on any platform, while ADAM is used as a simple LDAP store. The following figure illustrates an ADAM extranet access management scenario.

**ADAM Extranet Access Management Scenario**

- ADAM Interfaces
- ADAM Physical Structure
- ADAM Logical Structure
- ADAM Security
- ADAM Processes and Interactions
- Network Ports Used by ADAM
- Related Information

Active Directory Application Mode (ADAM) is a new mode of Active Directory that is designed specifically for directory-enabled applications. ADAM is a Lightweight Directory Access Protocol (LDAP) directory service that runs as a user service, rather than as a system service. You can run ADAM on servers and domain controllers running operating systems in the Windows Server 2003 family (except for Windows Server 2003, Web Edition) and also on client computers running Windows XP Professional.

ADAM does not require the deployment of domains or domain controllers. You can run multiple instances of ADAM concurrently on a single computer, with an independently managed schema and independently managed data for each ADAM instance.

The ideal environment for ADAM includes the following:

- A computer running Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; Windows Server 2003, Datacenter Edition; or Windows XP Professional and containing hardware that meets the minimum hardware requirements of each respective operating system
- For environments consisting of multiple, replicating ADAM instances, the presence of a fully functioning replication topology
- A regular backup schedule

This section describes the fundamental elements of ADAM, including its architecture, protocols, interfaces, physical structure, logical structure, security concepts, processes and interactions, and network ports.

**ADAM Architecture**

The ADAM architecture consists of several components that work together to provide directory services. These components include the following:

- Interfaces: LDAP and replication (REPL)and management interface
- Directory System Agent (DSA)

- Database layer
- Extensible Storage Engine (ESE)
- Directory database

The ADAM architecture is illustrated in the following figure.

**ADAM Architecture**

The following table describes the ADAM components.

**ADAM Components**

| Component | Description |
|---|---|
| Interfaces (LDAP and REPL) | The data store interfaces provide a way for directory clients and other directory servers to communicate with the data store. |
| DSA | The DSA, which runs as Adamdsa.dll on each ADAM instance, provides the interfaces through which directory clients and other ADAM instances gain access to the directory database. In addition, the DSA enforces directory semantics, maintains the schema, guarantees object identity, and enforces data types on attributes. |
| Database layer | The database layer is an application programming interface (API) that resides in Adamdsa.dll and provides an interface between applications and the directory database to protect the database from direct interaction with applications. Calls from applications are never made directly to the database; they go through the database layer. In addition, because the directory database is flat — with no hierarchical namespace — the database layer provides the database with the abstraction of an object hierarchy. |
| ESE | The ESE, which runs as Esent.dll, manages the tables of records — each with one or more columns — that make up the directory database. |
| Directory database | The data store stores directory information in a single database file called Adamntds.dit. |

**DSA**

The DSA runs on an ADAM instance as Adamdsa.dll, and it provides access to the directory database. On computers running multiple instances of ADAM, a single, shared copy of Adamdsa.dll supports all ADAM instances.

**Note**

- Multiple instances of ADAM running on a single computer share all ADAM-related binaries. Therefore, a hotfix that is applied to one ADAM instance affects all ADAM instances running on that computer.

The DSA runs as a user service, in the security context of the service account under which the ADAM instance is running. Clients can use one of the supported interfaces to connect (bind) to the DSA and then search for, read, and write to ADAM objects and their attributes.

An object in the configuration partition of the directory, the NTDS Settings object (with a distinguished name of CN=NTDS Settings,CN=*computername*$*instancename*,CN=Servers,CN=Default-First-Site-Name,CN=Sites,CN=Configuration,CN={*GUID*}), represents the DSA. This object contains configuration information about the DSA.

In addition to providing the interfaces through which directory clients gain access to directory data, the DSA provides the following functionality.

**Object identification**
Every object in ADAM has a permanent globally unique identifier (GUID) and an object name. The object name can be changed; all permanent references to the object are kept in terms of the GUID. The object name is used for hierarchy navigation and display purposes. The DSA maintains the GUID association with an object when the object's name changes, for example, when the object is moved to a different folder.

**Schema enforcement**
The DSA ensures that data in the directory adheres to the data definitions that are provided by the directory schema. The schema is the set of rules that determines what kind of data the directory can hold.

### Note

- If an update does not produce a conflict with the schema at the originating replica, the update is considered acceptable at all replicas. Therefore, replicated updates do not perform schema checks, and you do not have to wait until the schema replicates before creating instances of a new object or attribute.

**Access control enforcement**
The DSA reads security IDs (SIDs) on the access token to identify the current user and the user's group memberships, and it enforces access control based on the identity and group memberships of the user.

**Support for replication**
The API that is called to initiate replication is implemented in the DSA.

**Referrals**
The DSA manages directory hierarchy information (referred to as "knowledge"), which it receives from the database layer. The DSA is responsible for cross-references of partition objects.

**DSA GUID and Invocation ID**
Both the DSA and the ADAM directory database are represented uniquely and have their own respective GUIDS. The DSA GUID is the GUID of the NTDS Settings object (class **nTDSDSA**). The value of the DSA GUID is stored in the **objectGUID** attribute of the NTDS Settings object of the ADAM server object, which resides in the Sites container in the configuration directory partition (with a distinguished name of CN=NTDS Settings,CN=*computername*$*instancename*,CN=Servers,CN=Default-First-Site-Name,CN=Sites,CN=Configuration,CN={*GUID*}).

The DSA GUID is created when the ADAM instance is initially installed. The DSA GUID is destroyed only if the ADAM instance is uninstalled. The DSA GUID ensures that the DSA remains recognizable when the computer on which ADAM is running is renamed. The DSA GUID is not affected by ADAM backup and restore processes.

The ADAM directory database has its own GUID, which the DSA uses to identify the database instance (the version of the database). The database GUID is stored in the **invocationId** attribute on the nTDSDSA object. Unlike the DSA GUID, which never changes for the lifetime of the ADAM instance, **invocationId** changes in two scenarios:

- During the ADAM restore process, to ensure the consistency of the replication process. The change in **invocationId** enables ADAM to distinguish changes that are made before and after a database restore.

- When an application directory partition is removed from and added back again to the ADAM instance.

**Database Layer**
The database layer is an API that resides in Adamdsa.dll and provides an object view of the directory database, making the data accessible to the DSA as a set of hierarchical containers. By applying schema semantics to database records, the database layer isolates the upper components of the directory service from the underlying database system. The database layer is an internal interface. No database access calls are made directly to the ESE; instead, all database access goes through the database layer.

In the directory database, each object is identified by its relative distinguished name, which is unique in the object's parent container. The relative distinguished name and the chain of successive parent object names make up the object's distinguished name. The database stores the relative distinguished name for each object, as well as a reference to the parent object. The database layer follows these parent references and concatenates the successive relative distinguished names to form distinguished names, thereby defining the object hierarchy.

The database layer is also responsible for the creation, retrieval, and deletion of individual records (objects), attributes within records, and values within attributes. To carry out these functions, the database layer uses the schema cache (an in-memory structure in the DSA) to get information about the attributes that it needs.

**ESE**

The ESE is a Windows component that is used by ADAM, as well as by several other Windows components, as an interface to the data that is stored in an indexed and sequential access method (ISAM) database. (The ADAM directory database is an ISAM database.) The ESE is responsible for indexing the data in the database file and for transferring the data in and out of the database. The purpose of the ESE is to enable applications to store and retrieve data by using the ISAM. The ESE provides applications with a consistent data state by means of transacted data update and retrieval. A crash recovery mechanism maintains data consistency, even in the event of a system crash. Transactions in the ESE are highly concurrent, making the ESE suitable for server applications. The ESE caches data intelligently to ensure high-performance access to data. In addition, the ESE is resource efficient, which makes it suitable for applications that perform auxiliary roles.

The version of the ESE that is used with ADAM is implemented in Esent.dll. Each ADAM instance running on a computer shares a single a copy of Esent.dll, which is located in *windir*\ADAM.

The following characteristics of the ESE make it well suited to the storage needs of ADAM. The ESE:

- Supports databases of up to 16 terabytes (TB) in size, and it can hold many millions of objects per instance.
- Supports indexing.
- Supports multivalue attributes.
- Supports update operations that are transacted for stability and integrity across system failures.
- Can be backed up while the ADAM instance is online.
- Handles sparsely populated objects well; that is, space in the database is not reserved for attributes that do not have values.

The ADAM schema defines all the attributes that are required and allowed for a given object. However, the ESE reserves storage only for the space that is used — that is, only for the attributes that have values, not for all possible attributes. For example, if a user object has 50 attributes defined in the schema and you create a user with values for only 4 attributes, storage space is allocated only for those 4 attributes. If more attributes are added later, more storage is allocated for them.

The ESE implements the search and retrieval functionality of the underlying database. Also, the ESE is able to store attributes that can have multiple values. For example, the database can store multiple phone numbers for a single user without requiring a different phone number attribute for each phone number.

The ESE provides transactional views of the database. The cost of providing these views is that any object that is modified in a transaction has to be temporarily copied so that two views of the object can be provided: one to the thread inside that transaction and one to threads in other transactions. This copy must remain as long as any two transactions in the process have different views of the object. The repository that holds these temporary copies is called the version store. Because the version store requires contiguous virtual address space, it has a size limit. If a transaction is open for a long time while changes are being made (either in that transaction or in others), eventually the version store can be exhausted. At this point, no further database updates are possible.

**ADAM Protocols**

The primary protocol that ADAM uses is LDAP, which runs on top of TCP/IP. In addition, the data store uses remote procedure call (RPC) for replication and management functions.

The following table describes the protocols that are used by ADAM.

### ADAM Protocols

| Protocol | Description |
|---|---|
| LDAP | LDAP is a directory service protocol that specifies directory communications. It runs directly over TCP/IP, and it can also run over User Datagram Protocol (UDP) connectionless transports. Clients can use LDAP to query, create, update, and delete information that is stored in a directory service over a TCP connection through the TCP default port 389. Active Directory supports LDAP v2 (Request for Comments (RFC) 1777, "Lightweight Directory Access Protocol") and LDAP v3 (RFC 2251, "Lightweight Directory Access Protocol v3"). LDAP v3 is an industry standard that can be used with any directory service that implements the LDAP protocol. LDAP is the preferred and most common way of interacting with Active Directory.<br><br>Historically, LDAP is a simplified ("lightweight") version of Directory Access Protocol (DAP), which is the original protocol that was used to interact with X.500 directories. X.500 defines an earlier set of standards that was developed by the International Organization for Standardization (ISO). LDAP is simpler than DAP in two key ways:<br><br>• Rather than using its own protocol stack according to the Open Systems Interconnection (OSI) networking model, LDAP communicates over Internet Protocol (IP) by using either UDP or TCP.<br><br>• LDAP syntax is easier to use than DAP syntax.<br><br>For these reasons, LDAP is widely used and accepted as the standard protocol for directory service access.<br><br>The following key aspects of LDAP characterize it:<br><br>• The protocol is carried directly over TCP for connection-oriented transport (receipt of data is acknowledged) and over UDP for connectionless transport (sent or received data is not acknowledged).<br><br>• Most protocol data elements can be encoded as ordinary strings, for example, as distinguished names.<br><br>• Referrals to other servers can be returned to the client.<br><br>• Simple Authentication and Security Layer (SASL) mechanisms can be used with LDAP to provide associated security services.<br><br>• Attribute values and distinguished names can be internationalized through the use of the ISO 10646 character set.<br><br>• The protocol can be extended to support new operations, and controls can be used to extend existing operations.<br><br>• The schema is published through an attribute on the directory root object (rootDSE) for use by clients. |
| RPC | The REPL interface uses RPC for management tasks, including replication and management functions, that are not well suited to the LDAP protocol. RPC is a powerful, robust, efficient, and secure interprocess communication (IPC) mechanism that enables data exchange and invocation of functionality that resides in a different process. That different process can be on the same computer, on the local area network (LAN), or across the Internet. |

**ADAM Interfaces**

As shown in the "ADAM Architecture" figure earlier in this section, network clients and other directory servers obtain access to ADAM through one of the interfaces that are described in the following table.

### ADAM Interfaces

| Interface | Description |
|---|---|
| LDAP | The primary interface for ADAM. Directory clients use LDAP v3 or LDAP v2 to connect to the DSA through the LDAP interface. The LDAP interface is part of Wldap32.dll. LDAP v3 is backward compatible with LDAP v2. |

| | |
|---|---|
| REPL | Provides functionality for finding data about ADAM instances, converting the names of network objects between different formats, manipulating service principal names (SPN) and DSAs, and managing replication of ADAM instances. |
| System.DirectoryServices<br><br>(ADSI for .NET Framework) | A namespace in the Microsoft .NET Framework that provides simple programming access to LDAP directories, such as ADAM. This API requires the .NET Framework to be installed. |
| Active Directory Service Interfaces (ADSI) (Ads*.dll) | A set of Component Object Model (COM) interfaces that abstracts the capabilities of directory services from different network providers (such as LDAP) in a distributed computing environment to present a single set of directory service interfaces for managing network resources. |
| Directory Services Markup Language (DSML) | Provides a means of representing directory structural information and directory operations as an XML document. |

**ADAM Physical Structure**

The ADAM physical structure consists of the following:

- Computers running ADAM (ADAM servers)
- ADAM instances
- Configuration sets
- Sites

**Note**

- Because ADAM is based on the same code as Active Directory, the service and scalability limits of ADAM are comparable to Active Directory. Therefore, ADAM supports a comparable number of sites as Active Directory.

**ADAM Servers**

A computer running ADAM is called an ADAM server. ADAM servers can run on any of the following operating systems:

- Windows Server 2003, Standard Edition
- Windows Server 2003, Enterprise Edition
- Windows Server 2003, Datacenter Edition
- Windows XP Professional

When you run ADAM on a computer running Windows XP Professional, certain considerations apply. The following table lists these considerations.

**Running ADAM on Windows Server 2003 and on Windows XP Professional**

| ADAM Feature | Windows Server 2003 | Windows XP Professional |
|---|---|---|
| Support for multiple processors | Supported. | Not supported. On multiple-processor computers, ADAM uses only one process at a time to prevent resource monopolization. |
| Maximum cache value | No limit. | Limited to one half of physical RAM. |

| | | |
|---|---|---|
| Data and log file locations | Data and log files can reside on different drives. | Data and log files must reside on the same drive. |
| Password policies | Supported. | Not supported. |
| Auditing | Supported. For more information, see “Auditing” later in this section. | Not supported. |
| ADAM service account requirements | See “Service Account” later in this section. | See “Service Account” later in this section. |
| Stopping and restarting an ADAM instance | You can stop and then restart an ADAM instance immediately. | If an LDAP client is connected when you shut down the ADAM instance, you may need to wait as long as two minutes before restarting the ADAM instance. This time is required to allow any existing connections to clear. |
| Backing up ADAM | Multiple ADAM instances running on the same computer can be backed up simultaneously. | For computers running multiple ADAM instances, only one ADAM instance can be backed up at a time. |
| Full ADSI functionality | No hotfixes are required. | For complete ADSI functionality with Windows XP Professional, you must install hotfix 817583. For more information about this hotfix, see article 817583, “Active Directory Services Does Not Request Secure Authorization Over an SSL Connection,” in the Microsoft Knowledge Base. |

**Using ADAM on Windows XP Professional as a Personal Data Store**
On computers running Windows XP Professional, ADAM has been designed primarily as a personal data store. It is recommended that you run ADAM on Windows Server 2003 if you need scalability to support a growing number of simultaneously connected clients or if you intend to use ADAM on a centralized directory server.

**Running ADAM on Windows XP Professional in a Workgroup**
When you install ADAM on a computer running Windows XP Professional that is joined to a workgroup, you must set the registry key **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa\forceguest** to **0**. (The default is **1**.) Otherwise, users connecting to ADAM over the network are forced to a security context of Guest, and binds to ADAM fail.

**ADAM Instances**
Each time that you install ADAM, you create a unique ADAM instance. Each ADAM instance consists of the following:

- Program files
- Data files
- Registry keys
- Service name
- Service account
- Event log
- Name:port

**Program Files**
After you install ADAM, the program files and tools of an ADAM instance reside in the *windir*\ADAM directory. If you install multiple instances of ADAM on a single computer, the program files and tools in the *windir*\ADAM directory are shared by all ADAM instances running on that computer.

**Note**

- If you apply a hotfix to one instance of ADAM, all ADAM instances on the same computer are affected.

**Data Files**

The data files for a given ADAM instance are installed in the directory Program Files\Microsoft ADAM*instancename*\Data, where *instancename* is the name that you provide for the ADAM instance during installation. If you install multiple instances of ADAM on a single computer, each instance that you install has a separate data directory. For example, if you install two ADAM instances named, respectively, instance1 and instance2 on a computer, the computer has the following ADAM data directories:

Program Files\Microsoft ADAM\instance1\Data

Program Files\Microsoft ADAM\instance2\Data

**Registry Keys**

Registry keys for ADAM are stored in the following location:

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_instancename**

For a detailed explanation of the ADAM registry keys, see "Active Directory Application Mode Tools and Settings."

**Service Name**

During setup, you assign a name to the ADAM instance, and that name is used in the creation of the file directory structure and registry keys for ADAM. In addition, the name that you assign is used to create the service name, service display name, and service description, as shown in the example in the following table.

**ADAM Service Name**

| Name Supplied During Setup | Service Name | Service Display Name | Service Description |
|---|---|---|---|
| Instance1 | ADAM_instance1 | Instance1 | Blank (no default description provided) |

The name that you specify for an ADAM instance during setup must meet the following requirements:

- It must be unique with respect to other ADAM instances running on the same computer.
- It must be no longer than 44 characters.
- It must use characters only from the ranges of a through z, A through Z, or 0 through 9.
- The name "ntds" cannot be used.

The service display name appears in Add or Remove Programs and in the Services snap-in in Microsoft Management Console (MMC). The service description appears in the Services snap-in. You can modify the service display name and the service description anytime after installation by using the **sc** command-line tool.

**Service Account**

Each ADAM instance runs as a user service in the security context of the service account that is specified for that instance. The service account for an ADAM instance is specified at installation, and it should be modified only with the **dsmgmt** command-line tool.

**Note**

- Change the ADAM service account only with the **dsmgmt** command-line tool. Changing the ADAM service account with the Services snap-in will cause errors.

The type of ADAM service account that you can choose for an ADAM instance depends on the Windows workgroup or domain environment in which you install the ADAM instance and on whether the ADAM instance participates in a configuration set.

The Active Directory Application Mode Setup Wizard helps you choose a service account for ADAM by only allowing you to choose a service account that is valid for a particular configuration. The following table shows ADAM service accounts that are valid for a given environment.

**ADAM Service Accounts**

| Environment | First ADAM Instance Service Account | Replica ADAM Instances Service Account |
|---|---|---|
| Workgroup (that is, no domain or forest) | Network service | Replica ADAM instances not allowed |
| Workgroup (that is, no domain or forest) | Workstation user | Workstation user |
| Windows 2000 Server or Windows Server 2003 domain or forest | Network service | Network service or domain user |
| Windows 2000 Server or Windows Server 2003 domain or forest | Workstation user | Workstation user |
| Windows 2000 Server or Windows Server 2003 domain or forest | Domain user | Domain user or network service |
| Windows NT 4.0 domain | Workstation user | Workstation user |
| Windows NT 4.0 domain | Domain user | Domain user |

**Note**

- When a workstation (local) user account is used on the first ADAM instance in a configuration set, all subsequent ADAM instances in the same configuration set must use an identical local workstation account name and password as the ADAM service account.

**Event Log**

Each ADAM instance that is installed on a computer writes events to the event log. These events appear in Event Viewer under **ADAM (***instancename***)**, where *instancename* is the name that you assigned to the ADAM instance.

**Name:Port**

For a directory-enabled application to communicate with an ADAM instance, the application must specify the network basic input/output system (NetBIOS) name, Domain Name System (DNS) name, or IP address of the computer on which ADAM is running. In addition, the application must specify the LDAP or Secure Sockets Layer (SSL) communication port that is being used by the ADAM instance. For example, a directory-enabled application that references an ADAM instance running on a computer with a DNS name of ADAMSrv1.microsoft.com — with a NetBIOS name of ADAMSrv and an IP address of 192.168.0.1 and using communication port 389 for LDAP connections — can address the ADAM instance by using one of the following:

- ADAMSrv1.microsoft.com:389
- ADAMSrv:389
- 192.168.0.1:389

**Configuration Sets**

ADAM instances replicate data based on participation in a configuration set. A configuration set is a group of ADAM instances that replicate a common schema partition and configuration partition. (For more information about partitions, see "Directory Partitions" later in this document.) ADAM instances in a configuration set can also replicate any number of application directory partitions. ADAM instances in a configuration set are not required to replicate all application directory partitions in the configuration set; a single ADAM instance can replicate all — or any subset of — the application directory partitions in its configuration set. An ADAM instance cannot, however, replicate an application directory partition from a different configuration set.

The following figure shows an example of two ADAM configuration sets, each with two ADAM instances. As shown in the figure, a single computer can run multiple ADAM instances, each in a different configuration set.

**ADAM Configuration Sets**

**Creating Configuration Sets**

When you install an ADAM instance, you can install a unique instance or you can install a replica of an existing instance, as shown in the following figure, which illustrates the **Setup Options** page in the Active Directory Application Mode Setup Wizard.

**Active Directory Application Mode Setup Wizard Setup Options**

The following table describes each of these options as they relate to configuration sets.

**Setup Options**

| Setup Option | Meaning |
|---|---|
| **A unique instance** | Choosing this setup option starts a new configuration set. |
| **A replica of an existing instance** | Choosing this option causes the ADAM instance being installed to join to an existing configuration set. |

**Note**

- An ADAM instance can be joined to a configuration set only during installation of the instance. After an ADAM instance is created, it cannot be added to or removed from a configuration set.

**Sites**

Like Active Directory, ADAM uses topology information, which is stored as site objects and site link objects in the configuration directory partition, to build the most efficient replication topology for a configuration set. You can use sites in ADAM to represent the physical structure, or topology, of your network. You can use ADAM ADSI Edit to define site objects and site link objects.

### Note

- For specific instructions about creating site objects, site link objects, and setting site link costs, see the ADAM Administrator's Guide. To view the ADAM Administrator's Guide, after you install ADAM click **Start**, point to **All Programs**, point to **ADAM**, and then click **ADAM Help**.

**Site Objects**
You can create a site object in ADAM to represent each area of your network (typically, a building or a group of buildings) in which all computers are connected by high-speed bandwidth. You can then move the directory objects of ADAM instances that are located in each area of the network into the corresponding site object. By default, the directory objects of each ADAM instance that you create belong to a single default site (CN=Default-First-Site-Name,CN=Sites,CN=Configuration,CN={*GUID*}).

**Site Link Objects**
You can use site link objects in the directory to represent low-speed bandwidth connections between the sites on your network. Site link objects help you tune replication on your network; you can use them to determine the relative cost of replication across each site link. By default, the default site (CN=Default-First-Site-Name) belongs to the default site link object (CN=DEFAULTIPSITELINK,CN=IP,CN=Inter-Site Transports,CN=Sites,CN=Configuration,CN={*GUID*}). You can add new sites that you create to the default site link object. You can also create additional site link objects to represent each of the actual site links on your network.

**Site Link Costs**
Each site link object in the directory has an associated "cost" that represents the relative preference that ADAM gives to one site link compared to another. You can edit the cost attribute on a site link object to specify the relative cost of replication across that site link. ADAM takes into consideration site link costs when it builds the replication topology. ADAM considers a site link with a higher cost to be less desirable than a site link with a lower cost. When multiple paths for replication are available, ADAM uses the site link with the lower cost.

**ADAM Logical Structure**
The ADAM logical structure consists of the following:

- Directory database
- rootDSE
- Namespaces
- Directory partitions
- Schema

**Directory Database**
All data that is stored by an ADAM instance is held in the directory database. The ADAM directory database is organized into two or more partitions. ADAM stores directory data in a hierarchical directory store. By default, the directory database for a given ADAM instance is called Adamntds.dit, and it is located in the following directory:

ProgramFiles\Microsoft ADAM*instancename*\Data\Adamntds.dit

**rootDSE**
At the root of the ADAM directory tree is a DSA-specific entry (DSE), which is not part of any directory partition. The rootDSE represents the top of the logical namespace for one ADAM instance. The rootDSE attributes contain information about the ADAM instance, including its capabilities and configuration. The rootDSE is visible, by design, to anonymous users. (The rootDSE is the *only* object in ADAM that is visible by default to anonymous users.)

### Note

- Some non-Microsoft security scanners report an issue regarding the ability of anonymous users to read the rootDSE. However, the rootDSE is visible to anonymous users by design, and it does not represent a security issue.

There is only one root for a given directory instance, but the information that is stored in the root is specific to the ADAM instance to which you connect. Among other things, the attributes of rootDSE identify the directory partitions (the application, schema, and configuration directory partitions) that are specific to one ADAM instance. In this way, the rootDSE provides a

"table of contents" for a given ADAM instance.

The rootDSE is always accessible for queries through an anonymous connection.

#### rootDSE Operational Attributes

The rootDSE publishes information through attributes on the rootDSE object. RFC 2251 and RFC 2252, "Lightweight Directory Access Protocol (v3): Attribute Syntax Definitions," define a set of seven rootDSE operational attributes that LDAP v3 servers are expected to publish, and these attributes are described in the following table. All LDAP servers recognize these attribute names, but when an attribute corresponds to a feature that the server does not implement, the attribute is absent.

**rootDSE Operational Attributes**

| Attribute | Description |
|---|---|
| **supportedLDAPVersion** | LDAP versions that the server implements. Domain controllers running Windows Server 2003 and Windows 2000 Server support LDAP v2 and LDAP v3. |
| **namingContexts** | Naming contexts (directory partitions) that this server masters (stores as a writable replica) or shadows (stores as a read-only replica). A client uses this attribute to choose suitable base objects for searching when the client contacts a server. |
| **subschemaSubentry** | The name of a subschema entry, which is used to administer information about the schema, in particular, the object classes and attribute types that are supported. |
| **altServer** | Uniform Resource Locators (URLs) of other servers that can be contacted when this server becomes unavailable. If the server cannot locate any other servers, this attribute is absent. Clients can cache this information in case their preferred LDAP server becomes unavailable. This attribute is absent by default for Active Directory servers. |
| **supportedExtension** | Object identifiers that identify the extended LDAP operations that the server supports. LDAP extensions include such operations as different query types, paging operations, and sorting methods, which each have a different object identifier. This attribute is absent by default for Active Directory servers. |
| **supportedControl** | Object identifiers that identify the LDAP controls that the server supports. If the server does not support any controls, this attribute is absent. Server controls extend LDAP functionality; examples include a control to move objects across domains and a control to delete an entire subtree of a container object. |
| **supportedSASLMechanisms** | The names of the SASL mechanisms that the server supports. SASL is a standard for negotiating an authentication mechanism and, optionally, an encryption mechanism to provide client authorization for accessing Active Directory. By default, Generic Security Service API (GSSAPI) is supported. |

**Note**

- A new extended LDAP operation on ADAM instances and domain controllers running Windows Server 2003 enables client refresh of a dynamic entry in the directory. Object identifier = 1.3.6.1.4.1.1466.101.119.1 is defined and published in the **supportedExtension** attribute of the rootDSE object.

#### rootDSE Informational Attributes

In addition to the previous operational attributes, ADAM also supports the informational attributes in the following table.

**rootDSE Informational Attributes**

| Attribute | Description |
|---|---|
| **configurationNamingContext *** | The naming context (directory partition) for the forest Configuration container |
| **currentTime *** | The current time in the generalized time format |

| | |
|---|---|
| **defaultNamingContext *** | The default naming context (directory partition) for a particular ADAM instance as set in the **msDS-defaultNamingContext** attribute on the NTDSA object at:<br><br>(CN=NTDS Settings,CN=*computername*$*instancename*,CN=Servers,CN=Default-First-Site-Name,CN=Sites,CN=Configuration,CN={*GUID*})<br><br>Setting a value for **msDS-defaultNamingContext** is optional. |
| **dnsHostName *** | The DNS name of this ADAM instance |
| **domainControllerFunctionality *** | The numeric level of Active Directory functionality for the ADAM instance |
| **dsaVersionString** | The version stamp of Adamdsa.dll. This is visible only to administrators. |
| **dsSchemaAttrCount** | The total number of attributes that are defined in the schema |
| **dsSchemaClassCount** | The total number of classes that are defined in the schema |
| **dsSchemaPrefixCount** | The total number of prefixes in the schema |
| **dsServiceName *** | The distinguished name of the NTDS settings object that represents this ADAM instance in the configuration directory partition |
| **forestFunctionality *** | The Windows forest functional level. With Active Directory:<br><br>• 0 equals Windows 2000 functional level<br><br>• 1 equals Windows Server 2003 interim functional level<br><br>• 2 equals Windows Server 2003 functional level<br><br>With ADAM, **forestFunctionality** is set to 2 by default. |
| **highestCommittedUSN *** | The highest update sequence number (USN) that is committed to the database on this ADAM instance |
| **isSynchronized *** | A Boolean indicator for whether the ADAM instance has completed its initial synchronization with replica partners |
| **msDS-PortLDAP** | The LDAP port used by the ADAM instance |
| **msDS-PortSSL** | The SSL port used by the ADAM instance |
| **msDS-PrincipalName** | The name of the current user. This is visible only to authenticated users. |
| **msDS-ReplAllInboundNeighbors**<br><br>**msDS-ReplAllOutboundNeighbors**<br><br>**msDS-ReplConnectionFailures**<br><br>**msDS-ReplLinkFailures**<br><br>**msDS-ReplPendingOps**<br><br>**msDS-ReplQueueStatistics** | Attributes that make replication information available through LDAP. By using these attributes, you can obtain information with LDAP that otherwise must be obtained with RPC and the DsReplicaGetInfo API. For more information about DsReplicaGetInfo, see DsReplicaGetInfo in the Microsoft Platform SDK on MSDN. |
| **msDS-TopQuotaUsage** | A sorted list (highest to lowest) of the top 10 quotas that are used across all directory partitions that are held by the ADAM instance |

| | |
|---|---|
| **pendingPropagations** | The number of work items in the security descriptor propagator queue |
| **schemaNamingContext *** | The naming context (directory partition) for the forest schema |
| **serverName *** | The fully qualified distinguished name for this ADAM instance |
| **serviceAccountInfo** | Contains details about the service account that is used by this ADAM instance. This service account information is used during replica promotions to detect invalid configurations (configurations for which replication will not work). This is visible only to ADAM administrators. |
| **spnRegistrationResult** | The most recent error that relates to service principal name (SPN) registration. This is visible only to ADAM administrators. |
| **supportedCapabilities *** | The object identifier values (including 1.2.840.113556.1.4.1851 and 1.2.840.113556.1791) that indicate the additional capabilities of an ADAM instance, such as support for LDAP policies |
| **supportedConfigurableSettings** | The list of configurable settings that are supported by the ADAM instance |
| **supportedLDAPPolicies *** | Supported LDAP administrative query policies, such as the maximum size of a result set (**MaxResultSetSize**) and maximum page size (**MaxPageSize**) |
| **tokenGroups** | The current user's individual and group SIDs |
| **validFSMOs** | Operations master roles (also known as flexible single master operations (FSMO) roles) that are held by the ADAM instance. Valid operations master roles for ADAM are the schema operations master role and the domain naming operations master role. |

*Default attributes (All other attributes must be explicitly requested.)

**Note**

- You can retrieve an active users individual and group SIDs by explicitly querying the **tokenGroups** attribute on the rootDSE.

**Namespaces**

Each ADAM directory partition has its own unique distinguished name. Unlike Active Directory, which supports only DNS-style (DC=) names for top-level directory partitions, ADAM supports both DNS-style and X.500-style names for top-level directory partitions. However, if you develop an application for ADAM but later intend to migrate the application to Active Directory, use only DC= naming components in directory partition names. Using only DC= naming components helps to prevent compatibility problems when you migrate the application from ADAM to Active Directory.

For directory partition naming, ADAM supports the distinguished name components that are listed in the following table.

**ADAM Directory Partition Distinguished Name Components**

| Distinguished Name Component | Description |
|---|---|
| C= | Country/region |
| CN= | Common name |
| DC= | Domain component |
| L= | Location |
| O= | Organization |
| OU= | Organizational unit |

**OUs in a Namespace**

Organizational Unit containers can be created only in certain types of parent objects. Therefore, if you want to create organizational units (OUs) in a given ADAM directory partition, consider this limitation when you name the directory partition.

OUs can be created only under the following objects:

- OU (OU=)
- Country/region (C=)
- Organization (O=)
- Domain (DC=)

For example, you can create an OU in an application partition named O=Microsoft,C=US, but you cannot create an OU in an application partition named L=Microsoft,C=US.

**Directory Partitions**

The ADAM directory store is organized into logical directory partitions, or naming contexts. There are three different types of directory partitions: configuration, schema, and application. Each ADAM directory store must contain a single configuration directory partition and a single schema directory partition. The directory store can contain zero or more application directory partitions. The following table describes each directory partition type, its distinguished name, whether it is required or optional, and its contents.

**Directory Partition Types**

| Partition Type | Distinguished Name | Required/Optional | Contents |
|---|---|---|---|
| Configuration | CN=Configuration,CN={*GUID*} | Required | ADAM configuration information |
| Schema | CN=Schema,CN=Configuration,CN={*GUID*} | Required | Class and attribute definitions |
| Application | (Assigned during partition creation) | Optional | Application data |

**Note**

- The distinguished names of the configuration partition and the schema partition contain the GUID of the ADAM instance as a part of their distinguished names.

**Configuration Directory Partition**

The configuration directory partition holds information about ADAM replication scheduling and replica sets, information that defines the other partitions in the replication set, information about the users and groups in the replica set, and other information.

The following table describes the default containers in the configuration directory partition.

**Default Containers in the Configuration Directory Partition**

| Container | Purpose |
|---|---|
| CN=DirectoryUpdates,CN=Configuration,CN={*GUID*} | Not currently used. |
| CN=Extended-Rights,CN=Configuration,CN={*GUID*} | Stores objects of the class **controlAccessRight** that applications can use to extend standard access control. |
| CN=ForeignSecurityPrincipals,CN=Configuration,CN={*GUID*} | Stores proxy objects for security principals that are from Active Directory domains. |
| CN=LostAndFoundConfig,CN=Configuration,CN={*GUID*} | Stores configuration directory partition objects that are being created in containers that are being deleted simultaneously on other ADAM instances in the same configuration set. If, before replication, an object is created in or moved to a location that no longer exists after replication, the “lost” object is added to the LostAndFoundConfig container. |

| | |
|---|---|
| CN=NTDS Quotas,CN=Configuration,CN={*GUID*} | Stores objects of the class **msDS-QuotaControl** that contain object ownership quota assignments for the configuration directory partition. Quotas limit the number of objects that a user (including inetOrgPerson), group, computer, or service can own in a configuration directory partition or application directory partition. |
| CN=Partitions,CN=Configuration,CN={*GUID*} | Stores the cross-references to every directory partition in the configuration set, including the configuration partition, the schema partition, and all application partitions. During LDAP searches, these cross-references to directory partitions make referrals to other domains possible. |
| CN=Roles,CN=Configuration,CN={*GUID*} | Stores the default groups for a given partition. |
| CN=Services,CN=Configuration,CN={*GUID*} | Stores data for various networking services and applications. |
| CN=Sites,CN=Configuration,CN={*GUID*} | Identifies all the sites in the network, the ADAM instances in those sites, and the replication topology. The contents of this container take the form of replication transports, subnets, and the first site and site link that are created, which are called Default-First-Site-Name and Default-First-Site-Link, respectively. |

**Schema Directory Partition**

The schema directory partition contains the definitions for the types of data that the directory database can hold. The definitions in the schema partition maintain data consistency for the ADAM directory service. In addition, applications can refer to the schema partition to determine the types of data that an ADAM instance allows. You can also extend the schema so that ADAM can hold data that is specific to a particular application. For more information about schemas, see the "Active Directory Schema Technical Reference."

**Application Directory Partitions**

Application directory partitions hold the data that your applications use. You can create an application partition during ADAM setup or anytime after installation. Depending on your application, you might extend the schema manually or your application might automatically extend the schema for you. Typically, you manage data in a given application directory partition through your application. After the application directory partition is created, ADAM holds the application partition reference objects in CN=Configuration,CN=Partitions.

### Note

- With ADAM you can create users in an application directory partition. ADAM differs from Active Directory in this respect, because Active Directory does not allow the creation of users in an application directory partition.

**Schema**

The ADAM schema uses object classes and attributes to define the kinds of objects and data that can be created and stored in an ADAM directory. Each ADAM configuration set has its own independently manageable schema, which is stored in the schema directory partition. In keeping with the ADAM design concepts of simplicity and flexibility, the base (or default) ADAM schema contains only the classes and attributes that are needed to start an ADAM instance. The schema can be extended with new classes and attributes, either by administrators or by the applications themselves. In addition, unneeded schema classes and attributes can be deactivated. As with all objects in the directory, access control lists (ACLs) protect schema objects so that only authorized users can alter the schema. Every object in an ADAM directory is an instance of an object class that is defined in a schema.

**Object Classes**

An object class represents a category of objects, such as users, printers, or applications, that share a set of common characteristics. The definition for each object class contains a list of the attributes that can be used to describe instances of the class. For example, the **User** class has attributes such as **givenName**, **surname**, and **streetAddress**. Attributes for a class are divided into those attributes that an object of that class must contain and additional attributes that the object may contain. The definition of each class also lists the classes whose objects can be parents of the objects of that class.

**Attributes**

The schema defines each attribute. The definition for each attribute includes unique identifiers for the attribute, the syntax for the attribute, optional range limits for the attribute values, whether the attribute can have only one value or multiple values, and whether the attribute is indexed. The directory schema defines each attribute exactly once. Each attribute can then be referenced by multiple object classes. For example, the **description** attribute is defined once, and then it is referenced by many

object classes.

**Single-value and multivalue attributes**
Attributes can be single valued or multivalued. An instance of a single-value attribute can contain only a single value. An instance of a multivalue attribute can contain multiple values, which must all use the same syntax. Each value of a multivalue attribute must be unique.

### Note

- A multivalue attribute stores its values in random order. Therefore, you should not make any directory decisions — programmatic or manual — based on the order of the values in a multivalue attribute.

**Indexed attributes**
Indexing attributes helps to improve the performance of queries that are based on the indexed attributes. Both single-value and multivalue attributes can be indexed; however, classes cannot be indexed. Attributes can be marked for indexing through their schema definition. Indexing an attribute makes it possible for users to use wildcard symbols (*) as prefixes and suffixes when they specify a search string.

When you mark an attribute as indexed, all instances of the attribute are added to the index, not just the instances that are members of a particular class. Indexing attributes, particularly multivalue attributes, can negatively affect replication and object creation time, as well as directory database size. Therefore, you should only index commonly used attributes.

For general information about schemas, see "Active Directory Schema Technical Reference."

**Schema Extensions**
Like the Active Directory schema, the ADAM schema can be extended through the importing of .ldf files into the schema. The ADAM package contains four .ldf files that can be imported as an option on the **Import LDIF Files** page of the Active Directory Application Mode Setup Wizard. Together, these files contain several **user** class schema definitions, along with objects that can be used with Windows Authorization Manager.

The following table describes each of the optional ADAM .ldf files.

### ADAM .ldf Files

| .ldf file | User Classes | Description |
|---|---|---|
| ms-user.ldf | **Person**<br>**Organizational-Person**<br>**User** | Used to create user objects in the ADAM directory. |
| ms-inetorgperson.ldf | **Person**<br>**Organizational-Person**<br>**User**<br>**inetOrgPerson** | Used to create user objects in the ADAM directory of the **inetOrgPerson** class (as defined in RFC 2798, "Definition of the inetOrgPerson LDAP Object Class"). |
| ms-userproxy.ldf | **User-Proxy** | Used to create proxy objects in ADAM for use in bind redirection. For more information about proxy objects and bind redirection, see "Bind Redirection for ADAM Proxy Objects" later in this section. |
| ms-azman.ldf | Not applicable | Used to prepare ADAM for use with Windows Authorization Manager. |

These .ldf files are installed to the *windir*\ADAM directory, and they can be imported anytime after ADAM installation.

### Note

- Each of these .ldf files contains within it the command-line instruction for importing the file into the ADAM schema. To import one of these files after ADAM installation:

1. Open the file in a text editor, such as Notepad.

2. Copy the command-line instruction for importing the file from the beginning of the file.

3. Open an ADAM tools command prompt. Click **Start**, point to **All Programs**, point to **ADAM**, and then click **ADAM Tools Command Prompt**.

4. Paste the copied command into the command prompt.

5. Run the command.

**ADAM Security**

Because ADAM is based on the same code as Active Directory, security in ADAM works very similarly to security in Active Directory. ADAM uses the same basic set of security concepts as Active Directory: authentication, authorization, users, groups, ACLs, tokens, and so on. This section describes how these security concepts are implemented in ADAM.

**Default Groups in ADAM**

ADAM uses groups to provide access to directory data. Like Active Directory, ADAM contains its own set of default groups that are created at installation time. After ADAM is installed, a set of default groups exist in each directory partition. In addition, you can create your own custom groups.

ADAM provides three default groups in each configuration and application directory partition. The groups reside in the CN=Roles container of each partition. These default groups include the following:

- Administrators (CN=Administrators,CN=Roles)

- Readers (CN=Readers,CN=Roles)

- Users (CN=Users,CN=Roles)

**Note**

- The schema partition does not contain any groups.

The following figure illustrates the default ADAM groups for each directory partition.

**Default ADAM Groups by Partition**

The following group resides only in the configuration directory partition: Instances (CN=Instances,CN=Roles).

**Note**

- ADAM uses the Instances group for replication. You should not add users to the Instances group.

You can use ADAM ADSI Edit to view the ADAM groups in the CN=Roles container. The following figure shows the groups that are contained in the CN=Roles container in the configuration partition of an ADAM instance.

**Groups in the ADAM Configuration Partition**

The following table describes the purpose and default members of each of the default ADAM groups.

| Partition | Group | Purpose | Default Members |
|---|---|---|---|
| Configuration | Administrators | This group administers the ADAM instance. | The ADAM administrator that is assigned during ADAM setup. The ADAM administrator is always a Windows security principal. |
| Configuration | Readers | This group has Read access to the configuration partition (including the schema). | None |
| Configuration | Users | This group is a computed group. | All users that are defined in any application directory partition |
| Application (0 to *n*) | Administrators | This group administers the application partition in which the group resides. | Members of the Administrator's group from the configuration partition |
| Application (0 to *n*) | Readers | This group has Read access to the application partition in which the group resides. | None |
| Application (0 to *n*) | Users | This is a computed group. | All users from the respective application directory partition |

You can create additional groups in any application partition. You cannot create additional groups in the configuration partition.

**Partition Membership and ACL Restrictions**

This section describes the partition membership and ACL restrictions in ADAM.

**ADAM users**

Cross-partition memberships are not allowed for ADAM users. In other words, an ADAM user cannot reside in groups in more than one directory partition. In addition, ADAM users can be assigned permissions only on objects in their own directory partition; they cannot be assigned permissions on objects outside their own directory partition.

By default, ADAM users cannot be created in the configuration directory partition, and they cannot be members of a group in the configuration directory partition. However, there is a hotfix for ADAM that you can use to create ADAM users in the configuration directory partition, which allows ADAM users to be administrators of an ADAM instance. For more information about this hotfix, contact Microsoft Product Support Services.

**Windows users**

Cross-partition memberships are allowed in ADAM for Windows users (both local and domain Windows users). In other words, a Windows user can reside in groups in more than one directory partition, including the configuration directory partition. In addition, Windows users can be assigned permissions on objects outside their own directory partition.

**Group Memberships in ADAM**

ADAM groups can contain ADAM users (also called ADAM security principals), as well as Windows users (also called Windows security principals), as members. An ADAM user is a user that is created in an ADAM directory partition. A Windows user is a user that exists as a Windows user on the local computer or as a domain member of an Active Directory domain.

An ADAM user or Windows user becomes a member of an ADAM group by being added to the multivalue **member** attribute on the respective group object. You can use ADAM ADSI Edit to add users to ADAM groups.

### Note

- Although ADAM provides a number of default groups, no default users exist in ADAM, except for the Windows security principal that you specify as the ADAM administrator during ADAM setup. The user that you specify as the ADAM administrator becomes a member of the Administrators group in the configuration directory partition.

#### Restrictions on the Administrators Group

By default, only Windows security principals can be made members of the Administrators group on the configuration directory partition. Therefore, by default only Windows security principals can administer an ADAM instance. However, there is a hotfix for ADAM that you can use to create ADAM users in the configuration directory partition that allows ADAM users to be administrators of an ADAM instance. For more information about this hotfix, contact Microsoft Product Support Services.

#### Group Scope

The scope of an ADAM group (or of an ADAM user) is restricted to the partition in which the group (or user) is created. In other words, a group that is created in partition A cannot be used to assign permissions on resources in partition B. The exception to this rule is the Administrators group in the configuration directory partition, whose members have full control of all objects in all partitions. In addition, a user in partition B cannot be added to a group in partition A. This includes groups in the configuration directory partition.

#### Security Principals in ADAM

The term security principal refers to any object (typically, a user) that has a unique SID and that can be assigned permissions to directory objects. In ADAM, security principals can be any of the following:

- ADAM security principals that are created in an ADAM directory partition
- Windows users that are defined on a local computer
- Windows users that are defined in an Active Directory domain

#### ADAM Security Principals

An ADAM security principal is a user or other bindable object that is created in ADAM. A newly installed ADAM instance does not include any default ADAM users. In fact, the default ADAM schema does not contain any user object classes. However, you can easily import the schema extensions that are provided with ADAM to add several different user object classes to the ADAM schema. These object classes include the **User** object class (which is very similar to the **User** object class in Active Directory) and the **inetOrgPerson** object class (which is derived from the **User** object class). You can import these object classes through the Active Directory Application Mode Setup Wizard.

In addition, you can make any object class in the ADAM schema a security principal by adding the **msDS-bindableobject** auxiliary class and the **unicodePwd** attribute to the schema definition of the object class in the ADAM schema.

### Note

- When you create an ADAM security principal, ADAM generates a SID for the security principal automatically.

#### Windows Security Principals

In addition to supporting ADAM security principals, ADAM supports the use of Windows security principals. In other words, Windows security principals can be assigned permissions on objects in ADAM, and Windows security principals can become members of ADAM groups. ADAM does not authenticate Windows security principals. Instead, Windows security principals are authenticated by Active Directory (for domain-based Windows security principals) or by the Local Security Authority (LSA) on the local computer (for local Windows security principals).

#### Default ACLs

Just like Active Directory, ADAM uses ACLs to control access to objects in ADAM. However, unlike Active Directory, the majority of ACLs in ADAM are on the partition head objects (the top-level containers of partitions). These ACLs are inherited throughout the entire partition on which they reside.

By default, the ACLs in the following table exist on the partition head objects in ADAM.

**ADAM Default Partition Head ACLs**

| Partition Head | Group: Default ACLs |
|---|---|
| Configuration | Administrators: Full Control<br><br>Readers: Read |
| Schema | Administrators (from the configuration partition): Full Control<br><br>Readers: Read |
| Application (0 to *n*) | Administrators: Full Control<br><br>Readers: Read<br><br>Instances: five replication-related access control entries (ACE) |

Other default ACLs for ADAM include the ACLs in the following table.

**Other Default ADAM ACLs**

| Security Principal | ACLs |
|---|---|
| Everyone | • "Query self quota" control on quota objects |
| Administrators group | • Full Control on the Roles container<br><br>• Full Control on the Quotas container<br><br>• Full Control on the Lost and Found container |
| Readers group | • Read control on the Roles container (inheritable)<br><br>• Read control on the Lost and Found container |
| **User** and **inetOrgPerson** classes | • "Change password" control for "self" in the default security descriptor in the schema |

**Adding SIDs to ACLs**

By adding the SIDs of particular users to the ACL of a particular object, you can provide access to that object to the security principals that the SIDs represent. To add a SID to an ACL in ADAM, you can use the Dsacls.exe command-line tool.

The general syntax to add a SID to an ACL using **dsacls** for granting permissions is as follows:

```
dsacls "\\
servername:portnumber
\Object DN" /G "User DN":
security descriptor
```

For example, to grant Delete permissions to a user named Mary Baker (CN=Mary Baker,OU=ADAM users,O=Microsoft) on the object ADAM testers (CN=ADAM testers,OU=ADAM users,O=Microsoft,C=US), you use the following syntax:

```
dsacls "\\
servername
:
portnumber
\CN=ADAM testers,OU=ADAM users,O=Microsoft,C=US" /G "CN=Mary Baker,OU=ADAM
users,O=Microsoft,C=US":SD;;
```

The general syntax to add a SID to an ACL using **dsacls** for denying permissions is as follows:

```
dsacls "\\servername:portnumber\Object DN" /D "User DN":security descriptor
```

For example, to deny the Delete, Delete Child, and Delete Tree permissions to Mary Baker (CN=Mary Baker,OU=ADAM users,O=Microsoft) on the ADAM users OU (OU=ADAM users,O=Microsoft,C=US), you use the following syntax:

```
dsacls "\\
servername
:
portnumber
\OU=ADAM users,O=microsoft,C=US" /D "CN=Mary Baker,OU=ADAM
users,O=Microsoft,C=US":SDDCDT;;
```

For additional information about **dsacls** syntax, type **dsacls /?** at an ADAM command prompt. For more information about using **dsacls**, see article 281146, "How to Use Dsacls.exe in Windows 2000," in the Microsoft Knowledge Base.

**Matching Tokens Against an ACL**

In ADAM, when a user is authenticated, ADAM (or the LSA, depending on the type of security principal) creates a security access token for that user. An access token contains the users name, the groups to which that user belongs, a SID for the user, and all of the SIDs for the groups to which the user belongs. The information in the access token is used to determine a user's level of access to objects whenever the user attempts to access them. The SIDs in the access token are compared with the list of SIDs that make up the discretionary access control list (DACL) for the object to ensure that the user has sufficient permission to access the object.

**Authentication in ADAM**

Authentication is the act of ensuring the identity of a user before granting that user access to resources. ADAM implements authentication to ensure the identity of users.

ADAM supports several types of authentication, or binding, depending on the type of user being authenticated:

- Anonymous binding, for anonymous users (users that do not supply a password)
- Simple LDAP binding, for ADAM security principals (security principals that reside in ADAM)
- SASL binding, for Windows security principals (Windows security principals that reside on a local computer or in Active Directory)
- Bind redirection, for ADAM proxy users (security principals that reside in ADAM but that contain a reference to a security principal that resides in Active Directory)

### Note

- Proxy users are designed for special circumstances and should only be used as a last resort, when Windows principals cannot be used directly. For more information, see "Bind Redirection for ADAM Proxy Objects" later in this section.

When a user attempts to authenticate against, or bind to, ADAM, the user might be authenticated by ADAM, the LSA, or Active Directory, depending on the type of user attempting the bind. The following table lists the types of authentication that ADAM supports, the types of users that are appropriate to each authentication method, and the authenticating authority that handles the authentication.

### Authentication Methods in ADAM

| Type of Authentication | Type of User | Authenticating Authority |
|---|---|---|
| Anonymous | Anonymous | Not applicable. The user is not authenticated. |

| | | |
|---|---|---|
| Simple LDAP bind | ADAM security principal | ADAM |
| SASL bind (using Kerberos, NTLM, or negotiated) | Local Windows security principal | LSA on the local computer |
| SASL bind (using Kerberos, NTLM, or negotiated) | Domain Windows security principal | Active Directory |
| Bind redirection (Simple LDAP bind to ADAM, then SASL bind to Active Directory) | ADAM proxy object | LSA and Active Directory |

The types of authentication that are used with ADAM are described in the following sections.

**Anonymous Authentication**

Anonymous authentication occurs when a user attempts to bind to ADAM without providing a password. Instead, the user presents ADAM with an empty (null) password in a simple LDAP bind request. In return, ADAM provides the user with anonymous access to the directory. Anonymous authentication is useful for any applications that require unrestricted, public access to data and for situations in which you do not want to maintain individual accounts for users.

**Note**

- By default, ADAM does not allow anonymous binding. However, you can enable anonymous binding in ADAM by modifying the **dsHeuristics** attribute. For more information, see "To allow anonymous LDAP binding to an ADAM instance" in the ADAM Administrators Guide. To view the ADAM Administrators Guide, click **Start**, point to **All Programs**, point to **ADAM**, and then click **ADAM Help**.

By default, the only object in ADAM to which an anonymous user has access is the rootDSE object. (The rootDSE object is visible to anonymous users whether or not anonymous binding is enabled.) If you enable anonymous binding, you can grant anonymous access to any object or attribute in the directory by assigning permissions on the object or attribute to NT Authority\Anonymous Logon (whose well-known SID is S-1-5-7). In addition to assigning permissions on the object or attribute, to allow anonymous users to read an object or attribute in ADAM, you must also grant the **ADS_RIGHT_DS_LIST_OBJECT** permission on the parent of the object or attribute. You can use **dsacls** to provide access to an object in the directory.

**Note**

- To grant anonymous access to an entire partition, grant anonymous access permissions on the partition head.

When a user binds to ADAM anonymously, ADAM generates a token that contains the following: S-1-5-7 (NT Authority\Anonymous Logon).

**Note**

- Tokens that ADAM generates for a user are exposed externally through an attribute on the rootDSE object called **tokenGroups**. The **tokenGroups** attribute is new with ADAM, and it does not appear in Active Directory.

**Simple LDAP Bind for ADAM Security Principals**

Simple LDAP binding occurs when a user binds to ADAM as a security principal that exists as an object in the ADAM directory. This authentication method uses a simple LDAP bind; no SASL options are available with basic authentication. This simple LDAP bind can be accomplished using the distinguished name of the security principal or the user principal name (UPN) of the security principal. In contrast to UPNs in Active Directory, the UPN for an ADAM security principal is not required to contain the @ symbol.

In a simple LDAP bind, the user password is sent in plaintext format to ADAM. For this reason ADAM requires an encrypted channel — using SSL between the client that connects to ADAM and the ADAM server — for basic authentication to occur securely. To enable SSL connections to ADAM, you must have certificates installed on the computer running ADAM. In addition, the clients that connect to ADAM should trust the certification authority (CA) that issues the certificate to the ADAM server. You can obtain certificates from a trusted CA, or, for internal use, you can issue certificates from your own internal CA by installing and using certificate services on Windows 2000 Server or Windows Server 2003.

**Notes**

- Before you attempt to use a certificate with ADAM, you must ensure that the service account under which ADAM is

running has Read access to the certificate that you install. The certificate is located in the following directory: C:\Documents and Settings\All Users\Application Data\Microsoft\Crypto\RSA\MachineKeys

- Although it is not recommended for production environments, you can disable the requirement for SSL in basic authentication by using the **ds-behavior** option of the Dsmgmt.exe command-line tool.

Any ADAM object can be used to bind to ADAM, as long as the object class from which the object is derived contains the **msDS-bindableobject** auxiliary class and the **unicodePwd** attribute. Adding **the msDS-bindableobject** auxiliary class to an object class causes ADAM to generate a SID automatically for any object that is created from that class.

**Note**

- The default ADAM schema contains no bindable object classes. However, several optional user class object definitions are provided with ADAM, including **User** and **inetOrgPerson**. You can import these user classes during ADAM installation.

For a user that is authenticated with basic authentication, the ADAM token contains the following SIDs:

- User SID
- Everyone [S-1-1-0]
- NT AUTHORITY\Authenticated Users [S-1-5-11]
- SID of the user's group from the user's partition
- SIDs of any additional groups that are determined through transitive group expansion

**Note**

- To determine the contents of a user's token, you can view the **tokenGroups** attribute on the rootDSE object.

**Password policy settings and account lockouts**

When basic authentication is used and ADAM is running on a computer running Windows Server 2003, ADAM supports and enforces the password policy settings and account lockout settings that are provided by Windows Server 2003, including the following:

- **Minimum age**
- **Maximum age**
- **Complexity**
- **History**
- **Too many failed logon attempts**
- **Disabling and enabling of accounts**

If the server on which ADAM is running belongs to a workgroup, the server's local password policy settings and account lockout settings are implemented. If the server on which ADAM is running belongs to a domain, the password policy settings and account lockout settings from Active Directory are implemented. Therefore, it is possible for two ADAM instances in the same configuration set to enforce different password policy settings and account lockouts.

**Note**

- You can disable the enforcement of password policy settings in ADAM by setting **ADAMDisablePasswordPolicies**, a value in the attribute **msDS-Other-Settings** on CN=Directory

Service,CN=Windows NT,CN=Services,CN=Configuration,CN=GUID, to **1**.

**SASL Bind for Windows Security Principals**

Integrated authentication occurs when a Windows security principal attempts to bind to an ADAM instance. ADAM does not authenticate Windows users itself. Instead, ADAM relies on the Windows Security API to authenticate the user. Integrated authentication uses SASL binds. All SASL mechanisms that are supported in Active Directory are supported in ADAM. These mechanisms include Kerberos, NTLM, and Negotiated (default). Integrated authentication supports the use of domain\user, UPN, or distinguished name as authentication credentials.

When ADAM receives a SASL bind request, ADAM forwards the request to Active Directory. If the bind request is authenticated by Active Directory, Active Directory returns a token to ADAM. ADAM uses that token in its internal context, augments it with ADAM groups that the Windows user is a member of across all the application partitions that are hosted by the ADAM instance, and then performs transitive group expansion across all the application partitions. That is, ADAM determines group memberships for the Windows user that result from the user being a member of a group that itself is a member of a different group.

For a user that is authenticated using integrated authentication, the ADAM token contains the following SIDs:

- SIDs of all groups from the Windows token that is obtained from Active Directory
- SIDs of all ADAM groups of which the Windows security principal is a member
- SIDs of any additional groups that are determined through transitive group expansion

**Bind Redirection for ADAM Proxy Objects**

ADAM bind redirection should be used only in special cases where an application can perform a simple LDAP bind to ADAM but the application still needs to associate the user with a security principal in Active Directory.

ADAM bind redirection occurs when a bind to ADAM is attempted using a special object called a proxy object. A proxy object is an object in ADAM that represents a security principal in Active Directory. Each proxy object in ADAM contains the SID of a user in Active Directory. When a user attempts to bind to a proxy object, ADAM takes the SID that is stored in the proxy object, together with the password that is supplied at bind time, and presents the SID and the password to Active Directory for authentication. A proxy object in ADAM does not store a password, and users cannot change their Active Directory passwords through ADAM proxy objects.

Because the initial bind request is a simple LDAP bind request, the password is presented in plaintext to ADAM. For this reason an SSL connection is required by default between the directory client and ADAM. ADAM uses Windows Security APIs to present the password to Active Directory.

### Note

- Because the password that is presented to ADAM during ADAM bind redirection is an Active Directory password that is presented in plaintext, you should not disable the requirement for SSL when using bind redirection.

**Proxy objects**

Proxy objects (and proxy object classes) do not exist by default in ADAM. However, you can import a proxy object class into the ADAM schema during ADAM installation. A proxy object can be created from any object class that contains the **msDS-bindProxy** auxiliary class. The **msds-BindProxy** class possesses a single “must contain” attribute, **ObjectSid**, which holds the SID of the associated Active Directory security principal. You can set the value of **ObjectSid** only at the time that the object is created. After a proxy object is created, the value of its **ObjectSid** attribute cannot be modified. You can set the **ObjectSid** of a proxy object to the SID of any local Windows user or to any user who is a member of a domain or forest that is trusted by the computer on which ADAM is running.

### Note

- You cannot create a proxy object for a domain user in an ADAM directory partition that already contains a foreign principal object (FPO) for that same domain user.

For a user that is authenticated through bind redirection, the token that is generated for the user is identical to a token that is generated for a Windows security principal that is binding to ADAM through integrated authentication.

**ADAM Processes and Interactions**
This section describes the following ADAM processes and interactions:

- Locating an ADAM instance
- Replication
- LDAP referrals
- Service publication
- Auditing
- ADAM and Microsoft Authorization Manager
- Backup and restore

**Locating an ADAM Instance**
For a directory-enabled application to be able to communicate with an ADAM instance, the application must specify the NetBIOS name, DNS name, or IP address of the computer on which ADAM is running. In addition, the application must specify the LDAP or SSL communication port that is used by the ADAM instance. For example, a directory-enabled application referencing an ADAM instance running on a computer with a DNS name of ADAMSrv1.microsoft.com — with a NetBIOS name of ADAMSrv and an IP address of 192.168.0.1 and using communication port 389 for LDAP connections — can address the ADAM instance by using one of the following:

- ADAMSrv1.microsoft.com:389
- ADAMSrv:389
- 192.168.0.1:389

**Locating ADAM Instances in Active Directory Environments**
When you run ADAM in an Active Directory environment, each ADAM instance creates and maintains service connection point (SCP) objects about itself in Active Directory. For more information, see "Service Publication" later in this document.

**Server Object Names**
By default, the relative distinguished name of a server object in ADAM is *servername*$*instancename*, where *servername* represents the computer on which the ADAM instance is running and *instancename* represents the service name of the ADAM instance.

**Modifying Settings on a Computer Running ADAM**
You initially specify the computer name, DNS name, NetBIOS name, and IP address when you set up the computer. You initially specify the communication port numbers that are used by a given ADAM instance when you install the ADAM instance.

You can change these settings on a computer running ADAM anytime. However, when you update any of these settings, you may also need to reconfigure directory-enabled applications to properly address the ADAM instance. For example, if the host name of the computer on which ADAM is running changes, your directory-enabled application may need to be updated accordingly.

**Replication**
ADAM uses replication to provide fault tolerance and load balancing for directory services. ADAM uses a type of replication called multimaster replication. Through replication, ADAM copies directory data updates that are made to a directory partition on one ADAM instance to other ADAM instances that hold copies of the same directory partition. ADAM instances that hold copies of the same directory partition or partitions form a logical grouping called a configuration set. ADAM prevents replication conflicts through the use of change tracking information.

### Note

- An ADAM configuration set maintains its own replication topology, separate from any Active Directory replication topology that might also exist. Directory partitions cannot be replicated between ADAM instances and Active Directory domain controllers.

**Multimaster Replication**
With multimaster replication, you can make changes to directory data on any ADAM instance. ADAM replicates these changes to other members of the configuration set automatically. Multimaster replication is characterized by loose data consistency with convergence. That is, when you make changes to data on a given directory partition at one ADAM instance, replicas of that directory partition that are stored on other ADAM instances become inconsistent with the most up-to-date replica of the directory partition (the partition where the changes were made). However, as changes get replicated through the configuration set, all partition replicas once again become identical; that is, they converge to the most recent data.

**Preventing Replication Conflicts**
What if two different users make changes to the same data on replicas of the same directory partition on two different ADAM instances? In this case, each ADAM instance attempts to replicate the changes, which creates a conflict. To resolve this conflict, replication partners that receive these conflicting changes examine the attribute data that is contained in the changes, each of which holds a version and a time stamp. ADAM instances accept the change with the higher version and discard the other change. If the versions are identical, ADAM instances accept the change with the more recent time stamp.

If two or more values in a multivalue attribute on an object are updated simultaneously on two different ADAM instances, only one of the updated values will be replicated. In other words, simultaneous updates to a multivalue attribute that occur on two different ADAM instances are considered to be in conflict, even if the updates apply to different values in the multivalue attribute. The only exception to this rule is for linked-value attributes (such as group memberships), which do allow for simultaneous updates to different values in the linked-value attribute.

**Sites and Replication**
In ADAM, the replication topology is the set of physical connections that is used to replicate directory updates among ADAM instances in a configuration set. ADAM builds the most efficient replication topology for a configuration set based on the site or sites in which members of the configuration set reside. ADAM treats replication within a site differently than replication between sites.

**Building the intersite replication topology**
One ADAM server in each site, called the intersite topology generator (ISTG), is assigned to build the topology. Together, these ISTGs build a least-cost, spanning-tree algorithm that eliminates redundant replication paths between sites. The intersite replication topology is updated regularly to respond to any changes that occur in the network. You can control intersite replication through the information that you provide when you create your site links.

**Determining when intersite replication occurs**
ADAM preserves bandwidth between sites by minimizing the frequency of replication and by enabling you to schedule the availability of site links for replication. By default, intersite replication across each site link occurs every 180 minutes (3 hours). You can adjust this frequency to match your specific needs. (Remember that increasing this frequency increases the amount of bandwidth that is used by replication.) In addition, you can schedule the availability of site links for use by replication. By default, a site link is available to carry replication traffic 24 hours a day, 7 days a week. You can limit this schedule to specific days of the week and times of the day. You can, for example, schedule intersite replication so that it only occurs after normal business hours.

**Building the intrasite replication topology**
The Knowledge Consistency Checker (KCC) on each ADAM instance automatically builds the most efficient replication topology for intrasite replication using a bidirectional ring design. This bidirectional ring topology attempts to create at least two connections to each ADAM instance (for fault tolerance) and no more than three hops between any two ADAM instances (to reduce replication latency). To prevent connections of more than three hops, the topology can include shortcut connections across the ring. The KCC updates the replication topology regularly.

The KCC in ADAM operates identically to the KCC in Active Directory. For more information about how the KCC in Active Directory works, see "How Active Directory Replication Topology Works."

**Determining when intrasite replication occurs**
Intrasite replication is optimized for speed, rather than bandwidth, because bandwidth within a site is assumed to be high speed. Intrasite replication occurs automatically on the basis of change notification, and it begins when a directory update occurs. By default, the source ADAM instance waits 15 seconds and then sends an update notification to its closest replication partner. If the source ADAM instance has more than one replication partner, subsequent notifications go out by default at three-second intervals to each partner. After receiving notification of a change, a partner ADAM instance sends a directory update request to the source ADAM instance. The source ADAM instance responds to the request with a replication operation. The three-second notification interval prevents the source ADAM instance from being overwhelmed with simultaneous update requests from its replication partners.

If no directory updates occur in a given time period, intrasite replication still occurs, based on a scheduled interval. By default,

this scheduled interval is once per hour. For information about modifying this time period, see the ADAM Administrator's Guide. After you install ADAM, to view the ADAM Administrator's Guide, click **Start**, point to **All Programs**, point to **ADAM**, and then click **ADAM Help**.

#### Ensuring Replication Security

To ensure replication security, ADAM authenticates replication partners before replication, and replication authentication always occurs over a secure channel. ADAM replication partners authenticate each other using the service account that is specified for each respective ADAM instance. ADAM uses the Security Support Provider Interface (SSPI) to establish the appropriate authentication security level between replication partners. The method that is used for replication authentication within a configuration set depends on the value of the **msDS-ReplAuthenticationMode** attribute on the configuration directory partition. After replication partners authenticate, all replication traffic between the two partners is encrypted.

The following table describes the security levels for ADAM replication and the corresponding authentication mode (**msDS-ReplAuthenticationMode)** attribute value for each security level. The default replication security level for a new, unique ADAM instance is 1, unless a local workstation user account is specified as the ADAM service account. If a local workstation account is specified as the ADAM service account, the replication security level is 0.

**ADAM Replication Security Levels**

| Replication Security Level | Authentication Mode | Description | Supported Environments |
|---|---|---|---|
| Mutual authentication with Kerberos | 2 | Kerberos authentication, using SPNs, is required. If Kerberos authentication fails, the ADAM instances will not replicate. | The configuration set must be fully contained in an Active Directory domain, forest, or forest trust. |
| Negotiated | 1 | Kerberos authentication (using SPNs) is attempted first. If Kerberos fails, NTLM authentication is attempted. If NTLM fails, the ADAM instances will not replicate. | The configuration set can contain Windows NT 4.0 member servers. This is useful for transitioning between negotiated pass-through mode and mutual authentication with Kerberos. |
| Negotiated pass-through | 0 | All ADAM instances in the configuration set use an account name and password that are identical to those of the ADAM service account. | The configuration set can include computers that are joined to one or more workgroups or that are joined to multiple domains or forests without trust relationships. |

To help maintain ADAM replication security, the following best practices are recommended:

- Use the highest level of replication security that your environment can support.
- In Active Directory environments, run ADAM on member servers — rather than on domain controllers — whenever possible.
- If you run ADAM on a domain controller in an Active Directory environment, do not use the Network Service account as the ADAM service account. Instead, use a domain user account that does not have administrative privileges.
- In workgroup and Windows NT 4.0 environments, do not use an account with administrative privileges as an ADAM service account.
- Use separate configuration sets for applications with strict isolation requirements.

#### Replication Monitoring

You can use the Repadmin.exe command-line tool to monitor ADAM replication.

**Repadmin /showutdvec** shows, from the perspective of the ADAM instance on which the command is run, the most recent change that the ADAM instance has received from each of its replication partners, both directly and transitively.

You can use **Repadmin /replicate** to force replication between ADAM instance replication partners.

For more information about the **repadmin** command, type **repadmin /?** at an ADAM tools command prompt.

**LDAP Referrals**

In accordance with RFC 2251, ADAM supports the use of LDAP referrals. With LDAP referrals, you can use ADAM to direct LDAP clients to a more appropriate location in response to a query from the client. Also in accordance with RFC 2251, ADAM can return referrals in response to any LDAP operation request, except "unbind" and "abandon" requests, which have no responses. ADAM maintains referral data in crossRef objects that are stored in the partitions container of the configuration directory partition.

ADAM creates and maintains crossRef objects for all directory partitions in the configuration set, including the configuration and schema directory partitions. These crossRef objects are used to generate referrals in response to queries that request data about objects that exist in the configuration set but that are not contained in the ADAM instance handling the request.

At a minimum, at least one URL must be present in the referral. When possible, ADAM returns at least three referrals to provide referral redundancy to clients in distributed environments. A referral is not returned for a **singleLevel** or **wholeSubtree** search in which the search scope spans multiple directory partitions and several different servers must be contacted to complete the operation. Instead, continuation references are returned.

If a crossRef object with a matching directory partition exists, ADAM uses it for referrals. However, if a crossRef object does not exist, but the queried namespace uses DNS-style (DC=) naming, ADAM constructs a DNS name to be used as a referral. If the queried namespace does not use DNS-style naming, a superior reference is used, if one exists. A superior reference can be configured by setting the **superiorDnsRoot** attribute on the configuration partition crossRef object. If a superior reference is not configured (it is not configured by default), an operational error is returned.

**Generating Referrals from a crossRef Object**

If the **dNSRoot** attribute has been set on the crossRef object (**dNSRoot** is not set by default), ADAM returns the DNS name as the referral for the queried namespace. (By default, the **dNSRoot** attribute is set to NULL.) Then, the client can chase the referral through registered DNS records for each host that contains the queried namespace.

If the **dNSRoot** attribute is NULL, the referral is generated based on other information on the crossRef object, as follows:

- ADAM refers to the **msDS-NC-Replica-Locations** attribute to find the NTDS Settingsobjects that represent the instances hosting this partition (for example, CN=NTDS Settings,CN=Machine1$instance1,CN=Servers,CN=Default-First-Site-Name,CN=Sites,CN=Configuration,CN={*GUID*}). If more than three ADAM instances host the directory partition, a randomly selected set of three instances is chosen.

- From the NTDS Settings object (the authoritative source in the directory for communications port information), ADAM retrieves the **msDS-PortLDAP** attribute for the communications port.

- From the parent object (Server Object), ADAM retrieves the **dNSHostName** attribute (instance1.machine1.domain.com). **dNSHostName** is the authoritative source for the server host name, and it can be either a DNS host name or a host IP address. If the server name changes, this object can be relied on to have the updated information.

- ADAM then constructs the referral based on the server and communications port information. ADAM returns multiple referrals for each request to ensure that the client can pursue the request, even if one or more hosts represented in the referrals cannot be reached. ADAM selects a random number of locations (three by default) and continues to use those defaults for five minutes, after which another three hosts are selected. Both the number of hosts and the number of minutes are configurable. If the number of specified hosts is greater than the actual number of instances holding the directory partition, all of the hosts are returned as referrals, and they will continue to be used indefinitely. This information is kept in the crossref cache, and it is refreshed anytime the crossref cache is rebuilt. The crossref cache is automatically rebuilt when **msds-nc-replica-locations** changes, that is, when an ADAM instance is added or removed.

- You can modify the values in the following table on the **msDS-Other-Settings** attribute of the directory service object — or on a crossRef object — to configure the referral behavior of an ADAM instance.

  **ADAM Referral Behavior Values**

| Value Name | Default | Meaning |
|---|---|---|
| **MaxReferrals** | 3 | Maximum number of referrals returned by ADAM |
| **ReferralRefreshInterval** | 5 minutes | Time interval at which referral information is updated |

| | | |
|---|---|---|
| **SelfReferralOnly** | 0 | Setting the value to 1 prevents ADAM from providing referral information. |

- Values that you set on a crossRef object take precedence over any values that you set on the directory service object.

**Generating Referrals Without crossRef Objects**
If a crossRef object does not exist for the search base, ADAM determines the DNS name if the distinguished name that is presented in the request uses DNS-style (DC=) syntax. Otherwise, ADAM uses the value of the **supref** attribute of the configuration directory crossRef object to generate a referral if **supref** contains a value. (This attribute is NULL by default, and it must be configured explicitly.) Otherwise, no referrals are generated.

**Service Publication**
In Active Directory environments, ADAM uses SCP objects to publish ADAM service information in the Active Directory directory store. Administering ADAM SCP objects includes the following operations:

- Manually creating SCPs when necessary
- Removing SCP objects when necessary
- Modifying permissions on SCP objects when necessary
- Managing SCPs efficiently
- Checking the ADAM event log for SCP errors

**Creating SCPs**
By default in Active Directory environments, the ADAM service creates SCPs in Active Directory when the ADAM service starts. To create SCPs successfully, the ADAM service account must have sufficient rights in Active Directory. If SCP creation fails, ADAM writes an event regarding the failure to the ADAM event log.

The default location for the ADAM SCP object is under the computer object that represents the computer on which ADAM is running. This default location can be altered by specifying a different location on the **SCPPublishingService** object.

When it is used as the ADAM service account on a computer that is joined to a domain, the Network Service account usually has sufficient rights to create SCPs in Active Directory. However, when it is used on an ADAM instance running on a domain controller, the Network Service account does not have sufficient rights to create SCPs in Active Directory.

**Removing SCPs**
An ADAM instance deletes its SCP from Active Directory when you remove the ADAM instance from the computer. Removing the SCP requires sufficient administrative credentials. If SCP removal fails, client applications may be directed to a nonexistent ADAM instance.

**Modifying SCPs**
An ADAM instance checks and updates, if necessary, its SCP each time that the ADAM instance starts. At startup, the ADAM instance searches the global catalog for its own GUID and retrieves the distinguished name of the SCP object. The ADAM instance then binds to that distinguished name and updates the SCP object as necessary. In addition, the ADAM instance reviews the SCP object on an hourly basis by default to confirm its validity, particularly regarding any directory partitions that have been added to or removed from the ADAM instance since the SCP object was last updated.

You can modify the default time interval at which ADAM reviews the SCP object by adding a **Server information update interval (mins)** value to the registry key **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\instancename\Parameters** and setting this value to the time interval (in minutes) that you want to use.

### Notes

- To prevent an ADAM instance from updating its SCP object, or to prevent an ADAM instance from recreating the SCP object after you have deleted the SCP object, set the registry key value **HKLM\System\CurrentControlSet\Services*instance name*\Parameters\Server information update interval (mins)** to **0**.
- To prevent the publication of SCPs for all ADAM instances in an ADAM configuration set, set the attribute **Enabled** on the object **CN=SCP Publication Service,CN=Directory**

**Service,CN=Windows NT,CN=Services,CN=Configuration,CN={*GUID*}** to **False**.

For more information about publishing and using SCPs, see the Microsoft Platform SDK on MSDN and search for "Service Publication."

**Managing ADAM SCPs**
One efficient way to manage SCPs for ADAM is to create an SCP container for your ADAM configuration set in Active Directory. In this container, place the computer objects of the computers on which ADAM instances are running. In addition, create a group called, for example, "ADAM instances," and then assign permissions on the SCP container to the group. Also, delegate control of the group to the assigned ADAM administrator. Then, each time the ADAM administrator installs a new ADAM instance under a new service account, the ADAM administrator can simply add the new service account to the ADAM instances group, and the ADAM instance creates and maintains its SCPs transparently.

**Checking the ADAM Event Log**
SCP-related errors do not prevent an ADAM instance from functioning properly. ADAM does, however, report SCP-related errors in the ADAM event log so that errors can be resolved. ADAM reports SCP-related errors as follows:

- When an SCP creation or update fails, the ADAM instance reports the error and points to an .ldf file that can be used to resolve the problem manually. Using this .ldf file to create or update the SCPs requires administrative credentials in Active Directory.

- When ADAM fails to remove an SCP object, ADAM reports this failure both in the audit log of the appropriate domain controller and in the ADAM event log.

**Auditing**
As with Active Directory, you can audit objects in ADAM for such activities as creation, modification, deletion, and reads. You can also audit ADAM objects at the attribute level. That is, you can specify specific attributes that you want to audit. However, in contrast to Active Directory, no user interface (UI) exists in ADAM for specifying which objects or attributes to audit. To enable auditing in ADAM, you must modify system access control lists (SACLs) for objects and attributes programmatically or by using Ldp.exe.

### Notes

- ADAM does not support auditing when it runs on Windows XP Professional.

- Before implementing auditing in ADAM, you should apply the hotfixes that are available for ADAM. For more information about ADAM hotfixes, contact Microsoft Product Support Services.

**ADAM and Microsoft Authorization Manager**
Microsoft Authorization Manager can use ADAM as a policy store for authorization policy. The ADAM installation process allows the installation of the Authorization Manager schema. The Authorization Manager schema must be installed and the container in which the store is to be created must exist before the Authorization Manager store is created. You can manage the policy store in ADAM either through the Authorization Manager scriptable COM interfaces or by using the Authorization Manager UI.

### Note

- Currently, you cannot use ADAM to store security principals for Authorization Manager.

**Backup and Restore**
By default, each instance of ADAM running on an ADAM server stores its database file, Adamntds.dit, and the associated log files in Program Files\Microsoft ADAM*Instancename*\Data. These files should be included as part of the regular backup plan of your organization. You can back up the directory stores using Ntbackup or any Windows Logo Program, non-Microsoft backup utility.

**Restoring ADAM**
When you restore a database to an existing ADAM instance, you must stop the ADAM instance before you run the restore operation. In addition, it is recommended that you move (or delete) the existing database and log files from the ADAM instance before beginning the restore operation.

**Authoritative Restore**

If objects in the directory are inadvertently deleted or modified, and if those objects are replicated in a configuration set, you must authoritatively restore those objects so that the correct version of the objects is replicated. To authoritatively restore directory data, run the **dsdbutil** utility after you have restored the data but before you restart the ADAM instance. With **dsdbutil**, you can mark directory objects for authoritative restore. When an object is marked for authoritative restore, its metadata version number is changed so that the number is higher than any other metadata version number in the configuration set. This ensures that any data you restore is properly replicated throughout the configuration set.

**Backup Latency Interval**

On computers running Windows Server 2003 with Service Pack 1 (SP1) and ADAM, a new NTDS Replication event provides a warning to administrators when an ADAM partition has not been backed up. Event ID 2089 provides the backup status of each directory partition that a domain controller stores, including application directory partitions. Specifically, event ID 2089 is logged in the Directory Service event log when partitions in the Active Directory forest are not backed up within a backup latency interval. The value for the backup latency interval is stored as a **REG_DWORD** value in the **Backup Latency Threshold (days)** entry in **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters**.

By default, the value of **Backup Latency Threshold (days)** is half the value of the tombstone lifetime of the forest. If halfway through the tombstone lifetime a directory partition has not been backed up, event ID 2089 is logged in the Directory Service event log and continues daily until the directory partition is backed up.

This event serves as a warning to administrators and monitoring applications to make sure that domain controllers are backed up before the tombstone lifetime expires. However, it is recommended that backups be taken at a much higher frequency than the default value of **Backup Latency Threshold (days)**.

**Network Ports Used by ADAM**

The following table lists the network ports that are used by ADAM.

### Default Port Assignments for ADAM

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | None | 389 |
| LDAP SSL | None | 636 |
| RPC Endpoint Mapper | 135 | 135 |

# Active Directory Application Mode Tools and Settings

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2012, Windows Server 2012 R2

### In this section

- ADAM Tools
- ADAM Registry Entries
- ADAM WMI Classes
- Network Ports Used by ADAM

This section contains information about the tools, registry entries, Windows Management Instrumentation (WMI) classes, and network ports that are associated with Active Directory Application Mode (ADAM).

**ADAM Tools**
The following tools are associated with ADAM.

### Note

Some ADAM tools are updated versions of tools that are provided with Active Directory. When you administer ADAM with the tools that are described in this section, you should always use the version of the tool that ships with ADAM. By default, these tools can be found in the *windir*\ADAM directory on the computer on which ADAM is installed.

For more information about the tools in this section, see the ADAM Administrator's Guide. To view the ADAM Administrator's Guide, after you install ADAM click **Start**, point to **All Programs**, point to **ADAM**, and then click **ADAM Help**.

**ADAM-adsiedit.msc: ADAM ADSI Edit**

**Category**
This tool ships with ADAM.

### Version compatibility

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers and servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition | Domain controllers and servers running ADAM:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition |
| Computers running:<br>• Windows XP Professional | Computers running ADAM:<br>Windows XP Professional |

ADAM ADSI Edit is a Microsoft Management Console (MMC) snap-in tool that you can use to view and modify directory objects.

**ADAMsetup: ADAM Setup**

**Category**
This tool ships with ADAM.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers and servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Computers running:<br>• Windows XP Professional | Runs locally. |

ADAM Setup performs an unattended installation of ADAM using a preconfigured setup script file.

**ADAMuninstall: ADAM Uninstall**

**Category**
This tool ships with ADAM.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| • Computers running ADAM | Runs locally. |

ADAM Uninstall uninstalls an ADAM instance.

**Csvde.exe: Csvde**

**Category**
This tool ships with ADAM.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers and servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers and servers running ADAM:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Computers running ADAM:<br>Windows XP Professional |

You can use Csvde to import and export data from Active Directory using files that store data in the comma-separated value (CSV) file format standard. Csvde also supports batch operations that are based on the CSV file format.

To find more information about Csvde, see "Command-Line References" in Tools and Settings Collection.

**Dsacls: Dsacls**

**Category**
This tool ships with ADAM.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers and servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers and servers running ADAM:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Computers running ADAM:<br>Windows XP Professional |

Dsacls displays and changes permissions (access control entries (ACEs)) in the access control list (ACL) of ADAM objects.

The ACEs that you add by using Dsacls must be object-specific permissions that override the default partition permissions that are defined in the ADAM schema. Do not add ACEs unless you are well informed about security for ADAM objects.

If you specify an object without additional parameters, Dsacls displays the ACEs in the ACL.

#### Dsdbutil: Dsdbutil

**Category**
This tool ships with ADAM.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| • Computers running ADAM | Runs locally. |

Dsdbutil provides management facilities for ADAM. This tool is intended for use by experienced administrators.

**Note**

- Some Dsdbutil commands can be used only against ADAM instances that are not currently running.

#### Dsdiag: Dsdiag

**Category**
This tool ships with ADAM.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers and servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers and servers running ADAM:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Computers running ADAM:<br>Windows XP Professional |

Dsdiag analyzes the state of the ADAM directory service and reports any problems to assist in troubleshooting. Dsdiag provides detailed information about how to identify abnormal behavior in the system.

Dsdiag consists of a framework for running tests and a series of tests to verify different functional areas of the system. This framework selects which directory services are tested, according to scope directives from the user.

**Dsmgmt: Dsmgmt**

**Category**
This tool ships with ADAM.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers and servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers and servers running ADAM:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Computers running ADAM:<br>Windows XP Professional |

Dsmgmt provides management facilities for ADAM, including partition management and Lightweight Directory Access Protocol (LDAP) policies.

**Ldifde.exe: Ldifde**

**Category**
This tool ships with ADAM.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers and servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers and servers running ADAM:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Computers running ADAM:<br>Windows XP Professional |

You can use Ldifde to create, modify, and delete directory objects. You can also use Ldifde to extend the schema, export ADAM user and group information to other applications or services, and populate ADAM with data from other directory services.

**Ldp.exe: Ldp**

**Category**
This tool ships with ADAM.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers and servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Computers running:<br>• Windows XP Professional | Computers running an LDAP directory service, such as ADAM |

Ldp is an LDAP graphical user interface (GUI) tool that you can use to perform operations such as connect, bind, search, modify, add, and delete against any LDAP-compatible directory, such as ADAM. You can also use Ldp to view objects, along with their metadata, that are stored in ADAM (for example, security descriptors and replication metadata).

You can use the online **dbdump** feature in Ldp to view values that are stored in the database while the domain controller is running. You can trigger **dbdump** by modifying the **dumpDatabase** attribute on the rootDSE.

**Repadmin: Repadmin**

**Category**
This tool ships with ADAM.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers and servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition | Domain controllers and servers running ADAM:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition |
| Computers running:<br>• Windows XP Professional | Computers running ADAM:<br>Windows XP Professional |

Repadmin performs tasks that are related to replication, including managing and modifying replication topology, forcing replication events, and displaying replication metadata and up-to-dateness vectors.

**ADAM Registry Entries**
The following registry entries are associated with ADAM.

The registry entries under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Diagnostics** control the logging level for the component or process that is specified in the entry name. The value for each entry is set to an integer from and including 0 (no logging) through 5 (most verbose logging).

The registry entries under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Parameters** control or contain information about the configuration of an ADAM instance.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_instancename\Diagnostics**
The following registry entries are located under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Diagnostics**.

**6 Garbage Collection**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Diagnostics

**Version**
Computers running ADAM.

Controls the logging of events that are generated when objects that are marked for deletion are actually deleted.

**7 Internal Configuration**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Diagnostics

**Version**
Computers running ADAM.

Controls the logging of internal operations.

**8 Directory Access**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Diagnostics

**Version**
Computers running ADAM.

Controls the logging of read and write operations to directory objects from all sources.

**9 Internal Processing**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Diagnostics

**Version**
Computers running ADAM.

Controls the logging of events that are related to internal directory service operations.

**11 Initialization/Termination**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Diagnostics

**Version**
Computers running ADAM.

Controls the logging of events that are generated by starting and stopping ADAM.

**12 Service Control**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Diagnostics

**Version**
Computers running ADAM.

Controls the logging of ADAM service events.

**13 Name Resolution**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Diagnostics

**Version**
Computers running ADAM.

Controls the logging of events that are generated by the resolution of addresses and ADAM names.

**14 Backup**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Diagnostics

**Version**
Computers running ADAM.

Controls the logging of events that are related to backing up ADAM. Specifically, controls the logging of events that occur when Extensible Storage Engine (ESE) database records are read or written during backup.

**16 LDAP Interface Events**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Diagnostics

**Version**
Computers running ADAM.

Controls the logging of events that are related to LDAP.

**22 DS RPC Client**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Diagnostics

**Version**
Computers running ADAM.

Controls the logging of events that are related to communication between ADAM instances. Examples of logged events include remote procedure call (RPC) errors, canceled calls, and service principal name (SPN)–related operations.

**23 DS RPC Server**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Diagnostics

**Version**
Computers running ADAM.

Controls the logging of events that are related to an ADAM instance acting as an RPC server. An ADAM instance acts as an RPC server, for example, during outbound replication and replication setup operations.

**24 DS Schema**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Diagnostics

**Version**
Computers running ADAM.

Controls the logging of events that are related to schema errors and operations. Such errors and operations include schema additions, deletions, modifications, look-up errors, look-up failures, and caching errors.

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_instancename\Parameters**
The following registry entries are located under
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters**.

**BinPath**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Parameters

**Version**
Computers running ADAM.

Contains the path to the program files for the ADAM instance.

**CommonBinPath**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Parameters

**Version**
Computers running ADAM.

Contains the path to the ADAM program files that are shared by all ADAM instances running on a given computer.

**Configuration NC**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Parameters

**Version**
Computers running ADAM.

Contains the distinguished name of the configuration directory partition.

**Database Backup Path**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Parameters

**Version**
Computers running ADAM.

Determines the directory that is used as the target directory when online backups of the directory database are performed.

**Database Log Files Path**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Parameters

**Version**
Computers running ADAM.

Determines the directory path that is used to store ADAM log files.

**Database Logging/Recovery**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Parameters

**Version**
Computers running ADAM.

Controls a Microsoft Jet database engine parameter called *JET_paramRecovery* that determines whether database operations are logged.

**DS Drive Mappings**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Parameters

**Version**
Computers running ADAM.

Tracks local drive mapping names so that the database file can be located if drive mappings are modified.

**DSA Database File**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Parameters

**Version**
Computers running ADAM.

Determines the file that is used by the ADAM instance for storing objects.

**DSA Working Directory**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Parameters

**Version**
Computers running ADAM.

Specifies the working directory of the ADAM instance.

**Long Instance Name**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Parameters

**Version**
Computers running ADAM.

Contains the instance name of the ADAM instance.

**Machine DN Name**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Parameters

**Version**
Computers running ADAM.

Contains the distinguished name of the computer on which ADAM is running.

**Port LDAP**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Parameters

**Version**
Computers running ADAM.

Contains the port number that is currently being used for LDAP.

**Port SSL**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Parameters

**Version**
Computers running ADAM.

Contains the port number that is currently being used for Secure Sockets Layer (SSL).

**Schema Version**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Parameters

**Version**
Computers running ADAM.

Contains the ADAM schema version for which a particular operating system is configured.

**Service Account SID**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Parameters

**Version**
Computers running ADAM.

Contains the security ID (SID) of the account that is being used as the service account for the ADAM instance.

**System Schema Version**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_*instancename*\Parameters

**Version**
Computers running ADAM.

Contains the version of the ADAM schema at the time that a backup is taken. This value is used to prevent an incompatible schema version from being restored from backup.

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\ADAM_instancename\Diagnostics**
The following registry entry is located under
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters**.

**Backup Latency Threshold (Days)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2003 with Service Pack 1 (SP1)

**Default value**
Half the value of the tombstone lifetime of the forest.

When the value is reached, logs event ID 2089 in the Directory Service event log, warning administrators and monitoring applications to make sure that domain controllers are backed up before the tombstone lifetime expires.

**ADAM WMI Classes**

The following table lists and describes the WMI classes that are associated with ADAM.

**WMI Classes Associated with ADAM**

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| **rootDSE** | root\directory\LDAP | Domain controllers and servers running ADAM:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Computers running ADAM:<br>Windows XP Professional |
| **DS_LDAP_Class_Containment** | root\directory\LDAP | Domain controllers and servers running ADAM:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Computers running ADAM:<br>Windows XP Professional |
| **DS_LDAP_Instance_Containment** | root\directory\LDAP | Domain controllers and servers running ADAM:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Computers running ADAM:<br>Windows XP Professional |

For more information about these WMI classes, search for “Mapping Active Directory to WMI” in the WMI SDK documentation on MSDN.

**Network Ports Used by ADAM**

The network ports that are used by the data store are listed in the following table.

**Port Assignments for the Data Store**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | None | 389 |
| LDAP SSL | None | 636 |
| RPC Endpoint Mapper | 135 | 135 |

# Active Directory Structure and Storage Technologies

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

Administrators use Active Directory to store and organize objects on a network (such as users, computers, devices, and so on) into a secure hierarchical containment structure that is known as the logical structure. Although the logical structure of Active Directory is a hierarchical organization of all users, computers, and other physical resources, the forest and domain form the basis of the logical structure. Forests, which are the security boundaries of the logical structure, can be structured to provide data and service autonomy and isolation in an organization in ways that can both reflect site and group identities and remove dependencies on the physical topology.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to Active Directory Domain Services. |

Domains can be structured in a forest to provide data and service autonomy (but not isolation) and to optimize replication with a given region. This separation of logical and physical structures improves manageability and reduces administrative costs because the logical structure is not affected by changes in the physical structure. The logical structure also makes it possible to control access to data. This means that you can use the logical structure to compartmentalize data so that you can control access to it by controlling access to the various compartments.

The data that is stored in Active Directory can come from many diverse sources. With so many different data sources and so many different types of data, Active Directory must employ some type of standardized storage mechanism so that it can maintain the integrity of the data that it stores. In Active Directory, objects are used to store information in the directory, and all objects are defined in the schema. The object definitions contain information, such as data type and syntax, that the directory uses to ensure that the stored data is valid. No data can be stored in the directory unless the objects that are used to store the data are first defined in the schema. The default schema contains all the object definitions that Active Directory needs to function; however, you can also add object definitions to the schema.

While the directory is exposed to you through a logical structure that consists of elements such as domains and forests, the directory itself is implemented through a physical structure that consists of a database that is stored on all domain controllers in a forest. The Active Directory data store handles all access to the database. The data store consists of both services and physical files. These services and physical files make the directory available, and they manage the processes of reading and writing the data inside the database that exists on the hard disk of each domain controller.

**Active Directory Structure and Storage Architecture**

The Active Directory structure and storage architecture consists of four parts:

- Active Directory domains and forests. Forests, domains, and organizational units (OUs) make up the core elements of the Active Directory logical structure. A forest defines a single directory and represents a security boundary. Forests contain domains.

- Domain Name System (DNS) support for Active Directory. DNS provides a name resolution service for domain controller location and a hierarchical design that Active Directory can use to provide a naming convention that can reflect organizational structure.

- Schema. The schema provides object definitions that are used to create the objects that are stored in the directory.

- Data store. The data store is the portion of the directory that manages the storage and retrieval of data on each domain controller.

  The following figure illustrates the Active Directory data structure and storage architecture.

**Active Directory Data Structure and Storage Architecture**

**Active Directory Domains and Forests**

Domains partition the directory into smaller sections within a single forest. This partitioning results in more control over how data is replicated so that an efficient replication topology can be established and network bandwidth is not wasted by replicating data where it is not required. OUs make it possible to group resources in a domain for management purposes, such as applying Group Policy or delegating control to administrators.

The following figure illustrates the relationships of OUs, domains, and forests in the logical structure architecture.

**Logical Structure Architecture**

**DNS Support for Active Directory**

Active Directory uses DNS as its domain controller location mechanism. When any of the principal Active Directory operations, such as authentication, updating, or searching, is performed, domain joined computers use DNS to locate Active Directory domain controllers, and these domain controllers use DNS to locate each other. For example, when a network user with an Active Directory user account logs on to an Active Directory domain, the user's computer uses DNS to locate a domain controller for the Active Directory domain to which the user wants to log on.

To log on to a network that consists of an Active Directory forest, a client workstation must first be able to locate a nearby domain controller. The domain controller is necessary for initial authentication of both the workstation and the user and for subsequent authorization of the user for the files and resources to which the user needs access. The support that is provided to Active Directory by DNS enables a client workstation to locate a domain controller.

**Active Directory Schema**

The Active Directory schema contains definitions for all the objects that are used to store information in the directory. There is one schema per forest. However, a copy of the schema exists on every domain controller in the forest. This way, every domain controller has quick access to any object definition that it might need, and every domain controller uses the same definition when it creates a given object. The data store relies on the schema to provide object definitions, and the data store uses those definitions to enforce data integrity. The result is that all objects are created uniformly, and it does not matter which domain controller creates or modifies an object because all domain controllers use the same object definition.

The following figure illustrates the relationship of the schema to the data store in the schema architecture.

**Schema Architecture**

**Active Directory Data Store**

The Active Directory data store is made up of several components that together provide directory services to directory clients. These components include the following:

- Four interfaces:
    - Lightweight Directory Access Protocol (LDAP)
    - Replication (REPL) and domain controller management interface
    - Messaging API (MAPI)
    - Security Accounts Manager (SAM)
- Three service components:
    - Directory System Agent (DSA)
    - The database layer
    - Extensible Storage Engine (ESE)
- The directory database where the data is actually stored

The following figure illustrates the relationships of these components in the data store architecture.

**Data Store Architecture**

**Active Directory Structure and Storage Components**

You can define some components for structure and storage in Active Directory, while others are defined by the system and cannot be modified.

- Forests, domains, and OUs are components that constitute the logical structure of Active Directory. You define them during the installation of Active Directory.
- DNS support for Active Directory includes components that are used to locate domain controllers and that use DNS naming schemes. Each domain in a forest must adhere to DNS naming schemes, and domains are organized in a root and subordinate domain hierarchy.
- The schema is a single component that exists inside the directory. The schema contains definitions of the objects that are

used to store information in the directory. These object definitions include two primary components: classSchema objects and attributeSchema objects.

- The data store consists of three layers of components. The first layer provides the interfaces that clients need to access the directory. The second layer provides the services that perform the operations that are associated with reading data from and writing data to the directory database. The third layer is the database itself, which exists as a single file on the hard disk of each domain controller.

**Active Directory Domains and Forests**

The logical structure of Active Directory is a hierarchical structure of Active Directory domains and OUs in a forest. The relationships of the components in the logical structure control access to stored data, and they control how information is replicated between the various domain controllers in the forest. The main components of the Active Directory logical structure are described in the following table.

**Domain and Forest Components**

| Component | Description |
|---|---|
| Forest | A forest is the highest level of the logical structure hierarchy. An Active Directory forest represents a single self-contained directory. A forest is a security boundary, which means that administrators in a forest have complete control over all access to information that is stored inside the forest and to the domain controllers that are used to implement the forest. |
| Domain | Domains partition the information that is stored inside the directory into smaller portions so that the information can be more easily stored on various domain controllers and so that administrators have a greater degree of control over replication. Data that is stored in the directory is replicated throughout the forest from one domain controller to another. Some data that is relevant to the entire forest is replicated to all domain controllers. Other data that is relevant only to a specific domain is replicated only to domain controllers in that particular domain. A good domain design makes it possible to implement an efficient replication topology. This is important because it enables administrators to manage the flow of data across the network, that is, to control how much data is replicated and where that replication traffic takes place. |
| OU | OUs provide a means for administrators to group resources, such as user accounts or computer accounts, so that the resources can be managed as one unit. This makes it much easier to apply Group Policy to multiple computers or to control the access of many users to a single resource. OUs also make it easier to delegate control over resources to various administrators. |

**DNS Support for Active Directory**

In Active Directory, DNS is the means by which directory clients locate, or discover, domain controllers. The primary components of the architecture for DNS support of Active Directory include the domain controller Locator, Active Directory domain names in DNS, and Active Directory DNS objects.

The following table describes the Active Directory components that help directory clients locate nearby domain controllers.

**Active Directory DNS Support Components**

| Active Directory/DNS Component | Description |
|---|---|
| Locator | Locator, which is implemented in the Net Logon service, enables a client to locate a domain controller. Locator contains Internet Protocol (IP)/DNS–compatible and Windows NT 4.0–compatible locators, which provide interoperability in a mixed Active Directory environment. |
| Active Directory domain names in DNS | Every Active Directory domain has a DNS domain name (for example, cohovineyard.com), and every domain joined computer has a DNS name (for example, server1.cohovineyard.com). Architecturally, domains and computers are represented both as objects in Active Directory and as nodes in DNS. |
| Active Directory DNS objects | When DNS data is stored in Active Directory, each DNS zone is an Active Directory container object (class **dnsZone**). The dnsZone object contains a DNS node object (class **dnsNode**) for every unique name in that zone. The dnsNode object has a **dnsRecord** multivalued attribute that contains a value for every resource record that is associated with that DNS name. |

For more information about DNS support for Active Directory, see "DNS Support for Active Directory Technical Reference."

**Active Directory Schema**

Everything that is stored in Active Directory is stored in an object. A definition for every type of object is stored in the schema. The definitions themselves consist of two types of objects: class objects and attribute objects. Classes define groups of attributes that are used to describe common objects. New object definitions are created by combining various class objects and attribute objects to make new combinations that contain the necessary attributes to meet the storage requirements of the new object type. The two main types of object definitions that are stored in the Active Directory schema are described in the following table.

**Schema Components**

| Component | Description |
|---|---|
| classSchema objects | classSchema objects are object definitions that are stored in the schema, and they are used to define classes. classSchema objects define groups of attributes that have something in common. For example, an object that is used to store a user account needs to store the user's logon name, first name, last name, and password. It is possible to create a **user** class that has a logon name attribute, a first name attribute, a last name attribute, and a password attribute. Anytime a new user account is created, the directory uses the **user** class as the definition, and every user account object that is created uses those attributes. classSchema objects can be nested to create more complex objects. |
| attributeSchema objects | attributeSchema objects define the individual attributes of a single object. For example, a user account object has a number of attributes that are used to store and define various pieces of data that are related to a user account, such as a logon name attribute and a password attribute. Each of these attributes also has its own attributes that specify the type of data that it stores, the syntax of the data that it stores, and whether or not the attribute is required or optional. The directory service uses attributeSchema objects to store data and verify that the stored data is valid. |

**Active Directory Data Store**

The Active Directory data store is implemented on every domain controller in the forest. The data store consists of components that store and retrieve data inside the directory. The components of the Active Directory data store are described in the following table.

**Data Store Components**

| Component | Description |
|---|---|
| Interfaces (LDAP, REPL, MAPI, SAM) | The data store interfaces provide a way for directory clients and other directory servers to communicate with the data store. |
| DSA (Ntdsa.dll) | The DSA (which runs as Ntdsa.dll on each domain controller) provides the interfaces through which directory clients and other directory servers gain access to the directory database. In addition, the DSA enforces directory semantics, maintains the schema, guarantees object identity, and enforces data types on attributes. |
| Database layer | The database layer is an application programming interface (API) that resides in Ntdsa.dll and provides an interface between applications and the directory database to protect the database from direct interaction with applications. Calls from applications are never made directly to the database; they go through the database layer. In addition, because the directory database is flat — with no hierarchical namespace — the database layer provides the database with an abstraction of an object hierarchy. |
| ESE (Esent.dll) | The ESE (which runs as Esent.dll) communicates directly with individual records in the directory database on the basis of an object's relative distinguished name attribute. |
| Database files | The data store stores directory information in a single database file. In addition, the data store also uses log files, to which it temporarily writes uncommitted transactions. |

# Domains and Forests Technical Reference

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

Domains and forests are logical representations of the directory hierarchy in the Active Directory directory service. Active Directory domains and forests allow administrators to organize elements of a network (such as users, computers, devices, resources, and application-specific data from Active Directory–enabled applications) into a non-physical hierarchical structure, known as the logical structure. You can use domains and forests to provide an information repository and services to make information available to users and applications.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to AD DS, but the information is also applicable to Active Directory. |

# What Are Domains and Forests?

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**What Are Domains and Forests?**

**In this section**

- The Logical Structure of Active Directory
- The Physical Structure of Active Directory
- What Are Domains?
- What Are Forests?
- Related Information

The Active Directory directory service is a distributed database that stores and manages information about network resources, as well as application-specific data from directory-enabled applications. Active Directory allows administrators to organize objects of a network (such as users, computers, and devices) into a hierarchical collection of containers known as the logical structure. The top-level logical container in this hierarchy is the forest. Within a forest are domain containers, and within domains are organizational units.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to Active Directory Domain Services. |

Understanding domains and forests requires understanding the possible relationships they might have in Active Directory. The relationships between these logical containers might be based on administrative requirements, such as delegation of authority, or they might be defined by operational requirements, such as the need to provide for data isolation. Service administrators can use domain and forest containers to meet a number of specific requirements, including:

- Implementing an authentication and authorization strategy for sharing resources across a network
- Providing a mechanism for centralizing management of multiple domains and forests
- Providing an information repository and services to make information available to users and applications
- Organizing objects of a network (such as users, computers, devices, resources, and application specific data from directory-enabled applications) into a non-physical hierarchical structure

To learn more about domains and forests, you must first understand the logical and physical structures of Active Directory. This section describes how those structures differ, and defines domains and forests in terms of the logical structure.

**The Logical Structure of Active Directory**

Active Directory stores network object information and implements the services that make this information available and usable to users. Active Directory presents this information through a standardized, logical structure that helps you establish and understand the organization of domains and domain resources in a useful way. This presentation of object information is referred to as the logical structure because it is independent of the physical aspects of the Active Directory infrastructure, such as the domain controllers required for each domain in the network.

**Benefits of the Logical Structure**

The logical structure provides a number of benefits for deploying, managing, and securing network services and resources. These benefits include:

- Increased network security. The logical structure can provide security measures such as autonomy for individual groups or complete isolation of specific resources.

- Simplified network management. The hierarchical nature of the logical structure simplifies configuration, control, and administration of the network, including managing user and group accounts and all network resources.

- Simplified resource sharing. The logical structure of domains and forests and the relationships established between them can simplify the sharing of resources across an organization.

- Low total cost of ownership. The reduced administration costs for network management and the reduced load on network resources that can be achieved with the Active Directory logical structure can significantly lower the total cost of ownership.

An efficient Active Directory logical structure also facilitates the system integration of features such as Group Policy, enabling desktop lockdown, software distribution, and administration of users, groups, workstations, and servers. In addition, the logical structure can facilitate the integration of services such as Exchange 2000, public key infrastructure (PKI), and domain-based distributed file system (DFS).

**Components of the Logical Structure**

The logical structure consists of leaf object and container object components that must conform to the hierarchical structure of an Active Directory forest. Leaf objects are objects that have no child objects, and are the most basic component of the logical structure. Container objects store other objects and occupy a specific level within the forest hierarchy.

The relationships among the components of the logical structure control access to stored data and determine how that data is managed across one or more domains within a single forest. The components that make up the Active Directory logical structure are described in the following table.

**Components of the Active Directory Logical Structure**

| Component | Description |
|---|---|
| Organizational Units | Organizational units are container objects. You use these container objects to arrange other objects in a manner that supports your administrative purposes. By arranging objects in organizational units, you make it easier to locate and manage them. You can also delegate the authority to manage an organizational unit. Organizational units can be nested in other organizational units.<br><br>You can arrange objects that have similar administrative and security requirements into organizational units. Organizational units provide multiple levels of administrative authority, so that you can apply Group Policy settings and delegate administrative control. This delegation simplifies the task of managing these objects and enables you to structure Active Directory to fit your organization's requirements. |
| Domains | Domains are container objects. Domains are a collection of administratively defined objects that share a common directory database, security policies, and trust relationships with other domains. In this way, each domain is an administrative boundary for objects. A single domain can span multiple physical locations or sites and can contain millions of objects. |
| Domain Trees | Domain trees are collections of domains that are grouped together in hierarchical structures. When you add a domain to a tree, it becomes a child of the tree root domain. The domain to which a child domain is attached is called the parent domain.<br><br>A child domain might in turn have its own child domain. The name of a child domain is combined with the name of its parent domain to form its own unique Domain Name System (DNS) name such as Corp.nwtraders.msft. In this manner, a tree has a contiguous namespace. |
| Forests | A forest is a complete instance of Active Directory. Each forest acts as a top-level container in that it houses all domain containers for that particular Active Directory instance. A forest can contain one or more domain container objects, all of which share a common logical structure, global catalog, directory schema, and directory configuration, as well as automatic two-way transitive trust relationships. The first domain in the forest is called the forest root domain. The name of that domain refers to the forest, such as Nwtraders.msft. By default, information in Active Directory is shared only within the forest. In this way, the forest is a security boundary for the information that is contained in that instance of Active Directory. |

| | |
|---|---|
| Site Objects | Sites are leaf and container objects. The sites container is the topmost object in the hierarchy of objects that are used to manage and implement Active Directory replication. The sites container stores the hierarchy of objects that are used by the Knowledge Consistency Checker (KCC) to effect the replication topology. Some of the objects located in the sites container include NTDS Site Settings objects, subnet objects, connection objects, server objects, and site objects (one site object for each site in the forest). The hierarchy is displayed as the contents of the Sites container, which is a child of the Configuration container. |

By understanding the purpose and hierarchical structure of these components, you can complete a variety of tasks, including installing, configuring, managing, and troubleshooting Active Directory. Although the logical structure of Active Directory is a hierarchical organization of all users, computers, and other physical resources, the forest and domain form the basis of the logical structure.

Forests, which are the security boundaries of the logical structure, can be structured to provide data and service autonomy and isolation in an organization in ways that can both reflect site and group identities and remove dependencies on the physical topology. Domains can be structured within a forest to provide data and service autonomy (but not isolation) and to optimize replication with a given region.

This separation of logical and physical structures improves manageability and reduces administrative costs because the logical structure is not impacted by changes in the physical structure, such as the addition, removal, or reorganization of users and groups.

**Note**

- You can view and manage components of the logical structure by using the Active Directory Users and Computers, Active Directory Domains and Trusts, and Active Directory Schema Microsoft Management Console (MMC) snap-ins, and other tools.

**The Physical Structure of Active Directory**

The physical structure of Active Directory is represented by a set of physical components which, when configured correctly, can help optimize the transmission of network replication and authentication in ways specifically tailored to fit your physical network. Physical network components, such as domain controllers and physical subnets, are used to facilitate network communication and to set physical boundaries around network resources. More specifically, the physical structure of Active Directory represents all of the physical subnets in your enterprise network, the domain controllers in those physical subnets (commonly referred to as Sites in Active Directory) and the replication connections between the domain controllers.

Sites and subnets are represented in Active Directory by site and subnet objects. Computers on TCP/IP networks are assigned to site objects based on their location in a physical subnet or a set of physical subnets. Physical subnets group computers in a way that identifies their physical proximity on the network. Each site object is associated with one or more subnet objects. Subnet objects are used during the process of domain controller location to find a domain controller in the same site as the computer that is logging on. This information also is used during Active Directory replication to determine the best routes between domain controllers. This enables you to use network bandwidth more efficiently. For example, it ensures that when users log on to the network they are authenticated by the authentication authority nearest to the user, thus reducing the amount of network traffic.

The physical domain controller contains the directory partitions that are replicated. Although the logical and physical structures are defined and configured independently, they have interdependencies that affect replication.

**Note**

- You can view the physical structure of Active Directory by using Active Directory Sites and Services.

For more information about the network components associated with the physical structure of Active Directory, see the "Active Directory Replication Topology Technical Reference."

**What Are Domains?**

Domains are logical directory components that you create to manage the administrative requirements of your organization. The logical structure is based on the administrative requirements of an organization, such as the delegation of administrative authority, and operational requirements, such as the need to control replication. In general, domains are used to control where in the forest replication of domain data occurs and organizational units are used to further organize network objects into a logical hierarchy and delegate control to appropriate administrative support personnel.

A domain is a partition in an Active Directory forest. Partitioning data enables organizations to replicate data only to where it is

needed. In this way, the directory can scale globally over a network that has limited available bandwidth. Domains can also be defined as:

- Containers within a forest
- Units of Policy
- Units of Replication
- Authentication and Authorization Boundaries
- Units of Trust

Each domain has a domain administrators group. Domain administrators have full control over every object in the domain. These administrative rights are valid within the domain only and do not propagate to other domains.

**Domains as Containers Within a Forest**
Within the scope of a forest, a domain is a container. Objects in that container inherently trust each other and the security services located in that same container. Each time you create a new domain container in a forest, a two-way, transitive trust relationship is automatically created between the new domain and its parent domain. Trusts are logical relationships established between domains to allow pass-through authentication in which a trusting domain honors the logon authentications of a trusted domain. Because all domain containers within a forest are joined together by two-way transitive trusts, objects within one domain container also inherently trust all other objects and security services located in every domain container located in that forest.

Domain containers are used to store and manage Active Directory objects, some of which have a physical representation. All of the objects within the domain container are stored in a central database that stores only objects created within that domain. Some objects represent people or groups of people, while others represent computers or network servers. Examples of Active Directory objects that have a physical representation are user, computer, and group objects.

While domains contain objects that represent physical things, they also contain objects that are used to help self-regulate domain operations such as trusted domain objects (TDOs) and site link objects. Domain containers can also hold subordinate containers such as organizational units. The following figure shows where objects are stored within the logical structure of a domain.

**Domain Containment Structure Within a Forest**

**Organizational Units and Objects**
Organizational units are used to group objects, including accounts and resources in a domain, for administrative purposes, such as the application of Group Policy or delegation of authority. Control over an organizational unit, including the objects within it, is determined by the access control lists (ACLs) on the organizational unit and on the objects in the organizational unit.

**Organizational Units**
The organizational unit is a particularly useful type of directory object contained within domains. Each organizational unit is an Active Directory container within a domain into which users, groups, computers, and other organizational units of the domain can be placed. An organizational unit cannot contain objects from other domains.

An organizational unit is the smallest scope or unit to which Group Policy settings can be assigned or to which administrative authority can be delegated. A hierarchy of organizational units can be extended as necessary to model the hierarchy of an

organization within a domain. The administrative model of the organizational unit can be scaled to any size. For more information about Group Policy, see "How Core Group Policy Works."

Administrative authority can be delegated for individual organizational units or for multiple organizational units. Organizational units can be nested to create a hierarchy within a domain and form logical administrative units for users, groups, and resource objects, such as printers, computers, applications, and file shares. The organizational unit hierarchy within a domain is independent of the structure of other domains: Each domain can implement its own hierarchy. Likewise, domains that are managed by the central authority can implement similar organizational unit hierarchies. The structure is flexible, which allows organizations to create an environment that mirrors the administrative model, whether it is centralized or decentralized.

**Objects**

Active Directory objects represent the physical entities that make up a network. An object stores an instance of a class. A class is defined in the Active Directory schema as a specific set of mandatory and optional attributes — that is, an attribute can be present in an object in Active Directory only when that attribute is permitted by the object's class. Classes also contain rules that determine which classes of objects can be superior to (parents of) a particular object of the class. Each attribute is also defined in the directory schema. The attribute definitions determine the syntax for the values the attribute can have.

Creation of an Active Directory object requires specification of values for the attributes of the object in its particular class, consistent with the rules of the directory schema. For example, creating a user object requires specification of alphanumeric values for the user's first and last names and the logon identifier, which are mandatory according to the directory schema. Other non-mandatory values can also be specified, such as telephone number and address.

Applications that create or modify objects in Active Directory use the directory schema to determine what attributes the object must and might have, and what those attributes can look like in terms of data structures and syntax constraints. The directory schema is maintained forest-wide so that all objects created in the directory conform to the same values.

Objects are either container objects or leaf objects. A container object stores other objects, and as such occupies a specific level in a subtree hierarchy. An object class is a container if at least one other class specifies it as a possible superior, so any object class defined in the schema can become a container. A leaf object does not store other objects, so it occupies the endpoint of a subtree. For more information about Active Directory Objects, see "How Domains and Forests Work" and "How the Active Directory Schema Works."

**Domains as Units of Policy**

A domain defines a scope or unit of policy within a forest. Some policy settings apply only to the scope of a domain, that is, the policy settings are domain-wide. Account policies, for example, apply uniformly to all user accounts in the domain. Although a domain is not the smallest unit of policy that can be assigned (policies can be assigned to organizational units) it is the most commonly used unit when splitting administrative duties between departments and subsidiaries located in different geographical locations. As shown in the following figure, you might need to create multiple domains to provide for policy variance among domains throughout a forest. A domain is also considered a unit of access control, in that it can be used for business groups requiring general autonomy.

**Delegation of Domains to Domain Admins that Require Different Policies or Autonomy**

You cannot define different account policies for different organizational units in the same domain. Policy settings are stored as Group Policy objects (GPOs) in Active Directory. A GPO establishes how domain resources can be accessed, configured, and used. The policies associated with a GPO are applied only within the domain and not across domains. A GPO can be associated with one or more Active Directory containers, such as a site, domain, or organizational unit.

Account policies and Public Key policies have domain-wide scope and are set at the domain GPO level. All other policies can be specified at the level of the organizational unit. Some policies that can be applied only at the domain container level include:

- Password policy. Determines the rules, such as password length, that must be met when a user sets a password.
- Account lockout policy. Defines rules for intruder detection and account deactivation.
- Kerberosticket policy. Determines the lifetime of a Kerberos ticket. A Kerberos ticket is obtained during the logon process and is used for network authentication. A particular ticket is only valid for the lifetime specified in the policy.

Because organizational units provide multiple levels of administrative authority, you can use them to systematically apply Group Policy settings and delegate administrative control. Delegation simplifies the task of managing these objects and enables you to structure Active Directory to fit the requirements of your organization. Using delegated authority in conjunction with GPOs and group memberships allows one or more administrators to be assigned rights and permissions to manage objects in an entire domain or in one or more organizational units within the domain.

For more information about Group Policy, see "How Core Group Policy Works."

**Domains as Units of Replication**

The physical significance of a domain is that it is a unit of replication. In fact, with the exception of application partitions, which replicate only non-security principal objects, the domain is the smallest unit of replication that can be administered within an Active Directory forest. This is because all objects that are located within a domain container, also referred to as domain data, are replicated to other domain controllers within that same domain, regardless of whether those domain controllers are located over a local area network (LAN) or wide area network (WAN) connection.

As shown in the following figure, Active Directory multi-master replication manages the transfer of domain objects to the appropriate domain controllers automatically, keeping domain data up-to-date among all domain controllers in the domain, regardless of location.

**Replication of Domain Data Within Each Domain in the Forest**

All domain controllers in the forest are also updated with changes to forest-wide data. For more information about replication at the Forest level, see "Forests as Units of Replication" later in this section Domain-wide replication relies on three components of the Active Directory physical structure to be in place for optimal performance, these include:

**Domain Controllers**

The physical domain controller contains the domain partition data that is replicated to other domain controllers in that same domain. A domain partition stores only the information about objects located in that domain. All domain controllers in a domain receive changes and replicate those changes to the domain partition stored on all other domain controllers in the domain. In this way, all domain controllers are peers in the domain and manage replication as a unit.

Domain controllers also have two non-domain directory partitions that store forest-wide data, which includes the directory schema and configuration data. Optionally, domain controllers, application partitions can be configured to be located on designated domain controllers anywhere in a forest. Unlike the schema and configuration partitions, application partitions are not located on every domain controller in a forest. For more information about the replication of forest-wide data, see "Forests as Units of Replication" later in this section.

Partitioning Active Directory data into three physical partitions on each domain controller helps to control replication so that data is replicated only to where it is needed. In this way, Active Directory can scale globally over a network that has limited available bandwidth.

**Sites**

Within the scope of a forest, sites are a representation of the physical network topology. This includes physical subnet and site definitions. Replication of updates to domain data occurs between multiple domain controllers to keep replicas synchronized. Multiple domains are common in large organizations, as are multiple sites in disparate locations. In addition, domain controllers for the same domain are commonly placed in more than one site.

Therefore, replication must often occur both within sites and between sites to keep domain and forest data consistent among domain controllers that store the same directory partitions. Replication within sites generally occurs at typical LAN speeds between domain controllers that are on the same network segment. Replication between sites usually occurs over WAN links that might be costly in terms of bandwidth. To accommodate the differences in distance and cost of replication within a site and between sites, the intrasite replication topology is used to optimize speed, and the intersite replication topology is used to minimize cost based on a configurable replication schedule.

The Knowledge Consistency Checker (KCC) is a distributed application that runs on every domain controller and is responsible for creating the connections between domain controllers that collectively form the replication topology. The KCC uses Active Directory data to determine where to create connections between source domain controllers and destination domain controllers.

Intersite replication is optimized for bandwidth efficiency, and directory updates between sites occur automatically based on a configurable schedule.

**Domain-Wide Operations Masters**

Active Directory supports multi-master replication of the directory data store between all domain controllers in the domain. However, some changes are impractical to perform in multi-master fashion, so only a single domain controller, called the operations master, accepts requests for such changes. Because these roles can be transferred to other domain controllers within the domain or forest, they are sometimes referred to as operations master roles.

There are three operations master roles per domain. These include the Relative Identifier (RID) Master, Primary Domain Controller (PDC) emulator, and Infrastructure Master. These three roles must be unique in each domain, so each domain can have only one RID master, one PDC emulator, and one Infrastructure Master. For information about forest-wide roles, see "Forest-Wide Operations Master Roles" later in this section. For more information about replication, see "How Active Directory Replication Topology Works."

**Domains as Authentication and Authorization Boundaries**

By default, a domain provides authentication and authorization services for all its accounts in order to facilitate logons and single sign-on access control to shared resources within the boundaries of the domain. The process of authentication ensures that users are who they claim to be. Once identified, the user can be authorized access to a specific set of network resources based on permissions.Authorization takes place through the mechanism of access control, using access control lists (ACLs) that define permissions on file systems, network file and print shares, and entries in Active Directory.

Authorization is determined not only by the identity of the user but also the membership of the user in one or more security groups. In fact, the preferred method of controlling domain-wide resources is to grant access to groups rather than to individuals, adjusting the level of authorization for a group according to the needs of its members. This method of controlling access makes it easier to keep ACLs up-to-date on domains that have thousands of users and objects. Group membership can be managed centrally by anyone with the appropriate administrative credentials. You can change the level of authorization a particular user has to many resources simply by adding or removing the user from a group. The following figure shows when authentication and authorization for a user in a given domain occur.

**Authentication and Authorization of a User Within the Same Domain**

Authentication is not limited to users. Computers and services are also authenticated when they make network connections to other servers. For example, domain joined computers connect Active Directory in their domain for policy information during startup. Computers and services also prove their identity to clients that request mutual authentication. Mutual authentication prevents an intruder from adding another computer as an imposter between the client and the real network server. The Kerberos version 5 authentication protocol is a technology for single sign-on to network resources. Kerberos V5 protocol is used to provide single sign-on to network services within a domain, and to services residing in trusted domains. The Kerberos V5 protocol verifies both the identity of the user and of the network services, providing mutual authentication.

Authentication and authorization services in one domain can be extended to accounts that are located in trusted domains. This can be done by using trusts. Trusts are logical relationships established between domains to allow pass-through authentication in which a trusting domain honors the logon authentications of a trusted domain. Consequently, trust relationships inherently

allow domain-specific authentication and authorization services to be extended, thereby enabling single sign-on access control capabilities throughout a forest. Because the domain trust relationships between all domains in the forest are bidirectional by default, authentication in one domain is sufficient for referral or pass-through authentication to resources in other domains in the forest.

**Domains as Units of Trust**

A domain is the smallest container within Active Directory that can be used in a trust relationship. All domains within a forest are connected by Kerberos-based trusts. Kerberos-based trusts are two-way and transitive in nature. Trusts act as authentication pipelines that must be present in order for users in one domain to access resources in another domain. All authentication requests made between domains located inside or outside of a forest must occur over trusts. Trust relationships within a forest are created as implicit two-way transitive trusts.

### Note

- "Access to resources" in any discussion of trust relationships always assumes the limitations of access control.

Within a forest, trust relationships are automatically created between the forest root domain and any tree root domains on the one hand, and all child domains that are subordinate to the forest root domain on the other. Because trust relationships are two-way and transitive by default, users and computers can be authenticated between any domain containers in the forest, as shown in the following figure.

**Domains as Units of Trust and the Authentication Paths they Provide**

In accordance with DNS naming standards, Active Directory domains within a single forest are created in an inverted tree structure, with the forest root domain at the top. This tree structure requires that trusts exist between domains to facilitate security of communications. Adding a domain tree to a forest requires specification of the forest root domain, which results in the establishment of a trust relationship between the root domain of the new tree and the forest root domain. For more information about trusts and root domains, see "Forests as Collections of Domain Containers that Trust Each Other" later in this section.

**What Domains Are Not**

Domains are not security boundaries within the scope of Active Directory and do not provide complete isolation in the face of possible attacks by malicious service administrators who might manage that forest. This is because a malicious service administrator, such as a member of the Domain Admins group, can use nonstandard tools and procedures to gain full access to any domain in the forest or to any computer in the forest. For example, service administrators in a non-root domain can make themselves members of the Enterprise Admins or Schema Admins group.

However, administrative rights do not flow across domain boundaries, nor do they flow down through a domain tree. For

example, if you have a domain tree with domains A, B, and C, where A is the parent domain of B and B is the parent domain of C, users with administrative rights in domain A do not have administrative rights in B, nor do users with administrative rights in domain B have administrative rights in domain C. For a user to obtain administrative rights in a given domain, a higher authority must grant them. This does not mean, however, that an administrator cannot have administrative rights in multiple domains; it simply means that all rights must be explicitly defined.

For more information about isolation, see "Forests as Security Boundaries" later in this section.

**What Are Forests?**
At its highest level, a forest is a single instance of Active Directory. Therefore, a forest is synonymous with Active Directory, meaning that the set of all directory partitions in a particular Active Directory instance (which includes all domain, configuration, schema and optional application information) makes up a forest. This means that when you have multiple forests in an enterprise they will, by default, act separately from each other as if they were the only directory service in your organization.

This behavior, however, is easily be modified so that multiple forests can share Active Directory responsibilities across an enterprise. This is done by creating external or forest trust relationships between the forests. In this way, each forest can be connected with every other forest to form a collaborative directory service solution for any enterprise with business needs that include multiple forest collaboration.

Forests can also be defined as:

- Collections of Domain Containers that Trust Each Other
- Units of Replication
- Security Boundaries
- Units of Delegation

**Forests as Collections of Domain Containers that Trust Each Other**
Within the scope of Active Directory, a forest is a collection of domain containers that inherently trust each other and other security services that are located in that same forest. All domain containers in a forest share a common global catalog, directory schema, and directory configuration, as well as automatic two-way transitive trust relationships. Because all of the domain containers are inherently joined through two-way transitive trusts, all authentication requests made from any domain in the forest to any other domain in the same forest will be granted. In this way, all security principals that are located in domain containers within a forest inherently trust each other.

Forests can be used to segregate domain containers into one or more unique DNS namespace hierarchies known as domain trees. Although each domain tree consists of a unique namespace the schema and configuration data for the forest are shared throughout all the domain containers in a forest irrespective of namespace. Each domain container in a forest must adhere to DNS naming schemes and all domains are organized in a root and subordinate domain hierarchy. Root domains, such as forest root and tree root domains, define the DNS namespace for their subordinate domains. Although a forest can consist of multiple domain trees, it represents one organization. However, an organization can have multiple forests. For more information about multiple forests, see "Forests as Units of Delegation" later in this section. As shown in the following figure, the namespace for each root domain must be unique.

**Domain Containers, Root Domains and DNS Namespaces Within a Forest**

**Forest Root Domain**

Although trees in a forest do not share the same DNS namespace, a forest does have a single root domain, called the forest root domain. The forest root domain is, by definition, the first domain created in the forest. The Enterprise Admins and Schema Admins groups are located in this domain. By default, members of these two groups have forest-wide administrative credentials. In Windows 2000 Active Directory, the forest root domain cannot be deleted, changed, or renamed. In Windows Server 2003 and later versions of Active Directory, the forest root domain cannot be deleted, but it can be restructured or renamed.

Objects are located within Active Directory domains according to a hierarchical path, which includes the labels of the Active Directory domain name and each level of container objects. The full path to the object is defined by the distinguished name (also known as a DN). The distinguished name is unambiguous (identifies one object only) and unique (no other object in the directory has this name). By using the full path to an object, including the object name and all parent objects to the root of the domain, the distinguished name uniquely and unambiguously identifies an object within a domain hierarchy.

The distinguished name of the forest root domain is used to locate the configuration and schema directory partitions in the namespace. The distinguished names for the Configuration and Schema containers in Active Directory always show these containers as child objects in the forest root domain. For example, in the child domain Noam.wingtiptoys.com (where Wingtiptoys.com is the name of the forest root domain), the distinguished name of the Configuration container is cn=configuration,dc=wingtiptoys,dc=com. The distinguished name of the Schema container is cn=schema,cn=configuration,dc=wingtiptoys,dc=com. However, this naming convention provides only a logical location for these containers.

These containers do not exist as child objects of the forest root domain, nor is the schema directory partition actually a part of the configuration directory partition: They are separate directory partitions. Every domain controller in a forest stores a copy of the configuration and schema directory partitions, and every copy of these partitions has the same distinguished name on every domain controller.

**Tree Root Domain**

A domain tree represents a unique DNS namespace: it has a single root domain, known as the tree root domain, and is built as a strict hierarchy: Each domain above the tree root domain has exactly one superior, or parent, domain (the forest root domain). The namespace created by this hierarchy, therefore, is contiguous — each level of the hierarchy is directly related to the level above it and to the level below it. In other words, the names of domains created beneath the tree root domain (child domains) are always contiguous with the name of the tree root domain. The DNS names of the child domains of the root domain of a tree reflect this organization; therefore, the children of a root domain called Somedomain are always children of that domain in the DNS namespace (for example, Child1.somedomain, Child2.somedomain, and so forth).

Multiple domain trees can belong to a single forest and do not form a contiguous namespace; that is, they have noncontiguous DNS domain names. Although the roots of the separate trees have names that are not contiguous with each other, the trees share a single overall namespace because names of objects can still be resolved by the same Active Directory instance. A forest exists as a set of cross-reference objects and trust relationships that are known to the member trees. Transitive trusts at the root domain of each namespace provide mutual access to resources.

The domain hierarchy in a forest determines the transitive trust links that connect each domain. Each domain has a direct trust link with its parent and each of its children. If there are multiple trees in a forest, the forest root domain is at the top of the trust tree and, from a trust perspective, all other tree roots are children. That means authentication traffic between any two domains in different trees must pass through the forest root.

**Forests as Units of Replication**

Unlike domains, forests are the largest unit of replication that can be administered in an Active Directory environment. To efficiently synchronize data between domain controllers throughout a forest, Active Directory replication transfers updates according to directory partition. Directory partitions are used to help organize how replication occurs within a forest. Active Directory uses four distinct directory partition types to store and copy four different types of data.

One directory partition contains domain data; the other three are forest-wide partitions, and contain configuration, schema, and application data. This storage and replication design provides directory information to users and administrators throughout the domain. Each domain controller receives directory updates to the data stored in its domain only, as well as updates to the data in the two directory partitions that store configuration and schema data for the forest. As shown in the following figure, schema and configuration data must be replicated to all domain controllers that exist in a forest, while optional Application data is replicated only to domain controllers within the same forest that are specified as replication partners.

**Forest-Wide Replication Scope**

The following table describes each of the three forest-wide partitions in more detail.

**Forest-Wide Directory Partitions**

| Partition | Description |
|---|---|

| | |
|---|---|
| Schema | The schema partition contains the forest-wide schema. Each forest has one schema so that the definition of each object class is consistent. The schema is the formal definition of all object and attribute data that can be stored in the directory. Active Directory domain controllers include a default schema that defines many object types, such as user and computer accounts, groups, domains, organization units, and security policies. Administrators and programmers can extend the schema by defining new object types and attributes or by adding new attributes for existing objects. Schema objects are protected by access control lists, ensuring that only authorized users can alter the schema. The schema partition is replicated to each domain controller in the forest. |
| Configuration | The configuration partition describes the topology of the forest as well as other forest, domain and domain controller settings. This configuration data includes a list of all domains, trees, and forests and the locations of the domain controllers and global catalogs. The configuration partition is replicated to each domain controller in the forest. |
| Application | Applications and services can use application directory partitions to store application-specific data. Data stored in the application directory partition is intended to satisfy cases where information needs to be replicated but not necessarily on a global scale. Application directory partitions can contain any type of object, except security principals. Application directory partitions are usually created by the applications that will use them to store and replicate data. One of the benefits of an application directory partition is that, for redundancy, availability, or fault tolerance, the data in it can be replicated to different domain controllers in a forest. The data can be replicated to a specific domain controller or any set of domain controllers anywhere in the forest. This differs from a domain directory partition in which data is replicated to all domain controllers in that domain.<br><br>Only domain controllers running Windows Server 2003 or higher can host a replica of an application directory partition. Application directory partitions are created, configured, and managed by the administrator. |

All forest replication is Multi-Master with the exception of the three domain-wide and two forest-wide operations master roles. Forest-wide replication requires domain controllers and three other components of the Active Directory physical structure to be in place for optimal performance. These components are forest-wide operations master roles, sites, and global catalogs.

**Forest-Wide Operations Master Roles**

There are two operations master roles assigned for the entire forest. These include the domain naming master and the schema master. Each forest must have one and only one schema master and one domain naming master, so these two roles must remain in the forest root domain. The other three operations master roles are assigned to each domain in the forest. These three roles must be unique in each domain, so each domain can have only one relative ID master, one PDC emulator, and one infrastructure master.

In an Active Directory forest with only one domain and one domain controller, that domain controller has all the operations master roles. For more information about operations master roles, see "How Operations Masters Work."

**Sites**

Sites in Active Directory represent the physical structure, or topology, of the network. Within the scope of a forest, sites are a representation of the physical network topology, including physical subnet and site definitions. When you establish sites, domain controllers within a single site communicate frequently. This communication minimizes the latency within the site; that is, the time required for a change that is made on one domain controller to be replicated to other domain controllers. You create sites to optimize use of the bandwidth between domain controllers in different locations. For more information about sites, see "How Active Directory Replication Topology Works."

**Global Catalogs**

The global catalog stores a full copy of all Active Directory objects in the directory for its host domain and a partial copy of all objects for all other domains in the forest. Users in a forest do not need to be aware of directory structure because all users see a single directory through the global catalog. Applications and clients can query the global catalog to locate any object in a forest. The global catalog is hosted on one or more domain controllers in the forest. It contains a partial replica of every domain directory partition in the forest. These partial replicas include replicas of every object in the forest, including the attributes most frequently used in search operations and the attributes required to locate a full replica of the object. A global catalog is created automatically on the first domain controller in the forest. Optionally, other domain controllers can be configured to serve as global catalogs.

A global catalog serves the following roles:

- Enables user searches for directory information about objects throughout all domains in the forest
- Resolves user principal names (UPNs) during authentication, when the authenticating domain controller does not have information about the account

- Supplies universal group membership information in a multiple domain environment
- Validates references to objects in other domains in the forest

For more information about global catalogs and their roles, see "How the Global Catalog Works."

**Forests as Security Boundaries**

Each forest is a single instance of the directory, the top-level Active Directory container, and a security boundary for all objects that are located in the forest. This security boundary defines the scope of authority of the administrators. In general, a security boundary is defined by the top-level container for which no administrator external to the container can take control away from administrators within the container. As shown in the following figure, no administrators from outside a forest can control access to information inside the forest unless first given permission to do so by the administrators within the forest.

**Enterprise Administrators Outside of a Forest Can Administer Only Within Their Own Forest**

A forest is the only component of the Active Directory logical structure that is a security boundary. By contrast, a domain is not a security boundary because it is not possible for administrators from one domain to prevent a malicious administrator from another domain within the forest from accessing data in their domain. A domain is, however, the administrative boundary for managing objects, such as users, groups, and computers. In addition, each domain has its own individual security policies and trust relationships with other domains.

**Forests as Units of Delegation**

The forest is the largest management unit of Active Directory as well as the ultimate unit of autonomy and isolation of authority. Members of the Enterprise Admins and forest root Domain Admins security groups are known as enterprise administrators. Enterprise administrators control the Active Directory objects in the configuration container that do not belong to any one domain, including Enterprise Certification Authority objects and other configuration data that affects all domains in the forest.

Because enterprise administrators have authority over all domains in the forest, the domain administrators in each domain must trust the enterprise administrators. You cannot truly restrict enterprise administrators from managing objects in any domain in the forest. Enterprise administrators can always regain control over objects. Some organizations with political challenges, such as those frequently encountered in mergers and acquisitions, might find the scope of this enterprise authority too great and require more than one forest. If your organization requires strict isolation of authority between domains, you must deploy multiple forests with manually created trusts between domains in the different forests.

Because each forest is administered separately, adding additional forests to your organization increases the management overhead of the organization. The number of forests that you need to deploy is based on the autonomy and isolation requirements of each group within your organization. Reasons to create multiple forests in your organization include:

- To secure data within each forest. Sensitive data can be protected so that only users within that forest can access it.
- To isolate directory replication within each forest. Schema changes, configuration changes, and the addition of new domains to a forest have forest-wide impact only within that forest, not on a trusting forest.

Because the forest is a security boundary, each forest does not trust or allow access from any other forest by default. However, in Windows Server 2003 and higher Active Directory, transitive trust relationships can be manually established between forests to establish cross-forest access to resources, so that users in one forest can access resources in another forest.

Forest trusts help you to manage a segmented Active Directory infrastructure within your organization by providing support for accessing resources and other objects across multiple forests. By using forest trusts, you can link two different Windows Server 2003 or higher forests to form a one-way or two-way transitive trust relationship. A forest trust allows administrators to federate two Active Directory forests with a single trust relationship to provide a seamless authentication and authorization experience across the forests.

When two forests are connected by a forest trust, authentication requests made using the Kerberos V5 or NTLM protocols can be routed between forests to provide access to resources in both forests. Trust security settings and firewalls can be configured between domains in different forests that are joined by trust relationships to limit cross-forest connectivity to specific users or applications. For more information about trust security settings, see "Security Considerations for Trusts."

A forest trust can be created only between a forest root domain in one Windows Server 2003 or higher forest and a forest root domain in another Windows Server 2003 or higher forest. Forest trusts can be created between two forests only and cannot be implicitly extended to a third forest. This means that if a forest trust is created between Forest 1 and Forest 2, and another forest trust is created between Forest 2 and Forest 3, Forest 1 does not have an implicit trust with Forest 3. The following figure shows two separate forest trust relationships between three forests in a single organization.

# How Domains and Forests Work

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**How Domains and Forests Work**

**In this section**

- Domain and Forest Structure
- Active Directory Objects
- Domain and Forest Protocols and Programming Interfaces
- Domain and Forest Processes and Interactions
- Network Ports Used by Domains and Forests
- Related Information

Active Directory stores data for an entire forest. A forest is a distributed database, which is made up of directory partitions spread across multiple computers. A domain is one partition of the database; each domain contains Active Directory objects, such as security principal objects (users, computers, and groups) to which you can grant or deny access to network resources. All domain data stored in the domain directory partition is replicated to domain controllers in that domain only.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to Active Directory Domain Services. |

The directory partitions that store configuration and schema information are replicated to domain controllers in all domains. In this way, Active Directory provides a data repository that is logically centralized but physically distributed. Because all domain controllers store forest-wide configuration and schema information, a domain controller in one domain can reference a domain controller in any other domain if the information that it is requesting is not stored locally.

This section details how domains and forests work, discusses the various components of domains and forests, describes several common processes that depend on domains and forests, and lists the network ports related to domains and forests.

**Domain and Forest Structure**

A forest consists of a hierarchical structure of domain containers that are used to categorically store information about objects on the network. Domain containers are considered the core functional units in the forest structure. This is because each domain container in a forest is used primarily to store and manage Active Directory objects, most of which have a physical representation (such as people, printers, or computers). Forests also provide the structure by which domain containers can be segregated into one or more unique Domain Name System (DNS) namespace hierarchies known as domain trees.

In addition, the domain tree hierarchy is based on trust relationships — that is, the domain containers are linked by intra-forest trust relationships. When it is necessary for domain containers in the same organization to have different namespaces, you can create a separate tree for each namespace. In Active Directory, the roots of trees are linked automatically by two-way, transitive trust relationships. Trees linked by trust relationships form a forest. A single tree that is related to no other trees constitutes a forest of one tree. The domain and forest structure is made up of the following components:

- Cross-References
- Trust Relationships
- Forest Root

- Domain Trees and Child Domains
- Domain Names

For more information about Active Directory Domains and DNS, see "How DNS Support for Active Directory Works."

This section describes the structure and function of these components, and describes how this structure helps administrators manage the network so that users can accomplish business objectives.

**Cross-References**

Cross-references enable every domain controller to be aware not only of the partitions that it holds, but of all directory partitions in the forest. The information contained within cross-references form the glue that holds the pieces of the domain and forest structure together. Because Active Directory is logically partitioned, and directory partitions are the discrete components of the directory that replicate between domain controllers, either all objects in a directory partition are present on a particular domain controller or no objects in the directory partition are present on the domain controller. For this reason, cross references have the effect of linking the partitions together, which allows operations such as searches to span multiple partitions.

Cross-references are stored as directory objects of the class **crossRef** that identify the existence and location of all directory partitions, irrespective of location in the directory tree. In addition, these objects contain information that Active Directory uses to construct the directory tree hierarchy. Values for the following attributes are required for each cross-reference:

- **nCName .** The distinguished name of the directory partition that the **crossRef** object references. (The prefix **nC** stands for naming context, which is a synonym for directory partition.) The combination of all of the **nCName** properties in the forest defines the entire directory tree, including the subordinate and superior relationships between partitions.
- **dNSRoot.** The DNS name of the domain where servers that store the particular directory partition can be reached. This value can also be a DNS host name.

**How Cross-Reference Information is Propagated Throughout the Domain and Forest Structure**

For every directory partition in a forest, there is an internal cross-reference object stored in the Partitions container (cn=Partitions,cn=Configuration,dc=*ForestRootDomain*). Because cross-reference objects are located in the Configuration container, they are replicated to every domain controller in the forest, and thus every domain controller has information about the name of every partition in the forest. By virtue of this knowledge, any domain controller can generate referrals to any other domain in the forest, as well as to the schema and configuration directory partitions.

When you create a new forest, the Active Directory Installation Wizard creates three directory partitions: the first domain directory partition, the configuration directory partition, and the schema directory partition. For each of these partitions, a cross-reference object is created automatically. Thereafter, when a new domain is created in the forest, another directory partition is created and the respective cross-reference object is created. When the configuration directory partition is replicated to the new domain controller, a cross-reference object is created on the domain naming master and is then replicated throughout the forest.

**Note**

- The state of cross-reference information at any specific time is subject to the effects of replication latency.

For more information about cross-reference objects, see "How Active Directory Searches Work." Cross-reference objects can also be used to generate referrals to other directory partitions located in another forest through external cross-references.

**External Cross-References**

An external cross-reference is a cross-reference object that can be created manually to provide the location of an object that is not stored in the forest. If your Lightweight Directory Access Protocol (LDAP) clients submit operations for an external portion of the global LDAP namespace against servers in your forest, and you want servers in your forest to refer the client to the correct location, you can create a cross-reference object for that directory in the Partitions container. There are two ways that external cross-references are used:

- To reference external directories by their disjoint directory name (a name that is not contiguous with the name of this directory tree). In this case, when you create the cross-reference, you create a reference to a location that is not a child of any object in this directory.

- To reference external directories by a name that is within the Active Directory namespace (a name that is contiguous with the name of this directory tree). In this case, when you create the cross-reference, you create a referenceto a location that is a child of a real object in this directory.

Because the domain component (dc=) portion of the distinguished names of all Active Directory domains matches their DNS addresses, and because DNS is the worldwide namespace, all domain controllers can generate external referrals to each other automatically.

**Trust Relationships**

Active Directory provides security across multiple domains through intra-forest trust relationships. When there are trust relationships between domains in the same forest, the authentication mechanism for each domain trusts the authentication mechanism for all other trusted domains. If a user or application is authenticated by one domain, its authentication is accepted by all other domains that trust the authenticating domain. Users in a trusted domain have access to resources in the trusting domain, subject to the access controls that are applied in the trusting domain.

**Note**

- Default intra-forest trust relationships are created at the time the domains are created. The number of trust relationships required to connect *n* domains is *n*–1, whether the domains are linked in a single, contiguous parent-child hierarchy or constitute two or more separate contiguous parent-child hierarchies.

A trust relationship is a relationship established between two domains that allows users in one domain to be recognized by a domain controller in the other domain. Trusts let users access resources in the other domain, and also let administrators manage user rights for users in the other domain. Account authentication between domains is enabled by two-way, transitive trust relationships. All domain trusts in an Active Directory forest are two-way and transitive and are have the following attributes:

- **Two-way.** When you create a new child domain, the child domain automatically trusts the parent domain, and vice versa. At the practical level, this means that authentication requests can be passed between the two domains in both directions.

- **Transitive.** A transitive trust reaches beyond the two domains in the initial trust relationship. For example, if Domain A and Domain B (parent and child) trust each other, and if Domain B and Domain C (also parent and child) trust each other, Domain A and Domain C also trust each other (implicitly), even though no direct trust relationship between them exists.

At the level of the forest, a trust relationship is created automatically between the forest root domain and the root domain of each domain tree added to the forest, with the result that complete trust exists between all domains in an Active Directory forest. At the practical level, because trust relationships are transitive, a single logon process lets the system authenticate a user (or computer) in any domain in the forest. As shown in the following figure, this single logon process lets the account access resources on any domain in the forest.

**Transitive Trusts Facilitate Cross-Domain Access to Resources With a Single Logon**

**Note**

- Single logons enabled by trusts do not necessarily imply that the authenticated user has rights and permissions in all domains in the forest. This is because in any discussion of trust relationships, access to resources always assumes the limitations of access control.

**Forest Root Domain**

The first domain created in the forest is called the forest root domain. When you create a new tree, you specify the root domain of the initial tree, and a trust relationship is established between the root domain of the second tree and the forest root domain. If you create a third tree, a trust relationship is established between the root domain of the third tree and the forest root domain. Because all trust relationships created within a forest are transitive and two-way, the root domain of the third tree also has a two-way trust relationship with the root domain of the second tree. In Windows 2000 Active Directory, the forest root domain cannot be deleted, changed, or renamed. In Windows Server 2003 Active Directory or higher, the forest root domain cannot be deleted, but it can be restructured or renamed.

The distinguished name of the forest root domain is used to locate the configuration and schema directory partitions in the namespace. The distinguished names for the configuration and schema containers in Active Directory always show these containers as child objects in the forest root domain. For example, in the child domain Noam.wingtiptoys.com, the distinguished name of the Configuration container is cn=configuration,dc=wingtiptoys,dc=com. The distinguished name of the Schema container is cn=schema,cn=configuration,dc=wingtiptoys,dc=com. However, this naming convention provides only a logical location for these containers.

The containers do not exist as child objects of the forest root domain, nor is the schema directory partition actually a part of the configuration directory partition. They are separate directory partitions. Every domain controller in a forest stores a copy of the configuration and schema directory partitions, and every copy of these partitions has the same distinguished name on every domain controller. The following operations occur when you create the forest root domain:

- The Schema container and the Configuration container are created.

- The Active Directory Installation Wizard assigns the PDC emulator, RID master, domain naming master, schema master, and infrastructure master roles to the domain controller.

The Enterprise Admins and Schema Admins groups are located in this domain. By default, members of these two groups have forest-wide administrative credentials.

**Domain Trees and Child Domains**

A forest is a collection of one or more domain trees, organized as peers and connected by two-way, transitive trust

relationships. A single domain constitutes a tree of one domain, and a single tree constitutes a forest of one tree. Thus, a forest is synonymous with Active Directory — that is, the set of all directory partitions in a particular directory service instance (which includes all domains and all configuration and schema information) makes up a forest.

Trees in the same forest do not form a contiguous namespace. They form a noncontiguous namespace that is based on different DNS root domain names. However, trees in a forest share a common directory schema, configuration, and global catalog. (The global catalog is a domain controller that stores all objects of all domains in an Active Directory forest, which makes it possible to search for objects at the forest level rather than at the tree level.) This sharing of common schema and configuration data, in addition to trust relationships between their roots, distinguishes a forest from a set of unrelated trees. Although the roots of the separate trees have names that are not contiguous with each other, the trees share a single overall namespace because names of objects can still be resolved by the same Active Directory instance.

**Note**

- The directory schema and configuration data are shared because they are stored in separate logical directory partitions that are replicated to domain controllers in every domain in the forest. The data about a particular domain is replicated only to domain controllers in the same domain.

**Domain Trees**

A domain tree is a DNS namespace: it has a single root domain and is built as a strict hierarchy; each domain below the root domain has exactly one superior, or parent, domain. The namespace created by this hierarchy, therefore, is contiguous — each level of the hierarchy is directly related to the level above it and to the level below it, if any. In Active Directory, the following rules determine the way that trees function in the namespace:

- A tree has exactly one name. The name of the tree is the DNS name of the domain at the root of the tree.

- The names of domains created beneath the root domain (child domains) are always contiguous with the name of the tree root domain.

- The DNS names of the child domains of the tree root domain reflect this organization; therefore, the children of a tree root domain called Somedomain are always children of that domain in the DNS namespace (for example, Child1.somedomain, Child2.somedomain, and so forth).

**Note**

- Tree and forest hierarchies are specific to Active Directory domains. A Windows NT 4.0 domain that is configured to trust or to be trusted by a Active Directory domain is not part of the forest to which the Active Directory domain belongs.

The forest structure provides organizations with the option of constructing their enterprise from separate, distinct, noncontiguous namespaces. Having a separate namespace is desirable under conditions where, for example, the namespace of an acquired company should remain intact. If you have business units with distinct DNS names, you can create additional trees to accommodate the names.

**Note**

- Before creating a new domain tree when you want a different DNS namespace, consider creating another forest. Multiple forests provide administrative autonomy, isolation of the schema and configuration directory partitions, separate security boundaries, and the flexibility to use an independent namespace design for each forest.

When you create a new domain tree, you specify the root domain of the initial tree, and a trust relationship is established between the root domain of the new tree (the second tree) and the forest root domain. If you create a third tree, a trust relationship is established between the root domain of the third tree and the forest root domain. Because a trust relationship is transitive and two-way, the root domain of the third tree also has a two-way trust relationship with the root domain of the second tree. The following operations occur when you create a new tree root domain in an existing forest:

- Location of a source domain controller in the forest root domain and synchronization of domain system time with the system time of the source domain controller.

- Creation of a tree-root trust relationship between the tree root domain and the forest root domain, and creation of the trusted domain object (TDO) in both domains. The tree-root trust relationship is two-way and transitive.

**Child Domains**
Child domains can represent geographical entities (for example, the United States and Europe), administrative entities within the organization (for example, sales and marketing departments), or other organization-specific boundaries, according to the needs of the organization. Domains are created below the root domain to minimize Active Directory replication and to provide a means for creating domain names that do not change. Changes in the overall domain architecture, such as domain collapses and domain re-creation, create difficult and potentially IT-intensive support requirements. A good namespace design should be capable of withstanding reorganizations without the need to restructure the existing domain hierarchy.

Each time you create a new child domain, a two-way transitive trust relationship (known as the parent-child trust) is automatically created between the parent and new child domain. In this way, transitive trust relationships flow upward through the domain tree as it is formed, creating transitive trusts between all domains in the domain tree. The parent-child relationship is a naming and trust relationship only. Administrators in a parent domain are not automatically administrators of a child domain. Likewise, policies set in a parent domain do not automatically apply to child domains.

The following operations occur when you create a child domain in an existing tree:

- Verification of the name that you provide as a valid child domain name.
- Location of a source domain controller in the parent domain and synchronization of the system time of the child domain with the system time of the source domain controller.
- Creation of parent-child TDOs in the System folder on both the parent domain and the child domain. The TDO objects identify two-way transitive trust relationships between the child domain and the parent domain.
- Replication of the Active Directory Schema container and the Configuration container from a domain controller in the parent domain.

**Domain Names**
Active Directory uses DNS naming standards for hierarchical naming of Active Directory domains and computers. For this reason, domain and computer objects are part of both the DNS domain hierarchy and the Active Directory domain hierarchy. Although these domain hierarchies have identical names, they represent separate namespaces.

The domain hierarchy defines a namespace. A namespace is any bounded area in which standardized names can be used to symbolically represent some type of information (such as an object in a directory or an Internet Protocol [IP] address) and that can be resolved to the object itself. In each namespace, specific rules determine how names can be created and used. Some namespaces, such as the DNS namespace and the Active Directory namespace, are hierarchically structured and provide rules that allow the namespace to be partitioned. Other namespaces, such as the Network Basic Input/Output System (NetBIOS) namespace, are flat (unstructured) and cannot be partitioned.

The main function of DNS is to map user-readable computer names to computer-readable IP addresses. Thus, DNS defines a namespace for computer names that can be resolved to IP addresses, or vice versa. In Windows NT 4.0 and earlier, DNS names were not required; domains and computers used NetBIOS names, which were mapped to IP addresses by using the Windows Internet Name Service (WINS). Although DNS names are required for Active Directory domains and Windows 2000–, Windows XP–, and Windows Server 2003–based computers, NetBIOS names also are supported in Windows Server 2003 for interoperability with Windows NT 4.0 domains and with clients that are running Windows NT 4.0 or earlier, Windows for Workgroups, Windows 98, or Windows 95. There is no interoperability between Windows Server 2008 and higher domains and Windows NT 4.0 domains.

**Note**

- WINS and NetBIOS are not required in an environment where computers run only Windows 2000, Windows XP, Windows Server 2003, Windows Vista, Windows Server 2008, Windows 7 or Windows Server 2008 R2, but WINS is required for interoperability between Windows 2000 Server– and Windows Server 2003–based domain controllers, computers that are running earlier versions of Windows, and applications that depend on the NetBIOS namespace — for example, applications that call NetServerEnum and other so-called Net* application programming interfaces (APIs) that depend on NetBIOS. There is no interoperability between Windows Server 2008 based domains and Windows NT 4.0 domains.

Active Directory domains have both DNS names and NetBIOS names. In general, both names are visible to end users. The DNS

names of Active Directory domains include two parts, a prefix and a suffix. The DNS prefix is the first label in the DNS name of the domain. The suffix is the name of the Active Directory forest root domain. For example, the first label of the DNS name for the Child1.wingtiptoys.com domain is Child1 and is referred to as the DNS prefix. The name of the forest root domain in that same forest is wingtiptoys.com and is referred to as the DNS suffix.

**Active Directory Domain Names and the Internet**

Active Directory domain names can exist within the scope of the global Internet DNS namespace. When an Internet presence is required by an individual or organization, the Active Directory namespace is maintained as one or more hierarchical Windows 2000 domains beneath a root domain that is registered as a DNS namespace. Registration of individual and organizational root domain DNS names ensures the global uniqueness of all DNS names and provides for the assignment of network addresses that are recorded in the global DNS database. Registration of the DNS name for the root domain of the individual or organization also grants that individual or organization the authority to manage its own hierarchy of child domains, zones, and hosts within the root domain.

### Note

- An organization might or might not choose to be part of the global Internet DNS namespace. However, even if the root domain of the organization is not registered as an Internet DNS namespace, the DNS service is required to locate Windows 2000–, Windows XP, Windows Server 2003, Windows Vista, Windows Server 2008, Windows 7 and Windows Server 2008 R2–based computers in general and Windows 2000 Server,Windows Server 2003, Windows Server 2008 and Windows Server 2008 R2–based domain controllers in particular.

For more information about domain names, see "How DNS Support for Active Directory Works."

**Active Directory Objects**

Active Directory objects represent the entities that make up a network. An object is a distinct, named set of attributes that represents something concrete, such as a user, a printer, or an application. When you create an Active Directory object, Active Directory generates values for some of the attributes of the object; others you provide. For example, when you create a user object, Active Directory assigns a globally unique identifier (GUID) and a security identifier (SID), and you provide values for such attributes of the user as the given name, surname, logon identifier, and so on. This section describes the key identifiers assigned to objects by Active Directory and their associated naming schemes

**Object Uniqueness**

Each object in Active Directory is associated with at least one identifier that identifies that object as unique in an enterprise. This object identifier is referred to as a globally unique identifier (GUID). Another identifier, referred to as a security ID (SID), is used on security-enabled objects so that authentication and authorization services can determine its origin and validity within the domain or forest. Active Directory objects that are security-enabled are referred to as security principals.

A security principal is an object managed by Active Directory that is automatically assigned a SID for logon authentication and for access to resources. A security principal can be a user account, computer account, or a group, and is unique within a single domain. A security principal object must be authenticated by a domain controller in the domain in which the security principal object is located, and it can be granted or denied access to network resources.

**GUIDs**

Every object in Active Directory has a GUID, a 128-bit number assigned by the Directory System Agent when the object is created. The GUID, which cannot be altered or removed, is stored in an attribute that is required for every object, not just security principal objects. The GUID of each object is stored in its Object-GUID (objectGUID) property. When storing a reference to an Active Directory object in an external store (for example, a Microsoft SQL Server database), the objectGUID value should be used.

Active Directory uses GUIDs internally to identify objects. For example, the GUID is one of the properties of an object that is published in the global catalog. Searching the global catalog for the GUID of a User object will yield results if the user has an account somewhere in the enterprise. In fact, searching for any object by Object-GUID might be the most reliable way of finding the object you want to find. This is because the values of other object properties can change, but the Object-GUID never changes. When an object is assigned a GUID, it always keeps that value.

**Security IDs (SIDs)**

When a new security principal is created, Active Directory stores the SID of the security principal in the Object-SID (objectSID) property of the object and assigns the new object a GUID. Each security principal (as well as the domain itself) has a SID, which is the property that authoritatively identifies the object to the Windows security subsystem. The SID of a user, group, or computer is derived from the SID of the domain to which the object belongs; this SID is made up of the value of the domain SID and one additional 32-bit component called the relative identifier (RID).

In Windows 2000 and later operating systems, ACLs are used to identify users and groups by SID, not by GUID — even ACLs

on resources in Active Directory. A user gains access to, for example, a Group Policy object, based on one of the SIDs belonging to the user, not based on the GUID for the User object.

**SIDs and Migrations**

When an employee moves to a different location or to a new position, their user account might need to be moved or migrated to a different domain within the organization. Migrating a user account from one domain to another replaces the SID of the account with a new SID and new RID assigned by the new domain. For example, if Nicolette moves from North America to Europe, but stays in the same company, her account can be transferred with her. An administrator with the appropriate credentials can simply move her User object from, say, the Noam.wingtiptoys.com domain to the Euro.wingtiptoys.com domain. When the account is moved, the User object for her account needs a new SID. The domain identifier portion of a SID issued in Noam is unique to Noam, so the SID for her account in Euro has a different domain identifier. The RID portion of a SID is unique relative to the domain, so if the domain changes, the RID also changes.

Thus when a User object moves from one domain to another, a new SID must be generated for the user account and stored in the Object-SID property. Before the new value is written to the property, the previous value is copied to another property of a User object, SID History (SIDHistory). This property can hold multiple values. Each time a User object moves to another domain, a new SID is generated and stored in the Object-SID property and another value is added to the list of old SIDs in SIDHistory. When a user logs on and is successfully authenticated, the domain authentication service queries Active Directory for all of the SIDs associated with the user — the current SID of the user, any old SIDs of the user, and the SIDs for the groups to which the user belonged. All of these SIDs are returned to the authentication client and are included in the access token of the user. When the user tries to gain access to a resource, any one of the SIDs in the access token, including one of the SIDs in SIDHistory, can be used to authorize the user to the resource.

For more information about SIDHistory, see "How Security Identifiers Work" and "Security Considerations for Trusts."

**Object Names**

Object names are used to identify accounts in an Active Directory network. Objects have both LDAP-related names and logon names. Each object name represents a unique attribute for that object.

**LDAP-Related Names**

Active Directory is a Lightweight Directory Access Protocol (LDAP)-compliant directory service. In Windows Server 2003 and higher operating systems, all access to Active Directory objects occurs through LDAP. LDAP defines what operations can be performed in order to query and modify information in a directory, and how information in a directory can be accessed in compliance with established security requirements. Therefore, you can use LDAP to find or enumerate directory objects and to query or administer Active Directory.

It is possible to query by LDAP distinguished name (which is itself an attribute of the object), but because these names are difficult to remember, LDAP also supports querying by other attributes (for example, by using the attribute "color" to find "color" printers). This lets you find an object without having to know the distinguished name. If your organization has several domains, it is possible to use the same user name or computer name in different domains.

Like some other types of object names, LDAP-related names can change. The SID, globally unique ID, LDAP distinguished name, and canonical name generated by Active Directory uniquely identify each user, computer, or group in the forest. If the security principal object is renamed or moved to a different domain, the SID, LDAP relative distinguished name, LDAP distinguished name, and canonical name change, but the globally unique ID generated by Active Directory does not change.

**Distinguished Name**

Objects are located within Active Directory domains according to a hierarchical path, which includes the labels of the Active Directory domain name and each level of container objects. The full path to the object is defined by the distinguished name (also known as a DN). The name of the object itself, separate from the path to the object, is defined by the relative distinguished name.

The distinguished name is unambiguous (identifies one object only) and unique (no other object in the directory has this name). By using the full path to an object, including the object name and all parent objects to the root of the domain, the distinguished name uniquely and unambiguously identifies an object within a domain hierarchy. It contains sufficient information for an LDAP client to retrieve information the about the object from the directory.

For example, a user named Samantha Smith works in the marketing department of a company as a promotions coordinator. Therefore, her user account is created in an organizational unit that stores the accounts for marketing department employees who are engaged in promotional activities. The user identifier for Samantha Smith is Ssmith, and she works in the North American branch of the company. The root domain of the company is wingtiptoys.com, and the local domain is noam.wingtiptoys.com. The following distinguished name is of the user object Ssmith in the noam.wingtiptoys.com domain.

cn=Ssmith,ou=Promotions,ou=Marketing,dc=noam,dc=wingtiptoys,dc=com

### Note

- Active Directory tools do not display the LDAP abbreviations for the naming attributes domain component (dc=), organizational unit (ou=), common name (cn=), and so forth. These abbreviations are shown only to illustrate how LDAP recognizes the portions of the distinguished name. Most Active Directory tools display object names in canonical form, as described later in this section. Because distinguished names are difficult to remember, it is useful to have other means for retrieving objects. Active Directory supports querying by attribute (for example, the building number where you want to find a printer), so an object can be found without having to know the distinguished name.

**Relative Distinguished Name**

The relative distinguished name of an object is the part of the name that is an attribute of the object itself — the part of the object name that identifies this object as unique from its siblings at its current level in the naming hierarchy. Using the distinguished name mentioned earlier, the relative distinguished name of the object is SSmith. The relative distinguished name of the parent object is Promotions. The maximum length allowed for a relative distinguished name is 255 characters, but attributes have specific limits imposed by the directory schema. For example, in the case of the common name (cn), which is the attribute type often used for naming the relative distinguished name, the maximum number of characters allowed is 64.

Active Directory relative distinguished names are unique within a specific parent — that is, Active Directory does not permit two objects with the same relative distinguished name under the same parent container. However, two objects can have identical relative distinguished names but still be unique in the directory because within their respective parent containers, their distinguished names are not the same. (For example, the object cn=SSmith,dc=noam,dc=wingtiptoys,dc=com is recognized by LDAP as being different from cn=SSmith,dc=wingtiptoys,dc=com.)

The relative distinguished name for each object is stored in the Active Directory database. Each record contains a reference to the parent of the object. By following the references to the root, the entire distinguished name is constructed during an LDAP operation.

**Canonical Name**

By default, the user interface in Windows 2000 and higher operating systems, displays object names that use the canonical name, which lists the relative distinguished names from the root downward and without RFC 1779 naming attribute descriptors; it uses the DNS domain name (the form of the name where domain labels are separated by periods). For the LDAP distinguished name in the previous example, the respective canonical name would appear as follows: noam.wingtiptoys.com/marketing/promotions/ssmith

### Note

- If the name of an organizational unit contains a forward slash character (/), Active Directory requires an escape character in the form of a backslash (\) to distinguish between forward slashes that separate elements of the canonical name and the forward slash that is part of the organizational unit name. The canonical name that appears in Active Directory Users and Computers properties pages displays the escape character immediately preceding the forward slash in the name of the organizational unit. For example, if the name of an organizational unit is Promotions/Northeast and the name of the domain is Wingtiptoys.com, the canonical name is displayed as Wingtiptoys.com/Promotions\/Northeast.

**Logon Names**

A unique logon name is required for user security principals to gain access to a domain and its resources. Security principals are objects to which Windows security is applied in the form of authentication and authorization. Users are security principals, and they are authenticated (their identity is verified) at the time they log on to the domain or local computer. They are authorized (allowed or denied access) when they use resources.

In Windows 2000 and higher operating systems, user security principals require a unique logon name to gain access to a domain and its resources. Security principal objects might be renamed, moved, or contained within a nested domain hierarchy. The names of security principal objects must conform to the following guidelines:

- The name cannot be identical to any other user, computer, or group name in the domain. It can contain up to 20 uppercase or lowercase characters except for the following:" / \ [ ] : ; | = , + * ? < >

- A user name, computer name, or group name cannot consist solely of periods (.) or spaces.

The two types of logon names are user principal name and Security Account Manager account names.

**User Principal Name**

In Active Directory, each user account has a user principal name (UPN) in the format *user@DNS-domain-name*. A UPN is a friendly name assigned by an administrator that is shorter than the LDAP distinguished name used by the system and easier to remember. The UPN is independent of the DN of the user object, so a user object can be moved or renamed without affecting the user logon name. When logging on using a UPN, users do not have to choose a domain from a list on the logon dialog box.

The three parts of a UPN are the UPN prefix (user logon name), the @ character, and the UPN suffix (usually a domain name). The default UPN suffix for a user account is the DNS name of the Active Directory domain where the user account is located. For example, the UPN for user Frank Miller, who has a user account in the Wingtiptoys.com domain (if Wingtiptoys.com is the only domain in the tree), is FMiller@Wingtiptoys.com. The UPN is an attribute (userPrincipalName) of the security principal object. If the userPrincipalName attribute of a User object has no value, the User object has a default UPN of userName@DnsDomainName.

If your organization has many domains forming a deep domain tree organized by department and region, default UPN names can become unwieldy. For example, the default UPN for a user might be Sales.westcoast.microsoft.com. The logon name for a user in that domain is *user*@sales.westcoast.microsoft.com. Instead of accepting the default DNS domain name as the UPN suffix, you can simplify both administration and user logon processes by providing a single UPN suffix for all users. (The UPN suffix is used only within the Active Directory domain and is not required to be a valid DNS domain name.) You can choose to use your e-mail domain name as the UPN suffix — *userName*@microsoft.com. This gives the user in the example the UPN name of *user*@microsoft.com.

For a UPN–based logon, a global catalog might be necessary, depending on the user logging on and the domain membership of the computer where the user logs on. A global catalog is needed if the user logs on with a non-default UPN and the computer account of the user is in a different domain than the user account of the user. For example, if, instead of accepting the default DNS domain name as the UPN suffix (in the example *user*@sales.westcoast.microsoft.com), you provide a single UPN suffix for all users (so that the user then becomes simply *user*@microsoft.com), a global catalog is required for logon.

You use the Active Directory Domains and Trusts tool to manage UPN suffixes for a domain. UPNs are assigned at the time a user is created. If you have created additional suffixes for the domain, you can select from the list of available suffixes when you create the user or group account. The suffixes appear in the list in the following order:

- Alternate suffixes (if any; last one created appears first)
- Root domain
- The current domain

**SAM Account Name**

A Security Accounts Manager (SAM) account name is required for compatibility with Windows NT 3.*x* and Windows NT 4.0 domains. The user interface in Windows 2000 or higher operating systems, refers to the SAM account name as User logon name (pre-Windows 2000). There is no interoperability between Windows Server 2008 or higher domains and Winows NT 3 and Windows NT 4.0 domains.

SAM account names are sometimes referred to as flat names because — unlike DNS names — SAM account names do not use hierarchical naming. Because SAM names are flat, each one must be unique in the domain.

**Organizational Units**

Active Directory allows administrators to create a hierarchy within a domain that meets the needs of their organization. The object class of choice for building these hierarchies is the **organizationalUnit**, a general-purpose container that can be used to group most other object classes together for administrative purposes. An organizational unit in Active Directory is analogous to a directory in the file system; it is a container that can hold other objects. You can use organizational units for purposes such as creating an administrative hierarchy, applying Group Policy, and delegating control of administration.

**Administrative Hierarchy**

Organizational units can be nested to create a hierarchy within a domain and form logical administrative units for users, groups, and resource objects, such as printers, computers, applications, and file shares. The organizational unit hierarchy within a domain is independent of the structure of other domains; each domain can implement its own hierarchy. Likewise, domains that are managed by a central authority can implement similar organizational unit hierarchies. The structure is completely flexible, which allows organizations to create an environment that mirrors the administrative model, whether it is centralized or decentralized.

**Group Policy**

Group Policy can be applied to organizational units to define the abilities of groups of computers and users that are contained within the organizational units. Levels of control range from complete desktop lockdown to a relatively autonomous user

experience. Group Policy can affect functionality, such as what applications are available to a group of users, what features within an application are accessible on a particular computer, where documents are saved, and can affect access and user permissions. Group Policy also affects where, when, and how application and operating system updates or special scripts are applied.

Group Policy settings are stored as Group Policy objects in Active Directory. A Group Policy object can be associated with one or more Active Directory containers, such as a site, domain, or organizational unit.

**Delegation of Control**

The Active Directory object-based security model implements default access control that is propagated down a subtree of container objects. You can use this technology to determine the security for an entire group of objects according to the security that you set on the organizational unit that contains the objects. By default, most Active Directory objects inherit ACEs from the security descriptor on their parent container object. If necessary, you can change the inherited permissions. However, as a best practice, you should avoid changing the default permissions or inheritance settings on Active Directory objects unless you have additional security requirements.

### Note

- Because Active Directory is indexed, you can organize the tree to match your administrative model, instead of having to organize it for ease of browsing.

Inheritance enables the access control information defined at a container object in Active Directory to apply to the security descriptors of any subordinate objects, including other containers and their objects. One benefit this provides is that it eliminates the need to apply permissions each time a child object is created. You can apply or delegate administrative control over directory objects to organizational units by setting access control.

This inheritance of access effectively delegates administrative control to individuals in the organization. The best way to take full advantage of delegation and inherited control on directory objects is to organize the hierarchy to match the way that the directory is administered.

**User Accounts and Access Control**

Active Directory authenticates and authorizes security principals such as user, inetorgperson, and computer accounts to access shared resources on the network. The Local Security Authority (LSA) is the security subsystem responsible for all interactive user authentication and authorization services on a local computer. The LSA also processes authentication requests made through the Kerberos V5 protocol or the NTLM protocol in Active Directory.

Once the identity of a user is verified in Active Directory, the LSA on the authenticating domain controller creates a security access token for that user. An access token contains the name of the user, the groups to which that user belongs, a SID for the user, SIDs included in the SIDHistory property and all of the SIDs for the groups to which the user belongs.

The information in the access token is used to determine the level of access a user has to resources whenever the user attempts to access them. The SIDs in the access token are compared with the list of SIDs that make up the discretionary access control list (DACL) on the resource to ensure that the user has sufficient permission to access the resource. This is because the access control process identifies user accounts by SID rather than by name.

### Note

- When a domain controller provides an access token to a user, the access token only contains information about membership in domain local groups if the domain local groups are local to the domain where the domain controller is located.

**User Authorization**

In addition to securing network access through user authentication, Active Directory protects shared resources by facilitating user authorization. Once a user logon has been authenticated by Active Directory, the user rights assigned to the user through security groups and the permissions assigned on the shared resource determine if the user will be authorized to access that resource. This authorization process protects shared resources from unauthorized access and permits access to only authorized users or groups.

Administrators can use access control to manage user access to shared resources for security purposes. In Active Directory, access control is administered at the object level by setting different levels of access, or permissions, to objects, such as Full Control, Write, Read, Delete, or No Access. Access control in Active Directory defines how users can use Active Directory objects. By default, most permissions on objects in Active Directory are at the most secure setting.

The elements that define access control permissions on Active Directory objects include security descriptors and the concept of

object inheritance.

**Security Descriptors**
Access control permissions are assigned to securable objects and Active Directory objects to control how different users can use each object. A securable object, or shared resource, is an object that is intended to be used over a network by one or more users, and includes files, printers, folders, and services. All securable objects and Active Directory objects store access control permissions in security descriptors.

A security descriptor contains two access control lists (ACLs) used to assign and track security information for each object: these are the discretionary access control list (DACL) and the system access control list (SACL).

Discretionary access control lists (DACLs). DACLs identify the users and groups that are assigned or denied access permissions on an object. If a DACL does not explicitly allow access to a user, or to any group that a user is a member of, the user is implicitly denied access to that object. By default, a DACL is controlled by the owner of an object or the person who created the object (In Windows, the creator of an object is also the owner). The DACL contains access control entries (ACEs) that determine user access to the object.

System access control lists (SACLs). SACLs identify the users and groups that you want to audit when they successfully access or fail to access an object. Auditing is used to monitor events related to system or network security, to identify security breaches, and to determine the extent and location of any damage. By default, a SACL is controlled by the owner of an object or the person who created the object. A SACL contains ACEs that determine whether to record a successful or failed attempt by a user to access an object using a given permission, for example, Full Control or Read.

Active Directory allows you to apply access control permissions to objects at very low levels, including the ability to assign permissions on a per-attribute basis. To view DACLs and SACLs on Active Directory objects using Active Directory Users and Computers, on the View menu, click Advanced Features to access the Security tab for each object. You can also use the DSACLS support tool to manage access control lists in Active Directory.

By default, DACLs and SACLs are associated with every Active Directory object, which helps reduce attacks to your network by malicious users or any accidental mistakes made by domain users.

**Computer Accounts**
Each computer account created in Active Directory has a relative distinguished name, a pre-Windows 2000 computer name (Security Accounts Manager account name), a primary DNS suffix, a DNS host name, and a service principal name (SPN). The administrator enters the computer name when creating the computer account. This computer name is used as the LDAP relative distinguished name.

Active Directory suggests the pre-Windows 2000 name using the first 15 bytes of the relative distinguished name. The administrator can change the pre-Windows 2000 name at any time.

The DNS name for a host is called a full computer name and is a DNS fully qualified domain name (FQDN). The full computer name is a concatenation of the computer name (the first 15 bytes of the SAM account name of the computer account without the $ character) and the primary DNS suffix (the DNS domain name of the domain in which the computer account exists). It is listed on the **Computer Name** tab in System Properties in Control Panel.

By default, the primary DNS suffix portion of the FQDN for a computer must be the same as the name of the Active Directory domain where the computer is located. To allow different primary DNS suffixes, a domain administrator might create a restricted list of allowed suffixes by creating the msDS-AllowedDNSSuffixes attribute in the domain object container. This attribute is created and managed by the domain administrator using Active Directory Service Interfaces (ADSI) or LDAP.

The SPN is a multivalue attribute. It is usually built from the DNS name of the host. The SPN is used in the process of mutual authentication between the client and the server hosting a particular service. The client finds a computer account based on the SPN of the service to which it is trying to connect. The SPN can be modified by members of the Domain Admins group.

**Domain and Forest Protocols and Programming Interfaces**
The primary protocol that is used by domain controllers in every domain throughout the forest is LDAP, which runs on top of TCP/IP. LDAP is both a protocol and an API. In addition, the secured communications between domain controllers must use the remote procedure call (RPC) protocol for Messaging Application Programming Interface (MAPI), replication, domain controller management, and SAM-related operations.

**LDAP**
LDAP is a directory service protocol that specifies directory communications. It runs directly over TCP/IP, and it can also run over User Datagram Protocol (UDP) connectionless transports. Clients can use LDAP to query, create, update, and delete information that is stored in a directory service over a TCP connection through the TCP default port 389. Active Directory supports LDAP v2 (RFC 1777) and LDAP v3 (RFC 3377). LDAP v3 is an industry standard that can be used with any directory service that implements the LDAP protocol. LDAP is the preferred and most common way of interacting with Active Directory.

Historically, LDAP is a simplified (lightweight) version of Directory Access Protocol (DAP), which is the original protocol that was used to interact with X.500 directories. X.500 defines an earlier set of standards that was developed by the International Organization for Standardization (ISO). LDAP is simpler than DAP in two key ways:

- Rather than using its own protocol stack according to the Open Systems Interconnection (OSI) networking model, LDAP communicates over Internet Protocol (IP) by using either UDP or TCP.
- LDAP syntax is easier to use than DAP syntax.

For these reasons, LDAP is widely used and accepted as the standard protocol for directory service access. The following key aspects characterize LDAP:

- The protocol is carried directly over TCP for connection-oriented transport (receipt of data is acknowledged) and over UDP for connectionless transport (sent or received data is not acknowledged).
- Most protocol data elements can be encoded as ordinary strings, for example, as distinguished names.
- Referrals to other servers can be returned to the client.
- Simple Authentication and Security Layer (SASL) mechanisms can be used with LDAP to provide associated security services. SASL Digest is supported as the authentication standard for LDAP.
- Attribute values and distinguished names can be internationalized using the ISO 10646 character set.
- The protocol can be extended to support new operations, and controls can be used to extend existing operations.
- The schema is published through an attribute on the directory root object (rootDSE) for use by clients.

For more information about LDAP, see "How Active Directory Searches Work."

**RPC**
Active Directory uses remote procedure call (RPC) for replication (REPL) and domain controller management communications, MAPI communications, and SAM-related communications. RPC is a powerful, robust, efficient, and secure interprocess communication (IPC) mechanism that enables data exchange and invocation of functionality located in a different process. That different process can be on the same computer, on the local area network (LAN), or across the Internet.

**Authentication Protocols**
Domain controllers authenticate users and applications by using one of two protocols: either the Kerberos version 5 authentication protocol or the NTLM authentication protocol. When two Active Directory domains or forests are connected by a trust, authentication requests made using these protocols can be routed to provide access to resources in both forests.

**NTLM**
The NTLM version 2 (NTLMv2) authentication protocol is a challenge/response authentication protocol. It is supported in Windows Server 2008, Windows Vista, Windows Server 2003, Windows 2000, and Windows XP, but it is not the default authentication protocol. Kerberos v5 is the default for these versions except when exchanging communications with a computer running Windows NT Server 4.0 or earlier. Networks with this configuration are referred to as mixed-mode. NTLM is also the authentication protocol for computers that are not participating in a domain, such as stand-alone servers and workgroups.

In Windows 7 and Windows Server 2008 R2, you can restrict the usage of NTLM. For more information see, Introducing the Restriction of NTLM Authentication (http://technet.microsoft.com/en-us/library/dd560653(WS.10).aspx)

When the NTLM protocol is used between a client and a server, the server must contact a domain authentication service on a domain controller to verify the client credentials. The server authenticates the client by forwarding the client credentials to a domain controller in the client account domain.

**Kerberos Version 5 Protocol**
The Kerberos version 5 protocol is the default authentication protocol used by computers running Windows 2000 or later operating system versions. This protocol is specified in RFC 1510 and is fully integrated with Active Directory, server message block (SMB), HTTP, and RPC, as well as the client and server applications that use these protocols. In Active Directory domains, the Kerberos protocol is used to authenticate logons when any of the following conditions is true:

- The user who is logging on uses a security account in an Active Directory domain.
- The computer that is being logged on to has an operating system that is Windows 2000 or later.
- The computer that is being logged on to is joined to an Active Directory domain.
- The computer account and the user account are in the same forest.
- The computer from which the user is trying to access resources is located in a non-Windows-based operating system Kerberos version 5 realm.

If any computer involved in a transaction does not support the Kerberos version 5 protocol, the NTLM protocol is used.

The authentication protocol of choice for Active Directory authentication requests is Kerberos V5. In contrast to NTLM, when the Kerberos protocol is used, the server does not have to contact the domain controller. Instead, the client gets a ticket for a server by requesting one from a domain controller in the server account domain; the server validates the ticket without consulting any other authority.

For more information about Kerberos, see "How the Kerberos Version 5 Authentication Protocol Works."

**Active Directory APIs**
You can use the following application programming interfaces (APIs) to access information in any LDAP directory including Active Directory:

- Active Directory Service Interfaces (ADSI)
- LDAP C API
- REPL
- MAPI
- SAM

**ADSI**
Active Directory Service Interfaces (ADSI) provides a simple, powerful, object-oriented interface to Active Directory. ADSI makes it easy for programmers and administrators to create directory programs by using high-level tools, such as Microsoft Visual Basic, without having to worry about the underlying differences between the different namespaces.

ADSI is supplied as a software development kit that enables you to build or buy programs that give you a single point of access to multiple directories in your network environment, whether those directories are based on LDAP or another protocol. ADSI is fully scriptable for ease of use by administrators.

ADSI also enables access to Active Directory by exposing objects stored in the directory as Component Object Model (COM) objects. A directory object is manipulated using the methods available on one or more COM interfaces. ADSI has a provider-based architecture that allows COM access to different types of directories for which a provider exists.

**LDAP C**
The LDAP C API, defined in Internet standard RFC 1823, is a set of low-level C-language APIs to the LDAP protocol. Microsoft supports LDAP C APIs on all Windows platforms.

Developers have the choice of writing Active Directory-enabled applications using LDAP C APIs or ADSI. LDAP C APIs are most often used to ease portability of directory-enabled applications to the Windows platform. ADSI is a more powerful language and is more appropriate for developers writing directory-enabled code on the Windows platform.

LDAP is the primary interface for the data store. Directory clients use LDAP v3 to connect to the DSA through the LDAP interface. The LDAP interface is part of Wldap32.dll. LDAP v3 is backward compatible with LDAP v2.

**REPL**
The REPL management interface provides functionality for finding data about domain controllers, converting the names of network objects between different formats, manipulating SPNs and DSAs, and managing replication of servers.

**MAPI**
Messaging clients gain access to the Microsoft Exchange Server directory service by using MAPI address book providers. For compatibility with existing messaging clients, Active Directory supports the MAPI-RPC address book provider, which provides access to Active Directory, for example, to find the telephone number of a user.

**SAM**
Security Accounts Manager (SAM) is a proprietary interface for connecting to the DSA on behalf of clients that use Windows NT 4.0 or earlier. These clients use Windows NT 4.0 networking APIs to connect to the DSA through SAM. Replication with Windows NT 4.0 backup domain controllers (BDCs) goes through the SAM interface as well.

**Domain and Forest Processes and Interactions**
Many network related operations depend on domains and forests in order to complete various tasks. This section describes some of the processes and interactions that commonly occur within the boundaries of domains or forests.

**Logging on to a Domain**
When a user with an account in an Active Directory domain logs on at the keyboard of a computer running a Windows 2000 or later operating system, the logon request is processed in three stages:

1. The user requests admission to the ticket-granting service for the domain.

   This is accomplished through an Authentication Service (AS) Exchange between the Kerberos security support provider (SSP) on the computer and the Key Distribution Center (KDC) in the domain in which the user account exists. The result is a ticket-granting ticket (TGT) that the user can present in future transactions with this KDC.

2. The user requests a ticket for the computer.

   This is accomplished through a Ticket-Granting Service (TGS) Exchange between the Kerberos SSP on the computer and the KDC for the domain in which the computer account exists. The result is a session ticket that the user can present when he or she requests access to system services on the computer.

3. The user requests admission to Local System services on the computer.

   This is accomplished when the Kerberos SSP on the computer presents a session ticket to the LSA on the computer.

If the account domain of the computer is different from the account domain of the user, an extra step is involved. Before the Kerberos SSP can request a session ticket for the computer, it must ask the KDC in the domain where the user account exists for a TGT that is good for admission to the KDC in the domain where the computer account exists. The SSP can then present the TGT to the KDC in the domain of the computer and get a session ticket for the computer.

The precise steps in the logon process depend on how the computer is configured. With standard configurations of Windows, interactive users log on with a password. In another optional configuration of Windows, users log on with a smart card. Although the basic process is the same for both configurations, there are some differences. For more information about the domain logon process, see "How Interactive Logon Works."

**Processing Authentications Across Domains and Forests**
When a request for authentication is referred to a domain, before the domain controller in that domain authenticates the user to access resources in the domain, it must determine whether a trust relationship exists with the domain from which the request comes, as well as the direction of the trust and whether the trust is transitive or nontransitive. The authentication process between trusted domains varies according to the authentication protocol in use. The Kerberos version 5 and NTLM protocols in Windows 2000 Server, Windows Server 2003, Windows Server 2008, and Window Server R2, process referrals for authentication to a domain differently, as do other authentication protocols, such as Digest and SChannel, that Windows 2000 Server, Windows Server 2003, Windows Server 2008, and Window Server R2 support.

In an Active Directory environment the Kerberos-based authentication process is most commonly used. To access a shared resource in another domain by using Kerberos authentication, a computer where the user logs on first requests a ticket from a domain controller in its account domain to the server in the trusting domain that hosts the requested resource. This ticket is then issued by an intermediary trusted by both the requesting computer and the server. The computer then presents this trusted ticket to the server in the trusting domain for authentication. This process, however, becomes more complex when a workstation in one forest attempts to access data on a resource computer in another forest.

In this case, the Kerberos authentication process contacts the domain controller for a service ticket to the SPN of the resource computer. Once the domain controller queries the global catalog and determines that the SPN is not in the same forest as the domain controller, the domain controller sends a referral for its parent domain back to the workstation. At that point, the

workstation queries the parent domain for the service ticket and continues to follow the referral chain until it reaches the domain where the resource is located. For more detailed information about how authentication requests are processed across domains and forests, see "How Domain and Forest Trusts Work."

**Joining a Computer to a Domain**

Joining a computer to a domain creates the computer account object for the client in an Active Directory location where all computer accounts are created by default during a join operation. The default location is set to the **Computers** container in Active Directory. A computer account differs from a user account in that it identifies the computer to the domain, while a user account identifies a user to a computer.

The act of joining a computer to a domain creates an account for the computer on the domain if it does not already exist. When you join a client computer running Windows 2000 or later, the following events occur:

- The domain name is validated.
- A domain controller in the domain is located through a call to the DsGetDcName API.
- A session is established with the domain controller under the security context of the passed-in credentials that are supplied in the **Network Identification** tab under **System Properties** in **Control Panel**.
- The computer account is enabled. If the flags so specify (NETSETUP_ACCT_CREATE), the APIs create the computer account on the domain controller.
- The local password for this account is created in the Local Security Authority (LSA).
- The local primary domain information LSA policy is set to refer to the new domain. This includes the domain name and the domain SID.

  **Note**

  - For clients running Windows 2000 or later, the LSA policy consists of the domain name, domain SID, DNS domain name, DNS forest name, and domain GUID.
- The DNS name assigned to the local computer is updated.
- The local group membership is changed to add members of the Domain Admins group to the Local Accounts Administrators group.
- The Net Logon trusted domain cache is initialized to the trusted domains domain list.
- For clients running Windows 2000 or later, the Windows Time Service is enabled and started.
- The Net Logon service is started.

To join a workstation or member server to a domain, you can use the Netdom tool. For example, to join a workstation to the Wingtiptoys.com domain in the engineering organizational unit, type the following command at the workstation:

**Netdom join /d:wingtiptoys.com /OU:OU=engineering,DC=wingtiptoys,DC=com**

When a computer joins a domain, the following changes occur on domain controllers running Windows 2000 Server, Windows Server 2003, Windows Server 2008 and Window Server 2008 R@:

- A computer object is created. The name of this object is generated by appending a dollar sign ($) to the name (uppercase letters) of the client.
- On Windows 2000 Server and later versions of Microsoft Server operating systems–based domain controllers only, the Net Logon service creates SPNs on the computer object.

**Netsetup.log**

When joining a computer to an Active Directory domain, the Networking Setup (NetSetup) utility installs all the necessary Microsoft supported networking components. The Netsetup.log file provides information about attempts to join domains and records any errors that might prevent the join operation from succeeding.

**Registering DNS Names and Locating Domain Controllers**
When a Windows 2000 Server and later versions of Microsoft Server operating systems –based member server is promoted to a domain controller by installing Active Directory, the Net Logon service registers the DNS resource records necessary for network hosts and services to locate the domain controller on the network. When network hosts and services attempt an operation (such as joining a domain) that requires a domain controller, the locator mechanism attempts to locate the domain controller through DNS.

DNS is used because every Active Directory–based domain controller dynamically registers SRV records in DNS. The SRV records enable servers to be located by service type (for example, LDAP) and protocol (for example, TCP). Because domain controllers are LDAP servers that communicate over TCP, SRV records can be used to find the DNS computer names of domain controllers. In addition to registering LDAP-specific SRV records, Net Logon also registers Kerberos v5 authentication protocol–specific SRV records to enable locating servers that run the Kerberos Key Distribution Center (KDC) service.

Domain controllers not only register their DNS domain names on a DNS server, but also register their NetBIOS names by using a transport-specific mechanism (for example, WINS). Thus, a DNS client locates a domain controller by querying DNS, and a NetBIOS client locates a domain controller by querying the appropriate transport-specific name service. The domain controller locator service consists of two main parts:

- Locator finds which domain controllers are registered with a DNS server.
- Locator submits a DNS query to the DNS server to locate a domain controller in the specified domain.

After this query is resolved, an LDAP User Datagram Protocol (UDP) lookup is sent to one or more of the domain controllers listed in the response to the DNS query to ensure their availability. Finally, the Net Logon service caches the discovered domain controller to aid in resolving future requests.

For more information about the DC Locator process, see "How DNS Support for Active Directory Works."

**Raising Domain and Forest Functional Levels**
When Active Directory is installed on a server, a set of basic Active Directory features is enabled by default. In addition to the basic Active Directory features on individual domain controllers, there are new domain- and forest-wide Active Directory features available when all domain controllers in a domain or forest are running Windows Server 2003. This also holds true for Windows Server 2008 and Windows Server 2008 R2.

To enable the new domain-wide features, all domain controllers in the domain must be running Windows Server 2003, and the domain functional level must be raised to Windows Server 2003. To enable new forest-wide features, all domain controllers in the forest must be running Windows Server 2003, and the forest functional level must be raised to Windows Server 2003. The same is true for Windows Server 2008 and Windows Server 2008 R2.

Before raising the forest functional level to Windows Server 2003, verify that all domains in the forest are set to the domain functional level of Windows 2000 native or Windows Server 2003. Note that domains that are set to the domain functional level of Windows 2000 native will automatically be raised to Windows Server 2003 at the same time the forest functional level is raised to Windows Server 2003. For more detailed information about Windows Server 2008 and Windows Server 2008 R2 functional levels, see the "How Active Directory Functional Levels Work."

**Replicating Directory Partitions**
Active Directory uses RPC over IP to transfer replication data between domain controllers. RPC over IP is used for both intersite and intrasite replication. To keep data secure while in transit, RPC over IP replication uses both authentication (using the Kerberos V5 authentication protocol) and data encryption.

When a direct or reliable IP connection is not available, replication between sites can be configured to use the Simple Mail Transfer Protocol (SMTP). However, SMTP replication functionality is limited, and requires an enterprise certification authority (CA). SMTP can only be used to replicate the configuration, schema and application directory partitions, and does not support the replication of domain directory partitions. For more detailed information about the replication process, see "How Active Directory Replication Topology Works."

**Network Ports Used by Domains and Forests**
The following tables list the network ports that are associated with domains and forests.

### Port Assignments for Raising Active Directory Functional Levels

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |
| LDAP SSL | N/A | 636 |

**Port Assignments for Data Store**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |
| LDAP SSL | N/A | 636 |
| RPC Endpoint Mapper | 135 | 135 |
| Global Catalog LDAP | N/A | 3268 |
| Global Catalog LDAP SSL | N/A | 3269 |

**Port Assignments for Service Publication and SPNs**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |
| LDAP SSL | N/A | 636 |
| RPC Endpoint Mapper | 135 | 135 |
| Global Catalog LDAP | N/A | 3268 |
| Global Catalog LDAP SSL | N/A | 3269 |
| Kerberos | 88 | 88 |

**Port Assignments for Raising Active Directory Searches**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |
| LDAP SSL | N/A | 636 |
| Global Catalog LDAP | N/A | 3268 |
| Global Catalog LDAP SSL | N/A | 3269 |

**Port Assignments for Global Catalogs**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | N/A | 3268 |
| LDAP | N/A | 3269 (global catalog Secure Sockets Layer [SSL]) |
| LDAP | 389 | 389 |
| LDAP | N/A | 686 (SSL) |
| RPC/REPL | 135 | 135 (endpoint mapper) |
| Kerberos | 88 | 88 |
| DNS | 53 | 53 |

| | | |
|---|---|---|
| SMB over IP | 445 | 445 |

**Port Assignments for Replication**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |
| LDAP | N/A | 686 (SSL) |
| RPC/REPL | N/A | 135 (endpoint mapper) |
| LDAP | N/A | 3268 |
| Kerberos | 88 | 88 |
| DNS | 53 | 53 |
| SMB over IP | 445 | 445 |

**Port Assignments for Operations Masters**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |
| LDAP | N/A | 686 (SSL) |
| RPC/REPL | N/A | 135 (endpoint mapper) |
| Netlogon | N/A | 137 |
| Kerberos | 88 | 88 |
| DNS | 53 | 53 |
| SMB over IP | 445 | 445 |

**Port Assignments for Interactive Logon**

| Service Name | UDP | TCP |
|---|---|---|
| Kerberos | 88 | 88 |
| Local Security Authority (LSA) RPC | Dynmaic RPC | Dynamic RPC |
| NTLM | Dynamic | Dynamic |

**Port Assignments for Kerberos V5 Protocol**

| Service Name | UDP | TCP |
|---|---|---|
| DNS | 53 | 53 |
| Kerberos | 88 | 88 |

**Port Assignment for DC Locator**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |

The following table shows the list of ports that might need to be opened before you establish trusts.

**Ports Required for Trusts**

| Task | Outbound Ports | Inbound Ports | From–To |
|---|---|---|---|
| Set up trusts on both sides from the internal forest | LDAP (389 UDP and TCP)<br><br>Microsoft SMB (445 TCP)<br><br>Kerberos (88 UDP)<br><br>Endpoint resolution — portmapper (135 TCP)<br>Net Logon fixed port | N/A | Internal domain domain controllers–External domain domain controllers (all ports) |
| Trust validation from the internal forest domain controller to the external forest domain controller (outgoing trust only) | LDAP (389 UDP)<br><br>Microsoft SMB (445 TCP)<br><br>Endpoint resolution — portmapper (135 TCP)<br>Net Logon fixed port | N/A | Internal domain domain controllers–External domain domain controllers (all ports) |
| Use Object picker on the external forest to add objects that are in an internal forest to groups and DACLs | N/A | LDAP (389 UDP and TCP)<br><br>Windows NT Server 4.0 directory service fixed port<br><br>Net Logon fixed port<br><br>Kerberos (88 UDP)<br><br>Endpoint resolution portmapper (135 TCP) | External server–Internal domain PDCs (Kerberos)<br><br>External domain domain controllers–Internal domain domain controllers (Net Logon) |
| Set up trust on the external forest from the external forest | N/A | LDAP (389 UDP and TCP)<br><br>Microsoft SMB (445 TCP)<br><br>Kerberos (88 UDP) | External domain domain controllers–Internal domain domain controllers (all ports) |
| Use Kerberos authentication (internal forest client to external forest) | Kerberos (88 UDP) | N/A | Internal client–External domain domain controllers (all ports) |
| Use NTLM authentication (internal forest client to external forest) | N/A | Endpoint resolution – portmapper (135 TCP)<br>Net Logon fixed port | External domain domain controllers–Internal domain domain controllers (all ports) |

| | | | |
|---|---|---|---|
| Join a domain from a computer in the internal network to an external domain | LDAP (389 UDP and TCP)<br><br>Microsoft SMB (445 TCP)<br><br>Kerberos (88 UDP)<br><br>Endpoint resolution — portmapper (135 TCP) Net Logon fixed port<br><br>Windows NT Server 4.0 directory service fixed port | N/A | Internal client–External domain domain controllers (all ports) |

# Domains and Forests Tools and Settings

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Tools for Managing Domains and Forests
- Domains and Forests Registry Entries
- Domains and Forests Group Policy Settings
- Domains and Forests WMI Classes
- Network Ports Used by Domains and Forests
- Related Information

Administrators can use a number of methods to configure and manage Active Directory domain and forest environments. This section contains information about the tools, registry entries, Group Policy settings, Windows Management Instrumentation (WMI) classes, and network ports that are associated with Active Directory domains and forests.

**Note**

- When using Windows Server 2003 Active Directory administrative tools to connect to a domain controller running Windows 2000 you must first make sure that the Windows 2000–based domain controller to which you are connecting has Service Pack 3 or later installed. This is because Windows Server 2003 administrative tools sign and encrypt all LDAP traffic by default. If business reasons do not permit the installation of Service Pack 3 or later on domain controllers running Windows 2000 it is possible to disable this default behavior.

**Tools for Managing Domains and Forests**

The following tools are associated with domains and forests.

**Adsiedit.exe: ADSI Edit**

**Category**

ADSI Edit is included when you install Windows Server 2003 Support Tools.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

ADSI Edit is a Microsoft Management Console (MMC) tool that uses Active Directory Service Interfaces (ADSI), which ultimately uses the LDAP protocol. This tool can be used to view and modify directory objects in the Active Directory database.

To find more information about ADSI Edit, see "Adsiedit Overview."

**Csvde.exe: Csvde**

**Category**
Csvde is a command-line tool that ships with Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Csvde to import and export data from Active Directory by using files that store data in the comma-separated value (CSV) file format. Csvde also supports batch operations that are based on CSV.

To find more information about Csvde, see Command-Line References in the "Tools and Settings Collection."

**Dcdiag.exe: Domain Controller Diagnostic Tool**

**Category**
The Domain Controller Diagnostic Tool command-line tool (Dcdiag) is included when you install the Windows Server 2003 Support Tools.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional with Adminpak.msi installed | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use the Domain Controller Diagnostic Tool to verify external trusts. This tool cannot be used to verify trust relationships based on the Kerberos version 5 authentication protocol; to verify Kerberos V5-based trust relationships, the recommended method is to use the Netdom tool. Using the Domain Controller Diagnostic Tool you can scope your external trust verification by site or by domain controller, check for trust establishment, check secured channel setup, and check for ticket validity between each pair of domain controllers. By default, errors are flagged. In verbose mode, successes are printed as well.

You can use the Domain Controller Diagnostic Tool to verify that there are sufficient resources for the DNS infrastructure when deploying the Windows 2000 Server or Windows Server 2003 Active Directory directory service. This tool analyzes the state of domain controllers in a forest or enterprise and reports any problems to assist in troubleshooting. As an end-user reporting program, the Domain Controller Diagnostic Tool queries the directory service infrastructure and uses the results to identify abnormal behavior in the system. The Domain Controller Diagnostic Tool provides a framework for executing tests to verify different functional areas of the system. This framework selects which domain controllers are tested according to scope directives from the user, such as enterprise, site, or single server.

**Dcpol.msc: Domain Controller Security Policy**

**Category**
Domain Controller Security Policy is a snap-in for MMC and is automatically installed when you install Active Directory. You can also use Domain Controller Security Policy on computers not running Active Directory by installing the Administration Tools Pack (Adminpak.msi).

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can set security settings for a domain controller in Domain Controller Security Policy.

For more information about Domain Controller Security Policy, see Help and Support Center in Windows Server 2003.

**Dcpromo.exe: Active Directory Installation Wizard**

**Category**
An Active Directory wizard that is included with Windows Server 2003 and is available from the command line or from the Configure Your Server Wizard on any computer running Windows Server 2003.

**Version compatibility**
This tool is compatible with computers running Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition, and Windows Server 2003, Datacenter Edition.

The Active Directory Installation Wizard provides a graphical user interface for setting up a domain controller by installing Active Directory and, optionally, DNS. The Active Directory Installation Wizard can also be used on a Windows NT 4.0 primary domain controller (PDC) when upgrading it to Windows Server 2003 and forming a new forest, to raise the forest functional level to Windows Server 2003 interim, if appropriate.

**Domain.msc: Active Directory Domains and Trusts**

**Category**
An Active Directory Administrative Tools MMC snap-in that is automatically installed on all domain controllers running Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional with Adminpak.msi installed | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

**Note**

- You cannot run the Windows Server 2003 Administration Tools Pack (Adminpak.msi) on a computer that is running Windows XP Professional, Windows XP Home Edition, or Windows XP 64-Bit Edition Version 2003 without Windows XP Service Pack 1 (SP1).

Active Directory Domains and Trusts provides a graphical interface in which you can view all domains in the forest. Using this tool, an administrator can manage each of the domains in the forest, trust relationships between domains, configure the functional level for each domain or forest, and configure the alternative user principal name (UPN) suffixes for a forest.

Active Directory Domains and Trusts can be used to accomplish most trust related tasks. It can be used to target all Active Directory domain controllers and can verify all Active Directory trust types. Trust verification takes place between two domains by enumerating all of the domain controllers in each domain. If you choose to have Active Directory Domains and Trusts create both sides of the trust at once, the trust password is automatically generated.

For more information about Active Directory Domains and Trusts, see Help in Active Directory Domains and Trusts.

**Dompol.msc: Domain Security Policy**

**Category**
Domain Security Policy is a snap-in for MMC and is automatically installed when you install Active Directory. You can also use Domain Controller Security Policy on computers not running Active Directory by installing the Administration Tools Pack (Adminpak.msi).

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

Security settings for a domain are set in Domain Security Policy. Group Policy settings can be applied to lock-down which users are allowed to log on to the server as well as who can access the server from the network.

For more information about Domain Security Policy, see Help and Support Center in Windows Server 2003.

**Dsa.msc: Active Directory Users and Computers**

**Category**
An Active Directory Administrative Tools MMC snap-in that is automatically installed on all Windows Server 2003 domain controllers running Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional with Adminpak.msi installed | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

Active Directory Users and Computers provides a graphical user interface that can be used to manage users and computers in Active Directory domains.

Additionally, LDAP Query can be used in this tool for the following:

- To identify domain controllers running Windows NT 4.0
- To connect to a domain

**Dsadd.exe: Dsadd**

**Category**
Dsadd is a command-line tool that ships with Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Dsadd to add specific types of objects to the directory.

To find more information about Dsadd, see Command-Line References in the "Tools and Settings Collection."

**Dsget.exe: Dsget**

**Category**
Dsget is a command-line tool that ships with Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Dsget to display the selected properties of a specific object in the directory.

- To find more information about Dsget, see Command-Line References in the "Tools and Settings Collection."

**Dsmod.exe: Dsmod**

**Category**
Dsmod is a command-line tool that ships with Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Dsmod to modify an existing object of a specific type in the directory.

To find more information about Dsmod, see Command-Line References in the "Tools and Settings Collection."

**Dsmove.exe: Dsmove**

**Category**
Dsmove is a command-line tool that ships with Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Dsmove to move a single object in a domain from its current location in the directory to a new location. You can also use Dsmove to rename a single object without moving it in the directory tree.

To find more information about Dsmove, see Command-Line References in the "Tools and Settings Collection."

**Dsquery.exe: Dsquery**

**Category**
Dsquery is a command-line tool that ships with Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Dsquery to perform searches against Active Directory according to specified criteria. To find more information about Dsquery, see Command-Line References in the "Tools and Settings Collection."

**Dsrm.exe: Dsrm**

**Category**
Dsrm is a command-line tool that ships with Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Dsrm to delete an object of a specific type, or any general object, from the directory.

To find more information about Dsrm, see Command-Line References in the "Tools and Settings Collection."

**Dssite.msc: Active Directory Sites and Services**

**Category**
An Active Directory Administrative Tools MMC snap-in that is automatically installed on all Windows Server 2003 domain controllers running Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional with Adminpak.msi installed | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Active Directory Sites and Services to create, modify, and delete site configuration objects in Active Directory, including sites, subnets, connection objects, and site links. You can also use Active Directory Sites and Services to create the intersite topology, including mapping subnet addresses to sites, creating and configuring site links, creating manual connection objects, forcing replication over a connection, setting a domain controller to be a global catalog server, and selecting preferred bridgehead servers.

For more information about Active Directory Sites and Services, see Help and Support Center in Windows Server 2003.

**Ldifde.exe: Ldifde**

**Category**
Ldifde is a command-line tool that ships with Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Ldifde to create, modify, and delete directory objects on domain controllers. You can also use Ldifde to extend the schema, export Active Directory user and group information to other applications or services, and populate Active Directory with data from other directory services.

To find more information about Ldifde, see Command-Line References in the "Tools and Settings Collection."

**Ldp.exe: Ldp**

**Category**
Ldp is included when you install Windows Server 2003 Support Tools.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

Ldp is a Lightweight Directory Access Protocol (LDAP) graphical user interface (GUI) tool that you can use to perform operations such as connect, bind, search, modify, add, and delete against any LDAP-compatible directory, such as Active Directory. You can also use Ldp to view objects that are stored in Active Directory, along with their metadata, such as security descriptors and replication metadata.

To find more information about Ldp, see "Windows Support Tools."

**Netdiag.exe: Network Connectivity Tester**

**Category**
The Network Connectivity Tester command-line tool (Netdiag) is included when you install Windows Server 2003 Support Tools.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional with Adminpak.msi installed | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

The Netdiag command-line tool examines .dll files, output from other tools, and the system registry to find potential problems. You can use Netdiag to troubleshoot connectivity over the secured channel that exists between a workstation and a domain controller.

For the various trust related tasks that can be performed using this tool, see the table Trust Tools Comparison by Task earlier in this section. To find more information about Netdiag, see "Windows Support Tools."

**Netdom.exe: Windows Domain Manager**

**Category**
The Windows Domain Manager command-line tool (Netdom) is included when you install Windows Server 2003 Support Tools.

**Version compatibility**
This tool is compatible with computers running Windows XP Professional; Windows Server 2003, Standard Edition; Windows Server 2003, Web Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Netdom is a command-line tool that allows you to create and manage Active Directory trust relationships (except forest trusts) and can help reduce the number of steps needed to create a trust by using Active Directory Domains and Trusts. You can also use the Netdom command line tool to complete batch management of trusts, join computers to domains, verify trusts (including forest trusts) and secured channels, and obtain information about the status of trusts.

Netdom can be targeted at all Active Directory domain controllers and can verify all Active Directory trust types. Verification is accomplished between two domains by enumerating the domain controllers in each domain. If you choose to have Netdom create both sides of the trust at once the trust password is automatically generated.

To find more information about Netdom, see "Windows Support Tools."

**Nltest.exe: NLTest**

**Category**
The NLTest command-line tool is included when you install Windows Server 2003 Support Tools.

**Version compatibility**
This tool is compatible with computers running Windows XP Professional; Windows Server 2003, Standard Edition; Windows Server 2003, Web Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

You can use the NLTest command-line tool to perform trust-related network administrative tasks such as testing the trust relationship between a Windows–based computer that is a member of a domain and the domain controller on which its

computer account is located. In domains where an external trust is defined, NLTest can be used to test the trust relationship between all domain controllers in the trusting domain and a domain controller in the trusted domain. Nltest can also be used to verify any secured channel.

To find more information about NLTest, see "Windows Support Tools."

**Ntdsutil.exe: Ntdsutil**

**Category**
Ntdsutil is a command-line tool that ships with Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition |

Ntdsutil.exe provides management capabilities for Active Directory. You can use Ntdsutil.exe to perform Active Directory database maintenance, manage and control single-master operations, and remove replication metadata left behind by domain controllers that are removed from the network without uninstalling Active Directory. You can also use Ntdsutil to create application directory partitions and perform authoritative restore operations. This tool is intended for use by experienced administrators.

To find more information about Ntdsutil, see Command-Line References in the "Tools and Settings Collection."

**Repadmin: Repadmin**

**Category**
Repadmin is included when you install Windows Server 2003 Support Tools.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

Administrators can use Repadmin to monitor and manage replication between domain controllers. You can determine the last successful replication of all directory partitions, identify inbound and outbound replication partners, identify the current bridgehead servers, view object metadata, and generally manage Active Directory replication topology. You can use Repadmin to force replication of an entire directory partition or of a single object. You can also list domain controllers in a site.

To find more information about Repadmin, at a command prompt type **repadmin /?** or see Command-Line References in the Tools and Settings Collection.

**Schmmgmt.msc: Active Directory Schema**

**Category**
An Active Directory Administrative Tools MMCsnap-in that is automatically installed on all domain controllers running Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional with Adminpak.msi installed | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

Active Directory Schema is a graphical user interface that can be used to manage Active Directory objects and their associated attributes. The Active Directory Schema snap-in allows members of the Schema Admins group to manage the schema through a graphical interface. You can create and modify classes and attributes and also specify what attributes are indexed and what attributes are replicated to the Global Catalog. The tool should only be used in a test environment because it does not permit the user to set some important values on new schema objects.

Before the snap-in can be used, it must be registered so that it appears as an available snap-in for MMC.

**Setspn.exe: Setspn**

**Category**
Setspn is included when you install Windows Server 2003 Support Tools.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

Administrators can use this command-line tool to read, modify, and delete values in the **servicePrincipalNames** attribute on an Active Directory service account object.

To find more information about Setspn, see "Windows Support Tools."

**Domains and Forests Registry Entries**

The following registry entries are associated with domains and forests.

- For data store related registry entries, see "Data Store Tools and Settings."
- For global catalog related registry entries, see "Global Catalog Tools and Settings."
- For replication related registry entries, see "Active Directory Replication Tools and Settings."
- For logon related registry entries, see "Interactive Logon Tools and Settings."
- For Kerberos related registry entries, see "Kerberos Authentication Tools and Settings."
- For Access Token related registry entries, see "Access Tokens Tools and Settings."

**Domains and Forests Group Policy Settings**

The following tables list and describe the Group Policy settings that are associated with domains and forests.

**Group Policy Settings Associated with Data Store**

| Group Policy Setting | Description |
|---|---|
| Audit Directory Services Access | When it is enabled, this Group Policy setting causes successful and failed directory access events to be logged in the Directory Service event log. |

**Group Policy Settings Associated with Active Directory Searches**

| Group Policy Setting | Description |
| --- | --- |
| Maximum size of Active Directory searches | Specifies the maximum number of objects that the system displays in response to a command to browse or search Active Directory.<br><br>This policy affects all browse displays that are associated with Active Directory, such as those in Local Users and Groups, Active Directory Users and Computers, and dialog boxes that are used to set permissions for user or group objects in Active Directory.<br><br>If you enable this policy, you can use it to limit the number of objects that are returned from an Active Directory search.<br><br>If you disable this policy or if you do not configure it, the system displays up to 10,000 objects. |
| Enable filter in Find dialog box | Displays the filter bar above the results of an Active Directory search. The filter bar consists of buttons for applying additional filters to search results.<br><br>If you enable this policy, the filter bar appears when the Active Directory **Find** dialog box opens, but users can hide it. |
| Hide Active Directory folder | Hides the Active Directory folder in My Network Places.<br><br>The Active Directory folder displays Active Directory objects in a browse window.<br><br>If you enable this policy, the Active Directory folder does not appear in the My Network Places folder.<br><br>If you disable this policy or if you do not configure it, the Active Directory folder appears in the My Network Places folder. |

**Group Policy Settings Associated with Global Catalogs**

| Group Policy Setting | Description |
| --- | --- |
| Automated Site Coverage by the DC Locator DNS SRV Records | Determines whether domain controllers dynamically register DC Locator site-specific SRV resource records for the closest sites where no domain controller for the same domain exists (or no global catalog server for the same forest exists). These DNS records are dynamically registered by the Net Logon service, and they are used to locate domain controllers. |
| Sites Covered by the GC Locator DNS SRV Records | Specifies the sites for which global catalog servers should register the site-specific GC Locator SRV resource records in DNS. These records are registered in addition to the site-specific SRV resource records registered for the site where the global catalog server is located and, if the global catalog server is appropriately configured, for the sites without a global catalog server in the same forest for which this global catalog server is the closest global catalog server. These records are registered by Net Logon service.<br><br>If this policy is not configured, it is not applied to any global catalog servers and global catalog servers use their local configuration. |

**Group Policy Settings Associated with Replication**

| Group Policy Setting | Description |
| --- | --- |

| | |
|---|---|
| Account Lockout Policy:<br>• Account lockout duration<br>• Account lockout threshold<br>• Reset account lockout counter after | Changes to these settings in the Domain Security Policy trigger urgent replication. |
| Password Policy:<br>• Enforce password history<br>• Maximum password age<br>• Minimum password age<br>• Minimum password length<br>• Password must meet complexity requirements<br>• Store passwords using reversible encryption | Changes to these settings in the Domain Security Policy trigger urgent replication. |
| Contact PDC on logon failure | Account lockout and domain password changes rely on contacting the primary domain controller (PDC) emulator urgently to update the PDC emulator with the change. If Contact PDC on logon failure is disabled, replication of password changes to the PDC emulator occurs non-urgently. |

**Group Policy Settings Associated with Interactive Logon**

| Group Policy Setting | Description |
|---|---|

| | |
|---|---|
| Password Policy:<br>• Enforce password history<br>• Maximum password age<br>• Minimum password age<br>• Minimum password length<br>• Password must meet complexity requirements<br>• Store password using reversible encryption for all users in the domain | Changes to the Password Policy settings control:<br>• The strength and complexity required of the password of every user |
| Audit Policy:<br>• Audit account logon events<br>• Audit account management<br>• Audit logon events | Changes to the Audit Policy settings control:<br>• Auditing of logons and log offs<br>• Auditing of password and permissions changes |
| User Rights Assignment:<br>• Access the computer from the network<br>• Deny logon as a batch job<br>• Deny logon as a service<br>• Deny logon locally<br>• Deny logon through terminal services<br>• Logon as a batch job<br>• Logon as a service<br>• Logon locally | Changes to the User Rights Assignment settings control:<br>• Which users are allowed or disallowed to log on to perform different tasks, including logging on as a batch job and a service<br>• Which users are allowed or disallowed to logon locally or through terminal services, as well as who can or cannot access the computer from the network |

| | |
|---|---|
| Security Options:<br>• Accounts: Limit local accounts use of blank passwords to console logon only<br>• Domain member: Maximum machine account password age<br>• Domain member: Require strong (in Windows 2000 or later) session key<br>• Interactive logon: Do not display last user name<br>• Interactive logon: Do not require CTRL+ALT+DEL<br>• Interactive logon: Message Text for users attempting to log on<br>• Interactive logon: Message title for users attempting to log on<br>• Interactive logon: Number of previous logons to cache (in case the domain controller is not available)<br>• Interactive logon: Require domain controller authentication to unlock workstation<br>• Interactive logon: Smart card removal behavior<br>• Recovery console: Allow automatic administrative logon<br>• Shutdown: Allow system to be shut down without having to log on | Changes to the Security Options settings control:<br>• Message text and title displayed by the GINA during an interactive logon<br>• Domain member settings<br>• Authentication settings, including allowing or disallowing blank passwords and password age |

**Group Policy Settings Associated with Access Tokens**

| **Group Policy Setting** | **Description** |
|---|---|
| User Rights Assignment:<br>• Create a token object<br>• Replace a process level token | Changes to these settings control:<br>• Calling APIs to create tokens.<br>• Whether a process can replace a token. |

| | |
|---|---|
| Audit Policy:<br>• Audit policy change<br>• Audit privilege use<br>• Audit process tracking | Changes to this setting will:<br>• Generate audits when rights are assigned with one of the tools discussed earlier.<br>• Enable audit privilege use. Will log when SeAssignPrimaryTokenPrivilege was used.<br>• Create an audit for assigning a primary token that contains the two processes involved and the identity of the token assigned. |
| Security Options:<br>• Network access: Let Everyone permissions apply to anonymous users | Changes to this setting affect whether Everyone is in the token for anonymous users. |

**Group Policy User Rights Assignment Settings Associated with Kerberos**

| Group Policy Setting | Description |
|---|---|
| Impersonate a client after authentication | Windows 2000 security setting that was first introduced in Windows 2000 SP4. When you assign this user right to a user, you permit programs that run on behalf of that user to impersonate a client. This security setting helps to prevent unauthorized servers from impersonating clients that connect to it through methods such as remote procedure calls (RPC) or named pipes.<br>By default, members of the Administrators group and the System account are assigned this user right. The following components also are assigned this user right:<br>• Services that are started by the Service Control Manager<br>• Component Object Model (COM) servers that are started by the COM infrastructure and that are configured to run under a specific account |

**Group Policy Kerberos Policy Settings Associated with Kerberos**

| Group Policy Setting | Description |
|---|---|
| Enforce user logon restrictions | Determines whether the KDC validates every request for a session ticket against the user rights policy on the target computer. When this policy is enabled, the user requesting the session ticket must have the right to either Log on locally or to Access this computer from network. Validation of each request is optional because the extra step takes time and might slow network access to services. By default, this policy is enabled. |
| Maximum lifetime for service ticket | Determines the maximum amount of time (in minutes) that a ticket granted for a service (that is, a session ticket) can be used to access the service. If the setting is zero minutes, the ticket never expires. Otherwise, the setting must be greater than ten minutes and less than the setting for Maximum lifetime for user ticket. By default, the setting is 600 minutes (10 hours). |
| Maximum lifetime for user ticket | Determines the maximum amount of time (in hours) that a ticket-granting ticket (TGT) for a user can be used. When a TGT expires, a new one must be requested or the existing one must be renewed. By default, the setting is ten hours. |
| Maximum lifetime for user ticket renewal | Determines the longest period of time (in days) that a TGT can be used if it is repeatedly renewed. By default, the setting is seven days. |

| | |
|---|---|
| Maximum tolerance for computer clock synchronization | Determines the maximum difference (in minutes) that the Kerberos V5 protocol tolerates between the clock time on a client and the clock time on a server while still considering the two clocks synchronous. By default, the setting is five minutes. |

To find more information about these Group Policy settings, see Group Policy Settings Reference in the "Tools and Settings Collection" or see "Account Policy Settings."

**Domains and Forests WMI Classes**

Windows Management Instrumentation (WMI) provides access to information about certain objects in a Windows 2000 Server or Windows Server 2003 operating system. WMI providers and classes represent the managed resources on a computer and are used by administrators and developers for scripting and monitoring purposes. The following tables list and describe the WMI classes that are associated with Active Directory domains and forests.

**WMI Classes Associated with Data Store, Service Principal Names (SPNs) and Active Directory Searches**

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| **rootDSE** | root\directory\LDAP | Domain controllers running:<br>• Windows Server 2003<br>• Windows 2000 Server |
| **DS_LDAP_Class_Containment** | root\directory\LDAP | Domain controllers running:<br>• Windows Server 2003<br>• Windows 2000 Server |
| **DS_LDAP_Instance_Containment** | root\directory\LDAP | Domain controllers running:<br>• Windows Server 2003<br>• Windows 2000 Server |

**WMI Classes Associated with Active Directory Replication**

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| **MSAD_DomainController** | \\root\MicrosoftActiveDirectory | Domain controllers running:<br>• Windows Server 2003<br>• Windows 2000 Server |
| **MSAD_NamingContext** | \\root\MicrosoftActiveDirectory | Domain controllers running:<br>• Windows Server 2003<br>• Windows 2000 Server |

| | | |
|---|---|---|
| **MSAD_ReplNeighbor** | \\root\MicrosoftActiveDirectory | Domain controllers running:<br>• Windows Server 2003<br>• Windows 2000 Server |
| **MSAD_ReplCursor** | \\root\MicrosoftActiveDirectory | Domain controllers running:<br>• Windows Server 2003<br>• Windows 2000 Server |
| **MSAD_ReplPendingOp** | \\root\MicrosoftActiveDirectory | Domain controllers running:<br>• Windows Server 2003<br>• Windows 2000 Server |

**WMI Classes Associated with Trusts**

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| **Microsoft_TrustProvider** | root\microsoftactivedirectory | Domain controllers running Windows Server 2003 |
| **Microsoft_DomainTrustStatus** | root\microsoftactivedirectory | Domain controllers running Windows Server 2003 |
| **Microsoft_LocalDomainInfo** | root\microsoftactivedirectory | • Domain controllers running Windows Server 2003 |

**WMI Classes Associated with Interactive Logon**

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| **Win32_LogonSession** | \root\cimv2 | Computers running:<br>• Windows Server 2003<br>• Windows XP |
| **Win32_LogonSessionMappedDisk** | \root\cimv2 | Computers running:<br>• Windows Server 2003<br>• Windows XP |
| **Win32_NetworkLoginProfile** | \root\cimv2 | Computers running:<br>• Windows Server 2003<br>• Windows XP |

**WMI Classes Associated with Access Tokens**

| Class Name | Namespace | Version Compatibility |
|---|---|---|

| | | |
|---|---|---|
| **Win32_TokenGroups** | \root\cimv2 | Computers running:<br>• Windows Server 2003<br>• Windows XP |
| **Win32_TokenPrivileges** | \root\cimv2 | Computers running:<br>• Windows Server 2003<br>• Windows XP |

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

**Network Ports Used by Domains and Forests**

The following tables list the network ports associated with domains and forests.

**Port Assignments for Raising Active Directory Functional Levels**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |
| LDAP SSL | N/A | 636 |

**Port Assignments for Data Store**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |
| LDAP SSL | N/A | 636 |
| RPC Endpoint Mapper | 135 | 135 |
| Global Catalog LDAP | N/A | 3268 |
| Global Catalog LDAP SSL | N/A | 3269 |

**Port Assignments for Service Publication and SPNs**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |
| LDAP SSL | N/A | 636 |
| RPC Endpoint Mapper | 135 | 135 |
| Global Catalog LDAP | N/A | 3268 |
| Global Catalog LDAP SSL | N/A | 3269 |
| Kerberos | 88 | 88 |

**Port Assignments for Raising Active Directory Searches**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |
| LDAP SSL | N/A | 636 |

| | | |
|---|---|---|
| Global Catalog LDAP | N/A | 3268 |
| Global Catalog LDAP SSL | N/A | 3269 |

**Port Assignments for Global Catalogs**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | N/A | 3268 |
| LDAP | N/A | 3269 (global catalog Secure Sockets Layer [SSL]) |
| LDAP | 389 | 389 |
| LDAP | N/A | 686 (SSL) |
| RPC/REPL | 135 | 135 (endpoint mapper) |
| Kerberos | 88 | 88 |
| DNS | 53 | 53 |
| SMB over IP | 445 | 445 |

**Port Assignments for Replication**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |
| LDAP | N/A | 686 (SSL) |
| RPC/REPL | N/A | 135 (endpoint mapper) |
| LDAP | N/A | 3268 |
| Kerberos | 88 | 88 |
| DNS | 53 | 53 |
| SMB over IP | 445 | 445 |

**Port Assignments for Operations Masters**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |
| LDAP | N/A | 686 (SSL) |
| RPC/REPL | N/A | 135 (endpoint mapper) |
| Netlogon | N/A | 137 |
| Kerberos | 88 | 88 |
| DNS | 53 | 53 |
| SMB over IP | 445 | 445 |

**Port Assignments for Interactive Logon**

| Service Name | UDP | TCP |
|---|---|---|

| | | |
|---|---|---|
| Kerberos | 88 | 88 |
| Local Security Authority (LSA) RPC | Dynamic RPC | Dynamic RPC |
| NTLM | Dynamic | Dynamic |

**Port Assignments for Kerberos V5 Protocol**

| Service Name | UDP | TCP |
|---|---|---|
| DNS | 53 | 53 |
| Kerberos | 88 | 88 |

**Port Assignment for DC Locator**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |

The following table shows the list of ports that might need to be opened before you establish trusts.

**Ports Required for Trusts**

| Task | Outbound Ports | Inbound Ports | From–To |
|---|---|---|---|
| Set up trusts on both sides from the internal forest | LDAP (389 UDP and TCP)<br><br>Microsoft SMB (445 TCP)<br><br>Kerberos (88 UDP)<br><br>Endpoint resolution — portmapper (135 TCP) Net Logon fixed port | N/A | Internal domain domain controllers–External domain domain controllers (all ports) |
| Trust validation from the internal forest domain controller to the external forest domain controller (outgoing trust only) | LDAP (389 UDP)<br><br>Microsoft SMB (445 TCP)<br><br>Endpoint resolution — portmapper (135 TCP) Net Logon fixed port | N/A | Internal domain domain controllers–External domain domain controllers (all ports) |
| Use Object picker on the external forest to add objects that are in an internal forest to groups and DACLs | N/A | LDAP (389 UDP and TCP)<br><br>Windows NT Server 4.0 directory service fixed port<br><br>Net Logon fixed port<br><br>Kerberos (88 UDP)<br><br>Endpoint resolution portmapper (135 TCP) | External server–Internal domain PDCs (Kerberos)<br><br>External domain domain controllers–Internal domain domain controllers (Net Logon) |

| | | | |
|---|---|---|---|
| Set up trust on the external forest from the external forest | N/A | LDAP (389 UDP and TCP)<br><br>Microsoft SMB (445 TCP)<br><br>Kerberos (88 UDP) | External domain domain controllers–Internal domain domain controllers (all ports) |
| Use Kerberos authentication (internal forest client to external forest) | Kerberos (88 UDP) | N/A | Internal client–External domain domain controllers (all ports) |
| Use NTLM authentication (internal forest client to external forest) | N/A | Endpoint resolution – portmapper (135 TCP) Net Logon fixed port | External domain domain controllers–Internal domain domain controllers (all ports) |
| Join a domain from a computer in the internal network to an external domain | LDAP (389 UDP and TCP)<br><br>Microsoft SMB (445 TCP)<br><br>Kerberos (88 UDP)<br><br>Endpoint resolution — portmapper (135 TCP) Net Logon fixed port<br><br>Windows NT Server 4.0 directory service fixed port | N/A | Internal client–External domain domain controllers (all ports) |

# Active Directory Schema Technical Reference

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

The schema is the component of the Active Directory directory service that defines all the objects and attributes that the directory service uses to store data. You can combine some objects in the schema to create more-complex definitions if objects of greater complexity are required. You can also add new definitions to the schema to support new types of objects in the directory.

# What Is the Active Directory Schema?

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**What Is the Active Directory Schema?**

**In this section**

- Using Objects to Store Data
- Building the Schema
- Related Information

The schema is the Active Directory component that defines all the objects and attributes that the directory service uses to store data.

Active Directory stores and retrieves information from a wide variety of applications and services. So that it can store and replicate data from a potentially infinite variety of sources, Active Directory standardizes how data is stored in the directory. By standardizing how data is stored, the directory service can retrieve, update, and replicate data while ensuring that the integrity of the data is maintained.

The directory service uses objects as units of storage. All objects are defined in the schema. Each time that the directory handles data, the directory queries the schema for an appropriate object definition. Based on the object definition in the schema, the directory creates the object and stores the data.

Object definitions control the types of data that the objects can store, as well as the syntax of the data. Using this information, the schema ensures that all objects conform to their standard definitions. As a result, Active Directory can store, retrieve, and validate the data that it manages, regardless of the application that is the original source of the data. Only data that has an existing object definition in the schema can be stored in the directory. If a new type of data needs to be stored, a new object definition for the data must first be created in the schema.

**Using Objects to Store Data**

Active Directory uses objects to store information. Objects are data structures that consist of multiple attributes that store both data and its related metadata. Metadata is data that describes the properties of other data. For example, an object that stores a user account has many attributes, including attributes that contain the user's logon name, first name, last name, and password. Each of those attributes has additional attributes that contain metadata about the information that the attribute stores. The logon name attribute, for example, has multiple attributes of its own. One attribute that is associated with the logon name specifies that the logon name is a required attribute, which means that the user object is not valid unless it contains the logon name attribute. Another attribute that is associated with the logon name specifies the syntax of the value that is stored in the logon name attribute. This ensures that the value that the logon name attribute contains is in a valid format. Both of these attributes contain metadata for the logon name attribute; that is, they define the characteristics of the logon name attribute.

The object definitions in the schema list all the object attributes and define how these attributes relate to each other. Some objects are simple and contain only a few attributes, while other objects are quite complex and contain hundreds of attributes. Attributes themselves are objects, and the schema contains a definition for each one. To define new objects, smaller objects are associated with one another to define the necessary attributes of the new objects.

For a user object, the user's logon name attribute is a smaller object that contains a number of attributes of its own. Among them are attributes that define the syntax of the logon name and specify whether or not the logon name attribute is optional or required. The first name and last name attributes are also smaller objects whose definitions can be found in the schema. The object definition that defines the user object lists the logon name attribute object, the first name and last name attribute objects, and many other attribute objects, and it defines how these objects relate to each other to store the data that represents a user account.

Defining objects and attributes in this manner gives the schema the ability to efficiently define many different types of objects while retaining the ability to add new types of objects when necessary. Many objects have some attributes in common. For example, many objects have a security descriptor to define who is allowed to access and change their contents. Rather than create a separate security descriptor definition for each object definition, the schema defines a single security descriptor object, and all other object definitions refer to the single security descriptor definition. This makes it possible for every object that

needs a security descriptor to have one security descriptor while keeping only one definition for the security descriptor in the schema.

**Building the Schema**

The Active Directory installation process that creates the forest also generates the default schema. Thereafter, the default schema replicates to each new domain controller during the installation of the directory on that new domain controller. The default schema contains all the standard object definitions that are necessary for Active Directory to function in a standard deployment.

Active Directory uses a multimaster replication topology, which means that any domain controller in a forest can write a change to the directory database and then replicate that change to other domain controllers in the same forest. For a domain controller to create a new object and write it to the directory, the domain controller must have access to the object definition that is needed to create the new object. Every domain controller in a forest maintains a copy of the schema, which makes it possible for domain controllers to have access to the object definitions that they need to store and retrieve information in the directory.

In some situations, the default attributes and object definitions in the schema are insufficient to create new object types that are required by some applications or services that interoperate with the directory. In these situations, it is possible to customize the schema by adding new object definitions to it. The process of adding definitions to the schema is referred to as "extending the schema."

It is important to plan the deployment of schema extensions carefully. The directory stores the schema and replicates schema changes to every domain controller throughout the forest. Therefore, extending the schema creates replication traffic, which can briefly affect network traffic. For more information about extending the schema, see "How the Active Directory Schema Works."

# How the Active Directory Schema Works

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**How the Active Directory Schema Works**

**In this section**

- Active Directory Schema Architecture
- Active Directory Schema Physical Structure
- Active Directory Schema Processes and Interactions
- Related Information

The schema is the Active Directory component that defines all the objects and attributes that the directory service uses to store data. The physical structure of the schema consists of the object definitions. The schema itself is stored in the directory.

The schema is stored in its own partition (the schema partition) in the directory. The schema is replicated among all the domain controllers in the forest, and any change that is made to the schema is replicated to every domain controller in the forest. Because the schema dictates how information is stored, and because any changes that are made to the schema affect every domain controller, changes to the schema should be made only when necessary — through a tightly controlled process — after testing has been performed to ensure that there will be no adverse effects on the rest of the forest.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to Active Directory Domain Services. |

**Active Directory Schema Architecture**

In Active Directory, the schema defines the following:

- Objects that are used to store data in the directory
- The rules that govern the structure of those objects
- The structure and the content of the directory itself

These definitions consist of objects, attributes, and classes, which are described in the following section.

**Schema Components**

Objects, attributes, and classes are the basic components that are used to build object definitions in the schema.

**Objects**

Objects are structures that store both data that the objects represent and data that controls the content and structure of the objects. For example, a user account object contains a user's logon name as well as data that indicates the proper syntax for storing the user's logon name in the user object.

Active Directory uses objects to store data while the data is maintained in the directory. When the directory stores an object, some associated data is also stored along with the object. The extra data is stored in the attributes of the object.

**Attributes**

Attributes contain data that defines the information that is stored in an object or in another attribute. For example, a user account object has attributes that store user information, such as the user's first name, last name, password, office number, and telephone number. Different types of objects have different attributes. A printer object has attributes that store information

that is related to printers, such as the printer model, the number of paper trays, the current location of the printer, and the port to which the printer is attached.

Some attributes contain information that relates to other attributes, such as syntax information or flags that label the attribute as optional or required. Syntax attributes define the format that is used to store data in other attributes. For example, because a telephone number comprises only digits, a syntax attribute might specify that the phone number attribute can only store digits 0 through 9, and letters of the alphabet are prohibited. Active Directory uses syntax attributes to ensure that information is stored in a legitimate format and that the information is a valid data type.

Attributes can be required or optional. A user account object requires a user name attribute and a password attribute, although the office number attribute is optional. That is, a user account cannot be used without a user name; however, it can be used without an office number. The office number attribute is included for convenience, and it is considered an optional attribute.

An object definition is really an association of various attributes that are used to describe the characteristics of an object that stores specific pieces of data. The kind of data that the object stores determines which attributes are needed to define the object.

Large objects are made up of many smaller objects. In the user account object example, the user's logon name attribute is a smaller object that contains a number of attributes of its own, including attributes that define the syntax of the logon name and that specify whether or not the logon name attribute is optional or required. The first name and last name attributes are also smaller objects that are defined in the schema. The object definition for the user account object lists the logon name attribute and the first name and last name attributes, as well as many other attributes, and it defines how these attributes relate to each other to store the data that represents a user account.

Defining objects and attributes this way gives the schema the ability to efficiently define many different types of objects. Many objects have some attributes in common. For example, many objects have a security descriptor to define who is allowed to access and make changes to the contents of the object. Rather than create a separate security descriptor definition for each object definition, the schema defines a single security descriptor object, and all other object definitions refer to the single security descriptor definition. This makes it possible for every object that needs a security descriptor to have one, while keeping only one definition for the security descriptor in the schema.

**Classes**

Object definitions are categorized into groups that are called classes. Classes act as blueprints that can be used each time a new object is created. When a new object is created in the directory, the object's class determines the attributes that are associated with the new object, including which attributes are required and which attributes are optional.

Active Directory has predefined classes that define all of the different object type's that the directory needs to function properly. For example, when a new user account object is created in the directory, its definition comes from the **classUser** class. The class dictates that the new account object is required to have a user name attribute and a password attribute, and optionally it might have an office number attribute.

Object definitions are created by nesting classes inside one another. Nesting classes produces a parent/child relationship between the classes. Classes that are nested inside another class are referred to as subclasses. The parent of a subclass is referred to as a superclass. When one class is nested inside another, the nested class inherits the properties of the parent superclass. When various classes that contain particular attributes are nested inside another object class, a new object definition is created. Which classes are nested depends on which attributes are needed to define the new object type.

The schema stores class information, but it does not store the actual objects that are derived from a class. For example, when a new user account object is created, it is not stored in the schema. Active Directory looks up the user *class* in the schema. Active Directory then retrieves information regarding the object type and its associated attributes from the user class in the schema and uses that information to create the new user account object. When the new account is created, the data is stored in the new object, and Active Directory then writes the new account information into the directory database.

The schema is the master list of all classes and attributes that can be used in the directory. During the installation of Active Directory, the Schema.ini file is used to build the default schema on the first domain controller in the forest. The default schema provides all the necessary classes that Active Directory needs to function. Administrators or developers might want to add their own classes or add their own attributes to an existing object type. They can do this through the process of extending the schema. The schema should only be extended in special situations. For more information about extending the schema, see "Modifying the Schema" later in this section.

**Schema Objects**

Active Directory uses objects to store and reference data in the directory. The schema defines the types of objects that are available to the directory service. The schema is stored in the schema partition, which is also defined as an object in the directory. The attributes and classes in Active Directory are stored in the schema partition as directory objects that are called schema objects. The schema partition itself is represented in Active Directory by an object that is an instance of the Directory

Management Domain (**dMD**) class.

Storing the schema in the directory has many advantages. For example, when user applications locate the schema in the directory, they can read the schema to discover what types of objects and properties are available. Because the schema is stored in the directory — like the rest of the data in the directory — applications can locate the schema by using the same process that they use to locate any other object in the schema.

A schema object, called a classSchema object, defines each class in the schema. Another schema object, called an attributeSchema object, defines each attribute in the schema. Therefore, every class is actually an instance of the **classSchema** class, and every attribute is an instance of the **attributeSchema** class, as shown in the following figure.

**Schema Objects**

Schema objects are used to define classes and attributes in the schema. Classes in the schema are used to define objects in the directory.

**attributeSchema Objects**

Attributes describe the classes that are defined in the schema. Attributes are defined in the schema separately from classes, which enables a single attribute definition to be applied to many classes.

Attributes are attributeSchema objects. Each attributeSchema object is an instance of the **attributeSchema** class. Like any other object, the attributeSchema object has its own attributes. The attributes for the attributeSchema object store, among other things, the following information:

- The Lightweight Directory Access Protocol (LDAP) display name of the attribute
- The object identifier for the attribute
- The globally unique identifier (GUID) for the attribute
- The syntax of the attribute
- The range for the attribute. For integers, range defines the minimum and maximum value; for strings, range defines the minimum and maximum length.
- Whether the attribute is a multivalue attribute. Note that multivalue attributes hold a set of values with no particular order. Multivalue attributes might not be returned in the order in which they were stored (or in any other order).
- Whether and how the attribute is indexed

**Attributes for the attributeSchema class**

Attributes for the **attributeSchema** class are described in the following table.

**Attributes for the attributeSchema Class**

| Attribute | Syntax | Mandatory? | Multivalue? | Description |
|---|---|---|---|---|
| **cn** | Unicode | Yes | No | Descriptive relative distinguished name for the schema object |

| | | | | |
|---|---|---|---|---|
| **attributeID** | Object identifier | Yes | No | Object identifier that uniquely identifies this attribute |
| **lDAPDisplayName** | Unicode | Yes, but automatic | No | Name by which LDAP clients identify this attribute |
| **schemaIDGUID** | String(Octet) | Yes | No | GUID that uniquely identifies this attribute |
| **mAPIID** | Integer | No | No | Integer by which Messaging API (MAPI) clients identify this attribute |
| **attributeSecurityGUID** | GUID | No | No | GUID by which the security system identifies the property set of this attribute |
| **attributeSyntax** | Object identifier | Yes | No | Syntax object identifier of this attribute |
| **oMSyntax** | Integer | Yes | No | Syntax of this attribute as defined by the XAPIA X/Open Object Model (XOM) specification |
| **isSingleValue** | BOOL | Yes | No | Indicates whether this attribute is a single-value or multivalue attribute<br><br>Note that multivalue attributes hold a set of values with no particular order. Multivalue attributes might not be returned in the order in which they were stored (or in any other order). |
| **extendedCharsAllowed** | BOOL | No | No | Indicates whether extended characters are allowed in the value of this attribute<br><br>Applies only to attributes of syntax String(teletex). |
| **rangeLower** | Integer | No | No | Lower range of values that are allowed for this attribute |
| **rangeUpper** | Integer | No | No | Upper range of values that are allowed for this attribute |
| **systemFlags** | Integer | No | No | Flags that determine specific system operations<br><br>**Note:** This attribute cannot be set or modified.<br><br>The following **systemFlags** attributes are relevant to the schema objects:<br><br>Attribute is required to be a member of the partial set = 0x00000002<br><br>Attribute is not replicated = 0x00000001<br><br>Attribute is a constructed attribute = 0x00000004 |

| | | | | |
|---|---|---|---|---|
| **searchFlags** | Integer | No | No | The **searchFlags** property of each property's attributeSchema object defines whether a property is indexed and other behavior.<br><br>The seven currently defined bits for this attribute are:<br><br>1 = Index over attribute only<br><br>2 = Index over container and attribute<br><br>4 = Add this attribute to the ambiguous name resolution (ANR) set (should be used in conjunction with 1)<br><br>8 = Preserve this attribute on logical deletion (that is, make this attribute available on tombstones)<br><br>16 = Include this attribute when copying a user object<br><br>32 = Create a Tuple index for the attribute to improve medial searches<br><br>64 = Reserved for future use; value should be 0.<br><br>128 = Available in Windows Server 2003 Service Pack 1 (SP1) only. Mark the attribute confidential (CONTROL_ACCESS is required to read it). |
| **isMemberof PartialAttributeSet** | BOOL | No | No | A Boolean value that defines whether the attribute is replicated to the global catalog<br><br>A value of TRUE means that the attribute is replicated to the global catalog. In environments where domain controllers are running Windows 2000 Server, changing this value might cause full synchronization of the Partial Attribute Set. For more information about the conditions under which full synchronization occurs, see How the Global Catalog Works on the Microsoft Web site at http://go.microsoft.com/fwlink/?LinkId=47817. |
| **systemOnly** | BOOL | No | No | Attributes on which Windows Server 2003 and Active Directory depend for normal operations<br><br>If TRUE, only the system can modify this attribute. No user-defined attribute must ever have the **systemOnly** flag set. |
| **objectClass** | Object identifier | Yes | Yes | Class of this object, which is always attributeSchema |
| **nTSecurityDescriptor** | NT-Sec-Des | Yes | No | Security descriptor on the attributeSchema object itself |
| **oMObjectClass** | String(Octet) | No | No | For object-syntaxed attributes (OM-syntax = 127), the Basic Encoding Rules (BER) encoded object identifier of the XOM object class<br><br>For more information about BER encoding, see Request for Comments (RFC) 2251 in the IETF RFC Database. |
| **LinkID** | Integer | No | No | Value that determines whether the attribute is a linked attribute. An even integer denotes a forward link; an odd integer denotes a back link.<br><br>A forward link references a target object in the directory; a back link refers back to the source object that has a forward link to it. |

**Single-value and multivalue attributes**
Some attributes contain a single value, and other attributes can contain multiple values. For example, the **password** attribute on a user object contains a single value: the password that is associated with the user account. The **memberOf** attribute contains multiple values: a list of the various groups of which the user account is a member. Each item in the list is stored as a separate value in the **memberOf** attribute. Attributes that can store more than a single value are referred to as "multivalue" attributes.

Whether or not attributes are single-value or multivalue is defined by the **singleValue** attribute as a Boolean value. The Active Directory Schema snap-in reports this attribute as "single-value" or multivalue rather than as the attribute-value pair. (Active Directory Schema is a Microsoft Management Console (MMC) graphical interface tool in Windows Server 2003 that administrators can use to manage the schema.)

All values that are defined for a multivalue attribute must have a uniform syntax. Multivalue attributes that are not linked can store a maximum of 1,300 entries. This limit is based on the size and type of the values that are stored.

### Note

- When it retrieves data, LDAP reads a multivalue attribute as a single entity. This can be inconvenient or even impossible when the number of values in a multivalue attribute becomes large. A property called **Range** can be specified as part of an attribute description to retrieve the values of a multivalue attribute incrementally. Servers might or might not honor the **Range** property. Servers that support the **Range** property include the object identifier 1.2.840.113556.1.4.802 in the **supportedControls** operational attribute on the **rootDSE**. Clients must not use the **Range** property unless this object identifier is present. The **Range** property is a constant, case-insensitive string value (Range=), followed by a range specifier that lists the initial value and terminal value in the range.

**Linked attributes**
Linked attributes make it possible to associate one object with another object. A linked attribute represents an interobject, distinguished-name reference. Linked attributes occur in pairs: forward link and backward link (back link). Linked attribute pairs exist on source objects and target objects, as follows:

- The forward link is a linked attribute on a source object (for example, the **member** attribute on the group object). It can be a single-valued attribute or a multi-valued attribute.

- As an option, a back link can be defined on a target object (for example, the **memberOf** attribute on the user object). A back-link attribute should be created as a multi-valued attribute, and it cannot exist without a corresponding forward link. The back-link attribute cannot be updated directly. Instead, it is automatically calculated when it is queried, based on the corresponding forward link. A back-link value on any instance of an object consists of the distinguished names of all source objects that have the target object's distinguished name in their corresponding forward link.

A linked pair is identified by the **linkID** values of two attributeSchema objects. The **linkID** of the forward link is an even, positive, nonzero value, and the **linkID** of the associated back link is the value of the forward **linkID**, incremented by one. For example, the value of **linkID** for **member** is 2 and the value of **linkID** for **memberOf** is 3.

**Automated links**
The **linkIDs** must be unique within the forest. In Windows 2000 Server, **linkIDs** are allocated by the applications that used them, and it is up to application developers to make sure that the **linkIDs** for the applications do not conflict with **linkIDs** that are already in use. Windows Server 2003 can generate link values automatically to ensure that there are no conflicts within the forest. When new objects that use linked attributes are created, Active Directory automatically generates the necessary **linkIDs**.

**Indexed attributes**
Directory searches for attributes that are indexed are more efficient than searches for attributes that are not indexed. Attributes are indexed when the least significant bit in their **searchFlags** attribute is set to the value 1. Changing the value of the bit to 1 dynamically builds an index; changing the value to 0 or deleting it removes an index for the attribute in question. The index is built automatically by a background thread on the directory server.

The values for indexed attributes are stored in a sorted list. This makes searching much more efficient because the system needs to search only until it locates the area in the list where the value should be, based on the sort. If the value is not there, the system can assume it will not find the value anywhere else in the list, and it can terminate the search. When attributes are not indexed, the entire list must be searched to determine whether or not a particular value actually exists.

Indexing requires more storage to maintain the lists, but it makes searching more efficient. Nonindexed attributes are less efficient to search, but they require less storage to maintain. With this in mind, only attributes that are frequently referenced

should be indexed. Ideally, indexed attributes are single-value attributes with unique values that are evenly distributed across the set of instances. Multivalue attributes can be indexed, but building the index requires more storage and updating.

**Confidential attributes**

On domain controllers running Windows Server 2003 SP1 and later, attributes whose **attributeSchema** objects are marked with a specific search flag are interpreted as confidential. Attributes that are so marked can be read only by users to whom the following access is granted:

- READ_PROPERTY
- CONTROL_ACCESS

The ability to mark attributes as confidential allows administrators to protect attributes from the read access that is granted by default to most users. Rather than changing the defaults that are expected by existing applications, administrators can create new attributes that can be read only by administrators or those to whom access is specifically granted. Because domain controllers must be running Windows Server 2003 SP1 or later to recognize the flag that marks the attribute as confidential, protection of marked attributes is fully effective only in environments where all domain controllers have been upgraded to Windows Server 2003 SP1 or later. In particular, the schema operations master (also known as the schema flexible single-master operations (FSMO) role holder) must be upgraded to Windows Server 2003 SP1 or later.

By default, Active Directory performs a read-access check on an object in the following cases:

- When evaluating whether the object matches the search filter
- When returning attributes of an object that matches the search filter

Default security allows read access to the Pre-Windows 2000 Compatible Access group, which usually contains Authenticated Users. Authenticated Users is a security group that includes users whose identities can be authenticated by the server or by a trusted security authority. Because the Pre-Windows 2000 Compatible Access group is granted Read_Property permissions on **user** objects (including **inetOrgPerson**) and **group** objects, it is difficult to introduce a new attribute on these objects that is protected from reading by most users. For example, you might want to add a social security number attribute to the **user** class.

To solve this problem, Windows Server 2003 SP1 and later provides a way to mark an attribute as confidential by setting a **searchFlags** value on the attributeSchema object in the schema. The search flag contains multiple bits representing various properties of an attribute. In the schemas, the **searchFlags** attribute has six bits that can be set. (See the bits that are defined for the **searchFlags** attribute in "Attributes for the attributeSchema class" earlier in this section.) For example, a value of 1 in the least significant bit means that the attribute is indexed. The binary form of this flag value is 00000001. A new bit is added in Windows Server 2003 SP1 or later: A value in bit 128 (10000000) designates the attribute as confidential. Therefore, on a domain controller running Windows Server 2003 SP1 or later, you can designate an attribute as confidential by setting bit 128 in the **searchFlags** attribute of the respective attributeSchema object.

| **Note** |
| --- |
| You cannot set this flag on base-schema attributes, such as common-name. |

When an attribute is so designated, in addition to READ_PROPERTY permission (for that attribute or all attributes on that object), CONTROL_ACCESS permission (for that attribute or a property set that contains that attribute) is required to read the attribute.

| **Note** |
| --- |
| When you assign CONTROL_ACCESS permissions to a user or group, you must specify a GUID — in this case, the GUID of the attribute or property set that contains the attribute. |

To set the bit flag when no values are set, you can simply add the value 128 to the **searchFlags** attribute in the properties of the attributeSchema object for the confidential attribute. If a value is already present in the attribute, perform a bitwise OR operation to add 10000000 to the existing binary value, and then convert to decimal. For example, if the bit is set for indexing and containerized search (00001001), the combined values 10000000 OR 00001001 equal 10001001, translating to a decimal value of 137.

By default, only members of the Administrators built-in group are granted CONTROL_ACCESS to all objects. Therefore, only

administrators can read confidential attributes. You can delegate the CONTROL_ACCESS right to any specific group by using the Dsacls command-line tool or by scripting. Dsacls is included in Windows Support Tools. To grant access to a confidential attribute, use Dsacls to grant the CONTROL_ACCESS right (CA) to the required group or user. Doing so introduces a way to impose additional security checks that control read access to selected attributes. For more information about Dsacls, see Dsacls.exe in the Active Directory Management Support Tools section of Windows Support Tools on the Microsoft Web site at http://go.microsoft.com/fwlink/?LinkId=43235. For more information about property sets and CONTROL_ACCESS permissions, see the Security Descriptors and Access Control Lists Technical Reference.

**Syntaxes**

The syntax for an attribute defines the storage representation, byte ordering, and matching rules for comparisons of property types. The syntax defines whether the attribute value must be a string, a number, or a unit of time. Each attribute of every object is associated with exactly one syntax. The syntaxes are not represented as objects in the schema, but they are programmed to be understood by Active Directory. The allowable syntaxes in Active Directory are predefined. You cannot add new syntaxes.

When you define a new attribute, you must specify both the **attributeSyntax** and the **oMSyntax** numbers of the syntax that you want for that attribute. The **attributeSyntax** number is an object identifier, and the **oMSyntax** number is an integer. **oMSyntax** is defined by the XOM specification. Using this model, the syntax can provide detailed syntax definitions. For example, distinct **oMSyntax** attributes distinguish several types of printable strings, according to such factors as the supported character set and whether case is significant. The following table lists the valid syntaxes for attributes in the Active Directory schema.

**Valid Syntaxes for Attributes in the Active Directory Schema**

| Syntax | attributeSyntax | oMSyntax | ASN 1-Encoded Object Identifier | Description |
|---|---|---|---|---|
| Undefined | 2.5.5.0 | | \x550500 | Not a legal syntax |
| Object(DN-DN) | 2.5.5.1 | 127 | \x550501 | The fully qualified name of an object in the directory |
| String(Object-Identifier) | 2.5.5.2 | 6 | \x550502 | The object identifier |
| Case-Sensitive String | 2.5.5.3 | 27 | \x550503 | General string — differentiates uppercase and lowercase |
| CaseIgnoreString(Teletex) | 2.5.5.4 | 20 | \x550504 | Teletex — does not differentiate uppercase and lowercase |
| String(Printable), String(IA5) | 2.5.5.5 | 19, 22 | \x550505 | Printable string or IA5-String<br><br>Both character sets are case sensitive. |
| String(Numeric) | 2.5.5.6 | 18 | \x550506 | A sequence of digits |
| Object(DN-Binary) | 2.5.5.7 | 127 | \x550507 | A distinguished name plus a binary large object |
| Boolean | 2.5.5.8 | 1 | \x550508 | TRUE or FALSE values |
| Integer, Enumeration | 2.5.5.9 | 2, 10 | \x550509 | A 32-bit number or enumeration |
| String(Octet) | 2.5.5.10 | 4 | \x55050A | A string of bytes |
| String(UTC-Time), String(Generalized-Time) | 2.5.5.11 | 23, 24 | \x55050B | UTC time or generalized-time |
| String(Unicode) | 2.5.5.12 | 64 | \x55050C | Unicode string |
| Object(Presentation-Address) | 2.5.5.13 | 127 | \x55050D | Presentation address |
| Object(DN-String) | 2.5.5.14 | 127 | \x55050E | A DN-String plus a Unicode string |

| | | | | |
|---|---|---|---|---|
| String(NT-Sec-Desc) | 2.5.5.15 | 66 | \x55050F | A Windows NT security descriptor |
| LargeInteger | 2.5.5.16 | 65 | \x550510 | A 64-bit number |
| String(Sid) | 2.5.5.17 | 4 | \x550511 | Security identifier (SID) |

**Object identifiers**

Object identifiers are unique numeric values that are granted by various issuing authorities to identify data elements, syntaxes, and other parts of distributed applications. Because they are globally unique, object identifiers ensure that the objects that are defined by these issuing authorities do not conflict with one another when different directories, such as Active Directory and Novell Directory Services, are used concurrently within a global directory namespace.

Object identifiers are found in Open Systems Interconnection (OSI) applications, X.500 directories, applications that use Simple Network Management Protocol (SNMP), and other applications in which uniqueness is important. Object identifiers are based on a tree structure in which a superior issuing authority allocates a branch of the tree to a subordinate authority, which in turn allocates subbranches of the tree.

LDAP requires a directory service, such as Active Directory, to identify object classes and attributes with an object identifier syntax. The object identifier is the value for the **governsID** attribute in a classSchema object and for the **attributeID** attribute in an attributeSchema object. These are required attributes; therefore, object identifiers are necessary when you create new classes or attributes.

Object identifiers in the Active Directory base schema include some object identifiers that are issued by the International Organization for Standardization (ISO) for X.500 classes and attributes and some object identifiers that are issued by Microsoft. Object identifier notation is a dotted string of nonnegative numbers, for example, 1.2.840.113556.1.5.4. The components of this object identifier are shown in the following table.

**Components of an Object Identifier (1.2.840.113556.1.5.4)**

| Numerical Values of the Object Identifier | What the Numerical Values Mean |
|---|---|
| 1 | ISO (“root” authority) issued 1.2 to ANSI. |
| 2 | ANSI issued 1.2.840 to the USA. |
| 840 | USA issued 1.2.840.113556 to Microsoft. |
| 113556 | Microsoft internally manages several object identifier branches under 1.2.840.113556 that include the following three identifiers. |
| 1 | A branch called Active Directory that includes the following two identifiers. |
| 5 | A branch called Classes that includes the following identifier. |
| 4 | A class called Builtin-Domain. |

Object identifiers ensure that every object is interpreted appropriately, for example, that a telephone number is not mistaken for an employee number. A series of widely used objects and attributes is standardized for use in object identifiers. New object identifiers are issued by standards authorities, and they form a hierarchy below which new object identifiers can be managed internally.

Most countries and regions in the world have an identified National Registration Authority (NRA) that is responsible for issuing object identifiers to enterprises. In the United States, the NRA is the American National Standards Institute (ANSI). The NRA issues root object identifiers. An enterprise can register a name for the object identifier as well. A fee is associated with registering root object identifiers and registered names. Contact the NRA for your country or region for details. The ISO recognizes NRAs and maintains a list of contacts on its Web site.

The issuing authority assigns an object identifier space that is a branch of the ISO-International Telecommunication Union (ITU) object identifier tree. For example, your organization might be assigned the space 1.2.840.111111. You can extend this space internally within the constraints of the structure of an object identifier. You can subdivide this space further (by appending dotted decimals to the object identifier root) and assign these subspaces to various divisions within your organization. Each division, in turn, can further subdivide the subspace that is allotted to it.

For the example object identifier 1.2.840.111111, your organization might use the subspace 1.2.840.111111.1.4 for attributes

and the subspace 1.2.840.111111.1.5 for classes. An internal issuing authority in your organization, using an Administrator account, might then allocate object identifiers from this space when requested. The **governsID** attribute on every classSchema object and the **attributeID** attribute on every attributeSchema object are mandatory attributes that contain an object identifier string. In this example, all of your organization-created classSchema objects have a **governsID** attribute of the form 1.2.840.111111.1.5.*x*, where *x* is a decimal number. Similarly, all of your organization-created attributeSchema objects have an **attributeID** attribute of the form 1.2.840.111111.1.4.*x*.

Microsoft also offers a free object identifier registration service.

#### classSchema Objects

The classSchema object specifies the various attributes of the class with which it is associated. Among other things, it defines the following constraints for objects that are instances of the class:

- **mustContain** attributes, which include mandatory attributes that must be present on any object that is an instance of this class
- **mayContain** attributes, which include optional attributes that may be found on an object that is an instance of this class
- Hierarchy rules that determine the possible parents in the directory tree of an object that is an instance of the class

An object can have attributes that belong only to either the **mustContain** list or the **mayContain** list for the class.

The classSchema object is essentially a template that contains the rules for creating objects in an Active Directory class. When a new object is created in a class, the classSchema object ensures that this new object has the same attributes as all other objects in the class.

The classSchema object contains, among other things, the following information:

- The LDAP display name of the class
- The object identifier for the class
- The GUID for the class
- The attributes that must be present for an instance of the class
- Other attributes that can be present for an instance of the class
- The classes to which the parent of instances of this class may belong
- The superclass from which this class inherits characteristics
- Other **auxiliary** classes from which this class inherits attributes
- The type of class (**abstract**, **structural**, or **auxiliary**)
- The default hiding state for the class. If you do not want instances of the class to be displayed by the end-user user interface (UI), you can define the class as hidden by default.

#### Attributes for classSchema objects

The following table lists the attributes that a classSchema object can have.

**Attributes for a classSchema Object**

| Attribute | Syntax | Mandatory? | Multivalue? | Description |
|---|---|---|---|---|
| **cn** | Unicode | Yes | No | Descriptive relative distinguished name for the schema object |

| | | | | |
|---|---|---|---|---|
| **governsID** | Object identifier | Yes | No | The object identifier that uniquely identifies this class |
| **lDAPDisplayName** | Unicode | Yes | No | The name by which LDAP clients identify this class |
| **schemaIDGUID** | String(Octet) | Yes, but defaulted | No | The GUID that uniquely identifies this class |
| **rDNAttID** | Object identifier | No | No | The relative distinguished name type of instances of this class (OU, CN) |
| **subClassOf** | Object identifier | Yes | No | The class from which this object inherits attributes |
| **systemMustContain** | Object identifier | No | Yes | The list of mandatory attributes for instances of this class<br><br>This list cannot be changed. |
| **mustContain2** | Object identifier | No | Yes | The mandatory attributes for instances of this class |
| **systemMayContain** | Object identifier | No | Yes | The optional attributes for instances of this class |
| **mayContain2** | Object identifier | No | Yes | The optional attributes for instances of this class |
| **systemPossSuperiors2** | Object identifier | No | Yes | The classes that can be parents of this class in the directory hierarchy<br><br>After the class is created, this property cannot be changed. |
| **possSuperiors2** | Object identifier | No | Yes | The classes that can be parents of this class in the directory hierarchy<br><br>For an existing classSchema object, values can be added to this property but not removed. |
| **systemAuxiliaryClass2** | Object identifier | No | Yes | The **auxiliary** classes from which this class inherits its optional (**mayContain**) and mandatory (**mustContain**) attributes<br><br>After creation of the class, this property cannot be changed. |
| **auxiliaryClass2** | Object identifier | No | Yes | The **auxiliary** classes from which this class inherits its optional (**mayContain**) and mandatory (**mustContain**) attributes<br><br>This is a multivalue property that specifies the auxiliary classes that this class inherits from. For an existing classSchema object, values can be added to this property but not removed. |
| **defaultHidingValue** | BOOL | No | No | The default hiding state for the class<br><br>If you do not want instances of the class displayed in the UI for Active Directory admin tools **New** menus, you can define the class as hidden. |

| | | | | |
|---|---|---|---|---|
| **defaultSecurityDescriptor** | String(Octet) | No | No | The default security descriptor that is assigned to new instances of this class if no security descriptor is specified during creation of the class or that is merged into a security descriptor if a security descriptor is specified |
| **objectClassCategory** | Integer | Yes | No | Class types are defined as follows:<br>88 Class = 0<br>Structural = 1<br>Abstract = 2<br>Auxiliary = 3<br>The 88 class type is included for compatibility with older directories. Active Directory does not use 88 class type objects, and they should not be used in defining new classes for Active Directory. |
| **systemOnly** | BOOL | No | No | An attribute of a classSchema object<br>If it is set to TRUE, only the system can create and modify instances of this class. If it is set to FALSE, modifications can also be made by users who have appropriate permissions. |
| **objectClass** | Object Identifier | Yes | Yes | This object's class, which is always **classSchema** |
| **nTSecurityDescriptor** | NT-Sec-Desc | Yes | No | The security descriptor on the classSchema object |
| **defaultObjectCategory** | Distinguished name | Yes | No | The default object category of new instances of this class<br>If none has been specified, the **objectClass** value is used. |

The attributes in a classSchema object's **mustContain** attribute list are not the complete set of attributes that must be present for an instance of a class to exist. For example, in a class A, the classSchema object B specifies a list of **mustContain** attributes that an instance of A must have through the **systemMustContain** and **mustContain** attributes. However, because mandatory attributes are also inherited, the complete list of attributes for an instance of class A includes the inherited **mustContain** attributes from all classes from which B inherits, that is, all classes in the **subClassOf** and **auxiliaryClass** lists for the classSchema object B. The **mayContain** attributes for object B are also defined this way. The **possSuperiors** attributes are defined this way as well, except that **possSuperiors** attributes are inherited only from classes in the **subClassOf** list, not from the classes in the **auxiliaryClass** list.

#### Mandatory attributes

Mandatory attributes are object attributes for which you must specify values. If you do not specify a value for a mandatory attribute, the attribute receives a default value or the object is not created until you specify a value for the attribute. The object's mandatory attributes are determined by the class to which the object belongs.

Some mandatory attributes are inherited. Because every classSchema object belongs to a superclass called **Top** in the class hierarchy, each classSchema object inherits the mandatory attributes that belong to **Top**. The following table lists the mandatory attributes that every object inherits from **Top**. To see a graphical representation of the Active Directory class hierarchy, see the figure under "Object class hierarchy" later in this section.

**Mandatory Attributes That All classSchema Objects Inherit**

| Inherited Mandatory Attribute | Default Status |
|---|---|
| **nTSecurityDescriptor** | Set to a default value if not specified. The default value depends on the default security descriptor for the classSchema object. |

| | |
|---|---|
| **objectCategory** | Automatically set to the value of the default object category of the class, which is usually the class itself. Can be changed after the class is created. |
| **objectClass** | No default. An administrator must specify the class. |

You can view an object's mandatory attributes by using the Active Directory Schema snap-in. The attributes are displayed on the **Attributes** tab in the properties dialog box for the object. Because some of an object's mandatory attributes are inherited from its parent class, you might need to view the attributes of the parent class to identify all the mandatory attributes of the object.

**System and changeable attribute pairs**

Some properties of a class-definition object are contained in pairs of attributes, in which the value of one of these attributes can be changed by administrators and the value of the other attribute cannot be changed. These attribute pairs are as follows:

- **mustContain/systemMustContain**
- **mayContain/systemMayContain**
- **possSuperiors/systemPossSuperiors**
- **auxiliaryClass/systemAuxiliaryClass**

In each of these pairs, the value of the attribute that begins with the word "system" cannot be changed by administrators. This enables Active Directory to protect certain key attributes of certain classes and to ensure that the schema stays consistent and usable. System-only properties can be changed only by the Directory System Agent (DSA). System-only properties are those properties on which Active Directory depend for normal operations. For example, the **attributeID** attribute and the **governsID** attribute in the schema are system-only attributes. The values of the other (nonsystem) attributes in each pair can be changed by administrators.

**Categories of Object Classes**

Different categories of object classes make it possible to define structure in the directory. The 1993 X.500 specification requires that object classes be assigned to one of three categories:

- Structural
- Abstract
- Auxiliary

A fourth category, which is referred to as 88 classes, is associated with object classes, although this category is not part of the 1993 specification. The 88 class category is in the specification that existed before 1993, and it should not be used for adding classes to Active Directory.

**Structural classes**

Structural classes are the only classes that can have instances in the directory. That is, you can create directory objects whose class is one of the structural classes. A structural class:

- Can be used in defining the structure of the directory.
- Is derived from either an abstract class or another structural class.
- Can include any number of auxiliary classes in its definition.

This type of class is specified by a value of 1 in the **objectClassCategory** attribute.

**Abstract classes**

Abstract classes are templates that are used to derive new structural classes. Abstract classes cannot be instantiated in the directory. This means that no object can belong only to an abstract class; each object of an abstract class also belongs to some structural subclass of that class. A new abstract class can be derived from an existing abstract class. This type of class is specified by a value of 2 in the **objectClassCategory** attribute. Abstract classes only provide attributes for subordinate classes,

which are called subclasses. A subclass contains all mandatory and optional attributes of the class from which it is derived (its superclass) in addition to those attributes that are specific to the class itself. Likewise, the subclass of that class contains all attributes of both superclasses, and so forth.

**Auxiliary classes**

Auxiliary classes are like include files; they contain a list of attributes. Adding an auxiliary class to the definition of a structural class or an abstract class' adds the auxiliary classs attributes to the definition. An auxiliary class cannot be instantiated in the directory, but new auxiliary classes can be derived from existing auxiliary classes. This type of class is specified by a value of 3 in the **objectClassCategory** attribute. For example, the **securityPrincipal** class is an auxiliary class, and it derives its attributes from the parent abstract class called **Top**. Although you cannot create a security principal object in the directory (because auxiliary classes cannot have instances), you can create an object of the structural class **user**, which has the **securityPrincipal** class as an auxiliary class. The attributes of the **securityPrincipal** class help the system recognize the user object as a security account. Similarly, the **group** class has **securityPrincipal** as an auxiliary class.

The behavior of auxiliary classes has changed in Windows Server 2003 and later. In Windows 2000 Server, changes that are made to an auxiliary class affect its parent class as well as all instances of the parent object. For example, adding an auxiliary class called **pager** to the structural class **user** affects all instances of **user**, which is all of the user accounts that are created with the **user** class.

In Windows Server 2003 and later, auxiliary classes can be assigned dynamically to individual instances of classes, rather than being applied automatically to all instances. For example, you can assign the **pager** auxiliary class to only those users who need it.

**88 classes**

Classes that were defined before 1993 are not required to fall into one of the preceding categories; assigning classes to categories was not required in the X.500 1988 specification. Classes that were defined before the X.500 1993 standards are assigned to the 88 class. This type of class is specified by a value of 0 in the **objectClassCategory** attribute. *Do not use 88 classes or define new 88 classes.*

**Object class hierarchy**

Inheritance, which is also referred to as derivation, is the ability to build new object classes from existing object classes. A new object is defined as a subclass of its parent object. A subclass is a class that inherits from some other class; for example, a subclass inherits structure and content rules from the parent class. The parent object becomes a superclass of the new object. A superclass is a class from which one or more other classes inherit information. The inherited information includes mandatory and optional attributes (**systemMustContain**, **mustContain**, **systemMayContain**, and **mayContain**) and the parent classes in the directory hierarchy (**systemPossSuperiors** and **possSuperiors**). This relationship between the superclasses and their subclasses represents the object class hierarchy, which is illustrated in the following figure.

**Object Class Hierarchy**

All structural object classes are subclasses, directly or indirectly, of a single abstract object class, which is called **Top**. Every object that is represented in the directory belongs to **Top**, and as a result every entry must have an **objectClass** attribute. When you create a new class, you must specify the superclass. If you do not create a subclass of an existing class, the new class is a subclass of **Top**.

A new class can inherit mandatory and optional attributes from more than one existing class. However, any additional classes must be specified by the **auxiliaryClass** attribute.

### Note

- If you later add another attribute to a class that has subclasses or auxiliary subclasses, the new attribute is automatically added to the subclasses after the schema cache has been updated.

#### Structure and Content Rules

The schema enforces rules that govern both the structure and the content of Active Directory. These rules validate changes to objects to ensure the integrity of the directory.

#### Structure rules

Structure rules define the possible tree structures. When you create a new object, structure rules determine the validity of the object class to which you designate the new object. You cannot create an object that belongs to a nonexistent class. You must first create the new class.

Conversely, these rules do not allow you to delete or modify an object that has already been deleted. In Active Directory, the structure rules are completely expressed by the **possSuperiors** and **systemPossSuperiors** attributes that are present on each classSchema object. These attributes specify the possible classes that can be parents of an object instance of the class. In other words, the **possSuperiors** and **systemPossSuperiors** attribute values determine the object classes and, therefore, the location in the directory tree under which objects of the class can be instantiated.

#### Content rules

Content rules determine the mandatory and optional attributes of the class instances that are stored in the directory. New objects must contain all the mandatory attributes that are specified by the classSchema object in the schema. New objects can contain any of the optional attributes. In Active Directory, the content rules are completely expressed by the **mustHave**, **mayHavemayContain**, **systemMustContain**, and **systemMayContain** attributes of the schema definitions for each class. In addition, there are some operational attributes that are read-only. These are identified by the first bit of the **systemFlags** property for an attribute definition that is set to 1, for example, **lastLogon**.

For more information about mandatory and optional attributes, see Active Directory Schema in the Microsoft Platform SDK on MSDN.

#### Active Directory Schema Physical Structure

The schema exists as a set of directory objects, and it is stored in the directory. Active Directory partitions the information in the directory to facilitate more efficient replication. The schema is stored in its own directory partition so that it can replicate independently of other data that is stored in the directory.

#### Schema Location

The objects that are stored in Active Directory are arranged in a logical hierarchy called the directory tree. The directory tree is divided into directory partitions. A directory partition is a tree of objects that forms a unit of replication in Active Directory. The schema has its own directory partition to prevent potential dependency problems that can arise when new schema classes and new instances of the class are replicated simultaneously. Because the schema has its own tree, it is possible to replicate new schema changes to other domain controllers before replicating any new objects that may have been created based on those changes. This is important because the other domain controllers must have access to the object definitions that are stored in the schema before those domain controllers can properly store any new objects that are created by using those definitions.

Active Directory includes a preconfigured database, commonly referred to as the base directory information tree (DIT), which contains the information that is required to install and run Active Directory. The base DIT is created during a fresh installation of a Windows Server 2003 or later domain controller. The base DIT is contained in a file named Ntds.dit. One section of the base DIT is the base schema.

#### Schema Head

The schema head is the topmost object of the schema directory partition. Conceptually, the schema head functions like other containers in the directory tree, which means that it contains all of the schema information. However, the schema head is not a container in the sense of a special Active Directory object that contains other objects; rather, it is a special-purpose object class. Therefore, it is referred to as the schema head rather than the Schema container. The schema head contains all of the class definitions and attribute definitions that are required to locate objects in Active Directory and create new objects.

The relationships of the schema head, Configuration container, and Domain container are illustrated in the following figure.

### Schema Head

Every Active Directory object can be referenced by a unique and unambiguous name known as the distinguished name. The distinguished name identifies the domain that holds the object as well as the complete path through the container hierarchy by which the object is reached. The distinguished name of the schema head can be expressed as follows:

cn=schema,cn=configuration,dc=*ForestRootDomainName*

You can view the contents of the schema head by using the Active Directory Schema snap-in. You can also bind to the schema directory partition and view schema objects by using the Active Directory Service Interfaces (ADSI) Edit snap-in or the Ldp tool.

**Note**

- ADSI Edit is not one of the default MMC snap-ins provided. To use ADSI Edit and Ldp, install the support tools that are located in the Support\Tools folder on the Windows Server 2003 or later operating system CD.

You can locate the schema head without knowing the domain name. Installation scripts and other applications can gain access to the schema because they bind to a special entry at the top of the logical namespace, called the root DSA-specific Entry (**rootDSE**), which provides the schema location. **rootDSE** represents the top of the logical namespace and, therefore, the top of the LDAP search tree. The attributes of **rootDSE** identify, among other things, the directory partitions — that is, the domain, schema, and configuration directory partitions — as well as the forest root domain directory partition. One attribute, **schemaNamingContext**, provides the location of the schema so that applications that connect to any domain controller can find and read the schema.

**subSchema Subentry**

**rootDSE** also carries a mandatory attribute called **subSchemaSubEntry**. The value of this attribute is the distinguished name of a subSchema object in the directory that defines the attributes (in **attributeTypes**) and classes (in **objectClasses**) that make up the Active Directory schema. This special object, which is an instance of the unique **subSchema** class, is used for administering information about the schema, in particular, the object classes and attribute types that are supported. This enables client applications to retrieve the schema information by querying the **subSchema** entry. Clients must only retrieve attributes from a **subSchema**entry by requesting a base object search of the entry, where the LDAP search filter is (objectClass=subSchema). The following distinguished name describes the location of the SubSchemaSubEntry container:

CN=Aggregate,CN=Schema,CN=Configuration,DC=*DomainName*,DC=*DomainRoot*

For more information about LDAP searches, distinguished names, and containers, see "Data Store Technical Reference."

**Schema Files**

Active Directory data is distributed among all domain controllers in the forest. No single domain controller stores all Active Directory data for the entire forest, but every domain controller does hold a copy of the schema. The database that stores the Active Directory data on a particular domain controller is in a file named Ntds.dit. The location of the Ntds.dit file is an option that you can set during the domain controller promotion process while you create the directory. The default location for Ntds.dit and the database log files is *systemroot*\Ntds. For more information about the Ntds.dit file, see "Data Store Technical Reference."

Another file, the Schema.ini initialization file, contains the information that is necessary for creating the default directory objects and the default security for the directory tree, as well as the Active Directory display specifiers. Although this file is named Schema.ini, the schema itself is actually stored in the Active Directory database, Ntds.dit. Schema.ini is only used by the Active Directory Installation Wizard to build the initial schema structure in the directory during the domain controller promotion process. The Schema.ini file must not be modified.

**Active Directory Schema Processes and Interactions**

Normally, you do not interact directly with the schema on a daily basis. Active Directory uses the schema to help create objects that are stored in the directory. You interact with those objects, not the schema. You interact directly with the schema when you make modifications to the schema by adding definitions to it or by modifying existing definitions.

Schema changes can affect the entire directory. Before you make any changes to the schema, you should thoroughly test those changes in an isolated environment to ensure that the directory continues to function as planned after the changes have been deployed. Only members of the Schema Admins group can make changes to the schema.

The two most common reasons for modifying the schema are:

- Installation of an application that needs to add customized object definitions so that it can store information in the directory, for example, an e-mail program that stores the user's e-mail names in the directory

- Testing of the development of applications that use the directory for data storage in which customized object definitions need to be added to the schema and modified throughout their lifetimes as the development process proceeds

**Modifying the Schema**

When the existing class and attribute definitions in the schema do not meet the needs of your organization, you can add or modify schema objects to extend the schema. You modify an existing attribute or add a new class or attribute to the schema to store a new type of information in the directory. The process of modifying or updating the schema is often referred to as extending the schema.

Before you extend the schema, you must take steps to ensure that the extension does not cause problems in the directory. Do not extend the schema in your production forest without testing the extension in a private forest. First, make changes in a test environment, and check that the changes behave as expected and that they meet your needs. After verifying the changes, you can use various utilities, such as Ldifde, and scripts or customized applications to export the extensions from the test environment and import them into the production environment. You perform most schema extensions by using applications or scripts that are written to extend the schema.

**Note**

- As is true for every object in Active Directory, schema objects are protected by access control lists (ACLs). Therefore, only authorized users can alter the schema.

To add or modify a class definition or attribute definition, you add or modify the corresponding **classSchema** object or **attributeSchema** object. This process is similar to adding or modifying any object in Active Directory, except that additional checks are performed to ensure that changes do not cause inconsistencies or problems in the schema.

**Adding Information to the Schema**

Extending the schema is a major change, with implications throughout the directory. Extend the schema only when it is absolutely necessary. Many schema modifications cannot be reversed; therefore, you must thoroughly plan and test changes before you deploy them in your production forest.

**Planning to extend the schema**

Planning to extend the schema involves examining the default schema that comes with Active Directory to verify that there is no way to use the existing classes or attributes for your needs. It also involves understanding the types of modifications that can and cannot be made.

For more information about modifying the schema, see "Active Directory Schema" in the Microsoft Platform SDK on MSDN.

**Enabling schema extensions**

After you decide to make changes to the schema and you carefully plan the types of changes that you are going to make, you can proceed by implementing and testing the schema extensions in a test environment that is isolated from your production network.

Because extending the schema is a significant operation, Active Directory has the following safety features, or interlocks, that restrict schema modifications:

- The Active Directory Schema snap-in must be registered. Active Directory Schema is not listed with the default MMC snap-ins. It must be registered before it can be made available. This means that Schmmgmt.dll must be registered by using Regsvr32.exe.

- Changes to the schema must be written only on the schema master. Although all domain controllers have a copy of the schema in their Active Directory database, only the domain controller that holds the schema operations master role (also known as flexible single master operations (FSMO)) is allowed to write changes to the schema.

- Administrators must have specific access rights. Only members of the schema administrators group (Schema Admins) or another administrator with explicit permission can make changes to the schema.

- Schema modifications must be enabled. By default, schema modification is disabled on all domain controllers, including

the domain controller that hosts the schema operations master role.

**Identifying or transferring the schema operations master role**
Active Directory performs schema updates in a single-master fashion to prevent conflicts such as conflicts resulting from simultaneous schema updates on two different computers. The one domain controller in the forest that is allowed to perform schema updates at any specific time is referred to as the schema master. The schema master is the domain controller that holds the schema operations master role. After the schema master completes an update, it replicates the changes to all other domain controllers by normal replication channels. In this way, changes to the schema are distributed throughout the forest.

### Note

- To update the schema, the domain controller that holds the schema operations master role must be available on the network. All schema modifications must be made to the domain controller that holds the schema operations master role. If you attempt to modify the schema from a domain controller that does not hold that role, the domain controller generates a referral to the current schema master to process the modifications.

Because the schema master must be used to extend the schema, the domain controller that currently holds the schema operations master role in the forest must be identified. As the forest grows and changes, it may also become necessary to assign the schema operations master role to a different domain controller. You can accomplish both of these tasks by using Active Directory Schema or the command-line tool Ntdsutil.

You can change the domain controller that serves as the schema master at any time. The current schema master in the enterprise is identified by the value of the **FSMORoleOwner** attribute on the schema head of the domain. By default, the first domain controller that is installed in the forest is the initial schema master.

**Granting access rights to make schema changes**
To modify the schema, you must use an account that is a member of the Schema Admins group. By default, the only member in the Schema Admins group is the Administrator account in the root domain of the enterprise. You must explicitly add other accounts.

You can use Active Directory Users and Computers in MMC to verify that an account is a member of the Schema Admins group. Restrict membership in the Schema Admins group to prevent unauthorized access to the schema. Improper modification of the schema can have serious consequences.

By default, only members of the Schema Admins group have permission to write to the schema. You can grant explicit permissions to use Active Directory Schema to specific users. However, this is not recommended.

**Enabling schema modifications on a domain controller**
If you want to allow the domain controller that holds the schema operations master role to modify the schema, use Active Directory Schema to enable schema modifications.

**Removing Information from the Schema**
It is not possible to remove object definitions from the schema. However, object definitions can be rendered unusable through the process of deactivation. When an object definition is deactivated, it can no longer be used to create new objects in the directory. Objects whose definitions have been deactivated in the schema are referred to as defunct.

**Deactivating schema objects**
You cannot deactivate schema objects that are part of the default schema that ships with Active Directory. You can freely deactivate schema objects that have been added to the default schema.

As a result of replication latency, it is not possible to accurately determine if any objects have been created by using a given schema definition or to predict if the objects may be restored from backup media. Therefore, Active Directory does not support the actual deletion of schema objects. Rather, it provides a mechanism for deactivating schema objects in such a way that they become unavailable for use in the directory. Although a schema object still physically exists in the directory after it has been deactivated, new instances of it cannot be created in the directory. Any existing instances of data that are associated with the deactivated schema object continue to exist in the directory; however, there is no way to modify these data instances other than to delete them. This behavior makes the schema object appear to be deleted from the schema.

You can use Active Directory Schema or ADSI Edit to deactivate a class or an attribute by setting the attribute **isDefunct** to the Boolean value of TRUE on the schema object.

You can use Active Directory Schema to view defunct schema objects: on the **View** menu, make sure that **Defunct Objects** is selected. In addition, you can write programs and scripts to search for all schema objects that have the attribute **isDefunct** set

to TRUE. You can also use the Search function of the Ldp tool to search the schema with a filter that is set to isDefunct=TRUE.

As with the addition or modification of classes or attributes, some special validation checks are performed on the deactivation of classes or attributes to ensure consistency of the schema. In particular, when you deactivate a class, Active Directory verifies that the class is not used in the **subClassOf**, **auxiliaryClass**, or **possSuperiors** attributes of any existing active class. Similarly, when you deactivate an attribute, Active Directory checks that the attribute is not used in the **mustContain** or **mayContain** attributes of any existing active class.

**Deactivating existing classes and attributes**

Deactivation of schema classes and attributes is subject to the following restrictions:

- You cannot deactivate a class or attribute that appears in the base Active Directory schema. You can only deactivate schema extensions of the base schema.

- You cannot deactivate an attribute that is referenced in the **mustContain**,**systemMustContain**, **mayContain**, **systemMayContain**, or **rdnAttId** properties of an active class.

- You cannot deactivate a class that is referenced in the **subClassOf**, **auxiliaryClass**, or **possibleSuperior** properties of an active class.

To deactivate an attribute, set the **isDefunct** attribute of itsattributeSchema object to TRUE. When an attribute is deactivated, it can no longer be added to new class definitions. To reactivate an attribute, set the **isDefunct** attribute to FALSE.

To deactivate a class, set the **isDefunct** attribute of its classSchema object to TRUE. When a class is deactivated, new object instances of the class can no longer be created. To reactivate a class, set the **isDefunct** attribute to FALSE.

**Effects of deactivating a schema object on schema updates**

After a class **salesUser** is deactivated, any subsequent addition or modification of instances of **salesUser** fails as if **salesUser** has been deleted from the system; the same error codes are returned as if **salesUser** never existed at all. For example, creating a new instance of **salesUser** fails, and trying to modify or rename an existing instance of **salesUser** fails. Similarly, if an attribute **hasPager** is deactivated, **hasPager** is treated as nonexistent for new object creations, and attempting to modify (add or replace) the value of **hasPager** in an existing object fails.

However, you can still search for and delete existing instances of deactivated schema objects. For example, you can still search for all existing instances of **salesUser** and delete them, if necessary. Note that what you are doing is searching for and deleting objects that were created in the directory using the deactivated class, **salesUser**, not deleting the actual class definition from the schema. Similarly, you can search for all instances that have a value for the attribute **hasPager** and delete **hasPager** from the existing objects. This facilitates cleanup after a schema object is deactivated. If you decide that a class is not needed anymore, you can deactivate it so that no one can use it for any modifications. You can then clean up the existing instances of the class by searching for all instances and deleting them. Active Directory does not perform any automatic cleanup of data instances after a schema object is deactivated.

Similarly, you can deactivate an attribute and clean up all its instances. Note that, for a deactivated attribute, you can delete only the entire attribute from an object, not certain values of the attribute. For example, if **hasPager** is a multivalue attribute and an object has more than one value for **hasPager**, you cannot delete only one value of **hasPager** from the object.

In addition to affecting instances of the schema object, deactivating a schema object also affects schema updates, because schema object updates are subject to special validation checks. For example, if you deactivate the class **salesUser** or the attribute **hasPager**, subsequent schema object updates behave as follows:

- Deactivated classes and attributes can be renamed in the schema. They can also be modified to make other changes to the corresponding classSchema and attributeSchema objects. Note that this behavior is different from the behavior of the Windows 2000 Active Directory schema, in which no modifications are allowed on defunct classes or attributes, except modifications of the **isDefunct** attribute to reactivate the deactivated class or attribute.

- Validation checks that are performed when you add a new class or attribute or when you modify an existing nondefunct class or attribute treat **salesUser** as nonexistent. For example, if **hasPager** is a defunct attribute, trying to modify an existing nondefunct class by adding mayContain=hasPager fails because the validation checks that are performed at schema modification time fail as if **hasPager** does not exist. Or, in the case of a defunct class **salesUser**, trying to add a new class with subClassOf=salesUser fails, because **salesUser** is treated as nonexistent by the validation checks that are performed during the addition of the class.

There is an exception to the rule of defunct classes being treated as nonexistent in Windows 2000 Active Directory. When you try to add or modify a class or attribute so that it has the same distinguished name; object identifier (**attributeID**, **governsID**); **lDAPDisplayName**; **mAPIID**; or **schemaIDGUID** as the defunct class or attribute, the operation fails. In these cases, the class or attribute is treated as an active schema object from the standpoint of schema consistency checks during schema update operations. In Windows Server 2003 or later, this behavior has changed. Defunct objects are still left in the directory. However, it is possible to create a new object that uses the same identification attribute values (that is, **attributeID**, **governsID**, **lDAPDisplayName**, **mAPIID**, or **schemaIDGUID**) as a defunct schema object, as long as the new object's distinguished name is unique. This makes it possible to deactivate a schema object and then create an entirely new schema object — reusing the same values in its definition as the deactivated object — as if the old object were actually deleted. For example, you can change the canonical name (CN) of a defunct object so that you can reuse its old name in the definition of a new schema object. This is very valuable for developers who must constantly modify various classes and attributes for testing purposes. It is possible now to mark an old version of an object definition as defunct and install a new version of the object that uses the same identifiers, making it much easier to develop and test applications that interact with the directory.

This ability to make schema objects defunct can be very useful in different ways in production environments. You can clean up schema objects that are no longer needed by making them defunct. Defunct schema objects are not visible in Active Directory Schema unless you specifically select them on the **View** menu. Then, you can delete existing instances of those classes or attributes if you want to. At the same time, if you need a schema object later, you can reactivate it by modifying the **isDefunct** attribute on the object. This also protects against the accidental removal of a schema object by making it defunct. Making a schema object defunct can be reversed easily with no side effects. Note that because Active Directory does not do any cleanup of data instances after a schema object is made defunct, all instances of the schema object that are made defunct by mistake remain and become valid data when the defunct schema object is made active again.

**Reactivating schema objects**

You can reactivate a defunct schema object either by removing the **isDefunct** attribute from the object or by setting the value of the **isDefunct** attribute to FALSE. You can perform both operations by using either Active Directory Schema or ADSI Edit. Because reactivating a defunct schema object requires schema updates that are similar to adding a new schema object, Active Directory performs the same validation checks as it does when you add a new schema object.

The following validation checks are performed when a defunct schema object is reactivated:

- A defunct class cannot be reactivated unless the attributes that are referenced in its **mustContain**, **systemMustContain**, **mayContain**, **systemMayContain**, or **rdnAttId** attributes — as well as the classes that are referenced in its **subClassOf**, **auxiliaryClass**, and **possibleSuperior** attributes — are already active.

- A defunct class cannot be reactivated if the value of any of the attributes **lDAPDisplayName**, **governsID**, or **schemaIDGUID** is the same as the value that is stored in an already active class or attribute.

- A defunct attribute cannot be reactivated if the value of any of the attributes **lDAPDisplayName**, **attributeID**, **schemaIDGUID**, **mAPIID** is already in use by an active class or attribute.

A defunct schema object can be reactivated at any time. The only restriction is that the **isDefunct** attribute should be the only attribute that is present in the modify call. This helps prevent any ambiguity problems while schema consistency checks are performed.

**Updating the Schema Cache**

When changes are made to Active Directory, they are validated against the schema, which can affect domain controller performance.

The schema is stored in the directory database. Because all changes are validated against the schema, they result in queries of the schema in the directory database, which can increase the workload on a domain controller. To make the operation more efficient, domain controllers cache the schema in memory. Anytime the schema is updated, the schema cache is also updated automatically.

After the domain controller is started, the schema cache is loaded from the schema information in the underlying database and updated automatically whenever the schema is updated. When changes are made, the schema cache is updated automatically within five minutes after the first change is applied. During the interval before the schema updates are copied to the schema cache, objects that reference a new or modified class or attribute cannot be added. If another domain controller attempts to use the new schema modifications, a replication interval must pass before the change becomes available. This behavior keeps the cache consistent, but it can be confusing because changes are not apparent until the cache is updated, even though they are applied to the directory database. When a change is replicated to a domain controller from a replication partner, the cache is updated immediately, without the five-minute delay.

You can update the schema cache by adding the **schemaUpdateNow** attribute to **rootDSE** with a value of 1. The value is not used; it acts as a trigger or operational attribute. You can write this attribute to start a cache reload.

Adding the **schemaUpdateNow** attribute causes a schema cache update to start immediately. The update operation is "blocking," which means that no other modifications can be made until this operation is complete. This prevents multiple changes from being made to the schema simultaneously. If the operation finishes with no errors, the cache is updated and all schema updates are ready to be used. The return of an error, however, indicates that the cache update is not successful. Applications that add the **schemaUpdateNow** attribute should be designed to accommodate the blocking write, particularly to provide feedback if the program or script runs interactively.

You can also update the schema cache immediately by using Active Directory Schema: in the console tree, right-click **Active Directory Schema** and then click **Reload the Schema**.

**Note**

- If you must make multiple changes to the schema, complete all changes before forcing an immediate schema cache update, rather than forcing an update after each change. Multiple cache loads can result in increased workload on the server.

#### Default Security Settings for Active Directory Objects

The default security descriptor for an Active Directory object is specified in the schema. When a new object is created, Active Directory configures the default access rights for that new object. The security descriptor contains the settings that are used to configure the default access rights, and the security descriptor is stored in the schema as part of that object types definition.

**Note**

- There are special cases in which default security is not applied on newly created objects. For more information about access rights, see "Active Directory Schema" in the Microsoft Platform SDK on MSDN.

#### Default security settings for the domain directory partition

The domain directory partition object is derived from the object class **domainDNS**. Therefore, the default security of the domain directory partition object is equivalent to the default security for **domainDNS**.

The default security descriptor for the domain directory partition includes the following permissions:

- Full Control to the Domain Admins group and the System group and Read to the Authenticated Users group.
- Read on all properties to the Everyone group. This permission provides backward compatibility for application programming interfaces (APIs).
- Replicating Directory Changes, Replication Synchronize, and Manage Replication Topology permissions to the Enterprise Domain Controllers group. These permissions allow members of the Enterprise Domain Controllers group to manage replication automatically.
- Replicating Directory Changes, Replication Synchronize, and Manage Replication Topology permissions to the Builtin Administrators group. Administrators of individual domain controllers can use these permissions to troubleshoot replication problems.
- Inheritable Full Control to the Enterprise Admins group. Enterprise Admins, by definition, have complete control of each domain.
- Inheritable List Contents to the Pre–Windows 2000 Compatible Access group.
- Inheritable Read Property on Remote Access Service (RAS) Information, General Information, Membership, User Account Restrictions, and User Logon on all User Objects permissions to the Pre–Windows 2000 Compatible Access group.
- Inheritable Read on all Group objects.
- Inheritable Auditing successful/failed writes to the Everyone group. Activating the auditing policy ensures that writes that are performed on any object in the directory are audited immediately, without the need for extra user intervention.

Inheritable access control entries (ACEs) provide a convenient way to remove auditing policy.

**Default security settings for the configuration directory partition**
The default security descriptor for the configuration directory partition includes the following permissions:

- Full Control to the Domain Admins group and System and Read to the Authenticated Users group.
- Replicating Directory Changes, Replication Synchronize, and Manage Replication Topology permissions to the Enterprise Domain Controllers group. These permissions enable domain controllers in the forest to replicate from each other and automatically reconfigure the replication topology on the basis of replication delays and latency for the configuration directory partition.
- Replicating Directory Changes, Replication Synchronize, and Manage Replication Topology permissions to the Builtin Administrators group. These permissions enable administrators from individual domain controllers to synchronize replication and topology management for the configuration directory partition.
- Enable Inheritable Full Control to the Enterprise Admins group. This permission allows members of the Enterprise Admins group exclusive control over the Configuration container. The Enable Inheritable Full Control permission is required to control the Configuration container throughout the forest.
- Enable Inheritable Auditing to the Writes by the Everyone group. Activating the auditing policy ensures that writes that are performed on any object in the directory are audited immediately, without the need for extra user intervention. Inheritable ACEs provide a convenient way to remove auditing policy.

**Default security settings for the schema directory partition**
The default security descriptor for the schema directory partition includes the following permissions:

- Write access to the schema head to the Schema Admins group.
- Change Schema Master control permission to the Schema Admins group. This permission enables members of the Schema Admins group to change which domain controller holds the schema operations master role.
- Inheritable Full Control permission to the Schema Admins group. By default, the Schema Admins group is the only group that has Write access to the entire schema head. A schema object does not have any exclusive control over its own security; therefore, the object inherits its security from the schema head.
- Replicating Directory Changes, Replication Synchronize, and Manage Replication Topology to the Enterprise Domain Controllers group. These permissions enable the members of the Enterprise Domain Controllers group to manage replication of the schema in the forest automatically.
- Replicating Directory Changes, Replication Synchronize, and Manage Replication Topology permissions to the Builtin Administrators group. These permissions enable the administrators of domain controllers to resolve replication issues.
- Read permissions to the Authenticated Users group. This permission gives the members of the Authenticated Users group the right to read the schema.
- Audit successful/failed writes to the Everyone group. Activating the auditing policy ensures that writes that are performed on any object in the directory are audited immediately without the need for extra user intervention. Inheritable ACEs provide a convenient way of removing auditing policy.

**Default security settings for attributes and classes**
All attributes and classes inherit security from the ACLs on the schema head. This ensures that security for the entire schema is consistent.

### Note

- The default security settings allow Write access to the schema head only to the Schema Admins group.

**Issues Related to Modifying the Schema**
Three main issues relate to modifying the schema:

- The impact on replication
- Managing concurrent schema modification operations
- Handling invalid object instances

**Impact on replication**
Because the schema is replicated across all domain controllers in the forest, a schema update that is performed at one domain controller is propagated throughout the forest. This guarantees that the schema is consistent across the forest. However, because of replication latencies, there can be temporary inconsistencies.

Active Directory solves this problem by explicitly replicating the schema head from the originating server when failures occur. Additionally, the replication of the schema head triggers an immediate schema cache update on the target server. Active Directory then replicates the failed object again.

**Managing concurrent schema modification operations**
Programs that modify the schema should not be run concurrently unless the programs include provisions to check that schema modifications that are made by one program will not conflict with schema modifications that are made by the other programs. Active Directory must ensure that different program threads do not perform simultaneous, conflicting schema updates, such as one thread deleting an attribute when another thread is adding the attribute to the **mayContain** list of a class.

To ensure that different program threads do not perform simultaneous, conflicting schema updates, any thread that attempts to perform a schema update also writes a special attribute on the schema head automatically as part of the transaction. Active Directory automatically causes the thread to write the attribute so that you do not have to do so in your program code. Only one thread can write this attribute at any one time. This method guarantees schema consistency, but it does not guarantee which of the updates is successful. This is an important consideration when schema updates are made in a batch, such as during the installation of directory-enabled applications.

For example, consider a scenario in which two programs, program A and program B, are being installed simultaneously. Both programs are designed to create several new schema objects. Because Active Directory creates one thread per object update, it is possible that *some* of the objects in program A and *some* of the objects in program B are created (if the internal threads do not overlap). Then, one of the installations fails because a thread for a schema object creation for program A overlaps with a thread for a schema object creation for program B.

Assume that program A fails because of the thread conflict and the resulting failure to create some of the needed schema objects. Attempting to reinstall program A again does not work because some of the objects that program A created are already in the schema, and trying to create them again in the second run returns an error.

**Handling invalid object instances**
Schema updates can make an existing instance of an object invalid. For example, suppose a user account object, JohnDoe, is an instance of **classSalesEmployee**. The **classSalesEmployee** class has an attribute, **POBox**, in its **mayContain** list. Therefore, because JohnDoe is an instance of **classSalesEmployee**, JohnDoe can have the **POBox** attribute defined in it. Assume that JohnDoe does have this attribute currently defined in it. A schema update is performed that modifies **classSalesEmployee** by deactivating the attribute **POBox** from its **mayContain** list. Note that this change makes the instance of JohnDoe invalid because JohnDoe now has an attribute, **POBox**, that it is not allowed to have according to the class definition of **classSalesEmployee** (of which JohnDoe is an instance). Active Directory allows the now-invalid objects to remain in the directory and ensures that they do not cause problems in the rest of the schema. Active Directory does not automatically clean up invalid objects, but invalid objects and attributes appear in searches and can be deactivated manually.

**Interoperating with Other Directories**
To provide more support for industry standards in Active Directory, the schema supports the **inetOrgPerson** object class and the use of a standard file format for importing and exporting schema modifications.

**inetOrgPerson Object Class**
The Active Directory schema in Windows Server 2003 supports the **inetOrgPerson** object class. The **inetOrgPerson** object class and its associated attributes are defined in RFC 2798. The **inetOrgPerson** object class is used in several non-Microsoft LDAP and X.500 directory services to represent users in the directory.

Support for inetOrgPerson makes migrations from other LDAP directories to Active Directory more efficient. The

**inetOrgPerson** class was added by adding new attributes to the schema and deriving inetOrgPerson from the **user** class and the new attributes. As a result, inetOrgPerson can be used as a security principal.

**inetOrgPerson in Windows Server 2003 and Later**
To help organizations migrate their applications and directory data to Active Directory, the **inetOrgPerson** class has been added to the base schema.

The definition of the **inetOrgPerson** class is based on RFC 2798. However, some issues have caused the Active Directory definition of this class to differ from the RFC definition, as follows:

- The **inetOrgPerson** class is derived from the **user** class, not the **organizationalPerson** class. This makes it possible for inetOrgPerson to operate as a security principal. Accounts that are created as inetOrgPerson objects can log in to Active Directory.

- Attributes that are already defined in the base schema are not changed.

  Several attributes in the base schema are defined as single-value instead of multivalue, or the reverse, as defined in the RFC 2798. The object identifier of some attributes differs from the definition in the RFC. Changing the definition of these attributes in the base schema to match the RFC causes backward compatibility problems with the Windows 2000 Active Directory schema and may result in application problems. For example, Microsoft Outlook will not display the data for attributes that have an unexpected value for the **isSingleValued** attribute. Active Directory management tools may treat the attributes incorrectly and inadvertently overwrite data or fail to update them at all.

- The **inetOrgPerson** class inherits two mandatory attributes:

  - The **cn** attribute is used to name a new instance of the class. The **samAccountName** attribute is the user's login ID.

  - The **objectCategory** attribute for inetOrgPerson is set to **Person**. This has the effect of returning all user, computer, and inetOrgPerson objects when the filter in a query is objectCategory=Person.

**Importing and Exporting Directory Information**
Active Directory supports the use of files that are formatted with LDAP Data Interchange Format (LDIF) for importing and exporting information in the directory. This includes information that is stored in the schema, such as schema modifications.

LDIF is an industry-standard, ASCII, text-based file format that can be used to define data in a text file that is used to import information, such as schema modifications, into LDAP-based directories. LDIF is defined in RFC 2849.

After an LDIF file is created, a tool such as Ldifde.exe, which is available in Windows Server 2003 or later, performs the import operation using the data file for input. Ldifde.exe can also be used to export data from the directory. Exported data is also stored using the LDIF file format to make it easier to import the data into another LDAP-based directory. For more information about LDAP, see "Data Store Technical Reference."

# Active Directory Schema Tools and Settings

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**Active Directory Schema Tools and Settings**

**In this section**

- Active Directory Schema Tools
- Related Information

When existing class and attribute definitions in the Active Directory schema do not meet the needs of your organization, you can use schema-based administrative tools to modify or add schema objects. You can modify an existing attribute or add a new class or attribute to the schema to store a new type of information in the directory. The process of modifying or updating the schema is often referred to as "extending the schema." In addition to using schema tools to extend the schema, you can perform most schema extensions by using customized applications or Active Directory Service Interfaces (ADSI) scripts.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to Active Directory Domain Services. |

**Note**

- Extending the schema is a major change with implications for the entire directory. Extend the schema only when it is absolutely necessary. Many schema modifications cannot be reversed; therefore, you must thoroughly plan and test changes in an isolated environment before you deploy them in your production forest.

This section contains information about the tools that are associated with the Active Directory schema.

**Active Directory Schema Tools**

Normally, you do not interact directly with the schema on a daily basis. Active Directory uses the schema to create objects that are stored in the directory. You interact with those objects, not with the schema. You interact directly with the schema when you make modifications to the schema by adding definitions to it or by modifying existing definitions.

Only members of the Schema Admins group can make changes to the schema. The two most common scenarios for modifying the schema are as follows:

- You install an application that adds customized object definitions so that it can store information in the directory; for example, you install an e-mail program that stores user e-mail names in the directory.
- You test the development of applications that use the directory for data storage. In this scenario, you add customized object definitions to the schema and modify them throughout their lifetimes as the development process proceeds.

**Note**

- Changes to the schema must be written only on the schema master. Although all domain controllers have a copy of the schema in their Active Directory database, only the domain controller that holds the schema operations master role (also known as flexible single master operations (FSMO)) is allowed to write changes to the schema.

The following tools are associated with the Active Directory schema.

**Adsiedit.exe: ADSI Edit**

**Category**

ADSI Edit is included when you install Support Tools for Windows Server 2003 and later.

**Version Compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

ADSI Edit is a Microsoft Management Console (MMC) snap-in that uses ADSI, which uses the Lightweight Directory Access Protocol (LDAP). You can use ADSI Edit to view and modify directory objects in the Active Directory database. You can also use it to view schema directory partition objects and properties. When you open ADSI Edit, the Schema container is displayed by default. You can expand the container to view schema classes and attributes.

To find more information about ADSI Edit, see "Support Tools Help" in Tools and Settings Collection.

**Csvde.exe: Csvde**

**Category**
Csvde is a command-line tool that ships with Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

The comma-separated value (CSV) file format is a simple format whose primary benefit is ease of use. In the CSV file format, each line represents a discrete object in the directory, and the object's attributes are separated by commas. The first line of the file always contains all of the attribute names. Each subsequent line represents a different entry in the directory. Values for multivalue attributes can also be specified, and they are delimited by semicolons (;).

Because this format is compatible with the Microsoft Excel CSV format, you can use Csvde.exe to export directory information to an Excel spreadsheet or to import data from a spreadsheet into Active Directory. You can use this format only for additions to the directory. Csvde.exe cannot be used to modify or delete objects. Csvde.exe also supports batch operations that are based on CSV.

The parameters that are used for the Csvde.exe tool are the same as the parameters that are used for the Ldifde.exe tool. However, unlike Ldifde.exe, Csvde.exe can export data from Active Directory into files that can be read by certain applications. For example, if you want to view all Active Directory users in an Excel report, you can use Csvde.exe to export the directory data into the CSV file format, which you can then read in Excel.

To find more information about Csvde.exe, see "Command-Line References" in Tools and Settings Collection.

**Dsa.msc: Active Directory Users and Computers**

**Category**
Active Directory Users and Computers is an MMC snap-in in Administrative Tools that is installed automatically on all domain controllers running Windows Server 2003.

### Version compatibility

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional with Adminpak.msi installed | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

Active Directory Users and Computers is a graphical user interface (GUI) tool that you can use to manage users and computers in Active Directory domains. To modify the schema, you must use an account that is a member of the Schema Admins group. By default, the only member in the Schema Admins group is the Administrator account in the root domain of the enterprise. You must explicitly add other accounts.

You can use Active Directory Users and Computers to verify that an account is a member of the Schema Admins group. Restrict membership in the Schema Admins group to prevent unauthorized access to the schema. Improper modification of the schema can have serious consequences.

By default, only members of the Schema Admins group have permission to write to the schema. You can assign explicit permissions to use the Active Directory Schema snap-in to specific users; however, this is not recommended.

**Ldifde.exe: Ldifde**

**Category**
Ldifde is a command-line tool that ships with Windows Server 2003.

### Version compatibility

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

Active Directory supports the use of files that are formatted with the LDAP Data Interchange Format (LDIF) for importing and exporting information in the directory. This includes information that is stored in the schema, such as schema modifications. After an LDIF file is created, a tool such as Ldifde.exe performs the import operation by using the LDIF file for input. You can also use Ldifde.exe to add, modify, and delete directory objects; export Active Directory user and group information to other applications or services; and populate Active Directory with data from other directory services.

To find more information about Ldifde.exe, see "Command-Line References" in Tools and Settings Collection.

**Ntdsutil.exe: Ntdsutil**

**Category**
Ntdsutil is a command-line tool that ships with Windows Server 2003.

**Version Compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition |

Ntdsutil.exe provides advanced management capabilities for Active Directory. For the Active Directory schema, you can use Ntdsutil.exe to identify, transfer, or seize the schema operations master role. This tool is intended for use by experienced administrators.

To find more information about Ntdsutil, see "Command-Line References" in Tools and Settings Collection.

**Schmmgmt.msc: The Active Directory Schema snap-in**

**Category**
The Active Directory Schema snap-in is an MMC snap-in in Administrative Tools that is installed automatically on all domain controllers running Windows Server 2003. However, you must register it manually before you use it for the first time.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
| --- | --- |
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional with Adminpak.msi installed | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

The Active Directory Schema snap-in is a GUI tool that members of the Schema Admins group can use to manage Active Directory objects and their associated attributes. You can use this tool to create and modify classes and attributes. You can also use it to specify what attributes are indexed and what attributes are replicated to the global catalog.

The Active Directory Schema snap-in is not one of the default MMC snap-ins that is provided with Windows Server 2003. To make it appear in the list of available snap-ins, install the Windows Server 2003 Administration Tools Pack (Adminpak.msi). To register the Active Directory Schema snap-in, run **Regsvr32 Schmmgmt.dll** from the command prompt or from the **Run** command on the **Start** menu.

**ADSI and Visual Basic Scripts**

Active Directory provides a set of interfaces that you can use programmatically to gain access to directory objects, including schema objects. ADSI conforms to the Component Object Model (COM), and it supports standard COM features. ADSI defines a directory service model and a set of COM interfaces that you can easily use with a variety of programming languages. With Microsoft Visual Basic, Scripting Edition and ADSI, you can write scripts to modify the directory in various ways, including extending the schema.

For more information about using ADSI and scripting to modify the schema, see Using Active Directory Service Interfaces in the Microsoft Platform SDK on MSDN.

**Related Information**

The following resources contain additional information that is relevant to this section:

- "Support Tools Help" in Tools and Settings Collection for information about ADSI Edit
- "Command-Line References" in Tools and Settings Collection for information about Csvde, Ldifde, and Ntdsutil

# Data Store Technical Reference

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

In the Active Directory directory service, the data store contains database files and processes that store and manage directory information for users, services, and applications. A copy of the data store runs on each domain controller in the forest. The data store provides access to directory information through a process called the Directory System Agent (DSA). The data store holds directory information in a database file called Ntds.dit. The Active Directory data store is often referred to as the directory.

# What Is the Data Store?

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- The Business Need
- The Data Store Solution
- Data Store Scenarios
- Directories and Databases
- Data Store Dependencies
- Related Information

In Active Directory, the data store contains database files and processes that store and manage directory information for users, services, and applications. A copy of the data store runs on each domain controller in the forest. The Active Directory data store is often referred to as the directory.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to Active Directory Domain Services. |

**The Business Need**

Organizations generate and store data about many different kinds of entities (computers, users, services, and so on) that exist in their information technology (IT) infrastructure. Historically, organizations maintain this information in multiple locations and formats. For example, an organization might store employee information in a human resources database, application data in an application-specific database, Quality of Service (QoS) rules on routers, and security information (user name and password) on a network server. Storing, managing, and making available many disparate data sets is expensive and time consuming.

**The Data Store Solution**

The Active Directory data store solves the problem of managing disparate data sets across an organization. The data store is a single, general-purpose database that can hold many types of data and distribute that data to users anywhere on the network. The following figure illustrates the use of the Active Directory data store as a single, general-purpose database for all of an organization's data.

**Data Store**

The Active Directory data store achieves the following major design goals:

- To provide distributed access to the directory by users and applications, a copy of the data store resides on all domain controllers in a domain or forest.
- To provide standard interfaces for accessing data, the data store includes a Lightweight Directory Access Protocol (LDAP) interface and a Messaging API (MAPI) interface.
- To support quick searches of directory data, the data store includes efficient query and index mechanisms.
- To ensure scalability, the data store uses a hierarchical, or tree, model that supports partitioning. The data store also ensures scalability by automatically managing database growth and increasing the database file size when necessary.
- To support both full and incremental restoration of data, the data store uses a transactional model, logging uncommitted transactions in log files.
- To ensure data consistency, the data store enforces a set of extensible data type and format constraints, called the schema.

**Data Store Scenarios**
Active Directory is required for the deployment and operation of Windows Server 2003 and later domains and forests. The data store is a key and required part of any Active Directory deployment. Therefore, the data store exists in any Windows Server 2003 and later domain or forest. Use of the data store can be further delineated into two main scenarios, based on the type of data that is stored. These scenarios are the network operating system (NOS) directory scenario and the NOS and application directory scenario.

**NOS Directory Scenario**
In the NOS directory scenario, an organization uses the data store only for storage of NOS-related information, including information about users, computers, services, printers, and so on. This scenario applies to organizations that are not running directory-enabled applications (applications that can communicate with and store data in a directory data store) or to organizations that are using a different directory data store than Active Directory for storing application data. In this scenario, you can manage the data in the data store by using the command-line and graphical user interface (GUI) tools that are provided with Windows Server 2003 and later.

**NOS and Application Directory Scenario**
In the NOS and application directory scenario, directory-enabled applications that are not a part of the NOS use the data store to hold application-specific data. Examples of directory-enabled applications include messaging, customer relationship management (CRM), enterprise resource planning (ERP), and document management applications. In this scenario, the schema (the set of rules that define the type and formatting of data) is generally extended to include data definitions that are specific to the directory-enabled applications that use the data store.

**Directories and Databases**
In the context of directory services, questions often arise regarding the differences between directories and databases. The Active Directory data store shares many aspects in common with databases, including the storage of data in rows and columns and the use of a hierarchical data model.

A directory differs from a database primarily in its intended use. A directory is optimized for read operations, while a database is optimized for write and change operations. Therefore, any data that is read many more times than it is written or modified is a good candidate for storage in a directory.

A directory also typically differs from a database in the protocols that it uses to access information in the data store. A directory, such as Active Directory, is most often accessed with LDAP. A database is most often accessed with an interface such as Structured Query Language (SQL).

**Data Store Dependencies**
The Active Directory data store depends on several related technologies and resources for its proper functioning. The following sections describe these technologies and resources.

**NTFS**
The data store requires a disk volume that is formatted with the NTFS file system. NTFS is more powerful than FAT16 or FAT32, and NTFS includes features that are required for hosting Active Directory. For more information about NTFS, see "NTFS Technical Reference."

**Network Connectivity**

So that users and computers can access the data store, and to support replication of the data store between domain controllers, network connectivity with TCP/IP is required. For more information about networking and TCP/IP, see "TCP/IP Technical Reference."

**Active Directory Replication**

Except for very small networks, directory data must reside in more than one place on the network to be equally useful to all users. Through the process of replication, Active Directory maintains copies, or replicas, of the data store on each domain controller in the forest, which helps to ensure data availability and performance for all users. For more information about replication, see "Active Directory Replication Model Technical Reference."

**FRS**

The File Replication service (FRS) is a process that is associated with the Distributed File System (DFS). FRS is used by Active Directory to replicate the system volume (SYSVOL) between domain controllers. SYSVOL holds certain kinds of Active Directory information, including Group Policy objects (GPOs) and scripts. For more information about FRS, see "FRS Technical Reference."

**Disk Space**

There are no practical limits to the number of objects that can be stored in the Active Directory data store. The Active Directory directory database has been tested for up to 40 million objects. Performance tests show logon performance for a single LDAP client to be the same with 10,000 objects, 100,000 objects, and 1 million objects; that is, the directory service does not slow measurably when the size of the database increases.

The minimum free disk space requirements for the directory database and log files depend on the size of the database. On partitions that hold the database only (and not the database log files), free disk space must not fall below the greater of 20 percent of the disk space that is consumed by the database or 500 megabytes (MB). On disk volumes that hold the database and the database log files, free disk space must not fall below the greater of 20 percent of the combined size of the Ntds.dit and log files or 1 gigabyte (GB). For more information about the Ntds.dit and log files, see "How the Data Store Works."

# How the Data Store Works

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Data Store Architecture
- Data Store Protocols
- Data Store Interfaces
- Data Store Logical Structure
- Data Store Physical Structure
- Data Store Processes and Interactions
- Network Ports Used by the Data Store
- Related Information

In Active Directory, the data store contains database files and processes that store and manage directory information for users, services, and applications. A copy of the data store runs on each domain controller in the forest. The Active Directory data store is often referred to as the directory.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to Active Directory Domain Services. |

The ideal environment for the data store includes the following:

- A domain controller running an operating system in the Windows Server 2003 or later family and containing hardware that meets the minimum hardware requirements of the edition of the operating system.
- For environments consisting of multiple domain controllers, the presence of a fully functioning Active Directory replication topology
- For environments consisting of multiple domain controllers, the presence of a fully functioning File Replication Service (FRS) topology
- A regular backup schedule
- Regular monitoring of Active Directory, either through manual review of event logs or through an automated monitoring solution, such as Microsoft Operations Manager (MOM)

This section describes the elements of the Active Directory data store, including its architecture, protocols, interfaces, logical structure, physical structure, processes and interactions, and network ports.

**Data Store Architecture**

The Active Directory data store consists of several components that together provide directory services to directory clients and to other directory servers. These components include three service components, four interfaces, and the directory database

where data is actually stored.

The following figure illustrates the architecture of the data store.

**Data Store Architecture**

The following table describes the components of the data store.

**Data Store Components**

| Component | Description |
|---|---|
| Interfaces: Lightweight Directory Access Protocol (LDAP), replication (REPL) and domain controller management interface, Messaging API (MAPI), Security Accounts Manager (SAM)) | The data store interfaces provide a way for directory clients and other directory servers to communicate with the data store. |
| Directory System Agent (DSA) (Ntdsa.dll) | The DSA, which runs as Ntdsa.dll on each domain controller, provides the interfaces through which directory clients and other directory servers gain access to the directory database. In addition, the DSA enforces directory semantics, maintains the schema, guarantees object identity, and enforces data types on attributes. |
| Database layer | The database layer is an application programming interface (API) that resides in Ntdsa.dll and provides an interface between applications and the directory database to protect the database from direct interaction with applications. Calls from applications are never made directly to the database; they go through the database layer. In addition, because the directory database is flat, with no hierarchical namespace, the database layer provides the database with the abstraction of an object hierarchy. |
| Extensible Storage Engine (ESE) (Esent.dll) | The ESE, which runs as Esent.dll, manages the tables of records — each with one or more columns — that make up the directory database. |
| Database files | The data store stores directory information in a single database file called Ntds.dit. In addition, the data store also uses log files, to which it temporarily writes uncommitted transactions. |

The DSA, database layer, and ESE are described in the following sections. For information about the interfaces, see "Data Store Interfaces" later in this section. For information about the database files, see "Data Store Physical Structure" later in this section.

**DSA**

The DSA runs on every domain controller as Ntdsa.dll, and it provides access to the directory database. The DSA runs as part of the Local Security Authority (LSA) process (Lsass.exe), which manages authentication packages and authenticates users and services. Running in Lsass.exe enables Active Directory to securely manage sensitive information, such as account passwords.

Clients can use one of the supported interfaces to connect (bind) to the DSA and then search for, read, and write to Active Directory objects and their attributes.

A forest-wide object in the directory, the NTDS Settings object (class **nTDSDSA**), represents the DSA on a domain controller, and this object contains configuration information about the DSA on that domain controller.

In addition to providing the interfaces through which directory clients gain access to directory data, the DSA provides the following functionality.

**Object identification**
Every object in Active Directory has a permanent globally unique identifier (GUID), which is associated with several string forms of the object name (SAMAccountName, user principal name, and distinguished name), as well as a security identifier (SID). The object names and the SID are not permanent; that is, they can be changed. All permanent references to the object are kept in terms of the GUID. The object name is used for hierarchy navigation and display purposes, and the SID is used for access control. The DSA maintains the GUID association with an object when the object's string name or SID changes, for example, when the object is moved to a different folder (the string name changes) or when the object is moved to a different domain (the string name and the SID change).

**Schema enforcement**
The DSA ensures that data in the directory adheres to the data definitions that are provided by the directory schema. The schema is the set of rules that determines what kind of data the directory can hold.

### Note

- In forests, if an update does not produce a conflict with the schema at the originating replica, the update is considered acceptable at all replicas. Therefore, replicated updates do not perform schema checks, and you do not have to wait until the schema replicates before creating instances of a new object or attribute. For more information about replication, see "Active Directory Replication Model Technical Reference".

**Access control enforcement**
The DSA enforces security limitations in the directory by reading SIDs on the access token.

**Support for replication**
The API that is called to initiate replication is implemented in the DSA.

**Referrals**
The DSA manages the directory hierarchy information (referred to as knowledge), which it receives from the database layer. The DSA is responsible for cross-references of Active Directory domain objects.

**Functional levels**
Beginning with Windows Server 2003 and later domain controllers, the DSA has a built-in numeric value that identifies its operating system version — and therefore its functional capabilities — to other services. Services that rely on the DSA can use this numeric value to determine which of their service features to enable.

**DSA GUID and Invocation ID**
Both the DSA and the Active Directory database are represented uniquely and have their own respective GUIDS. The DSA GUID is the GUID of the NTDS Settings object (class **nTDSDSA**). The value of the DSA GUID is stored in the **objectGUID** attribute of the NTDS Settings object of the given domain controller server object, which resides in the Sites container in the configuration directory partition.

Domain controllers use the DSA GUID to locate replication partners. Replication uses a special Domain Name System (DNS) name that contains the DSA GUID. This GUID-based DNS name is an alias for the local computer name. The Net Logon service registers this alias resource record in DNS in the form of the CNAME (canonical name) resource record.

The DSA GUID is created when the domain controller is initially promoted, that is, when Active Directory is installed. The DSA GUID is destroyed only if Active Directory is removed from the domain controller. The DSA GUID ensures that the DSA remains recognizable when a domain controller is renamed. The DSA GUID is also not affected by the Active Directory backup and restore process.

The Active Directory database has its own GUID, which the DSA uses to identify the database instance (the version of the database). The database GUID is stored in the **invocationId** attribute on the nTDSDSA object. Unlike the DSA GUID, which never changes for the lifetime of the domain controller, the invocation ID changes during the Active Directory restore process to ensure the consistency of the replication process. On domain controllers running Windows Server 2003 or later, the invocation ID also changes when an application directory partition is removed from or added to the domain controller.

**Database Layer**
The database layer is an API that resides in Ntdsa.dll and provides an object view of the directory database, making the data

accessible to the DSA as a set of hierarchical containers. By applying schema semantics to database records, the database layer isolates the upper components of the directory service from the underlying database system. The database layer is an internal interface. No database access calls are made directly to the ESE; instead, all database access is routed through the database layer.

In the directory database, each object is identified by its relative distinguished name, which is unique in the object's parent container. The relative distinguished name and the chain of successive parent object names make up the object's distinguished name. The database stores the relative distinguished name for each object, as well as a reference to the parent object. The database layer follows these parent references and concatenates the successive relative distinguished names to form distinguished names, thereby defining the object hierarchy.

The database layer is also responsible for the creation, retrieval, and deletion of individual records (objects), attributes within records, and values within attributes. To carry out these functions, the database layer uses the schema cache (an in-memory structure in the DSA) to get the information about the attributes that it needs.

**ESE**

The Extensible Storage Engine (ESE) is a Windows component that is used by Active Directory, as well as by several other Windows components, as an interface to the data that is stored in an indexed and sequential access method (ISAM) database. (The Active Directory database is an ISAM database.) The ESE is responsible for indexing the data in the database file and for transferring the data in and out of the database. Its purpose is to enable applications to store and retrieve data by using the ISAM. The ESE provides applications with a consistent data state by means of transacted data update and retrieval. A crash recovery mechanism maintains data consistency, even in the event of a system crash. Transactions in the ESE are highly concurrent, making the ESE suitable for server applications. The ESE caches data intelligently to ensure high-performance access to data. In addition, the ESE is resource efficient, making it suitable for applications that perform auxiliary roles.

The version of the ESE that runs on domain controllers is implemented in Esent.dll.

The following characteristics of the ESE make it well suited to the storage needs of Active Directory. The ESE:

- Supports databases of up to 16 terabytes (TB) in size, and it can hold many millions of objects per domain.
- Supports indexing.
- Supports multivalued attributes.
- Supports update operations that are transacted for stability and integrity across system failures.
- Can be backed up while the domain controller is online.
- Handles sparsely populated objects well; that is, space in the database is not reserved for attributes that do not have values.

**Note**

- The encrypting file system (EFS) enables users to encrypt individual files, folders, or entire data drives. Because EFS initialization and domain controller startup occur in parallel, EFS recovery operations can interfere with the ability of the ESE to start Active Directory and cause domain controller startup to fail.

The Active Directory schema defines all the attributes that are required and allowed for a given object. However, the ESE reserves storage only for the space that is used — that is, only for the attributes that have values, not for all possible attributes. For example, if a user object has 50 attributes defined in the schema and you create a user with values for only 4 attributes, storage space is allocated only for those 4 attributes. If more attributes are added later, more storage is allocated for them.

The ESE implements the search and retrieval functionality of the underlying database. Also, the ESE is able to store attributes that can have multiple values. For example, the database can store multiple phone numbers for a single user without requiring a different phone number attribute for each phone number.

ESE provides transactional views of the database. The cost of providing these views is that any object that is modified in a transaction has to be temporarily copied so that two views of the object can be provided: one to the thread inside that transaction and one to threads in other transactions. This copy must remain as long as any two transactions in the process have different views of the object. The repository that holds these temporary copies is called the version store. Because the

version store requires contiguous virtual address space, it has a size limit. If a transaction is open for a long time while changes are being made (either in that transaction or in others), eventually the version store can be exhausted. At this point, no further database updates are possible.

**Note**

- The percentage of version store space that is available for processing has been significantly increased in Windows Server 2003 and later.

**Data Store Protocols**

The primary protocol that is used by the Active Directory data store is Lightweight Directory Access Protocol (LDAP), which runs on top of TCP/IP. In addition, the data store uses remote procedure call (RPC) for MAPI, replication, domain controller management, and SAM-related operations. And, although it is not widely used, the data store also supports the use of Simple Mail Transfer Protocol (SMTP) for replication between domain controllers where "always on" network connections do not exist.

The following figure illustrates the protocols and interfaces that are used by the data store. For more information about the data store protocols, see the table that follows this figure. For more information about the data store interfaces, see "Data Store Interfaces" later in this section.

**Data Store Protocols**

The following table describes the protocols that are used by the data store.

**Data Store Protocols**

| Protocol | Description |
|---|---|

| | |
|---|---|
| LDAP | LDAP is a directory service protocol that specifies directory communications. It runs directly over TCP/IP, and it can also run over User Datagram Protocol (UDP) connectionless transports. Clients can use LDAP to query, create, update, and delete information that is stored in a directory service over a TCP connection through the TCP default port 389. Active Directory supports LDAP v2 (RFC 1777) and LDAP v3 (RFC 2251). LDAP v3 is an industry standard that can be used with any directory service that implements the LDAP protocol. LDAP is the preferred and most common way of interacting with Active Directory.<br><br>Historically, LDAP is a simplified ("lightweight") version of Directory Access Protocol (DAP), which is the original protocol that was used to interact with X.500 directories. X.500 defines an earlier set of standards that was developed by the International Organization for Standardization (ISO). LDAP is simpler than DAP in two key ways:<br><br>• Rather than using its own protocol stack according to the Open Systems Interconnection (OSI) networking model, LDAP communicates over Internet Protocol (IP) by using either UDP or TCP.<br><br>• LDAP syntax is easier to use than DAP syntax.<br><br>For these reasons, LDAP is widely used and accepted as the standard protocol for directory service access.<br><br>The following key aspects characterize LDAP:<br><br>• The protocol is carried directly over TCP for connection-oriented transport (receipt of data is acknowledged) and over UDP for connectionless transport (sent or received data is not acknowledged).<br><br>• Most protocol data elements can be encoded as ordinary strings, for example, as distinguished names.<br><br>• Referrals to other servers can be returned to the client.<br><br>• Simple Authentication and Security Layer (SASL) mechanisms can be used with LDAP to provide associated security services. SASL Digest is supported in Windows Server 2003 and later as the authentication standard for LDAP.<br><br>• Attribute values and distinguished names can be internationalized through the use of the ISO 10646 character set.<br><br>• The protocol can be extended to support new operations, and controls can be used to extend existing operations.<br><br>• The schema is published through an attribute on the directory root object (rootDSE) for use by clients. |
| RPC | The data store uses RPC for replication (REPL) and domain controller management communications, MAPI communications, and SAM-related communications. RPC is a powerful, robust, efficient, and secure interprocess communication (IPC) mechanism that enables data exchange and invocation of functionality residing in a different process. That different process can be on the same computer, on the local area network (LAN), or across the Internet. |
| SMTP | The data store can use Internet-standard SMTP as the protocol for replication communications when a permanent, "always on" network connection does not exist between two domain controllers. SMTP is used to transport and deliver messages based on specifications in Request for Comments (RFC) 821 and RFC 822. SMTP also includes enhancements that build on the basic delivery functions of the protocol. There are SMTP options available that provide control over the routing and delivery of messages and that provide secure communications. |

**Data Store Interfaces**

As shown in the "Data Store Architecture" figure earlier in this section, network clients and other directory servers obtain access to Active Directory through one of the interfaces that are described in the following table.

**Data Store Interfaces**

| Interface | Description |
|---|---|

| | |
|---|---|
| LDAP | LDAP is the primary interface for the data store. Directory clients use LDAP v3 to connect to the DSA through the LDAP interface. The LDAP interface is part of Wldap32.dll. LDAP v3 is backward compatible with LDAP v2. |
| REPL | The REPL management interface provides functionality for finding data about domain controllers, converting the names of network objects between different formats, manipulating service principal names (SPNs) and DSAs, and managing replication of servers. |
| MAPI | Messaging clients gain access to the Microsoft Exchange Server directory service by using MAPI address book providers. For compatibility with existing messaging clients, Active Directory supports the MAPI-RPC address book provider, which provides access to Active Directory, for example, to find the telephone number of a user. |
| SAM | SAM is a proprietary interface for connecting to the DSA on behalf of clients that use Windows NT 4.0 or earlier. These clients use Windows NT 4.0 networking APIs to connect to the DSA through SAM. Replication with Windows NT 4.0 backup domain controllers (BDCs) goes through the SAM interface as well. |

**Note**

- The MAPI interface is provided only for support of legacy Microsoft Outlook clients. Development against the MAPI interface is no longer supported.

**Data Store Logical Structure**

The Active Directory data store uses the LDAP information model as its model for organizing data. In addition, the data store is organized into logical partitions that can each be replicated independently, so that individual domain controllers only need to store data that is pertinent to the domain in which they reside.

**LDAP Information Model**

The LDAP information model is based on the entry, which contains information about some object, for example, a person or computer. In Active Directory, an LDAP entry is referred to as an object. Active Directory objects are composed of attributes, which have a type and one or more values.

The implementation of the information model is called the schema, which is a set of objects that defines the structure and content of every object that can be created in a directory service.

**Directory Tree**

Active Directory organizes objects into a hierarchical tree structure. The directory tree represents the hierarchy of Active Directory objects for a given forest. The structure of the hierarchy is derived from the schema, and the directory service implements the hierarchy. The hierarchy provides the basis both for using names for navigation and for defining the scope of search requests.

Every object in Active Directory has exactly one parent, and a reference to the parent object is stored with the object. As a result of these parent references, the hierarchy of objects that are managed by Active Directory forms a tree structure. The objects that populate the directory create this tree structure according to the rules of the schema. For example, the schema might dictate that a given class of object can be the child of one class but not the child of another class.

The architectural restrictions and requirements in the directory tree are as follows:

- Domain objects, which are containers, can be children only of other domain objects. For example, a domain cannot be the child of an organizational unit (OU).

- The root object of the directory tree is called the DSA-specific Entry (DSE), or rootDSE. The rootDSE object has no hierarchical name or schema class, but it does have a set of attributes that identify the contents of the domain controller on which it resides. Therefore, rootDSE constitutes the root of the directory tree from the perspective of the domain controller to which you are connected.

- Below the rootDSE, every directory has a root domain, which is the first domain that is created in a forest. This domain always has a child container called Configuration, which contains configuration data for the forest.

**rootDSE**

In the LDAP information model, one or more directory servers can jointly provide access to a directory tree. The servers that host directories are known in LDAP terminology as Directory System Agents (DSAs). In Active Directory, the DSAs are always domain controllers.

At the root of a directory tree is a DSE, which is not part of any directory partition. TherootDSE represents the top of the logical namespace for one domain controller. The rootDSE attributes contain information about the directory server, including its capabilities and configuration.

There is only one root for a given directory, but the information that is stored in the root is specific to the domain controller to which you connect. Among other things, the attributes of rootDSE identify the following key information:

- The directory partitions (the domain, schema, and configuration directory partitions) that are specific to one domain controller.
- The forest root domain directory partition.

In this way, the rootDSE provides a "table of contents" for a given domain controller.

**rootDSE operational attributes**
The rootDSE publishes information through attributes on the rootDSE object. RFC 2251 and RFC 2252 define a set of seven rootDSE operational attributes that LDAP v3 servers are expected to publish, and these attributes are described in the following list. All LDAP servers recognize these attribute names, but when the attribute corresponds to a feature that the server does not implement, the attribute is absent.

**supportedLDAPVersion**
LDAP versions that the server implements. Domain controllers running Windows 2000 Server and later support LDAP v2 and LDAP v3.

**namingContexts**
Naming contexts (directory partitions) that this server masters (stores as a writable replica) or shadows (stores as a read-only replica). A client uses this attribute to choose suitable base objects for searching when the client contacts a server.

**subschemaSubentry**
The name of a subschema entry, which is used to administer information about the schema, in particular, the object classes and attribute types that are supported.

**altServer**
Uniform Resource Locators (URLs) of other servers that can be contacted when this server becomes unavailable. If the server does not know of any other servers, this attribute is absent. Clients can cache this information in case their preferred LDAP server becomes unavailable. This attribute is absent by default for Active Directory servers.

**supportedExtension**
Object identifiers that identify the supported extended LDAP operations that the server supports. LDAP extensions include operations such as different query types, paging operations, and sorting methods, which each have a different object identifier. This attribute is absent by default for Active Directory servers.

### Note

- A new extended LDAP operation on domain controllers running Windows Server 2003 enables client refresh of a dynamic entry in the directory. Object identifier = 1.3.6.1.4.1.1466.101.119.1 is defined and published in the **supportedExtension** attribute of the rootDSE object.

**supportedControl**
Object identifiers that identify the LDAP controls that the server supports. If the server does not support any controls, this attribute is absent. Server controls extend LDAP functionality; examples include a control to move objects across domains and a control to delete an entire subtree of a container object.

**supportedSASLMechanisms**
The names of the SASL mechanisms that the server supports. SASL is a standard for negotiating an authentication mechanism and, optionally, an encryption mechanism to provide client authorization for accessing Active Directory. By default, Generic Security Service API (GSSAPI) is supported.

**rootDSE informational attributes**
In addition to the previous operational attributes, Active Directory also supports the following informational attributes.

**currentTime**
The current time in the generalized time format.

**dsServiceName**
The distinguished name of the NTDS settings object that represents this domain controller in the configuration directory partition.

**defaultNamingContext**
The default naming context (directory partition) for a particular server. This value is the distinguished name of the domain directory partition for which this domain controller is authoritative.

**schemaNamingContext**
The naming context (directory partition) for the forest schema.

**configurationNamingContext**
The naming context (directory partition) for the forest Configuration container.

**rootDomainNamingContext**
The distinguished name for the domain naming context (directory partition) of the first domain that is created in this forest. This domain functions as the forest root domain.

**supportedLDAPPolicies**
Supported LDAP administrative query policies, such as the maximum size of a result set (**MaxResultSetSize**) and maximum page size (**MaxPageSize**).

**highestCommittedUsn**
Highest update sequence number (USN) that is committed to the database on this domain controller.

**dnsHostName**
The DNS name of this domain controller.

**serverName**
The fully qualified distinguished name for this domain controller.

**supportedCapabilities**
The object identifier value (1.2.840.113556.1.4.800) that indicates the additional capabilities of an Active Directory server, such as dynamic update, integrated DNS zones, and LDAP policies.

**LdapServiceName**
The SPN for the LDAP server, which is used for mutual authentication.

**isSynchronized**
A Boolean indicator for whether the domain controller has completed its initial synchronization with replica partners.

**isGlobalCatalogReady**
A Boolean indicator for whether the domain controller is prepared to advertise itself as a global catalog.

**domainControllerFunctionality**
The numeric level of Active Directory functionality for the domain controller.

**Distribution of Directory Data**
So that it can scale to tens of millions of objects, the Active Directory data store is logically partitioned in such a way that each domain controller does not store the entire directory. To accomplish logical partitioning, the data is categorized according to a naming scheme: object names group objects into logical categories so that the objects can be managed and replicated appropriately. In Active Directory, the largest of these logical categories is called a directory partition.

Every domain controller holds at least one directory partition that stores domain data, such as users, groups, and OUs. Every domain controller also stores two nondomain directory partitions that store forest-wide data, which includes the schema and configuration data.

The data store holds data for a single forest. Although there is a single directory, some directory data is distributed within domains, while other data is distributed throughout the forest without regard for domain boundaries. In Windows Server 2003 and later, data can also be distributed to domain controllers according to applications that use the data, where the scope of distribution is set by the application. The following table describes the three types of data that are stored in the Active Directory data store.

### Types of Active Directory Data

| Data Type | Description |
| --- | --- |
| Domain-wide data | • Domain-specific data is stored in a domain directory partition.<br>• A full, writable replica of the domain directory partition is replicated to every domain controller in the domain. |
| Forest-wide data | • Forest-wide data is stored in two directory partitions: the configuration directory partition and the schema directory partition. The Configuration container is the topmost object of the configuration directory partition; the Schema container is the topmost object of the schema directory partition.<br>• A full, writable replica of the configuration directory partition is replicated to every domain controller in the forest.<br>• A read-only replica of the schema directory partition is replicated to every domain controller in the forest. The schema is writable on only the domain controller that holds the schema operations master role, and writing to the schema requires first adding a registry entry on the schema master. Schema updates replicate to every domain controller in the forest.<br>• In addition to a full, writable replica of a single domain (the domain for which the domain controller is authoritative), special domain controllers that are designated as global catalog servers also store partial, read-only replicas of every other domain directory partition in the forest. (The read-only replicas in the global catalog are "partial" because they store only some of the attributes for each object.) A domain controller that is a global catalog server can be queried to find any object in the forest. |
| Application data | • Applications can use a new type of directory partition in Windows Server 2003 and later Active Directory, called an application directory partition, to store application-specific data that has a scope of interest that is smaller than the entire forest or domain. This data can be characterized as either changing frequently (dynamic) or having a short useful lifetime (volatile). For example, Windows Server 2003 and later DNS can use application directory partitions to store dynamically updated DNS zone data on only those domain controllers that are DNS servers rather than on all domain controllers in the domain, as is required for Windows 2000 Active Directory–integrated zones. |

**Directory Partition Hierarchy**

In Active Directory, a directory partition is a portion of the directory namespace. Each directory partition contains a subtree of the directory objects in the directory tree. The same directory partition can be stored as a replica on many domain controllers, and the replicas are updated through directory replication.

There is an important distinction between the physical storage of a directory partition and its logical position in the directory tree. Physically, all objects are stored in a single database table, regardless of the directory partition to which they are assigned because of their object names. Logically, the head of a directory partition appears in the naming hierarchy as the topmost object; that is, the Domain container, the Configuration container, and the Schema container each has a distinguished name that identifies its position in the hierarchy.

Every domain controller stores a replica of a domain directory partition, the configuration directory partition, and the schema partition. For more information about these partitions, see "Directory Partitions" later in this section.

**Note**

- Although the schema directory partition is replicated to every domain controller in the forest, it can be updated only on the domain controller that holds the schema operations master role.

The following figure is a conceptual diagram of the directory tree hierarchy, including the directory root (rootDSE) and the default directory partitions below the directory root. TherootDSE represents the top of the logical namespace for one domain controller and, as such, it represents the top of the LDAP search tree. There is only one root for a given directory, but the information that is stored in the root is specific to the domain controller to which you connect.

In any Active Directory forest, the first domain directory partition that is created in the forest (the forest root domain), the configuration directory partition, and the schema directory partition always form the hierarchy that is illustrated in the

following figure.

**Default Active Directory Partitions**

Additional directory partitions are possible in the form of application directory partitions, but these partitions are not stored by default on every domain controller.

**Directory Partition Cross-Reference Objects**

When Active Directory is installed to create the first domain controller in a new forest, the three directory partitions that are shown in the previous figure are created on the domain controller. At this time, a cross-reference object (class **crossRef**) is created for each directory partition in the Partitions container in the configuration directory partition (CN=partitions,CN=configuration,DC=*forestRootDomain*). Creation of each subsequent directory partition in the forest, either by installing Active Directory to create a new domain or by creating a new application directory partition on an existing domain controller, initiates the creation of an associated cross-reference object in the Partitions container.

**Note**

- You can also manually create a cross-reference object for an application directory partition.

A cross-reference object identifies the name and server location of each directory partition in the forest. The replication system uses this information to identify servers that store the same directory partitions. LDAP queries use cross-reference objects to create referrals to different domains.

**Forest Root Domain**

Because the forest root domain is the first domain that is created in a forest, it is the root name in the domain namespace hierarchy. In naming only, the topmost object of the configuration directory partition — the Configuration container — is the child of the forest root domain object in the hierarchy. The LDAP distinguished name of the Configuration container (CN=configuration,DC=*forestRootDomain*) reflects this naming hierarchy, which links the configuration directory partition to the forest.

Similarly, the topmost object in the schema directory partition — the Schema container — is the child of the Configuration container. The distinguished name of the Schema container (CN=schema,CN=configuration,DC=*forestRootDomain*) links the schema to the forest.

**Directory Partitions**

The Active Directory data store holds three default directory partitions:

- The configuration directory partition
- The schema directory partition
- The domain directory partition

Optionally, the data store may also hold one or more application directory partitions.

**Configuration Directory Partition**

The configuration directory partition is created initially when the first domain of a forest is created during the installation of Active Directory. Thereafter, it is replicated to every new domain controller that is added to the forest. The configuration directory partition holds information of global interest, for example, the default configuration and policy information for all instances of a given service in the forest.

**Note**

- Global information should be stored in one of two places: in a child of the Services container or in a child of a site object.

**Contents of the configuration directory partition**
In Active Directory tools, such as ADSI Edit, the configuration directory partition is represented by a Configuration container. When you open ADSI Edit (Adsiedit.msc) from the **Run** dialog box, the Configuration container for the forest of the domain to which you are connected is displayed, along with the current domain directory partition and the schema directory partition.

### Note

- If you open ADSI Edit with Microsoft Management Console (MMC) (as opposed to opening ADSI Edit from the **Run** dialog box), you must connect to the directory partition to view it.

The following objects are child containers in the Configuration container.

**DisplaySpecifiers**
Contains the objects that define different user interfaces (UIs) for each object class in the schema that requires a graphical user interface (GUI), for example, context menus and property pages. The display specification system uses the information that is stored in the display specifiers to form different UIs for administrators and end users. One set of elements can be associated with administrative applications, and a different set of elements can be associated with end-user applications. What you see and what the user sees are different, even though in both cases the UI references the same objects. The display specification system stores information for property sheets, context menus, icons, creation wizards, and localized class and attribute names.

This UI specification occurs at the level of each object class as defined in the schema in classSchema objects. Each classSchema object can have UI display specification information that is uniquely associated with it.

The DisplaySpecifiers container stores other containers that correspond to each locale that is supported. A locale is either a language or a language in combination with a country/region. Windows supports more than 150 locales, such as French (Belgium), Arabic (Saudi Arabia), and so forth. The names of locale containers are the hexadecimal representations of the locale identifiers (LCIDs). For example, the English (United States) locale container is 409.

Display-specifier objects (class **displaySpecifier**) are named by appending the LDAP Display Name of the class object with the string -"-Display.". For example, the **user** class has a corresponding display-specifier object called user-Display. Therefore, when an Active Directory administrative tool displays an object of a particular class, the object is displayed according to information that is contained in the display-specifier object whose name contains the same name as the respective class in the container for the current locale.

Because the Active Directory schema can be modified by creating new classes and attributes or by modifying existing classes, display-specifier objects can be modified to reflect any new UI elements that schema modifications require.

**Extended-rights**
Stores objects of the class **controlAccessRight** that can be used by applications to extend standard access control.

**ForestUpdates**
Stores operation objects that are generated by forest preparation tasks (when you run **adprep /forestprep**) so that the system can check for the tasks that have and have not been completed when you upgrade the first domain controller in the forest to Windows Server 2003 or later. The child object CN=Operations contains the objects that represent each update operation. These objects are named for the GUID of the operation. The child object CN=Windows2003Update is created to indicate that all **adprep** operations have run.

**LostAndFoundConfig**
Provides storage for configuration directory partition objects that are being created in containers that are simultaneously being deleted on another domain controller in the same forest. If, before replication, an object is created in or moved to a location that no longer exists after replication, the "lost" object is added to the LostAndFoundConfig container. A LostAndFound container in each domain directory partition serves the same purpose for domain-specific objects.

**NTDS Quotas**
Stores objects (class **msDS-QuotaControl**) that contain object ownership quota assignments for the configuration directory partition. Quotas limit the number of objects that a user (including inetOrgPerson), group, computer, or service can own in a domain directory partition, configuration directory partition, or application directory partition.

**Partitions**
Stores the cross-references to every directory partition in the forest, including the configuration partition, the schema partition, and all domain directory partitions. These cross-references to directory partitions make referrals to other domains possible during LDAP searches.

**Physical locations**

Not used in this version of Windows but reserved for future use.

**Services**
Stores data for various networking services and applications, such as Message Queuing (**MsmqServices**), public key services, and Routing and Remote Access. In the Windows NT container, the Directory Service object (**nTDSService**) has attributes that you can use to manage garbage collection intervals and dynamic object Time to Live (TTL). For the most part, however, objects in the Services container do not require administration. Specifically, do not publish application services in this container. Such services are best published in the Program Data container in the domain directory partition.

**Sites**
Identifies all of the sites in the network, the domain controllers in those sites, and the replication topology. The contents take the form of replication transports, subnets, and the first site and site link that are created, called Default-First-Site-Name and Default-First-Site-Link, respectively.

**Well-known security principals**
Contains the special identities that are defined by the security system, such as Everyone, Local System, Principal Self, Authenticated User, and Creator Owner.

**Schema Directory Partition**
The Active Directory schema is stored in the Schema container in the schema directory partition. The schema consists of a set of object classes, attributes, and syntaxes. It also defines rules that ensure that objects are created and modified with consistency. Active Directory contains a default set of classes and attributes that cannot be modified. However, if you have Schema Admins credentials and if schema modification is enabled for the domain controller, you can extend the schema by adding new attributes and classes to represent application-specific classes. These changes are targeted at the domain controller that is the schema master for the forest. Only the schema master stores a writable copy of the schema.

**Domain Directory Partition**
When you create a new domain, a domain directory partition is created in Active Directory as an instance of the class **domainDns**. A cross-reference object is added for the domain in the Partitions container to advertise the domain's location in the directory.

**Contents of a domain directory partition**
The topmost object in each domain directory partition is a domainDns object that is named with the DNS name of the domain.

A domain directory partition is represented by a domain container, and a domain directory partition has the following child containers.

**Builtin**
Default local group accounts, such as Administrators and Users, that are installed whenever a new workstation, server, or domain controller is set up.

**Computers**
A default storage area for "new" computer objects that were originally created through legacy APIs. When a Windows NT 4.0 domain or a Windows NT 3.51 domain is upgraded to Windows 2000, or when a Windows NT 4.0 domain is upgraded to Windows Server 2003 or later, the computer accounts are moved automatically to the Computers container. The Computers container also supports the Windows NT 4.0 tool User Manager (Usrmgr). This container cannot be renamed, but when a Windows Server 2003 or later domain has a domain functional level of Windows Server 2003 or later, the default location for computer accounts can be specified as an OU to redirect the location of newly created computer objects.

**Domain Controllers**
The default container for new domain controllers. The Domain Controllers container cannot be renamed.

**ForeignSecurityPrincipals**
Proxy objects for security principals that are from Windows NT 4.0 domains or Windows NT 3.51 domains, or that are from different forests, and that have been added to Windows 2000 or later groups.

**LostAndFound (advanced features)**
A storage area for new domain objects whose containers were deleted elsewhere at the same time that the object was created. If an object has been created in or moved to a location that is missing after replication, the "lost" object is added to the LostAndFound container. The LostAndFoundConfig container in the configuration directory partition serves the same purpose for forest-wide objects.

**NTDS Quotas (advanced features)**
A storage area for objects of the class **msDS-QuotaControl** that contain object ownership quotas for the domain directory partition. Quotas limit the number of objects that a user, group, computer, or service can create in a directory partition.

**Program Data (advanced features)**
An empty container that is available for applications to store application-specific data in the domain directory partition.

**System (advanced features)**
Built-in system settings for the various system service containers and objects.

**Users**
A default storage area for new user accounts created through legacy APIs that are not Active Directory–aware. When a Windows NT 4.0 domain or a Windows NT 3.51 domain is upgraded to Windows 2000 or later, or when a Windows NT 4.0 domain is upgraded to Windows Server 2003 or later, the user accounts and groups are moved automatically to the Users container. The Users container also supports the Windows NT 4.0 tool User Manager (Usrmgr). This container cannot be renamed, but when a Windows Server 2003 or later domain has a domain functional level of Windows Server 2003 or later, the default location for user and group accounts can be specified as an OU to redirect the location of newly created user objects.

### Note

- The Users and Computers containers and several other special containers, called "well-known" containers, can be located dependably by applications.

**Deleted Objects**
A special container, which is not visible in the UI, to which objects are moved when they are deleted. The deleted objects are stored as tombstones, which are eventually removed by garbage collection. The contents of the Deleted Objects container are visible if you search by using the 1.2.840.113556.1.4.417 control, which enables you to see deleted objects.

**Infrastructure**
An object of class **infrastructureUpdate** that identifies the NTDS Settings object of the domain controller that holds the infrastructure operations master role for the domain.

**Contents of the System container**
The System container stores per-domain operational information, which includes the default local security policy, file link tracking, Microsoft NetMeeting network meeting objects, objects representing other trusted domains, and containers for RPC and Windows Sockets (Winsock) connection points.

The System container has the following child containers.

**AdminSDHolder**
Administrator security descriptor holder. Windows Server 2003 and later implements protection of administrative groups through a background task that computes the set of memberships and checks whether their security descriptors are well-known protected security descriptors. If the security descriptor of any administrative account does not match that of AdminSDHolder, the security descriptor is overwritten with the security descriptor of AdminSDHolder. This task is executed only on the domain controller that holds the primary domain controller (PDC) emulator operations master role.

**COMPartitions**
A namespace that is used by Component Services to allow multiple versions of the same COM+ application to exist on the same physical computer.

**ComPartitionSets**
A conceptual collection of COM+ partitions.

**Default Domain Policy**
The common domain location for the AppCategories container (class **classStore**), which holds objects of the class **categoryRegistration**. These objects are managed by the Group Policy Software Installation MMC extension, and they can be associated with applications that are deployed through Group Policy in the domain.

### Note

- The Group Policy object (GPO) for the default domain policy is stored in the Policies container.

**Dfs-Configuration**
Lists the fault-tolerant Distributed File System (DFS) configuration and DFS volume information.

**DomainUpdates**
Stores operation objects that are generated by domain preparation tasks (when you run **adprep /domainprep**) so that the

system can check for tasks that have and have not been completed when you upgrade the first domain controller in the domain to Windows Server 2003 or later. The child Operations object contains the objects that represent each update operation. These objects are named for the GUID of the operation. The child Windows2003Update object is created to indicate that all **adprep** operations have run.

**File Replication Service**
Lists the Domain System Volume (SYSVOL) and provides a replication schedule from Sunday through Saturday, 12:00 A.M. to 12:00 A.M.

**FileLinks**
Used by the Distributed Link Tracking Server service (TrkSvr) to store information about linked files that have moved across NTFS volumes. Includes **ObjectMoveTable**, which tracks moved files, and **VolumeTable**, which maps volume IDs to computer IDs.

**IP Security**
Contains the Internet Protocol security (IPSec) policies that are applied to local computers, domain member servers, domains, OUs, or any GPO in Active Directory. Depending on your organization's guidelines, IPSec policies can store multiple security specifications, called rules, so that one policy can be applied to multiple computers. These rules apply to all users who log on to the computer

**Meetings**
A folder that is used by Microsoft NetMeeting to publish network meeting objects.

**MicrosoftDNS**
A container in which Active Directory–integrated zone database records are created when the scope of replication is all domain controllers in the domain. When DNS data is stored in Active Directory, each DNS zone is an Active Directory container object (dnsZone). The dnsZone object contains a dnsNode object for every unique name in that zone. The dnsNode object has a **dnsRecord** multivalue attribute that contains a value for every resource record that is associated with an object's name. When the scope of replication of DNS data is all DNS servers in the domain or all DNS servers in the forest, DNS zone data is stored in application directory partitions, not in the domain directory partition.

**Policies**
Contains GPOs, which specify user and computer configurations for groups of users and computers. This container stores the default domain policy (lists the security groups and default permissions for the domain); default domain controller policy; and policy for passwords, lockouts, Kerberos, EFS data recovery, and trusted root certificates. Each GPO in the Policies container is identified by a GUID, and each GPO includes the following:

- Version information that is used to ensure that information is synchronized with Group Policy template information
- Status information that indicates whether the GPO is enabled or disabled
- A list of components, or extensions, that have settings in the GPO

In addition to being stored in the Policies container, GPOs are also stored in a Group Policy template, and they are identified by GUID. The Group Policy template is located in the SYSVOL, and it is used to store file type data for the GPOs.

**RAS and IAS Servers Access Check**
Verifies permissions for the RAS and IAS Servers domain local security group to access user account properties. When Routing and Remote Access (configured for Windows authentication) or Internet Authentication Service (IAS) queries a domain controller to validate user account credentials and receives a failure notification, there is no indication why the failure occurred. It might have occurred because the user's credentials were invalid or because the server running Routing and Remote Access or IAS did not have the appropriate permissions to access user account properties. Routing and Remote Access and IAS servers obtain access to user account properties by adding the computer account of the server to the RAS and IAS Servers group. The RAS and IAS Servers group has Read permission to the RAS and IAS Servers Access Check container. By attempting access to the RAS and IAS Servers Access Check container, the Routing and Remote Access or IAS server determines whether or not it has permissions to access user account properties.

**RpcServices**
Includes the RPC name service lookup for domains using versions of Windows earlier than Windows 2000.

**WinsockServices**
Winsock services that publish themselves by using the registration and resolution (RnR) APIs are published in this container.

**WMIPolicy**
Stores Windows Management Instrumentation (WMI) filters. A WMI filter is a query based on configuration and event information that is made available by WMI providers. By associating a WMI filter with a specific GPO, that WMI filter determines which computers process policy settings in that GPO. Computers that meet all of the conditions that are specified in the WMI filter return a value of TRUE and then process the GPO.

**Application Directory Partitions**
Application directory partitions are special partitions that can be created on domain controllers running Windows Server 2003 or later to provide LDAP storage for dynamic and volatile data. In Windows 2000 Server, nondomain data is limited to configuration and schema data, which is replicated to every domain controller in the forest. In a Windows Server 2003 or later forest, application directory partitions provide storage for nondomain, application-specific data that can be replicated to any arbitrary set of domain controllers in the forest — as few or as many as needed by the application that uses the data.

### Note

- Applications must be specifically programmed to use application directory partitions.

**Characteristics and requirements**
Application directory partitions have characteristics that make them suitable for storing dynamic data (data that is updated frequently) or volatile data (data that has a specified useful lifetime), as opposed to more static data that domain directory partitions and other directory partitions store. Although application directory partitions are represented as instances of the **domainDNS** class, as are domain directory partitions, they have characteristics that differentiate their behavior from domain directory partitions.

### Note

- Applications can create application directory partitions on Windows Server 2003 or later based domain controllers by explicitly creating a domainDNS object. Only Windows Server 2003–based and later domain controllers allow creation of domainDNS objects by means other than Active Directory installation. Because Windows 2000 Server and earlier domain controllers do not recognize the request to create a domainDNS object, no special instance type is required to differentiate between application directory partitions and domain directory partitions.

**Similarities to domain directory partitions**
The following characteristics of application directory partitions are the same as the characteristics of domain directory partitions:

- Naming: Application directory partitions can be named in the same manner as domains, and they can be attached anywhere in the Active Directory namespace where a domain can be attached. Therefore, an application directory partition can be a child of a domain or of another application directory partition.

- DNS location: Application directory partitions can be discovered through DNS.

- Cross-reference object: A cross-reference object is created in the CN=partitions,CN=configuration,DC=*ForestRootDomain* container for each application directory partition.

- Change notification for replication: The time intervals that control the latency of the initiation of an originating change notification to replication partners within a site can be configured. These configuration changes are applied to all directory partitions, but they are most useful for application directory partition replication of dynamic data.

- Access control: The security and access control model for the application directory partition is the same as that for other partitions in Active Directory.

- TTL: For objects that are stored in an application directory partition, you can assign a TTL value that is configurable. The only requirement is that the domain controller is running Windows Server 2003.

  For objects that are stored in a domain directory partition replica on a Windows Server 2003–based or later domain controller in a forest that has a forest functional level of Windows Server 2003 or later, you can assign a TTL. For all other functional levels, however, TTL values cannot be assigned to objects in domain directory partitions.

**Differences from domain directory partitions**
The following characteristics are different from domain directory partitions and specific to application directory partitions:

- Credentials for creation: Creating an application directory partition requires Domain Admins credentials in the forest root domain or Enterprise Admins credentials.

- Replication scope: Whereas domain directory partitions are replicated to every domain controller in a domain, application directory partitions can be replicated to any selected set of domain controllers in the forest. Because application directory partitions do not have domain or site affiliations, either an administrator or the application that creates the directory partition must explicitly define the scope of replication.

  **Note**

  - It is best to store replicas of dynamic data on domain controllers in the same site because intersite replication latency might not be acceptable for replica consistency.

- NetBIOS name: Application directory partition objects do not have network basic input/output system (NetBIOS) names. For this reason, their cross-reference objects, which are usually identified by the unique NetBIOS names of their respective directory partitions, are named by GUIDs.

- Contents: Security principals (users, groups, services, and computers) cannot be stored in application directory partitions.

- Global catalog: Application directory partitions are not replicated to the global catalog.

- Volatility: Whereas domain data should be relatively static, application directory partition data can be volatile, such as the real-time data that is used by Microsoft Telephony API (TAPI) voice conferencing applications.

**Stored objects**
Any type of object, with the exception of security principals, can be stored in an application directory partition. In addition, objects that reside in an application directory partition:

- Can maintain distinguished-name references to other objects in the same application directory partition, objects in the configuration and schema directory partitions, and any directory partition root object.

- Cannot maintain distinguished-name references to objects in other application directory partitions or in domain directory partitions.

- Cannot be moved to other Active Directory partitions outside the application directory partition in which they were created.

Applications can be programmed to store their dynamic data in application directory partitions. The following are examples of applications and the kinds of dynamic objects that they store:

- Real-time communication applications: These types of applications typically maintain rendezvous information about active users (user name, computer, and IP address) and conferences in progress (conference name, description, time, and originator).

- Network services: Routing and Remote Access, Remote Authentication Dial-In User Service (RADIUS), Dynamic Host Configuration Protocol (DHCP), and Common Open Policy Service (COPS) servers need to store dynamically changing forms of data in a directory so that they can be accessed using one uniform method: LDAP. This data generally does not require global replication, and it is also shared by many applications in the proximity of a single directory. (In this case, the data is shared between RAS, RADIUS, DHCP, and COPS servers in a particular site.) The object types include information about user sessions and bandwidth used.

- Directory-enabled networking: For implementing policy-based networking, there is a large amount of nonstatic, or volatile, information that must be maintained, including information about the state of network links, the flows that are active through a router, and the data rate for each flow. Policy servers might need access to such information to make a

decision based on policies that are predicated on dynamic network state in addition to static data that is stored in the directory.

The application directory partition, with its controlled replication scope, can accommodate transient data needs in Active Directory by providing network applications with uniform and consistent access through LDAP to both static and dynamic data.

**Security descriptor reference domains**

When an object is created in Active Directory, it is assigned a security descriptor that contains default access control entries (ACEs) that are taken from the **defaultSecurityDescriptor** attribute of the class of which the object is an instance. The default ACEs can include domain-relative, well-known SIDs. In the case of objects in a domain directory partition, the reference domain by which the system interprets the domain-relative SIDs is the domain that is represented by the domain directory partition.

In the case of an application directory partition, there is no security association between the application directory partition and the domain of the domain controller on which it is created. In a Windows Server 2003 or later forest, a new, single-valued attribute on the cross-reference object — **msDS-SDReferenceDomain** — stores the name of the reference domain that is used to interpret the domain-relative SIDs in default ACEs for new objects in an application directory partition.

When an application directory partition is created, the value of **msDS-SDReferenceDomain** on the respective cross-reference object is determined as follows:

- If the parent object of the application directory partition is another application directory partition, the value of **msDS-SDReferenceDomain** is set to the value of **msDS-SDReferenceDomain** on the cross-reference object of the parent application directory.
- If the parent object is a domain directory partition, the value of **msDS-SDReferenceDomain** is set to the parent domain.
- If there is no parent object, the value of **msDS-SDReferenceDomain** is set to the forest root domain.

**Note**

- It is recommended that domain local groups not be used in the access control lists (ACLs) of objects in application directory partitions. If an application directory partition has replicas on domain controllers in two different domains, the membership of such domain local groups in ACLs can expand to yield different results, depending on the domain controller to which a user connects.

**GUID names for cross-reference objects**

Domains in Active Directory must have NetBIOS names that are unique in the forest so that they are backward compatible with computers that are running earlier versions of Windows. Domains must also have DNS names that are unique. The relative distinguished name of the cross-reference object for each domain directory partition is taken from its NetBIOS name, which guarantees that each cross-reference object is unique within the Partitions container. For example, if a domain has a NetBIOS name of CONCORP and a fully qualified DNS domain name of concorp.contoso.com, the distinguished name of its cross-reference object is CN=concorp,CN=partitions,CN=configuration,DC=contoso,DC=com. The domain component (DC) of the cross-reference object distinguished name is always the forest root domain, which is always the parent of the configuration directory partition. If there were another domain in the same forest named concorp.avionics.contoso.com, this domain would necessarily be given a NetBIOS name other than CONCORP (for example, CONCORPAV).

In the case of application directory partitions, there is no associated NetBIOS name, only the DNS name. Given the nature of DNS hierarchical naming, which allows identical left-most name components, a cross-reference object cannot use the left-most DNS name component as its relative distinguished name. For this reason, cross-reference objects that reference application directory partitions use their object GUID as their relative distinguished names.

To associate a cross-reference object with its application directory partition, you can read the **nCName** attribute of the cross-reference object, which gives the distinguished name of the directory partition.

**Data Store Physical Structure**

The physical structure of the data store consists of the Active Directory database file (Ntds.dit) and its associated log and temporary files. The data that is held in the database file includes both static data and dynamic data. The following figure illustrates the physical structure of the data store.

### Data Store Physical Structure

The following table describes the physical components of the data store.

**Data Store Physical Structure Components**

| Component | Description |
|---|---|
| NTDS.DIT | The physical database file in which all directory data is stored. This file consists of three internal tables: the data table, link table, and security descriptor (SD) table. |
| EDB.LOG | The log file into which directory transactions are written before being committed to the database file. |
| EDB.CHK | The file that is used to track the point up to which transactions in the log file have been committed. |
| RES1.LOG, RES2.LOG | Files that are used to reserve space for additional log files if EDB.LOG becomes full. |

**Active Directory Database**

Active Directory data is stored in the Ntds.dit database file. The Active Directory database (Ntds.dit) contains three internal tables, the data table, link table, and SD table, which are described in the following sections.

Two copies of Ntds.dit are present in separate default locations on a domain controller, *systemroot*\NTDS and *systemroot*\System32:

- *systemroot*\NTDS\Ntds.dit stores the database that is in use on a domain controller. It contains the values for the domain and a replica of the values for the forest (the Configuration container data).

- *systemroot*\System32\Ntds.dit is the distribution copy of the default directory that is used when you install Active Directory on a server running Windows Server 2003 or later to create a domain controller. Because this file is available, you can run the Active Directory Installation Wizard without having to use the server operating system CD.

**Data Table**

The data table contains all the information in the Active Directory data store: users, groups, application-specific data, and any other data that is stored in Active Directory after its installation. The data table can be thought of as having rows (each representing an instance of an object, such as a user) and columns (each representing an attribute in the schema, such as **GivenName**). For each attribute in the schema, the table contains a column, called a field. Field sizes can be fixedor variable. Fixed-size fields contain an integer or long integer as the data type. Variable-size fields typically hold string types, for example, Unicode strings. The database allocates only as much space as a variable-size field needs: 16 bits for a 1-character Unicode string, 160 bits for a 10-character Unicode string, and so on.

The database space that is used to store an object depends on the number of attributes for which values are set and the size of the values. For example, if the administrator creates two user objects (User1 and User2), sets only the minimum attributes on them, and then later adds a 10-character description to User2, the User2 space is approximately 80 bytes bigger than the User1 space (20 bytes for the 10 characters, plus metadata on the newly generated attribute).

Database records cannot span database pages; therefore, each object is limited to 8 kilobytes (KB). However, some attribute values of an object do not count fully against this limit. Long, variable-length values can be stored on a different page than the object record, leaving behind only a 9-byte reference. In this way, an object and all its attribute values can be much larger than 8 KB.

**Link Table**

The link table contains data that represents linked attributes, which contain values that refer to other objects in

Active Directory. An example is the **MemberOf** attribute on a user object, which contains values that reference groups to which the user belongs. The link table is much smaller than the data table.

**SD Table**
The SD Table contains data that represents inherited security descriptors for each object. With the introduction of the SD table in Windows Server 2003 or later, inherited security descriptors no longer have to be duplicated on each object that inherits security descriptors. Instead, inherited security descriptors are stored in the SD table and linked to the appropriate objects.

**Log Files**
The Active Directory data store includes the log files that are described in the following table. For information about how these log files are used, see "Logging Transactions to Enable Log-based Recovery" later in this section.

### Log Files

| File | Description |
|---|---|
| Edb.log | This file stores directory transactions before they are written to the Ntds.dit directory database file. This file has a fixed size of 10 megabytes (MB). |
| Edb00001.log, Edb00002.log, Edb00003.log, and so on | Active Directory creates additional log files as necessary as existing log files fill up. Each log file has a fixed size of 10 MB. |
| Edb.chk | This file keeps track of the point up to which transactions in the log file have been committed. |

**Minimum Space Requirements**
The minimum space requirements for the directory database and log files — and the requirements for which monitoring is essential — are free disk space on the partition or partitions that store the directory database and logs, as follows:

- Ntds.dit partition and log file partition: On either partition, free disk space must not fall below the greater of 500 MB or 20 percent of the combined Ntds.dit and log file sizes.

- Ntds.dit and log files on the same volume: Free disk space must not fall below the greater of 1 gigabyte (GB) or 20 percent of the combined Ntds.dit and log file sizes.

**Objects and Capacity**
There are no practical limits to the number of objects that can be stored in Active Directory. The Active Directory database has been tested for up to 60 million objects. Performance tests show logon performance for a single LDAP client to be the same with 10,000 objects, 100,000 objects, and 1 million objects; that is, the directory service does not slow measurably when the size of the database increases.

### Note

- In a mixed environment in which backup domain controllers (BDCs) are running Windows NT 4.0, the recommended limit for the number of security principal objects per domain is 40,000 (the sum of users, groups, and computers). This limit is based on the Windows NT 4.0 SAM database storage capacity.

**Maximum Database Record Size**
The maximum size of a database record is 8110 bytes, based on an 8-kilobyte (KB) page size. Because of variable overhead requirements and the variable number of attributes that an object might have, it is impossible to provide a precise limit for the maximum number of multivalues that an object can store in its attributes. For all practical purposes, the size of objects is not significant in Active Directory if you use the recommended guidelines described in "Static Data" later in this chapter.

The only value that can actually be computed is the maximum number of values in a nonlinked, multivalued attribute when the object has only one attribute (which is impossible). In Windows 2000 Active Directory, this number is computed at 1575 values. From this value, taking various overhead estimates into account and generalizing about the other values that the object might store, the practical limit for number of multivalues stored by an object is estimated at 800 nonlinked values per object across all attributes.

| Note |
|---|
| Attributes that represent links do not count in this value. For example, the members linked, multivalued attribute of a group object can store many thousands of values because the values are links only. |

The practical limit of 800 nonlinked values per object is increased in Windows Server 2003 and later. When the forest has a functional level of Windows Server 2003 or higher, for a theoretical record that has only one attribute with the minimum of overhead, the maximum number of multivalues possible in one record is computed at 3937. Using similar estimates for overhead, a practical limit for nonlinked multivalues in one record is approximately 1200. These numbers are provided only to point out that the maximum size of an object is somewhat larger in Windows Server 2003 and later.

**Active Directory Data**

The key characteristics of data that is stored by any directory service are size and latency. A directory service should store objects that are not so large that they hamper replication. Therefore, large unstructured data sets are not appropriate for storage in Active Directory. Domain data and configuration data are typically static in nature, having a useful lifetime at least as long as a single period of replication latency.

In a Windows 2000 Server forest, Active Directory does not support storage of nonstatic (dynamic or volatile) data. In a Windows Server 2003 or later forest, however, Active Directory can store nonstatic data in application directory partitions, which can be configured for limited replication or used as real-time data stores for data that is too volatile for replication.

**Static Data**

Active Directory is appropriate for the storage of static data that has the following characteristics:

- The data is globally useful information in the domain that needs to be replicated to each Active Directory domain controller.

- The data has well-defined object attributes and semantics.

- The data has a useful life that is at least two times the maximum replication latency for the forest, including replication of data that is marked to replicate to the global catalog. In general, if data can become outdated before the completion of a replication cycle or shortly thereafter, it should not be stored in Active Directory. Clients should be able to tolerate the inability to update data for at least as long as it takes for the data to be replicated throughout the domain.

- The data-per-attribute value is not so large that it affects performance. Most attribute values are replicated as a single block of data; therefore, an attribute that is *x* MB in size requires an equivalent amount of buffer space in the sending domain controller and in the receiving domain controllers. If the amount of required buffer space is large, the performance of the domain controllers can be affected adversely.

  Attributes can have large values when the attribute is multivalued and linked. For these attributes, only the values that change are replicated, not the entire attribute.

**Dynamic Data**

An object that has a TTL value is considered to be dynamic data. Windows Server 2003 introduces a new auxiliary class, **dynamicObject**, that can be attached to object instances for the storage of TTL values. For an object containing a TTL value, when the time that is specified by the TTL value is reached, the object is automatically removed from Active Directory by garbage collection. Dynamic data typically changes faster than the replication latency that is required for propagating the change to all replicas of the data.

The following characteristics apply to dynamic data:

- A dynamic object that is deleted as a result of expiration of its TTL does not leave a tombstone.

- Dynamic objects are treated in the same manner as nondynamic objects during search, compare, add, delete, and modify (including rename) operations.

- A nondynamic object, after it is created, cannot be changed to a dynamic object. Likewise, a dynamic object, after it is created, cannot be changed to a nondynamic object.

- A nondynamic object cannot be added in a subordinate position to a dynamic object.

- Dynamic objects with TTL values are supported in the following directory partitions:

  - Domain directory partitions at the Windows Server 2003 or higher forest functional level

- Application directory partitions on a Windows Server 2003 or higher–based domain controller, irrespective of domain or forest functional level

- Dynamic objects are not supported in configuration directory partitions or schema directory partitions.

**TTL for dynamic objects**
The TTL for a dynamic object is set when the object is created, and it is automatically decremented thereafter. When its TTL expires, the dynamic object disappears without leaving a tombstone. However, a client application can programmatically cause a dynamic object to remain longer than its current remaining lifetime by refreshing (modifying) its TTL value, as stored in the **entryTTL** attribute on the object.

The Directory Service object (nTDSService) in the Configuration container (CN=Directory Service,CN=Windows NT,CN=Services,CN=Configuration,DC= *forestRootDomain*) stores the default and minimum dynamic object TTL values for the forest in the multivalue attribute **msDS-Other-Settings**.

The default values for the two configurable TTL parameters are as follows:

- Default TTL value = 86400 seconds (1 day)

- Minimum TTL value = 900 seconds (15 minutes)

The default TTL value is assigned to a newly created dynamic object if a TTL is not explicitly specified by the application that creates the object. The minimum TTL overrides any client-specified TTL value that is lower than the configured minimum. No configurable maximum TTL value needs to be provided, because a maximum is imposed by the attributeSchema object.

The syntax for the two configurable TTL parameters is as follows, where NNNN is expressed in seconds:

```
                DynamicObjectDefaultTTLSeconds=NNNN
DynamicObjectMinTTLSeconds=NNNN
```

By configuring these values, you can set TTL values that enforce a low level of refresh traffic or, conversely, provide a highly up-to-date directory.

**Data Store Processes and Interactions**
The Active Directory data store performs a number of processes and interactions that are important to the functioning of Active Directory. The following sections describe these processes and interactions.

These descriptions make the following assumptions regarding the environment in which the Active Directory data store is running:

- The disk volume on which the directory database is stored contains ample free space.

- Network connectivity on the domain controller is functioning properly.

**Database Operations**
Data operations (such add, modify, and delete) are committed to the Active Directory database as transactions, which are the units of work that are performed by a database. Transactions are atomic; that is, they are either completed in full or not applied at all. If for any reason an error occurs and a transaction is unable to complete all of its steps, the system is returned to the state that existed before the transaction began. An example of an atomic transaction is an account transfer transaction in which money is removed from account A and placed into account B. If the system fails after it removes the money from account A and before it places the money into account B, the transaction processing system puts the money back into account A and returns the system to its original state; that is, the transaction processing system rolls back the transaction.

In Active Directory, operations on a single object cannot be applied across multiple objects. Active Directory writes a transaction synchronously to the transaction log file and then to the database. First, a change is made to an in-memory copy of the object. Then, the change is written to the log file, which ensures that the change takes effect, even if the database shuts down after that point. The database engine continually updates the database file with recent changes. The database update works from memory — not from the log files — and it keeps pace with the updates, rather than waiting for the server to be available. This method of performing updates is referred to as “advancing the checkpoint,” where the checkpoint is the point in time at which all changes that have been made so far have been fully written to the database.

**LDAP Functional Model**
Database operations in Active Directory are based on the LDAP functional model. The LDAP functional model includes support for common database operations, such as connecting to a directory database, searching for data, and modifying data. An LDAP client connects to Active Directory and requests information or performs an operation. Active Directory performs the operation or provides the information, or it refers the client to another LDAP server that might be able to do so.

Nine operations form the LDAP functional model. These operations are grouped into three areas:

- Authentication. Enables the client to prove its identity to the DSA:
    - Bind
    - Unbind
    - Abandon
- Interrogation. Enables the client to interrogate the directory and retrieve information:
    - Search
    - Compare
- Update. Enables the client to update information in the directory tree:
    - Add
    - Delete
    - Modify
    - Modify relative distinguished name

A typical LDAP client application interacts with Active Directory through the operations that are described in the following sections.

For more information about LDAP, see "Lightweight Directory Access Protocol (LDAP)" in the Microsoft Platform SDK on MSDN.

**Establishing a connection**
When an LDAP client connects to Active Directory, an LDAP session is established. Options are available to affect the way in which the connection is established. These options include setting a time-out value, connecting to a secure LDAP server, and verifying that a server is available.

For the purposes of protocol exchanges, all protocol operations are encapsulated in a common envelope. LDAPMessageis encapsulated in the Protocol Data Unit (PDU) format. LDAPMessage consists of protocol operations, such as LDAP Bind Request, LDAP Bind Response, LDAP Search Request, and LDAP Search Response operations.

LDAPMessage PDUs are mapped directly to the TCP data stream. Active Directory clients use the following LDAP ports:

- Port 389. In accordance with RFC 2251, Active Directory uses port 389 as the default port for domain controller communications.
- Port 636. Active Directory supports port 636 for LDAP Secure Sockets Layer (SSL) communications.
- Port 3268 and port 3269. The global catalog monitors port 3268 for LDAP communications and port 3269 for LDAP SSL communications.

**Modifying a directory object**
The LDAP API contains functions for adding and deleting directory objects and for comparing and modifying attribute values in

existing objects. LDAP v3 provides extensions to add, delete, and modify functions that enable the use of controls to perform these operations. Controls are described in RFC 2251 as a mechanism to extend the functionality of LDAP. Windows Server 2003 and later supports several extension controls that go beyond the controls that are identified by LDAP v3.

**Searching the directory**
Searching is the most common directory activity, and the LDAP APIs provide a variety of search criteria and result-retrieval methods. The client searches the LDAP server by passing it a set of parameters that describe the information of interest. These parameters describe where and how to search, and they define the search criteria that a client needs. The client uses a search filter to describe the objects that it wants. Search filters are defined in RFC 2254. Extensions to the base LDAP API, in the form of LDAP v3 controls, provide the ability to sort results and set various limits on the search operation. Search results can be processed by paging and by sorting. Paging and sorting are supported in Windows 2000 Server and later as new LDAP v3 control extensions for processing search results on the server.

**Closing the connection (unbinding)**
Unbinding closes the connection between the directory client and the DSA and disposes of the session handle. Applications call the unbind function when an LDAP client finishes communicating with a server. There is no server response to an unbind request.

**Logging Transactions to Enable Log-based Recovery**
To maximize system efficiency and ensure data integrity, Active Directory uses “write ahead” logging. With “write ahead” logging, transactions are written as quickly as possible to a transaction log file, and they are then written to the Ntds.dit database file as the system has time or at system shutdown.

The log file that is used by Active Directory to record transactions is called Edb.log, which has a fixed size of 10 MB. When this log file becomes full, Active Directory automatically creates a new log file, for example, Edb00001.log, which also has a fixed size of 10 MB. Active Directory continues to create additional log files as they become necessary. Through circular logging, the oldest log file is purged when all transactions in that log have been written to the Ntds.dit database. In addition to the active log files, two reserve log files exist, called Res1.log and Res2.log, ,also with a fixed size of 10 MB. These files reserve the last 20 MB of disk space on the drive to provide room for a graceful shutdown if all other disk space is consumed.

Active Directory also maintains a checkpoint file (Edb.chk) that records which transactions in the log have been committed to the database. In circular logging, log files are deleted when the checkpoint advances past the last transaction that is included in that log file. The checkpoint cannot be advanced past the beginning of any transaction that is still open.

If the computer stops responding, the ESE can detect an improper shutdown by checking the last log recorded. If the last record is not a “shutdown” record, the ESE reprocesses the logs from the checkpoint that is stored in Edb.chk. This event occurs at the first reboot after the system is shut down improperly. If the checkpoint file is missing for any reason, every transaction within the log file is reprocessed.

The number of log files that exist at any point in time is related to the number and size of transactions that are running in the database. If a system is idle, you can expect to see one log file. If a domain controller is making large changes (for example, replicating a 5,000-member group), you can expect to see several log files. If you just edited the schema to define an index on an attribute that has many large data values, you might see hundreds of log files. (The checkpoint cannot be advanced until the index creation is completed.)

**Growth and Space Management**
The directory database is a self-maintained system in which growth is managed by periodically compacting data and reorganizing free space into contiguous pages. Other than regular backup, the directory database requires no maintenance during ordinary operation. The only requirement is adequate space to accommodate normal growth.

The directory database grows when more data is added to it than free space is available to accommodate the new values. Free space, also called “white space,” is managed automatically by the directory database. Conditions under which free space is made available to the database can affect database size, sometimes in ways that are not expected. For this reason, an understanding of how free space is managed can help provide correct interpretation of changes in the size of the directory database file. The following sections describe space allocation and free space reclamation.

**Space Allocation**
Space is allocated hierarchically in the directory database, with the database at the top of the hierarchy. Object tables are children of the database. Each table has a child long-value table, and each table can have child indexes. The long-value table stores values that are too large for the main object table. Security descriptors are examples of values that are often large enough to require storage in the long-value table.

As objects are deleted and values are replaced with smaller values, free space is returned to the database. However, there is no optimum or target amount of white space to be maintained. The amount of unused space in the directory database is of concern only when monitoring indicates that free disk space is becoming limited. You can configure a domain controller to log

an event that reports the amount of unused space in the directory database that can be reclaimed by offline defragmentation.

**Requesting space**
The database can use free space if the space is available to the table or index that needs it and if the space occurs in blocks that are large enough to accommodate the transaction. When an index or table requires additional space, it can request space only from its parent. For example, the available space in an index cannot be used by another index. If the parent table requires space, it must request space from the database. If space is not available at the database level to complete the request, the database increases its size to accommodate the transaction.

**Space consumption by indexes**
The estimated space that is required for adding an index to an attribute is rarely greater than 1 percent of database size. However, Tuple indexes, which index an attribute in a way that allows users to search the attribute by using partial text strings, can be quite large. To provide partial text string searching, a Tuple index includes one entry for each substring of a **Text** or **Long Text** column, with a minimum and maximum length allowed for the substrings that are indexed. Although Tuple indexes can dramatically speed queries of the form "find all records that contain *string value*," they can potentially increase database size by as much as 20 percent, and they should be used with caution.

**Storing data**
Objects are stored in records that are written to 8-KB data pages. The maximum record size is 8110 bytes, with the exception of long-value columns, which can be up to 2 GB. As values are deleted, space that is freed by transactions is returned to the table that owns the space. Free space is returned gradually in small segments, and it is periodically reorganized into contiguous pages through an automatic process called online defragmentation.

Data pages are filled with records in an ordered fashion. For example, all records beginning with A must be stored in the page that is designated as storing the values that range from A to some other value. For example, given pages A-E and F-J, if a value corresponds to the A-E page and that page is full, the value cannot be stored in the F-J page, even if space is available. Instead, one or more new pages are added. When a table grows, it grows in increments equal to one-fourth its initially allocated size.

In this way, Active Directory data storage optimizes lookup speed as opposed to storage space. However, because of the hierarchical means of allocating free space and the order that is required for filling data pages, free space that is present in the database is not always available for use.

**Free Space Reclamation**
The version store is the area of the database that manages version control. When a transaction is committed to the database, a cleanup process returns space that is freed by modify and delete transactions to the database. For each modify or delete operation, the existing version of the record is written to the version store so that the database maintains a copy of the old version until the new version is written to the database. After the transaction is committed to the database, any space that is freed from deleted records and long values is returned to the table or index that owns the space. Until the change is committed to the database, requests for the object continue to access the old version. If the transaction is rolled back, the version store record is used to undo the transaction.

The version store has a size limit that is the lesser of the following: one-fourth of total random access memory (RAM) or 100 MB.

Because most domain controllers have more than 400 MB of RAM, the most common version store size is the maximum size of 100 MB. If too many large changes or deletions occur simultaneously, it is possible for the version store to run out of processing space. In this event, cleanup of free space is suspended temporarily. On domain controllers running Windows 2000 Server, the most common cause of version store overload is large-scale bulk deletions.

**Bulk deletions and database growth in Windows 2000**
Delete operations are the most CPU-intensive operations that the version store processes. On domain controllers running Windows 2000 Server, bulk deletions, such as the deletion of an entire tree of objects at one time, can cause a temporary condition in which free space cannot be returned to the database in a timely fashion because the cleanup process cannot keep up with the deletions. Event ID 602 is logged in the Directory Services event log to indicate this condition.

During the time that pages are being skipped by the cleanup process, free space is not released to the database, and space is not reclaimed until the next scheduled online defragmentation occurs. In the meantime, processing requirements can cause the database to grow. In particular, when bulk deletions or other bulk changes coincide with database additions, significant growth can occur. In addition, space from the deletion of long values is not returned to the database by online defragmentation. As a result of these conditions, the directory database on domain controllers running Windows 2000 Server can actually increase in size following a bulk deletion.

On domain controllers running Windows Server 2003 or later, the effects of these conditions are greatly reduced by improvements in version store cleanup and online defragmentation. However, if event ID 602 is logged in the Directory Services event log, running online defragmentation manually can alleviate the problem. On domain controllers running

Windows 2000 Server, the only way to prompt online defragmentation is to change the garbage collection interval to the minimum value of one hour to force garbage collection and online defragmentation to occur as soon as possible.

**Improved space processing in Windows Server 2003 and Later**
Two improvements in the Windows Server 2003 and later processing of free space eliminate the database growth problems that can result from large-scale bulk deletions:

- The threshold at which the database begins skipping cleanup operations is increased from 5 percent to 90 percent.
- Space is reclaimed from long-value deletions.

The threshold of maximum pages that can be processed by the version store is the limiting factor in whether the cleanup process can keep pace with deletions. The version store cleanup process can take place only as long as the version store has sufficient space. With a maximum version store size of 100 MB, only 5 MB (5 percent) is available in Windows 2000 Server, and this low threshold is responsible for early suspension of the cleanup process. The threshold of 90 MB (90 percent) in Windows Server 2003 and later eliminates this problem. For this reason, large-scale bulk deletions that can be problematic on domain controllers running Windows 2000 Server present no significant growth concerns on domain controllers running Windows Server 2003 or later.

In addition, online defragmentation on domain controllers running Windows Server 2003 or later returns the space that is freed by long values to the long-value table, which further optimizes the availability of space in the database.

**Bulk Changes and Inheritable Security Descriptors**
In addition to bulk deletions, large-scale bulk changes can cause database growth, particularly on domain controllers running Windows 2000 Server. The most common cause of database growth on domain controllers running Windows 2000 Server is the propagation of inherited security descriptor changes in a large directory tree.

Every object in Active Directory has a security descriptor attribute that contains the identification and authorization values that apply to that object. Authorization information takes the form of discretionary access control lists (DACLs) (access information) and system access control lists (SACLs) (auditing information). Because every object has a security descriptor, a security descriptor change that affects every object in a large tree (for example, an entire domain) can significantly affect database size.

**How Inheritable Security Descriptors Are Written**
The value of the security descriptor attribute changes when a new permission, right, or auditing setting is added or an existing permission, right, or auditing setting is removed from an object's DACL or SACL by adding, removing, or modifying an ACE. When an inheritable ACE is applied to an object in a directory tree, you can specify the type of object that is affected by the ACE. However, the change is written to every object in the tree, not just to the object type to which the permission, right, or auditing setting applies. The ACE applies to all objects, but it is effective only on objects whose object type matches the object GUID that is specified in the ACE.

This system ensures that the appropriate security descriptor can always be inherited from a parent object. For example, suppose you apply an inheritable ACE at the domain level that applies to all computers. Computers exist in container objects, to which the ACE does not directly apply. However, when you create a computer object in the container, the computer object receives its inherited security descriptor from its parent container. Every object that is within the scope of the inheritance receives the update to the security descriptor.

**Security Descriptors in Windows 2000 Server**
On domain controllers running Windows 2000 Server, the full security descriptor value is stored for every object. The average size of a security descriptor is 5 KB, and as a result security descriptors can account for 40 percent or more of database size. On domain controllers running Windows 2000 Server, an ACL change that is inherited by a large directory tree (for example, a domain) that contains hundreds of thousands or millions of objects can cause significant database growth. For example, suppose you add 30 ACEs to an inheritable SACL or DACL on the domain object of a domain that has 1,000,000 objects. At an estimated 52 bytes per ACE, each object grows by approximately 1.5 KB. The propagation of this change to 1 million objects results in database growth of 1.4 GB. In the worst-case scenario, the database grows beyond its storage limits, and Active Directory cannot function.

You can use Active Directory administrative tools to manage security settings on Active Directory objects to a high degree of specificity. Significant and unexpected changes to security descriptors can occur during the management of access control and auditing if an administrator does not understand the effects of the changes. The UI provides the ability to select general ACE categories that have prepopulated permissions, but the UI also provides the ability to modify the properties of a general ACE. The effect of editing an existing general ACE on a DACL or SACL by removing one of the properties is the replacement of a single ACE with multiple ACEs, one for each of the permissions that is selected in the modified ACE. On domain controllers running Windows 2000 Server, such a change can cause significant database growth if the modified ACE is inherited to a large tree of objects. For example, if directory services access auditing is enabled and an administrator edits the access to specify

only a subset of the activity and objects to be audited, the result is propagation of a separate ACE for each selection to every object in the tree. Given the default settings for the Everyone group in Windows 2000 Server, such a change can result in significant database growth.

Default settings in Windows Server 2003 and later, and the storage of only unique security descriptors greatly decrease the likelihood that such a change can cause unmanageable growth.

**Single-Instance Security Descriptors in Windows Server 2003 and Later**
On domain controllers running Windows Server 2003 or later, the potential for database growth as a result of the volume of changes that might be caused by security descriptor inheritance is mitigated by a new method of storing single instances of unique security descriptors.

On domain controllers running Windows Server 2003 or later, a unique security descriptor is stored only once rather than being stored for every object that inherits it. For every object that inherits the security descriptor or otherwise stores an identical security descriptor, only a pointer is stored. This change eliminates data redundancy and the database growth that can result from changes to inheritable ACEs.

The object itself stores an 8-byte pointer to the appropriate unique security descriptor. Unique security descriptors are stored in memory in a relatively small table. In addition, the information that is required to map these pointers to the respective security descriptor is cached on domain controllers. By using this cached information and the in-memory table of unique security descriptors, domain controllers can match pointers to security descriptors without having to access the database itself. Therefore, checks to establish whether a new security descriptor matches an existing one have no significant impact on domain controller performance.

### Note

- When you upgrade a domain controller from Windows 2000 Server to Windows Server 2003, the conversion of duplicate security descriptors to pointers can result in +40 percent of the database size being converted to unused space. Performing offline defragmentation after the upgrade decreases the database size by removing that unused space.

**Effect of Object Ownership on Unique Security Descriptors**
Having different owners causes objects that would otherwise have the same security descriptor to require several unique security descriptors. For example, if a member of the Domain Admins group creates a container object and sets permissions on the container that are inherited by all child objects, all child objects have the same security descriptor. In this case, only one security descriptor is actually stored in Active Directory; the rest of the objects simply reference that unique security descriptor. However, if objects that are created in the parent container are created by individuals who are not members of the Domain Admins group, those objects have security descriptors that are different from the security descriptors of the objects that are created by members of the Domain Admins group.

Despite the fact that having different object owners requires unique security descriptors, most Active Directory databases contain a relatively small number of user objects in comparison to the number of nonuser objects. In addition, most objects are created by the system and not by individual users. Because duplication of security descriptors far outweighs the potential for different object owners, the positive effect of single-instance security descriptors is not usually lessened to a noticeable degree by multiple object owners.

**Storage and Removal of Object Deletions**
When data is deleted from Active Directory, the data cannot simply disappear from the directory because the deletion must be replicated. Therefore, instead of deleting an object physically from the database, the directory service removes most of the attributes and then tags the object as a tombstone by setting the **isDeleted** attribute value to TRUE, which means that the object has been logically deleted from the directory but not yet completely removed. Tombstones are replicated to communicate object deletions. The **isDeleted** attribute value alerts replication partners that the object has been deleted. Objects that are identified as tombstones are moved to the hidden Deleted Objects container of their respective directory partition. Tombstones remain in the directory for a default period of 60 days, which is referred to as the tombstone lifetime.

**Garbage Collection: Permanent Removal of Expired Tombstones**
Garbage collection is a housekeeping process that runs on every domain controller to permanently remove expired tombstones from the directory database. Although they represent deleted objects, tombstones take up space in every directory partition replica. Eventually, the tombstones themselves must be deleted to keep the directory database from growing without limit. At regular intervals, objects that are no longer needed by the directory service are deleted as “garbage.”

The garbage collection process:

- Deletes tombstones.

- Defragments the database file to compact data and optimize free space (triggers online defragmentation).

Garbage collection runs independently on each domain controller. When the garbage collection process occurs, the process finds the set of tombstones whose originating deletion occurred more than a tombstone lifetime ago, and then it deletes each tombstone in that set.

Two attributes of the Directory Service object (nTDSService) in the configuration container (CN=Directory Service,CN=Windows NT,CN=Services,CN=Configuration, DC=*forestRootDomain*) control how garbage collection runs and what it removes, as follows:

- The tombstone lifetime determines the amount of time that a deleted object lives as a tombstone in the directory before being collected as garbage. This amount of time is set in the **tombstoneLifetime** attribute. The minimum setting is 2 days. The default setting for this attribute varies according to operating system and forest creation or upgrade, as follows:

    - Forests that were created on a domain controller running Windows Server 2003 with no service pack installed or any version of Windows 2000 Server: 60 days.

    - Forests that were upgraded from Windows Server 2003 with no service pack installed or any version of Windows 2000 Server: 60 days.

    - Forests that were created on a domain controller running Windows Server 2003 with Service Pack 1 (SP1) or later: 180 days.

    **Note**

    - You cannot purge tombstones before the expiration of the tombstone lifetime.

- The garbage collection interval determines how often a domain controller examines its database for expired tombstones that can be collected. This interval is set in the **garbageCollPeriod** attribute. The default setting is 12 hours, and the minimum setting is 1 hour.

    **Note**

    - The default value for each of these two attributes applies if the attribute is not set (which is the initial state of the system). The minimum value applies if the attribute is set to a value that is below the minimum (that is, if the minimum is not declared in the schema).

The maximum garbage collection interval is one-third of the tombstone lifetime (in hours). For example, if you set **tombstoneLifetime** to 30 days and **garbageCollPeriod** to 300 hours, the actual garbage collection period is only 10 days or 240 hours.

**Tombstone Lifetime and Active Directory Backup and Restore**

Active Directory does not allow a restore from a directory backup that is older than the tombstone lifetime. A restore from backup creates a directory partition replica that has not performed replication since the time of backup (or earlier). If the backup is taken more than a tombstone lifetime before the restore, objects that are deleted in the meantime have no tombstones; therefore, a new directory partition replica that is created by the restore operation never receives these deletions. For this reason, a restore procedure will not restore a backup that is taken more than one tombstone lifetime before the time of the restore. Therefore, it is a recommended best practice to back up Active Directory at least twice during a tombstone lifetime. On domain controllers running Windows Server 2003 with SP1 and later, event ID 2089 in the Directory Service event log provides notification when any directory partition, including application directory partitions and Active Directory Application Mode (ADAM) partitions, has not been backed up since the beginning of a specified time period. By default, this period is half the tombstone lifetime interval, as defined in the registry entry **Backup latency interval (days)** in **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics**.

It is likewise important that the tombstone lifetime be substantially longer than the expected replication latency. The default setting of 60 days or 180 days for the tombstone lifetime is generous enough to accommodate unforeseen circumstances. However, monitoring domain controller operation is essential for ensuring that a domain controller does not remain offline without detection.

Because the expiration of a tombstone lifetime is based on the time when an object is deleted logically — rather than the time when a particular server receives that tombstone through replication — an object's tombstone is collected as garbage on all servers at approximately the same time. If the tombstone has not yet replicated to a particular server, that server never records the deletion. A domain controller that becomes outdated by being disconnected from the replication topology for longer than a tombstone lifetime cannot be restored from backup. However, an object that remains on an outdated domain controller is retained if the domain controller is reconnected to the replication topology. An object that remains after its tombstone is deleted is called a lingering object. Such objects create inconsistency in Active Directory and should be removed. For information about removing lingering objects, see "Fixing Replication Lingering Object Problems (Event IDs 1388, 1988, 2042)" in "Troubleshooting Active Directory Replication Problems" in the Windows Server 2003 Operations Guide at http://go.microsoft.com/fwlink/?LinkId=44131.

**Garbage Collection Scheduling Enhancements**

The process for completing garbage collection has changed in Windows Server 2003 and later to improve storage conditions in the directory database. Garbage collection removes a maximum of 5,000 objects per pass to avoid indefinitely delaying other directory service tasks. However, the rate at which remaining tombstones are deleted when more than 5,000 tombstones have expired has increased from Windows 2000 Server to Windows Server 2003 or later, as follows:

- Windows 2000 Server: If collection stops because of the 5,000-object limit (rather than by running out of objects to collect), the next garbage collection pass is scheduled for half the normal garbage collection interval (by default, every 6 hours instead of 12 hours). Garbage collection continues running at this accelerated pace until all objects have been collected.

- Windows Server 2003 and later: Rather than waiting a set time to remove a subsequent set of 5,000 tombstones, a domain controller continues deleting tombstones according to CPU availability. If no other process is using the CPU, garbage collection proceeds. Removing tombstones in this way keeps the database size from increasing inordinately as a result of the inability of garbage collection to fully complete removal of all tombstones during a garbage collection interval.

**Garbage Collection and Linked Attributes**

When an object that has a linked attribute is deleted, although the object itself becomes a tombstone (for example, when a user object is deleted), the referent object (for example, a group object to which the user belonged) does not reference the tombstone of the deleted object. Rather, the group-user link value is simply deleted from the database, and the group object shows no evidence of the former user's membership.

However, when an object to which a link refers is removed as a referent (for example, when a user is removed from a group), the user value is treated differently by Active Directory in Windows 2000 Server and in Windows Server 2003 and later. In Windows 2000 Server, the entire group **member** attribute is replicated. In Windows Server 2003 and later, the link value for the removed user is marked "absent" and then replicated, much like a tombstone.

**Reanimating Tombstones — Restoring Individual Objects Online**

The Windows Server 2003 and later directory database supports an LDAP API that reanimates the tombstone of a single object (undeletes the object) to avoid the necessity for an offline restore process in the event that an object is deleted unintentionally. This API is available for creating applications to restore the attributes that are preserved on tombstones, which include the object SID, GUID, and security descriptor, as well as any indexed attributes.

| **Note** |
| --- |
| When the deletion is performed on a domain controller that is running Windows Server 2003 with SP1 or later, the **sIDHistory** attribute is also retained. |

Only attributes that are retained on the tombstone are restored; all other data must be recreated. Therefore, to restore an entire deleted container or a set of multiple objects, authoritative restore is still the best option.

**Stale Account Detection**

Stale account detection is required so that unused computer and user accounts can be removed from Active Directory. On domain controllers running Windows Server 2003 and later, these accounts can be identified by the value in the **lastLogonTimeStamp** attribute of user and computer objects. This attribute identifies the last time that a user or computer successfully logged on to a domain. The attribute value is replicated to all domain controllers in the domain. **lastLogonTimeStamp** is new in Windows Server 2003, and its use is enhanced in Windows Server 2003 with SP1.

**Scenarios that generate stale accounts**

The following common scenarios result in the proliferation of computer and user accounts that are often abandoned by the

users who create the accounts:

- Delegated computer account creation, which is common in corporate environments, provides the freedom to create multiple accounts but no requirement for deleting them.
- Web applications allow external partners to create and manage user accounts that are provided by the host company.
- Employees leave the company.

**Detection of successful password verification**

In earlier versions of Windows, the **pwdLstSet** attribute was used to identify stale accounts. However, many conditions interfere with the accuracy of this method, such as users who are on sabbatical or otherwise temporarily not using an account. In addition, password time limits can vary throughout an organization. The most efficient way to identify an account that is stale is by evaluating the last time that the user successfully logged on to the domain, rather than the last time the password was reset.

The introduction of the **lastLogonTimeStamp** attribute in Windows Server 2003 and later provides the ability to mark an account each time that the system is asked to validate the account password (that is, at logon) for NTLM and Kerberos authentication. These two security protocols update the **lastLogonTimeStamp** attribute during successful authentication.

**Implementation in the domain**

Updates to **lastLogonTimeStamp** are replicated in the domain directory partition. Therefore, the value of this attribute can be checked on any domain controller in the domain. To minimize the effect of domain-wide replication every time that a user or computer logs on, **lastLogonTimeStamp** is updated only periodically. The period of update is configurable, as follows:

- Object: DC=*DomainName*
- Attribute: **msDS-LogonTimeSyncInterval**
- Default value: 14 days

Because the **lastLogonTimeStamp** attribute is available only when the Windows Server 2003 and later schema is in effect on all domain controllers in the domain, the feature is activated when the domain functional level is raised to Windows Server 2003 or higher. After the domain functional level increase, the first time that a successful logon occurs, the **lastLogonTimeStamp** attribute is activated on the user or computer object. This method of activation can result in loopholes for certain accounts, as follows:

- Accounts that are created before the domain functional level increase but that are not used subsequently
- Accounts that are created after the domain functional level increase but that are not used

In these cases, **lastLogonTimeStamp** is not present on the account object. To identify these accounts, you can query for user and computer objects that have no **lastLogonTimeStamp** attribute and that have a value in the **whenCreated** attribute that is earlier than or equal to a specified date.

For example, suppose a user account is created on 1/1/2005. The user leaves the company on 5/1/2005. The domain functional level is raised on 6/1/2005. On 9/1/2005, you query for accounts that do not have the **lastLogonTimeStamp** attribute. The query returns the account of the user who left the company before the raising of the functional level. However, you need to know if the account was created recently and has not yet been used or if the account was created before the functional level increase and is legitimately out of use. To answer this question, you query for accounts that do not have the **lastLogonTimeStamp** and that have a **whenCreated** value of 8/15/2005 or earlier. You select this date on the assumption that any account that was created within the last two weeks will have been used and any account that was created between June 1 and August 15 will certainly have been used. Accounts that are returned by the query are therefore legitimately out of use and can be deleted.

**Randomization mechanism for initial use of lastLogonTimeStamp**

To avoid network overloads due to thousands of concurrent **lastLogonTimeStamp** updates when the domain functional level is raised, a five-day window is used to calculate whether the **lastLogonTimeStamp** value should be updated. The following randomization mechanism is applied to control updates after the domain functional level is raised:

1. At the time that the functional level is raised, the default value of 14 days for **msDS-LogonTimeSyncInterval** is used, regardless of whether a different value is set in the attribute.

2. The value in **lastLogonTimeStamp** is used to determine the number of days since the last valid logon of the account.

3. A random percentage of the value 5 is taken and then subtracted from the value in **msDS-LogonTimeSyncInterval**.

4. If the result is greater than or equal to the value in **lastLogonTimeStamp**, the value in **lastLogonTimeStamp** is updated.

For example, suppose that the value in **lastLogonTimeStamp** indicates 12 days since the last successful logon. Suppose also that the random percentage is 80 percent of 5 = 4. With the default value of 14 days in effect for **msDS-LogonTimeSyncInterval**, the calculation is 14 - 4 = 10. Because 12 > 10, **lastLogonTimeStamp** is updated. In this example, in all cases where the value is less than 10, **lastLogonTimeStamp** is not updated until the first successful logon that occurs after the **msDS-LogonTimeSyncInterval** value is reached.

| **Note** |
| --- |
| If the value in **msDS-LogonTimeSyncInterval** is set to **0**, the stale account detection feature is disabled and **lastLogonTimeStamp** is not updated. |

**Security protocols that update lastLogonTimeStamp in Windows Server 2003**

In the initial implementation of **lastLogonTimeStamp** in Windows Server 2003, **lastLogonTimeStamp** is updated by the following authentication protocols:

- NTLM
- Kerberos

Security protocols notify the directory database of a successful logon so that the account can be marked appropriately in the **lastLogon** and **lastLogonTimeStamp** attributes. Therefore, to use stale account detection effectively, it is important that administrators are aware of the security protocols that are in use in their environments.

For example, in Windows Server 2003 environments, the following security protocols request that the system validate a user password:

- Secure channel setup (computer accounts only)
- NTLM authentication (both interactive and network)
- Kerberos authentication
- Digest authentication
- Third-party Security Support Provider Interfaces (SSPIs) when using the LSA APIs

The following security protocols can reference an account for a security operation:

- Schannel, when mapped to an account
- Kerberos Service-for-User (S4U) logons
- AuthZ APIs in non-S4U mode

The obvious problem is that some accounts might be authenticated without updating the **lastLogonTimeStamp**, and if this detection method is relied on for stale account cleanup, accounts might be deleted that are still in use.

For example, the following issues occur in Windows Server 2003 implementations:

- The NTLM authentication protocol does not update the **lastLogonTimeStamp** attribute for all network logons. NTLM is therefore not reliable for stale account detection.

- The Kerberos S4U authentication protocol, which is used for Web single sign on (SSO) provisioning, does not update **lastLogonTimeStamp**. Specifically, when extranet users log on to servers running Microsoft Internet Information Services (IIS), Active Directory user accounts are mapped to certificates that are trusted by the IIS server. These certificates are distributed to the client computer so that users do not have to specify credentials. (That is, they are not directly authenticated by a security protocol.)

#### lastLogonTimeStamp improvements in Windows Server 2003 SP1

Windows Server 2003 SP1 corrects the problems of some protocols not updating **lastLogonTimeStamp**, as follows:

- The inconsistency of NTLM updates of **lastLogonTimeStamp** is corrected.

- Updates to the Key Distribution Center (KDC) ensure that **lastLogonTimeStamp** is updated in Active Directory when a user logs on to a protected IIS Web site.

#### Scripting stale account detection

You can implement a scripting solution for managing stale account detection and cleanup. For more information about **lastLogonTimeStamp** and instructions for creating scripts, see "Dandelions, VCR Clocks, and Last Logon Times: These are a Few of Our Least Favorite Things" on the Microsoft Web site at http://go.microsoft.com/fwlink/?LinkId=47965.

#### Database Defragmentation

As described earlier in this section, the database system uses the quickest way to fill database pages. Although this system is efficient in searching and updating the database quickly, it does not make the most efficient use of space in the database. As write operations occur and data pages fill, a certain amount of space often remains in a page that cannot be used by other transactions because the space is not large enough. In addition, space that is freed by version store cleanup is returned to the owning indexes or tables in noncontiguous chunks. Therefore, free space that exists in the database is not always available for use because it is fragmented.

Defragmentation rearranges how the data is stored in the database, compressing the data and making free space available in contiguous pages. Free space is managed automatically during database defragmentation.

Database defragmentation can take place online (while the computer is running as a domain controller) or offline (while the computer is running in Directory Services Restore Mode). Defragmentation has different effects on database size, depending on whether defragmentation is run while the domain controller is online or offline:

- Online defragmentation: Occurs automatically by default. Online defragmentation compacts data and optimizes free space for database use, thereby maintaining the file size of the database.

- Offline defragmentation: Occurs only manually in Directory Services Restore Mode. Offline defragmentation compacts data and returns free space to the file system, thereby decreasing the file size of the database.

#### Online Defragmentation

During online defragmentation, space in partially filled data pages is reorganized to consolidate it into full 8-KB pages. In addition, any pages that have been skipped by version store cleanup are reclaimed for use by the database. Online defragmentation returns a freed page directly to the part of the tree (database, object table, index, or long-value table) that owns the page that is being freed. When a sufficient number of contiguous free pages (approximately 16) exist in a given child tree, the space is released to the parent tree.

### Note

- On domain controllers running Windows 2000 Server, online defragmentation does not reclaim free space that is deleted from long-value tables.

#### Automatic online defragmentation

Windows 2000 Server and later based domain controllers perform online defragmentation automatically. The ESE invokes online defragmentation after each garbage collection, which occurs every 12 hours by default.

**Manual online defragmentation**
On domain controllers running Windows Server 2003 and later, you can prompt online defragmentation to run manually. Although online defragmentation occurs automatically following garbage collection and the garbage collection interval is known and configurable, the duration of the garbage collection process is variable, depending on how many tombstones have expired and the load requirements of the domain controller at the time of garbage collection. The variable nature of garbage collection can cause unpredictable performance between the time garbage collection begins and online defragmentation completes.

By performing online defragmentation during off-peak hours, you can ensure more-even directory performance during peak hours. To control when online defragmentation occurs, you can configure domain controllers running Windows Server 2003 and later as follows:

- To start online defragmentation manually at any time, irrespective of garbage collection intervals, you can add the operational attribute **doOnlineDefrag** to the rootDSE object. The value of this attribute dictates the duration (in seconds) for which online defragmentation runs. After setting this attribute value, you can create a script that takes the duration as input so that online defragmentation can be triggered by the script at any time for any duration of runtime.

- If you want online defragmentation to always occur only on demand, you can configure the registry so that automatic online defragmentation is disabled.

  **Note**

  - The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

You do not have to disable automatic online defragmentation to manually start online defragmentation. After you add the **doOnlineDefrag** attribute, you can start manual online defragmentation at any time that conditions warrant it, while allowing automatic online defragmentation to continue as well.

**Offline Defragmentation**
Offline defragmentation rebuilds the directory database and releases unneeded space back to the file system. Offline defragmentation must be performed in Directory Services Restore Mode, which restarts the computer as a stand-alone server, that is, as a computer that is not acting as a domain controller. In Directory Services Restore Mode, you can use the **ntdsutil** command-line tool to defragment the Ntds.dit file. Offline defragmentation produces a defragmented version of the database file in a separate directory. You can archive the original Ntds.dit file and move the defragmented file into the current directory.

Only offline defragmentation provides a clear picture of the amount of space that is consumed by the database file. You can use offline defragmentation to test database growth by comparing the defragmented version of the file with the fragmented version. For example, on a newly installed domain controller, if you perform a bulk load of objects and then defragment the database file offline, the difference between the two files is the space that is occupied by the new objects. There is no standard or optimal value for the percentage of free space that might exist in the database at any given time. If you are concerned about database size, set the DSA to log a message in the Directory Service event log during garbage collection that states how much disk space could be freed up through offline defragmentation.

**Linked Attribute Management**
Attributes of certain objects can be linked in the directory database to attributes of other objects to provide interobject references from one object back to the other object for either usability or administrative purposes. For example, a user object can be a member of a group, and a group can have users and groups as members. To define this relationship, the group object has a **member** attribute that can have multiple values of the distinguished names of every user, computer, or group that has membership in the group. Similarly, the user, computer, and group objects have a multivalued **memberOf** attribute that identifies all the groups to which a user, computer, or group belongs. These attributes are “linked” in the Active Directory database so that you can, for example, look at the **member** attribute on the object GroupA and determine that UserB is a member of GroupA. Likewise, you can look at the **memberOf** attribute on the object UserB and determine that UserB belongs to GroupA.

The GUID of an object unambiguously indicates which object the linked value applies to, even if the object has been renamed, deleted, or garbage-collected (permanently removed from the database). Individual values of multivalued attributes do not have an associated GUID. Instead, a link-value identifier serves the purpose of distinguishing existing values (including value

tombstones) from values that have been garbage-collected and then recreated. This identifier, called the link ID, remains fixed from the creation of the value until the value is garbage-collected. When the originating server creates a new value, an ID is assigned to the value. Linked values replicate with the GUID of the object that contains them.

**Effect of Moving Linked Objects**

Active Directory maintains referential integrity between objects that reference each other by distinguished name so that when one object is moved in the directory tree, the referencing object can track the referenced object. For example, an object UserB is a member of GroupA. If you move the object UserB from the CN=Users,DC=concorp,DC=contoso,DC=com container to the OU=Sales,DC=concorp,DC=contoso,DC=com OU, the distinguished name value for UserB in the **member** attribute on the GroupA object automatically changes as follows:

- Before the move: CN=UserB,CN=users,DC=concorp,DC=contoso,DC=com
- After the move: CN=UserB,OU=sales,DC=concorp,DC=contoso,DC=com

This change occurs as soon as the move occurs. In this way, linked attributes effectively share their values.

**Identifying Link Pairs**

The sharing of values by linked attributes is achieved when two attributes are marked in the schema as having the same link-pair identifier — one is marked as the forward link (it points to another object in the directory) and the other as the back-link (it points back to the object that has a forward link to it). Changing the forward link attribute on one object affects the back-link on the referenced object. In the current example, the **member** attribute is the forward link and the **memberOf** attribute points back to the value in **member**. For reasons that relate to security and replication, only the forward-linked attribute can be modified.

### Note

- The decision to link two objects must be made at the time that the objects are added to the schema.

To find all the objects that are members of GroupA, links are examined for all records in which the link pair is **member**/**memberOf** and the back-linked attribute identifies GroupA. The link pairs of those records provide the database identifiers of all the records (objects) that are members of GroupA.

The **member** and **memberOf** example uses a multivalued forward link and a multivalued back-link, but there is no requirement that the forward link be a multivalued link. For example, each group has one manager, but a manager can manage multiple groups. This relationship is identified in the database by the **manager**/**directReports** link pair, where **manager** is a single-valued attribute of a user object and **directReports** (common name Reports) is a multivalued attribute of a user object. The back-linked attribute must always be multivalued because it is impossible to restrict who creates links to various objects.

**Deleting Linked Objects**

When an object that is linked through a multivalued attribute is deleted, all of its linked attribute values are removed from the respective linked objects. In the preceding example, if a user manages multiple users and one of the users is deleted, the **directReports** multivalued attribute on the user object of the user that is the manager suddenly (and with no change to any replication-related metadata) loses a value. Similarly, if the user object for the manager is deleted, the value of the **manager** attribute on the user object of the user who was a direct report is suddenly blank. Nothing about the nondeleted object changes in either case, except that the attribute value is gone.

**Restoring Linked Objects and Their Back-Links**

When objects are deleted by mistake, you can restore them in Active Directory by performing an authoritative restore of the deleted objects. You perform authoritative restore by restoring the domain controller from its latest backup and then marking the deleted objects as authoritative so that they are not removed by replication.

However, when an object that has back-links is restored on a domain controller running Windows 2000 Server, its back-links are not restored as part of the authoritative restore process. For example, when user objects or group objects are deleted and then authoritatively restored, the **memberOf** values must be restored manually. You must add a restored user or group back to the groups to which it belonged at the time that its account was deleted.

On domain controllers running Windows Server 2003 or later in a forest that has a forest functional level of Windows Server 2003 or higher, back-links are restored automatically for authoritatively restored objects under the following conditions:

- The link was added after the forest functional level was raised to Windows Server 2003 or higher (linked-value replication was in effect).

- Replication of a restored user object precedes replication of a restored group to which it belongs when the user and group are both authoritatively restored at the same time.

If the domain controller on which you are authoritatively restoring objects is running Windows Server 2003 with SP1 or later, you can use the Windows Server 2003 SP1 or later version of Ntdsutil to restore back-links for any authoritatively restored objects that have links, including objects in different domains. For more information about how to restore back-links on domain controllers running Windows Server 2003 with SP1 or later, see "Performing an Authoritative Restore of Active Directory Objects" in "Administering Active Directory Backup and Restore" in the Windows Server 2003 Operations Guide at http://go.microsoft.com/fwlink/?LinkId=44194.

For more information about replication of deleted linked objects, see "Active Directory Replication Model Technical Reference".

**Phantom Records for Interdomain Object References**
An attribute that has a distinguished name as a value references (points to) the named object. When the referenced object does not actually exist in the local directory database because it is in a different domain, a placeholder record called a phantom is created in that database as the object reference. Because there is a reference to it, the referenced object must exist in some form, either as the full object (if the domain controller stores the respective domain directory partition) or as an object reference (when the domain controller does not store that domain).

A phantom record contains the GUID and the distinguished name of the object that is being referenced. In the case of references to security principals, the phantom also contains the SID. A common example of a distinguished name value that references an object in a different domain is the **nCName** attribute of a cross-reference (crossRef) object. Every domain controller stores a cross-reference object (in the configuration directory partition) for every other domain directory partition in the forest. Therefore, the **nCName** attribute value for every cross-reference object necessarily references a phantom in the local directory database.

**Infrastructure Master and Phantom Records**
The infrastructure master is a single domain controller in each domain that tracks name changes of referenced objects and updates the references on the referencing object. When a referenced object is moved to a different domain (which effectively renames the object), the infrastructure master updates the distinguished name of the phantom. (The infrastructure master finds phantom records by using a database index that is created only on domain controllers that hold the infrastructure operations master role.) When the reference count of the phantom falls to zero (no objects are referencing the object that the phantom represents), garbage collection on each domain controller removes the phantom.

### Note

- Because objects can reference objects in different domains, the infrastructure operations master role is not compatible with global catalog server status if there is more than one domain in the forest. If a global catalog server holds the infrastructure operations master role, phantom records are never created because the referenced object is always located in the directory database on the global catalog server.

**Ownership Quotas on Directory Objects**
On domain controllers running Windows Server 2003 or later, you can specify quotas that limit the number of objects that a security principal (user, group, computer, or service) can own in a domain, configuration, or application directory partition. By default, the security principal (or administrative group in some cases) that creates an object is the object owner, although ownership can be transferred. With Active Directory quotas, no one can create unlimited numbers of objects in a directory partition, which is a method that can be used to launch denial-of-service attacks.

### Note

- The term "user" in this discussion of security principals indicates both the **user** and **inetOrgPerson** classes of objects.

By default, quotas are not set, so there are no limits to the number of objects that can be owned by any security principal. For each target directory partition, you can set different limits for different security principals or you can set limits that apply to all security principals, or you can do both.

Quotas can be set per directory partition, except for the schema directory partition, which does not support quotas. You can set quotas to apply to security principals for a directory partition by using the command line. Use the following commands to manage quotas:

- **dsadd quota** to set quotas for a directory partition

- **dsmod quota** to modify existing quotas
- **dsmod partition** to modify default quota settings for a partition
- **dsquery quota** to search for quota assignments and quota consumption

For more information about directory quotas and how to use **dsadd**, **dsmod**, and **dsquery** commands to manage directory quotas, see "Data Store Tools and Settings".

**Quota Assignment Objects**

Quota assignments for security principals are represented in a directory partition as instances of the object class **msDS-QuotaControl**. Each object in this class has the following attributes:

- **Common-Name**: The relative distinguished name (also known as RDN) of the security principal object. This mandatory value should be a friendly name (or **sAMAccountName**) of the security principal whose quota is being specified.
- **msDS-QuotaTrustee**: The SID of the security principal (user, computer, or group) for which the quota is being assigned.
- **msDS-QuotaAmount**: The mandatory value of the assigned quota (number of objects owned in the database) for the security principal. A value of `-1` for this attribute denotes an unlimited quota.
- **Flags**: This optional attribute is reserved for future use.

Instances of **msDS-QuotaControl** objects are stored in a well-known container called NTDS Quotas in the directory partition to which the quota applies.

**Quota Containers**

The NTDS Quotas container (class **msDS-QuotaContainer**) is a special system container that the quota system uses. The NTDS Quotas container has the following characteristics:

- It is a child object of the root of a parent directory partition (including domain, configuration, and application directory partitions).
- It cannot be deleted, but it can be renamed.
- It is tracked by the parent container through the **wellKnownObjects** attribute on the parent container.

Each directory partition has exactly one well-known NTDS Quotas container that stores explicit quota assignment objects for the partition.

Two attributes of this well-known container specify a default quota value and how quotas are computed for that directory partition:

- **msDS-DefaultQuota**: A default quota that applies to any security principal that creates objects in the directory partition and for which no explicit quota assignment exists. If no value is set for this attribute or if the attribute has the value -1, there is no default quota for the directory partition. In this case, security principals that do not have explicit quotas assigned have the ability to create unlimited objects in that directory partition, subject to access control. The default value for **msDS-DefaultQuota** on a directory partition is unlimited (not set). To manage this value, use the **dsmod partition** command.
- **msDS-TombstoneQuotaFactor**: The percentage factor by which tombstone object count should be reduced for the purpose of quota accounting. By default, the setting is 100, which means that a tombstone (a deleted object) that was originally created by a security principal is equal to 1 object of that user's quota. If the percentage factor were set to 50, each tombstone would represent only half an object rather than an entire object. Likewise, a tombstone quota factor of 25 means that four tombstones are the equivalent of 1 owned object. In this way, the quota for a security principal is computed relative to objects and tombstones. To manage this value, use the **dsmod partition** command.

**Tracking Object Ownership**
To enforce compliance with Active Directory quotas, object ownership is tracked by each domain controller running Windows Server 2003 or later. After a domain controller is upgraded to Windows Server 2003 or later, the system determines the number of objects that are owned by each security principal and for each directory partition that the domain controller hosts, and the system generates a tracking table for internal object ownership to track quota consumption. Thereafter, when objects are created, deleted, or reanimated or their ownership is transferred in a directory partition that the domain controller hosts, the quota tracking data is suitably updated.

**Enforcing Quotas**
Quotas are enforced only on originating updates and only by domain controllers running Windows Server 2003 or later. When an update originates on a Windows Server 2003 or later domain controller, quotas are enforced. At the time of the operation, if the requestor is not exempt from quotas, the effective quota limit for the requestor is computed on the basis of the default quota setting for the directory partition or any explicit quota assignments. Further, the requestor's current quota consumption is computed using the object ownership tracking data and the tombstone quota factor. If the pending object transaction (create, delete, reanimate, or transfer of ownership) causes the quota limit to be exceeded, the transaction fails.

If an originating update occurs on a domain controller running Windows 2000 Server, quotas are not enforced. However, as Windows Server 2003 or later domain controllers receive replicated updates, regardless of their origin, they update object ownership tracking data for the respective security principal.

Thus, although Windows Server 2003 and later domain controllers can always update quota tracking data, quotas are effectively enforced at the domain level only when all domain controllers in the domain are running Windows Server 2003 or later and at the forest level (for the configuration directory partition) only when all domain controllers in the forest are running Windows Server 2003 or higher.

**Effective quota**
Multiple quota assignments can exist for a given security principal through an individual quota assignment or through quota assignments for one or more security groups of which the principal is a member, or both. When multiple quota assignments exist for a security principal, the effective quota is computed to be the maximum of the applicable quota assignments that are specified. For example, if a user belongs to two groups that have different quotas specified for the same directory partition, the higher of the two quota values applies to the user.

If no quota assignments are specified for a security principal or for any of the security groups of which the security principal is a member, the effective quota is the default quota that is specified for the directory partition in the **msDS-DefaultQuota** attribute on the NTDS Quotas container.

**Quota exemptions**
Members of the Domain Admins and Enterprise Admins groups are exempted from all quota-imposed limits.

**Using Quotas**
You can use quotas in combination with security groups to manage objects that are created in Active Directory. The following examples illustrate using a default quota, with exceptions to set explicit quota assignments for those groups that need the ability to create large numbers of objects.

**Managing DNS data in application directory partitions**
When you use Active Directory–integrated DNS, zone data can be stored in the domain directory partition, if you want DNS data to replicate to all domain controllers, or in application directory partitions, if you want DNS data to replicate only to domain controllers that are DNS servers.

To decrease domain-wide replication and avoid replicating zone data to the global catalog, you can take advantage of application directory partitions on DNS servers running Windows Server 2003 or later. By default, members of the Authenticated Users group have the ability to create resource records on DNS servers that are in the domain of the client computer. This ability is required to allow all computers to dynamically update DNS zone data. A typical authenticated user needs to register a maximum of 10 records in DNS. To ensure that malicious users or applications do not create inappropriate resource records, you can set a default quota on the application directory partitions ForestDnsZones and DomainDnsZones, which are replicated to every DNS server in the forest and domain, respectively. A default limit of 10 objects ensures that all computers can update DNS appropriately but cannot launch denial-of-service attacks.

**Explicit quotas for domain controllers and other servers**
The number of resource records that must be registered in DNS is significantly greater for domain controllers and for multihomed computers that register adapter-specific records for all of their connections. To accommodate the resource record requirements of atypical authenticated users such as domain controllers, multihomed computers, and multiadapter servers, you can create special groups for these specific types of computers. For example, you might create the Enterprise Domain Controllers group that has all domain controllers as members. To ensure that this group can create the maximum DNS resource records that might be required, set a quota of 300 to 400 objects for this group on the DomainDnsZones and

ForestDnsZones application directory partitions.

The same rule applies to servers such as virtual private network (VPN) or Web servers, which are required to register a large number of resource records in DNS. Depending on how many adapter-specific resource records your VPN or Web server must register, you can create a group for those servers and assign the appropriate quota to ensure that the Authenticated Users default quota does not apply.

**Explicit quotas for DHCP servers**
To allow DHCP servers to have essentially unlimited ability to create resource records when clients depend on DHCP-assigned IP addresses, you can create a group that contains all DHCP servers in the domain or forest and then set an explicit quota assignment for that group on the DomainDnsZones and ForestDnsZones application directory partitions, respectively. Set a quota that is appropriate to the number of clients for which your DHCP server registers records, multiplied by the upper limit of the number of records registered per computer. In this way, DHCP servers can update DNS with client resource records as needed.

**Managing print objects in domain directory partitions**
When Active Directory is used to publish shared printing resources, print servers require the ability to create potentially large numbers of objects in Active Directory. Print servers publish printers in Active Directory as print queue objects (class **printQueue**), which are child objects of the print server computer object and which contain a subset of the information that is stored on the print server for a printer. When print servers go offline for any reason, they must republish their print queues when they return to service. For this reason, print servers require the ability to create large numbers of objects in the domain directory partition.

To ensure that print servers can create appropriate numbers of objects in the domain, you can create a group that contains all print servers in the domain and then specify an explicit quota assignment on the domain that is higher than the default assignment.

**Network Ports Used by the Data Store**
The network ports that are used by the data store are listed in the following table.

### Port Assignments for the Data Store

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | None | 389 |
| LDAP SSL | None | 636 |
| RPC Endpoint Mapper | 135 | 135 |
| Global Catalog LDAP | None | 3268 |
| Global Catalog LDAP SSL | None | 3269 |

**Related Information**
The following resources contain additional information that is relevant to this section.

# Data Store Tools and Settings

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Data Store Tools
- Data Store Registry Entries
- Data Store Group Policy Settings
- Data Store WMI Classes
- Network Ports Used by the Data Store

This section contains information about the tools, registry entries, Group Policy settings, Windows Management Instrumentation (WMI) classes, and network ports that are associated with the data store.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to Active Directory Domain Services. |

**Data Store Tools**

The following tools are associated with the data store.

**Adsiedit.msc: ADSI Edit**

**Category**

This tool ships with Support Tools for Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |

|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

ADSI Edit is a Microsoft Management Console (MMC) tool that you can use to view and modify directory objects.

To find more information about ADSI Edit, see Support Tools Help in Tools and Settings Collection.

**Csvde.exe: Csvde**

**Category**
This tool ships with Windows Server 2003.

**Version compatibility**

| **Can Be Run From** | **Can Be Run Against** |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Csvde to import and export data from Active Directory by using files that store data in the comma-separated value (CSV) file format standard. Csvde also supports batch operations that are based on CSV.

To find more information about Csvde, see "Command-Line References" in Tools and Settings Collection.

**Dsadd.exe: Dsadd**

**Category**
This tool ships with Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |

|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Dsget to display the selected properties of a specific object in the directory.

To find more information about Dsget, see "Command-Line References" in Tools and Settings Collection.

**Dsmod.exe: Dsmod**

**Category**
This tool ships with Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Dsmod to modify an existing object of a specific type in the directory.

To find more information about Dsmod, see "Command-Line References" in Tools and Settings Collection.

**Dsmove.exe: Dsmove**

**Category**
This tool ships with Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Dsmove to move a single object, within a domain, from its current location in the directory to a new location. You can also use Dsmove to rename a single object without moving it in the directory tree.

To find more information about Dsmove, see "Command-Line References" in Tools and Settings Collection.

**Dsquery.exe: Dsquery**

**Category**
This tool ships with Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Dsquery to query Active Directory according to specified criteria.

To find more information about Dsquery, see "Command-Line References" in Tools and Settings Collection.

**Dsrm.exe: Dsrm**

**Category**
This tool ships with Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Dsrm to delete an object of a specific type, or any general object, from the directory.

To find more information about Dsrm, see "Command-Line References" in Tools and Settings Collection.

**Ldifde.exe: Ldifde**

**Category**
This tool ships with Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Ldifde to create, modify, and delete directory objects on domain controllers. You can also use Ldifde to extend the schema, export Active Directory user and group information to other applications or services, and populate Active Directory with data from other directory services.

To find more information about Ldifde, see "Command-Line References" in Tools and Settings Collection.

**Ldp.exe: Ldp**

**Category**
This tool ships with Support Tools for Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

Ldp is a Lightweight Directory Access Protocol (LDAP) graphical user interface (GUI) tool that you can use to perform operations such as connect, bind, search, modify, add, and delete against any LDAP-compatible directory, such as Active Directory. You can also use Ldp to view objects that are stored in Active Directory, along with their metadata, for example, security descriptors and replication metadata.

You can use the online **dbdump** feature in Ldp to view values that are stored in the database while the domain controller is running. You can trigger **dbdump** by modifying the **dumpDatabase** attribute on the **rootDSE**.

To find more information about Ldp, see "Support Tools Help" in Tools and Settings Collection.

**Ntdsutil.exe: Ntdsutil**

**Category**
This tool ships with Windows Server 2003.

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition |

You can use Ntdsutil to perform Active Directory database maintenance, manage and control single master operations, and remove metadata left behind by domain controllers that are removed from the network without being properly uninstalled. This tool is intended for use by experienced administrators.

To find more information about Ntdsutil, see "Command-Line References" in Tools and Settings Collection.

**Data Store Registry Entries**
The following registry entries are associated with the data store.

The registry entries under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics** control the logging level for the component or process that is specified in the entry name. The value for each entry is set to an integer from and including 0 (no logging) through 5 (most verbose logging).

The registry entries under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters** control or contain information about the configuration of the data store.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics**
The following registry entries are located under
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics**.

**3 ExDS Interface Events**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Controls the logging of events that result from communication between Active Directory and Microsoft Exchange clients.

**4 MAPI Interface Events**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Controls the logging of events that result from communication between Active Directory and Microsoft Exchange clients.

**6 Garbage Collection**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Controls the logging of events that are generated when objects that are marked for deletion are actually deleted.

**7 Internal Configuration**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Controls the logging of internal operations.

**8 Directory Access**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics

**Version**

Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Controls the logging of read and write operations to directory objects from all sources.

**9 Internal Processing**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Controls the logging of events that are related to internal directory service operations.

**11 Initialization/Termination**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Controls the logging of events that are generated by starting and stopping Active Directory.

**12 Service Control**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Controls the logging of Active Directory service events.

**13 Name Resolution**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Controls the logging of events that are generated by the resolution of addresses and Active Directory names.

**14 Backup**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Controls the logging of events that are related to backing up Active Directory. Specifically, controls the logging of events that occur when Extensible Storage Engine (ESE) database records are read or written during backup.

**16 LDAP Interface Events**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Controls the logging of events that are related to LDAP.

**18 Global Catalog**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Controls the logging of events that are related to the global catalog.

**22 DS RPC Client**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Controls the logging of events that are related to communication between Directory System Agents (DSAs). Examples of such communication include replication and the forwarding of look-ups to a global catalog. Examples of logged events include remote procedure call (RPC) errors, canceled calls, Domain Name System (DNS) resolution failures, and service principal name (SPN)–related operations.

**23 DS RPC Server**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Controls the logging of events that are related to a DSA acting as an RPC server. A DSA acts as an RPC server, for example, during outbound replication, replication setup operations, cross-domain moves, and membership queries or when a client makes a look-up call.

**24 DS Schema**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Controls the logging of events that are related to schema errors and operations. Such errors and operations include schema additions, deletions, modifications, look-up errors, look-up failures, and caching errors.

**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters**
The following registry entries are located under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters**.

**Configuration NC**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Contains the distinguished name of the configuration directory partition.

**Database Backup Path**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Determines the directory that is used as the target directory when online backups of the directory database are performed.

**Database Log Files Path**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Determines the directory path that is used to store Active Directory log files.

**Database Logging/Recovery**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Controls a Microsoft Jet database engine parameter called *JET_paramRecovery* that determines whether database operations are logged.

**DS Drive Mappings**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Used to track local drive mapping names, so that the database file can be located if drive mappings are modified.

**DSA Database File**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server;

Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Determines the file that is used by the domain controller for storing Active Directory objects.

**DSA Working Directory**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Determines the working directory of Active Directory.

**Hierarchy Table Recalculation Interval (minutes)**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Determines how frequently the hierarchy table for the directory database is built. The hierarchy table is used only by the Messaging API (MAPI) interface.

**Ldapserverintegrity**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Determines whether connection integrity is required (by means of checksum-signed packets) for LDAP connections.

**Machine DN Name**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Contains the distinguished name of the computer on which the domain controller is running.

**Root Domain**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Contains the distinguished name of the root domain of the Active Directory forest to which the domain controller is connected.

**Schema Version**

**Registry path**

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Domain controllers running Windows 2000 Server; Windows 2000 Advanced Server; Windows 2000 Datacenter Server; Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Contains the schema version for which a particular operating system is configured.

**System Schema Version**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Domain controllers running Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.

Contains the version of the schema at the time that a backup is taken. This value is used to prevent an incompatible schema version from being restored from backup.

**Data Store Group Policy Settings**
The following table lists and describes the Group Policy settings that are associated with the data store.

### Group Policy Settings Associated with the Data Store

| Group Policy Setting | Description |
|---|---|
| Audit Directory Services Access | When it is enabled, this Group Policy setting causes successful and failed directory access events to be logged in the Directory Service event log. |

**Data Store WMI Classes**
The following table lists and describes the WMI classes that are associated with the data store.

### WMI Classes Associated with the Data Store

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| **rootDSE** | root\directory\LDAP | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

| | | |
|---|---|---|
| **DS_LDAP_Class_Containment** | root\directory\LDAP | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |
| **DS_LDAP_Instance_Containment** | root\directory\LDAP | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

For more information about these WMI classes, see "Mapping Active Directory to WMI" in the WMI SDK documentation on MSDN.

**Network Ports Used by the Data Store**

The network ports that are used by the data store are listed in the following table.

**Port Assignments for the Data Store**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | None | 389 |
| LDAP SSL | None | 636 |
| RPC Endpoint Mapper | 135 | 135 |
| Global Catalog LDAP | None | 3268 |
| Global Catalog LDAP SSL | None | 3269 |

# DNS Support for Active Directory Technical Reference

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

Active Directory is the directory service for the Windows Server 2003 operating system; DNS is the primary name resolution service for Windows Server 2003, and a core component of Windows Server 2003 TCP/IP networking.

Strictly speaking, DNS is not a component of Active Directory. However, knowledge of how Active Directory depends on DNS is necessary to understand how Active Directory components are able to perform their assigned operations. DNS is used by Active Directory for domain controller location and DNS naming is leveraged by Active Directory for domain naming. Because Active Directory depends on DNS for domain controller location and DNS influences Active Directory domain naming, DNS is discussed in this technical reference subject as a component of the Windows Server 2003 directory service solution.

**In this subject**

# What Is DNS Support for Active Directory?

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**What Is DNS Support for Active Directory?**
DNS is the primary name resolution service for Windows Server 2003 and later. Active Directory depends on DNS for domain controller location, and DNS influences Active Directory domain naming. Thus, to fully understand Active Directory, it helps to understand how DNS acts as an integral component in the design of Active Directory.

Active Directory requires:

- A name resolution service that enables network hosts and services to locate Active Directory domain controllers.
- A naming structure that enables an enterprise to reflect its organizational structure in the names of its directory service domains.

DNS provides Active Directory with both a name resolution service for domain controller location and a hierarchical design that Active Directory leverages to provide a naming convention that can reflect organizational structure.

Typically, a DNS domain namespace deployed to accommodate the Active Directory mirrors the Active Directory domain namespace. In cases where there is an existing DNS namespace prior to Active Directory deployment, the DNS namespace is typically partitioned for Active Directory, and a DNS subdomain and delegation for the Active Directory forest root is created. Additional DNS domain names are then added for each Active Directory child domain.

DNS data is used to support the location of Active Directory domain controllers also. During or after the creation of the DNS zones used to support Active Directory domains, the zones are populated with DNS resource records that enable network hosts and services to locate Active Directory domain controllers.

- Network Ports Used by DNS in Support of Active Directory
- Related Information

Active Directory uses DNS as its domain controller location mechanism and leverages the namespace design of DNS in the design of Active Directory domain names. As a result, DNS is positioned within the discoverability and logical structure components of Active Directory technology components.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to Active Directory Domain Services. |

Typically, a Windows Server 2003 and later DNS namespace is deployed to mirror an Active Directory forest and domain infrastructure. In such a deployment, a partition of the DNS namespace is set aside for Active Directory, where a DNS domain name such as corp.contoso.com is used support the Active Directory forest root domain, and then subdomains of this name are created to suit additional Active Directory domains as needed.

**DNS Support for Active Directory Architecture**

Active Directory is dependent on DNS as a domain controller location mechanism and uses DNS domain naming conventions in the architecture of Active Directory domains. There are three components in the dependency of Active Directory on DNS:

- Domain controller locator (Locator)
- Active Directory domain names in DNS
- Active Directory DNS objects

**DNS Support for Active Directory Components**

| Component | Description |
| --- | --- |
| Domain controller locator (Locator) | The Windows Server 2003 or later domain controller locator, implemented in the Net Logon service, enables a client to locate a domain controller. The component contains the DNS–compatible and the Windows NT 4.0–compatible locators that provide interoperability in a mixed Windows Server 2003 or later – and Windows NT 4.0–based environment. |

| | |
|---|---|
| Active Directory domain names in DNS | Every Windows Server 2003 or later Active Directory domain has a DNS domain name (for example, contoso.com), and every Windows Server 2003 or later based computer has a DNS name (for example, win2kserver.contoso.com). Architecturally, domains and computers are represented both as objects in Active Directory and as nodes in DNS.<br><br>Because DNS domains and Active Directory domains share identical domain names, it is easy to confuse their roles. The two namespaces, although typically sharing an identical domain structure, store different data and, therefore, manage different objects:<br><br>• DNS stores zones and resource records, and Active Directory stores domains and domain objects. Both systems use a database to resolve names.<br><br>• DNS resolves domain names and computer names to resource records through requests received by DNS servers as DNS queries to the DNS database.<br><br>• Active Directory resolves domain object names to object records through requests that are received by domain controllers either as LDAP search requests or as modify requests to the Active Directory database.<br><br>Thus, the Active Directory domain computer account object is in a different namespace from the DNS host record that represents the same computer in the DNS zone. |
| Active Directory DNS objects | When DNS data is stored in Active Directory, each DNS zone is an Active Directory container object (class **dnsZone**). The dnsZone object contains a DNS node object (class **dnsNode**) for every unique name within that zone. These unique names include the variations assigned to a specific host computer when it functions, for example, as a primary domain controller or as a global catalog server. The dnsNode object has a dnsRecord multivalue attribute that contains a value for every resource record that is associated with an object's name.<br><br>For more information about Active Directory DNS objects, see How DNS Works. |

**Active Directory and DNS Domain Names**

Active Directory domains have two types of names: DNS names and NetBIOS names. In general, both names are visible to end users. The DNS names of Active Directory domains include two parts, a prefix and a suffix. The DNS prefix is the first label in the DNS name of the domain. The suffix is the name of the Active Directory forest root domain.

When a Windows NT 4.0 master user domain (MUD) is upgraded, the decision is made whether or not to use the current NetBIOS name of the domain as a DNS prefix. If the name is appropriate to represent the organizational structure of the enterprise and satisfies the prefix naming rules in the table below, the name is typically kept. In this case, the NetBIOS name of the domain is the same as the DNS prefix of the domain.

**Registered DNS Name Prefix Rules**

| Rule | Explanation |
|---|---|
| Select a prefix that is not likely to become outdated. | Avoid names such as a business line or operating system that might change in the future. Geographical names are recommended. |
| Select a prefix that includes Internet standard characters only. | A-Z, a-z, 0-9, and (-), but not entirely numeric. |
| Include 15 characters or less in the prefix. | If you choose a prefix length of 15 characters or less, then the NetBIOS name is the same as the prefix. |

If the current NetBIOS name of the domain is inappropriate to represent the organizational structure of the enterprise or if the current name fails to satisfy the prefix naming rules, a new prefix is used. In this case, the NetBIOS name of the domain will be different from the DNS prefix of the domain.

For each new Active Directory domain, a prefix that is appropriate for the organizational structure of the enterprise and that satisfies prefix naming rules is used. Typically, the NetBIOS name of the domain will be the same as the name of the DNS prefix.

The Active Directory forest root domain is also the name of the Active Directory forest. The forest root name is a DNS name that consists of a prefix and a suffix in the form of prefix.suffix. For example, an organization might have the forest root name corp.contoso.com. In this example, corp is the prefix and contoso.com is the suffix.

The suffix is selected from a list of existing DNS names on the network. For the prefix, a new name that has not been used on the network previously is selected. By attaching a new prefix to an existing suffix, a unique namespace is created. Creating a new namespace for Active Directory ensures that any existing DNS infrastructure does not need to be modified to accommodate Active Directory.

Typically, the DNS names that are used in the Active Directory namespace are registered with an Internet authority. Only registered names are guaranteed to be globally unique. If two organizations register the same DNS domain name, or if an organization merges with, acquires, or is acquired by another company that uses the same DNS name, then the two infrastructures cannot interact with one another.

Active Directory domain names should be fully qualified, such as corp.contoso.com or contoso.com. Commonly accepted top level domains for AD domains can consist of traditional three-letter top level domains such as .com, .biz, or .gov and two-letter country code domains such as .uk or .jp. For more information about top-level domain names and two-letter country code domains, see Root Zone Database.

Single-label names, such as contoso, can never be registered on the Internet. They require additional configuration, causing higher total cost of ownership (TCO). Furthermore, some Active Directory-enabled applications are incompatible with single-label domain names, or they have announced intentions to drop support for them in the future.

If you create an Active Directory domain with a single-label name, it can be very difficult to rename or migrate to a fully qualified domain name. Beginning with Windows Server 2008 R2, the Active Directory Installation Wizard does not allow creation of new domains with single label names. Both Windows Server 2008 and Windows Server 2008 R2 continue to allow installation of additional domain controllers to existing domains that have a single-label DNS name. In-place upgrades of domain controllers in a domain that has a single-label DNS name is also allowed, subject to the upgrade compatibility matrix (for example, and x86-based domain controller cannot be in-place upgraded to x64-based operating system).

For more information, see Microsoft Knowledge Base article 300684.

**DNS Physical Structure in Support of Active Directory**

The physical structure of Active Directory information in DNS is represented in DNS zones and resource records, which, in turn, are typically stored in Active Directory as Active Directory–integrated DNS zones. The DNS zones that support Active Directory domains can also be stored in standard, file-based, DNS zones. In addition, the DNS dynamic update protocol is utilized by Active Directory in order to make the registration of domain controller DNS resource records automatic.

The following diagram illustrates the physical storage of Active Directory domain information in DNS zones hosted on domain controllers, and in standard DNS zones hosted on member servers.

**DNS Physical Structure in Support of Active Directory**

The following table describes the physical components in the Active Directory/DNS physical structure.

**DNS Physical Structure in Support of Active Directory Components**

| Active Directory/DNS Physical Structure Component | Description |
|---|---|
| Active Directory/DNS physical structure requirements | The DNS server used to support Active Directory must support the SRV resource record and, ideally, the DNS dynamic update protocol. If the DNS server does not support the DNS dynamic update protocol, the SRV resource records required to locate Active Directory domain controllers can be added to DNS manually. |
| _msdcs DNS subdomain | The Microsoft-specific subdomain enables location of domain controllers that have specific roles in the Active Directory domain or forest. Resource records for the DNS root domain of a new Active Directory forest are stored in a _msdcs zone instead of a subdomain, and that zone is stored in the forest-wide application directory partition. |
| Domain controller SRV resource records registered in DNS | There are multiple DNS SRV resource records registered on behalf of domain controllers. A description of each resource record is below. |
| DNS application directory partitions | In Windows Server 2003 and later, the Active Directory–integrated DNS zones that support Active Directory domains can be stored in Active Directory application directory partitions. By default, the DNS root domain of a new Active Directory forest is stored in the domain-wide application directory partition for the forest root domain. |

**DNS Support for Active Directory Physical Structure Requirements**

In order for a DNS server to be able to support Active Directory, the server is required to support the service (SRV) resource record type and the dynamic update protocol, as described in the RFC 2136. Active Directory uses DNS as the location mechanism for domain controllers, enabling computers on the network to obtain IP addresses of domain controllers. During the installation of Active Directory, the service (SRV) and address (A) resource records are dynamically registered in DNS. Both types of records are necessary for the functionality of the domain controller locator (Locator) mechanism.

To find domain controllers in a domain or forest, a client queries DNS for the SRV and A DNS resource records of the domain controller. The resource records provide the client with the names and IP addresses of the domain controllers. In this context, the SRV and A resource records are referred to as Locator DNS resource records.

When a domain controller is added to a forest, a DNS zone hosted on a DNS server is updated with the Locator DNS resource records for that domain controller. For this reason, the DNS zone must allow dynamic updates (RFC 2136), and the DNS server hosting that zone must support the SRV resource records (RFC 2782) to advertise the Active Directory directory service.

At the very least, the DNS server must support the SRV resource record; but the SRV resource records can be added to DNS manually. After installing Active Directory, these records can be found on the domain controller in the following location: *systemroot*\System32\Config\Netlogon.dns.

**Note**

- The configuration of reverse lookup zones is not based on the Windows Server 2003 and later domain structure; instead, it is based on the range of IP addresses assigned to a company. If a company is assigned B class IP addresses such as 172.56.X.Y., then a reverse lookup zone of 56.172.in-addr.arpa. will be created. It might contain delegations to some other domains such as 1.56.172.in-addr.arpa., 2.56.172.in-addr.arpa., or others. It is also possible to configure classless reverse lookup zones as described in the RFC Best Current Practice paper “Classless IN_ADDR.ARPA delegation.”

**_msdcs Subdomain**

To facilitate locating Windows Server 2003 or later based domain controllers, in addition to the standard *_Service*.*_Protocol*.*DnsDomainName* format, the Net Logon service registers SRV records that identify the well-known server-type pseudonyms “dc” (domain controller), gc (global catalog), pdc (primary domain controller), and “domains” (globally unique identifier, or GUID) as prefixes in the _msdcs subdomain. This Microsoft-specific subdomain enables location of domain controllers that have Windows Server 2003 or laterspecific roles in the domain or forest, as well as the location by GUID when a domain has been renamed. To accommodate locating domain controllers by server type or by GUID (abbreviated “dctype”), Windows Server 2003 and later based domain controllers register SRV records in the following form:

*_Service._Protocol.DcType.* **_msdcs.** *DnsDomainName*

**Note**

- There are also site–specific DNS resource records that use a slightly different format. For more information about site discovery, see "Domain Controller Location in the Closest Site" later in this document.

The subdomain _msdcs.*DnsDomainName* is used to find an LDAP server that is running TCP and also functioning in a particular Windows Server role. The name _msdcsis reserved for locating domain controllers and Kerberos servers. The single keyword _msdcswas chosen to avoid cluttering the DNS namespace unnecessarily. Other constant, well-known names (pdc, dc, and gc) were kept short to avoid exceeding the maximum length allowed for a DNS name.

**Domain Controller SRV Resource Records**

When a Windows Server 2003 or later based domain controller starts up, the Net Logon service uses dynamic updates to register SRV and A resource records in the DNS database, as described in Internet Engineering Task Force (IETF) RFC 2782, "A DNS RR for specifying the location of services (DNS SRV)." Windows Server 2003 also uses secure dynamic update using the GSS-TSIG algorithm, as described in RFC 3645, "Generic Security Service Algorithm for Secret Key Transaction Authentication for DNS (GSS-TSIG)."

The SRV record is used to map the name of a service (in this case, the LDAP service) to the DNS computer name of a server that offers that service. In a Windows Server 2003 network, an LDAP resource record locates a domain controller.

When a workstation logs on to a Windows Server 2003 or later domain, it queries DNS for SRV records in this general form:

*_Service* **.**_ *Protocol* **.** *DnsDomainName*

Because Active Directory servers offer the LDAP service over the TCP protocol, clients find an LDAP server by querying DNS for a record of the form:

**_ldap._tcp.** *DnsDomainName*

**Note**

- The service and protocol strings require an underscore (_) prefix to prevent potential collisions with existing names in the namespace.

Active Directory site-specific resource records are also used during logon. For more information, see "Domain Controller Location in the Closest Site" later in this document.

**SRV Records Registered by Net Logon**

The list in the following table provides the definitions of the names associated with registered SRV records. It also describes the lookup criteria supported by each record and the checks performed by Net Logon as each record is registered.

In the descriptions of registered SRV records, *DnsDomainName* refers to the DNS domain name that is used during creation of the domain controller when the domain tree is joined or created (that is, when the computer runs the Active Directory Installation Wizard). *DnsForestName* refers to the DNS domain name of the forest root domain.

An owner name is the name of the DNS node to which a resource record pertains. These resource records are used by domain controller Locator. The following table lists the owner names of the SRV records that are registered by Net Logon.

**SRV Records That Are Registered by Net Logon**

| SRV Resource Record | Description |
|---|---|
| **_ldap._tcp.** *DnsDomainName* **.** | Enables a client to locate a server that is running the LDAP service in the domain named *DnsDomainName*. The server is not necessarily a domain controller — that is, the only assumption that can be made about the server is that it supports the LDAP application programming interface (API). All Windows Server 2003–based domain controllers register this SRV record (for example, _ldap._tcp.contoso.com.). |
| **_ldap._tcp.** *SiteName* **. _sites.** *DnsDomainName* **.** | Enables a client to locate a server that is running the LDAP service in the domain named *DnsDomainName* in the site named *SiteName*. *SiteName* is the relative distinguished name of the site object that is stored in the Configuration container in Active Directory. All Windows Server 2003 and later based domain controllers register this SRV record (for example, _ldap._tcp.charlotte._sites.contoso.com.). |

| | |
|---|---|
| **_ldap._tcp.dc._msdcs.** *DnsDomainName* **.** | Enables a client to locate a domain controller (dc) of the domain named *DnsDomainName*. All Windows Server 2003 and later based domain controllers register this SRV record. |
| **_ldap._tcp.** *SiteName* **. _sites.dc._msdcs.** *DnsDomainName* **.** | Enables a client to locate a domain controller for the domain named *DnsDomainName* and in the site named *SiteName*. All Windows Server 2003 and laterbased domain controllers register this SRV record. |
| **_ldap._tcp.pdc._msdcs.** *DnsDomainName* **.** | Enables a client to locate the server that is acting as the primary domain controller (PDC) in the mixed-mode domain named *DnsDomainName*. Only the PDC emulator master of the domain (the Windows Server 2003 and laterbased domain controller that advertises itself as the primary domain controller to computers that need a primary domain controller) registers this SRV record. |
| **_ldap._tcp.gc._msdcs.** *DnsForestName* **.** | Enables a client to locate a global catalog (gc) server for this forest. Only domain controllers that are functioning as gc servers for the forest named in *DnsForestName* register this SRV record (for example, _ldap._tcp.gc._msdcs.contoso.com.). |
| **_ldap._tcp.** *SiteName* **. _sites.gc._msdcs.** *DnsForestName* **.** | Enables a client to locate a global catalog (gc) server for this forest in the site named in SiteName. Only domain controllers that are serving as gc servers for the forest named in DnsForestName register this SRV record (for example, _ldap._tcp.charlotte._sites.gc._msdcs.contoso.com.). |
| **_gc._tcp.***DnsForestName***.** | Enables a client to locate a global catalog (gc) server for this domain. The server is not necessarily a domain controller. Only a server that is running the LDAP service and functioning as the GC server for the forest named *DnsForestName* registers this SRV record (for example, _gc._tcp.contoso.com.). In Windows Server 2003 and later, a GC server is a domain controller. Other implementations of directory services (that are not Windows Server 2003 or later implementations) can also register servers as GC servers. |
| **_gc._tcp.***SiteName***. _sites.***DnsForestName***.** | Enables a client to locate a global catalog (gc) server for this forest in the site named *SiteName*. The server is not necessarily a domain controller. Only a server that is running the LDAP service and functioning as the GC server for the forest named *DnsForestName* registers this SRV record (for example, _gc._tcp.charlotte._sites.contoso.com.). |
| **_ldap._tcp.** *DomainGuid* **. domains._msdcs.** *DnsForestName* **.** | Enables a client to locate a domain controller in a domain on the basis of its GUID. A GUID is a 128-bit number that is automatically generated for referencing objects in Active Directory — in this case, the domain object. This operation is expected to be infrequent; it occurs only when the DnsDomainName of the domain has changed, the DnsForestName is known, and DnsForestName has not also been renamed (for example, _ldap._tcp.4f904480-7c78-11cf-b057-00aa006b4f8f.domains. _msdcs.contoso.com.).<br><br>All domain controllers register this SRV record. |
| **_kerberos._tcp.** *DnsDomainName* **.** | Enables a client to locate a server that is running the Kerberos KDC service for the domain that is named in *DnsDomainName*. The server is not necessarily a domain controller. All Windows Server 2003 and later based domain controllers that are running an RFC 1510–compliant Kerberos KDC service register this SRV record. |
| **_kerberos._udp.** *DnsDomainName* **.** | Same as **_kerberos._tcp.***DnsDomainName*, except that UDP is implied. |
| **_kerberos._tcp.** *SiteName* **. _sites.** *DnsDomainName* **.** | Enables a client to locate a server that is running the Kerberos KDC service for the domain that is named *DnsDomainName* and is also in the site named *SiteName*. The server is not necessarily a domain controller. All Windows Server 2003 and later based domain controllers that are running an RFC 1510–compliant Kerberos KDC service register this SRV record. |
| **_kerberos._tcp.dc._msdcs.** *DnsDomainName* **.** | Enables a client to locate a domain controller that is running the Windows Server 2003 or later implementation of the Kerberos KDC service for the domain named in *DnsDomainName*. All Windows Server 2003 and later based domain controllers that are running the KDC service (that is, that implement a public key extension to the Kerberos v5 protocol Authentication Service Exchange subprotocol) register this SRV record. |

| | |
|---|---|
| **_kerberos.tcp.** *SiteName* **. _sites.dc._msdcs.** *DnsDomainName* **.** | Enables a client to locate a domain controller that is running the Windows Server 2003 implementation of the Kerberos KDC service for the domain that is named *DnsDomainName* and that is also in the site named *SiteName*. All Windows Server 2003 and later based domain controllers that are running the KDC service (that is, that implement a public key extension to the Kerberos v5 protocol Authentication Service Exchange subprotocol) register this SRV record. |
| **_kpasswd._tcp**.*DnsDomainName***.** | Enables a client to locate a Kerberos Password Change server for the domain. All servers that provide the Kerberos Password Change service (which includes all Windows Server 2003 and later based domain controllers) register this name. This server must at least conform to the Kerberos Change Password Protocol. (For more information about this draft, see the Microsoft Platform SDK.) The server is not necessarily a domain controller. All Windows Server 2003 and later based domain controllers that are running an RFC 1510–compliant Kerberos KDC service register this SRV record. |
| **_kpasswd._udp**.*DnsDomainName***.** | Same as **_kpasswd._tcp.***DnsDomainName*, except that UDP is implied. |

In addition to the SRV records listed in the table above, Net Logon also registers a DNS alias (CNAME) record for use by Active Directory replication, in the format: *DsaGuid***._msdcs.***DnsForestName*. The Locator does not use this record. This record enables a client to locate any domain controller in the forest by looking up an A record. The only information that is known about the domain controller is the GUID of the directory system agent (DSA) object for the domain controller and the name of the forest in which the domain controller is located. This record is used to facilitate renaming a domain controller.

If multiple domain controllers have the same criteria, multiple records exist with the same owner name. A client that is looking for a domain controller with specific criteria would receive all the applicable records from the DNS server. The client would pick one of the returned records to select a domain controller, as described in RFC 2782.

**Other SRV Record Content**

The following information is also included in an SRV record.

| SRV Record Field | Description |
|---|---|
| Priority | The priority of the server. Clients attempt to contact the server with the lowest priority. |
| Weight | A load-balancing mechanism that is used when selecting a target host from those that have the same priority. Clients randomly choose SRV records that specify target hosts to be contacted, with probability proportional to the weight. |
| Port number | The port where the server is listening for this service. |
| Target | The fully qualified domain name of the host computer. |

The algorithm by which clients interpret and select among SRV resource records is defined in RFC 2782, "A DNS RR for specifying the location of services (DNS SRV)."

**Host Records for Non-SRV-Aware Clients**

Net Logon registers the following DNS A records for the use of LDAP clients that do not support DNS SRV records (that is, clients that are non-SRV-aware). Locator does not use these records.

### Host (A) Records Registered by Net Logon

| Host (A) Resource Record | Description |
|---|---|
| *DnsDomainName* **.** | Enables a non-SRV-aware client to locate any domain controller in the domain by looking up an A record. A name in this form is returned to the LDAP client through an LDAP referral. A non-SRV-aware client looks up the name; an SRV-aware client looks up the appropriate SRV resource record. |
| **gc._msdcs.** *DnsForestName* **.** | Enables a non-SRV-aware client to locate any global catalog server in the forest by looking up an A record. A name in this form is returned to the LDAP client through an LDAP referral. A non-SRV-aware client looks up this name; an SRV-aware client looks up the appropriate SRV resource record. |

**Example of Registered Resource Records**
The following example illustrates the combined information that is contained in A resource records and SRV resource records.

A domain controller named Phoenix in the domain contoso.com has an IP address of 157.55.81.157. It registers the following A records and SRV records with DNS:

```
phoenix.contoso.com   A   157.55.81.157
_ldap._tcp.contoso.com    SRV  0 0 389 phoenix.contoso.com
_kerberos._tcp.contoso.com   SRV  0 0 88 phoenix.contoso.com
_ldap._tcp.dc._msdcs.contoso.com  SRV  0 0 389 phoenix.contoso.com
_kerberos._tcp.dc._msdcs.contoso.com  SRV  0 0 88 phoenix.contoso.com.
```

When the appropriate SRV records and A records are in place, a DNS query for _ldap._tcp.dc._msdcs.contoso.com returns the names and addresses of all domain controllers in the domain.

For more information about A records, SRV records, DNS, and dynamic updates, see "DNS Protocol" and "DNS Physical Structure" in How DNS Works.

**DNS Application Directory Partitions**
DNS zones stored in Active Directory replicate to Active Directory domain controllers according to different replication scopes. In Windows 2000 Server, a DNS zone stored in Active Directory is replicated to all domain controllers in the Active Directory domain. Windows Server 2003 and later have added application directory partitions, which enable the DNS zone to be stored in different replication scopes. The following table describes all of the replication scopes available to a DNS zone stored in Active Directory.

**Windows Server 2003 and later Active Directory Storage Options**

| Active Directory Storage Option | Replication Scope |
|---|---|
| Domain partition | Active Directory domain partition for each domain in the forest. DNS zones stored in this partition are replicated to all domain controllers in the domain. This is the only Active Directory storage option for DNS zones that are replicated to domain controllers running Windows 2000 Server. |
| Forest-wide DNS application directory partition | DNS application directory partition for the entire forest. DNS zones stored in this application directory partition are replicated to all DNS servers running on domain controllers in the forest. This DNS application directory partition is created when you install the DNS Server service on the first Windows Server 2003 or later domain controller in the forest. |
| Domain-wide DNS application directory partition | DNS application directory partition for each domain in the forest. DNS zones stored in this application directory partition are replicated to all DNS servers running on domain controllers in the domain. For the forest root domain, this DNS application directory partition is created when you first install the DNS Server service on a Windows Server 2003 or later domain controller in the forest.<br><br>For each new domain in the forest (child domain), this DNS application directory partition is created when you first install the DNS Server service on a Windows Server 2003 or later domain controller for the new domain. |
| Custom DNS application directory partition | DNS application directory partition for any domain controller that is enlisted in its replication scope. This type of DNS application directory partition does not exist by default and must be created. DNS zones stored in this application directory partition are replicated to all DNS servers running on domain controller that enlist in the partition. |

As stated earlier, the Locator DNS resource records for an Active Directory domain are stored in the _msdcs.*DnsDomainName* subdomain for the Active Directory domain. In Windows Server 2003 or later, when the DNS root domain of a new Active Directory forest is created on a Windows Server 2003 or later domain controller, a DNS zone is automatically created for the _msdcs.*DnsForestName* and stored in the forest-wide DNS application directory partition, which replicates to all Windows Server 2003 and later domain controllers in the forest running the DNS Server service.

**Note**

- DNS zones stored in application directory partitions cannot be accessed by Windows 2000 Server domain controllers.

**DNS Support for Active Directory Processes and Interactions**

When a Windows Server 2003 or later member server is promoted to an Active Directory domain controller by installing Active Directory, the Net Logon service registers the DNS resource records necessary for network hosts and services to be able to locate the domain controller on the network. When network hosts and services attempt to perform an operation (such as joining a domain, for example) that requires an Active Directory domain controller, the Locator mechanism is used to locate the domain controller through DNS. The following table describes the processes and interactions involved in the registration and location of domain controllers in DNS.

### Active Directory and DNS Processes and Interactions

| Process or Interaction | Description |
|---|---|
| Domain controller DNS name registration | The Net Logon service registers DNS resource records on behalf of the Active Directory domain controller in the DNS zone with the same name as the Active Directory domain hosted by the domain controller. |
| DNS delegation, forwarders | DNS delegation resource records are created in the zone that is a parent of the zone supporting the Active Directory domain. The delegation enables the DNS name of the domain controller to be resolved downward from the root of the DNS hierarchy.<br><br>DNS forwarders are another DNS feature that enable domain controller location, and are commonly used for an Active Directory client in one domain to locate a domain controller in another domain. |
| DNS domain controller location | Network hosts and services use the DNS Locator mechanism to locate domain controllers in the Active Directory forest. |

**Domain Controller Name Registration**

Every Windows Server 2003 or laterbased domain controller registers two types of names at startup:

- A DNS domain name with the DNS service (for example, noam.contoso.com).
- A NetBIOS name with Windows Internet Name Service (WINS) or another transport-specific service (for example, noam).

When a user starts a computer and logs on to a domain, the computer must do one of two things:

- If the name of the logon domain is a DNS name, the computer must query DNS to find a domain controller with which to authenticate.
- If the name of the logon domain is a NetBIOS name, the computer must send a mailslot message to find a domain controller for the specified domain.

After the computer has found a domain controller, the information is cached so that a new query is not required for subsequent logon sessions.

**DNS Domain Name Registration**

Active Directory supports dynamic registration of domain controller addresses in DNS. After Active Directory has been installed during domain controller creation, the Net Logon service dynamically creates records in the DNS database that are used to locate the server. Dynamic update (described in RFC 2136) is a recent addition to the DNS standard; this addition to the standard defines a protocol for dynamically updating a DNS server with new or changed resource record values. Before the advent of this new protocol, administrators had to manually create the records that are stored on DNS servers. The implementation of DNS server that is included with Windows Server 2003 and later supports dynamic updates, as does the Berkeley Internet Name Domain (BIND) version 8.*x* implementation of DNS.

### Note

- By default, the Windows Server 2003 or later DNS Server service running on a domain controller is configured to accept secure dynamic update only.

Every Windows Server 2003 or later based domain controller dynamically registers SRV records in DNS. The SRV records enable servers to be located by service type (for example, LDAP) and protocol (for example, TCP). Because domain controllers

are LDAP servers that communicate over TCP, SRV records can be used to find the DNS computer names of domain controllers. In addition to registering LDAP-specific SRV records, Net Logon also registers Kerberos v5 authentication protocol–specific SRV records to enable locating servers that run the Kerberos Key Distribution Center (KDC) service.

Every Windows Server 2003 or later based domain controller also dynamically registers a single host (A) resource record that contains the name of the domain (*DnsDomainName*) where the domain controller is and the IP address of the domain controller. The host (A) resource record makes it possible for clients that do not recognize service (SRV) resource records to locate a domain controller by means of a generic host lookup.

**NetBIOS Domain Name Registration**
A domain controller registers its NetBIOS name (*DomainName*[1C]) by broadcasting or directing a NetBIOS name registration request to a NetBIOS name server, such as a WINS server. Registering the NetBIOS name makes it possible for Windows-based clients that are not DNS-enabled to find the domain controllers are running Windows NT 3.51 or later. In this case, the client finds the domain controller by sending a Net Logon mailslot request that is based on the NetBIOS domain name.

### Note

- NetBIOS recognizes domain controllers by the [1C] registration.

**DNS Delegation, Forwarders**
To fully support an Active Directory domain, the DNS infrastructure must have the DNS delegations that are necessary to enable name resolution during domain controller location. When an Active Directory domain is created, a DNS delegation entry must exist in the DNS zone that is the parent of the zone supporting the Active Directory domain. The delegation enables the name of the domain controller hosting the domain to be resolved by any host or service in the DNS namespace. The delegation resource records must be added by the network administrator who administers the DNS server hosting the parent zone. Alternately, the parent zone could host the DNS resource records for the domain name and, in this case, the delegation is unnecessary.

For example, if there is a DNS zone supporting the domain corp.contoso.com, then a delegation for this name must exist in the parent zone contoso.com. When a DNS query for the name is sent to the root of the DNS namespace, delegations can be followed until the DNS server hosting the zone for corp.contoso.com is identified. Without this delegation, only those network hosts and services configured with the IP address of the DNS server hosting the zone for corp.contoso.com will be able to resolve its DNS name. All other network hosts and services will be unable to resolve the name, and the domain controller will not be available to them for such Active Directory operations as joining a domain, logging on to a domain, or searching Active Directory.

When the Active Directory domain name is specified in the Active Directory Installation Wizard, the wizard reads the delegation entry in DNS, prompts the user to install the DNS Server service locally and configures the corresponding DNS zone automatically. Also, if the computer is already configured with a preferred DNS server, the wizard will configure a forwarder on the DNS Server service with the IP address of the prior preferred DNS server.

Forwarders are also commonly configured on the DNS server hosting a zone in support of an Active Directory domain. Forwarders are used by a DNS server to forward queries for a domain name about which it has no local data. If an Active Directory client in one domain needs to access a resource in another Active Directory domain, it will need to locate a domain controller in that domain. If the DNS server used by that client is unable to locate a domain controller for the other domain using its local data, it can forward the client request to another DNS server, such as the DNS server that hosts the zone for the Active Directory forest root domain.

In summary, delegation enables name resolution in a descending direction from the root of the hierarchy, and forwarders enable name resolution in a ascending direction toward the root of the hierarchy.

Windows Server 2003 and later introduces an enhancement to forwarding called conditional forwarders. When you use conditional forwarding, you can configure your DNS servers to forward queries to different servers based on the domain name specified in the query. This eliminates steps in the standard forwarding chain and reduces network traffic. When conditional forwarding is applied, the DNS server hosting a zone in support of the one Active Directory domain can forward queries to DNS servers hosting zones in support of the Active Directory domain name specified in the client query.

Although root hints (resource records that list the DNS servers hosting the DNS root zone) can also be used to facilitate domain controller location in place of forwarders, DNS deployments commonly use forwarders for remote domain controller location to reduce the complexity of administering root hints for both internal and Internet resolution.

For more information about delegation, forwarders, and root hints, see "How DNS Works."

**Domain Controller Locator**
The domain controller locator (Locator) algorithm consists of two main parts:

- Locator finds which domain controllers are registered with a DNS server.
- Locator submits a DNS query to the DNS server to locate a domain controller in the specified domain.

After this query is resolved, an LDAP User Datagram Protocol (UDP) lookup is sent to one or more of the domain controllers listed in the response to the DNS query to ensure their availability. Finally, the Net Logon service caches the discovered domain controller to aid in resolving future requests.

**Domain Controller Locator Process**

Each Windows Server 2003 or later based domain controller registers its DNS domain name on the DNS server and registers its NetBIOS name by using a transport-specific mechanism (for example, WINS). Thus, a DNS client locates a domain controller by querying DNS, and a NetBIOS client locates a domain controller by querying the appropriate transport-specific name service. Because the code for the DNS-compatible Locator and the Windows NT 4.0–compatible Locator is shared, both DNS clients and NetBIOS clients are supported.

The process that the Locator follows can be summarized as follows:

1. On the client (the computer that is locating the domain controller), the Locator is initiated as a remote procedure call (RPC) to the local Net Logon service. The Locator API (DsGetDcName) is implemented by the Net Logon service.
2. The client collects the information that is needed to select a domain controller and passes the information to the Net Logon service by using the DsGetDcName API.
3. The Net Logon service on the client uses the collected information to look up a domain controller for the specified domain in one of two ways:
    - For a DNS name, Net Logon queries DNS by using the DNS-compatible Locator — that is, DsGetDcName calls DnsQuery to read the SRV records and A records from DNS after it appends an appropriate string to the front of the domain name that specifies the SRV record.
    - For a single label name, Net Logon performs domain controller discovery by using the Windows NT 4.0–compatible Locator — that is, by using the transport-specific mechanism (for example, WINS).

    **Note**

In Windows NT 4.0 and earlier, "discovery" is a process for locating a domain controllerfor authentication in either the primary domain or a trusted domain.

1. The Net Logon service sends a datagram to the discovered domain controllers that register the name. For NetBIOS domain names, the datagram is implemented as a mailslot message. For DNS domain names, the datagram is implemented as an LDAP UDP search.
2. Each available domain controller responds to the datagram to indicate that it is currently operational and then returns the information to DsGetDcName.
3. The Net Logon service returns the information to the client from the domain controller that responds first.
4. The Net Logon service caches the domain controller information so that it is not necessary to repeat the discovery process for subsequent requests. Caching this information encourages the consistent use of the same domain controller and, thus, a consistent view of Active Directory.

**Domain Controller Location in the Closest Site**

During a search for a domain controller, the Locator attempts to find a domain controller in the site closest to the client. When the domain that is being sought is a Windows Server 2003 or later domain, the domain controller uses the information stored in Active Directory to determine the closest site. When the domain being sought is a Windows NT 4.0 domain, domain controller discovery occurs when the client starts and uses the first domain controller that it finds.

Each Windows Server 2003 or later based domain controller registers DNS records that indicate the site where the domain

controller is located. The site name (the relative distinguished name of the site object in Active Directory) is registered in several records so that the various roles the domain controller might perform (for example, global catalog server or Kerberos server) can be associated with the domain controller's site. When DNS is used, the Locator searches first for a site-specific DNS record before it begins to search for a DNS record that is not site-specific (thereby preferentially locating a domain controller in that site).

A client computer stores its own site information in the registry, but the computer is not necessarily located physically in the site associated with its IP address. For example, a portable computer that was moved to a new location could contact a domain controller in its home site, which is not the site to which the computer is currently connected. In this situation, the domain controller looks up the client site on the basis of the client IP address by comparing the address to the sites that are identified in Active Directory, and then returns the name of the site that is closest to the client. The client then updates the information in the registry.

The domain controller stores site information for the entire forest in the Configuration container. The domain controller uses the site information to check the IP address of the client computer against the list of subnets in the forest. In this way, the domain controller ascertains the name of the site in which the client is assumed to be located, or the site that is the closest match, and returns this information to the client.

**Active Directory Site and Subnet Objects**
A site is a collection of subnets that have high-speed connections. In Active Directory, a site is defined by a site object in the cn=Sites,cn=Configuration,dc=*ForestRootDomain* container. A subnet is an addressed segment within a site and is represented by an object in the cn=Subnets,cn=Sites,cn=Configuration,dc=*ForestRootDomain* container.

The site in which a domain controller is located is identified in the Configuration container by the domain controller object that is located within the cn=Servers container beneath the site object for a particular site. A domain controller can identify the site of a client by using the subnet object in the Sites container. Each subnet object has a *siteObject* property ("attribute") that links it to a site object; the value of the *siteObject* property is the distinguished name of the site object. This link enables a domain controller to identify clients that have an IP address in the specified subnet as being in the specified site.

Subnet names in Active Directory take the form "network/bits masked" (for example, the subnet object 172.16.72.0/22 has a subnet of 172.16.72.0 and a 22-bit subnet mask). If this subnet had a *siteObject* property value that contained the distinguished name of the Seattle site object, all IP addresses in the 172.16.72.0/22 subnet would be considered to be in the Seattle site. The *siteObject* property is a single value, which implies that a single subnet maps to a single site. However, multiple subnet objects can be linked to the same site object. The directory administrator manually creates subnet objects and, hence, the *siteObject* property value.

The Configuration container (including all of the site and subnet objects in it) is replicated to all domain controllers in the forest. Therefore, any domain controller in the forest can identify the site in which a client is located, compare it to the site in which the domain controller is located, and indicate to the client whether that domain controller's site is the closest site to the client.

For more information about networks, subnets, and subnet masks, see "How TCP/IP Works."

**IP Addresses Mapped to Site Names**
During Net Logon startup, the Net Logon service on each domain controller enumerates the site objects in the Configuration container. Net Logon on each domain controller is also notified of any changes made to the site objects. Net Logon uses the site information to build an in-memory structure that is used to map IP addresses to site names.

When a client that is searching for a domain controller receives the list of domain controller IP addresses from DNS, the client begins querying the domain controllers in turn to find out which domain controller is available and appropriate. Active Directory intercepts the query, which contains the IP address of the client, and passes it to Net Logon on the domain controller. Net Logon looks up the client IP address in its subnet-to-site mapping table by finding the subnet object that most closely matches the client IP address and then returns the following information:

- The name of the site in which the client is located, or the site that most closely matches the client IP address.
- The name of the site in which the current domain controller is located.
- A bit that indicates whether the found domain controller is located (bit is set) or not located (bit is not set) in the site closest to the client.

The domain controller returns the information to the client. The response also contains various other pieces of information that describe the domain controller.

The client inspects the information to determine whether to try to find a better domain controller. The decision is made as follows:

- If the returned domain controller is in the closest site (the returned bit is set), the client uses that domain controller.
- If the client has already tried to find a domain controller in the site in which the domain controller claims the client is located, the client uses that domain controller.
- If the domain controller is not in the closest site, the client updates its site information and sends a new DNS query to find a new domain controller in the site. If the second query is successful, the client uses the new domain controller. If the second query fails, the client uses the original domain controller.
- If the domain that is being queried by a computer is the same as the domain to which the computer is joined, the site in which the computer resides (as reported by a domain controller) is stored in the computer registry. The client stores this site name in the **DynamicSiteName** registry entry in HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters. Therefore, the DsGetSiteName API returns the site in which the computer is located.

You can override the dynamically determined value using the registry, but you should never change dynamically determined values. To override the dynamic site name, add the **SiteName** entry with the REG_SZ data type in HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters. When a value is present for the **SiteName** entry, the **DynamicSiteName** entry is not used.

**Note**

- Editing the registry directly can have serious, unexpected consequences that can prevent the system from starting and require that you reinstall Windows Server 2003 or later. There are programs available in Control Panel or Microsoft Management Console (MMC) for performing most administrative tasks. These programs provide safeguards that prevent you from entering conflicting settings or settings that are likely to degrade performance or damage your system. Registry editors bypass the standard safeguards that are provided by these administrative tools. Modifying the registry is recommended only when no administrative tool is available. Before you make changes to the registry, it is recommended that you back up any valuable data on the computer. For instructions about how to edit registry entries, see Help for the registry editor that you are using.

If the domain being located is the same as the domain to which the computer is joined and the computer has not physically moved to a different site since the last query, the dynamically determined site name in the registry is the actual site in which the computer is located. Thus, the client finds a domain controller in the correct site without having to retry the operation. On the other hand, if the site name in the registry is not the current site of the computer (for example, if the computer is portable), the domain controller location process serves to update the site information in the registry.

**Automatic Site Coverage**

There is not necessarily a domain controller in every site. For various reasons, it is possible that no domain controller exists for a particular domain at the local site. By default, each domain controller checks all sites in the forest and then checks the replication cost matrix. A domain controller advertises itself (registers a site-related SRV record in DNS) in any site that does not have a domain controller for that domain and for which its site has the lowest-cost connections. This process ensures that every site has a domain controller that is defined by default for every domain in the forest, even if a site does not contain a domain controller for that domain. The domain controllers that are published in DNS are those from the closest site (as defined by the replication topology).

For example, given one domain and three sites, a domain controller for that domain might be located in two of the sites, but there might be no domain controller for the domain in the third site. Replication to the domain that does not have a domain controller in the third site might be too expensive in terms of cost or replication latency. To ensure that a domain controller can be located in the site closest to a client computer, if not the same site, Windows Server 2003 and later automatically attempts to register a domain controller in every site. The algorithm that is used to accomplish automatic site coverage determines how one site can cover another site when no domain controller exists in the second site.

**Determining Site Coverage on the Basis of Site-link Cost**

Site coverage is determined according to site-link costs, and domain controllers register themselves in sites accordingly. For example, given one domain and sites A, B, and C, site A has no domain controllers for the domain. If a client in site A attempts to locate a domain controller, which domain controller should be returned? The answer depends on which site covers site A for the domain.

In the example, a site link exists between site A and both of the other sites — that is, the connections between domain controllers in site A, site B, and site C are configured for replication over site links in Active Directory Sites and Services. Costs are associated with site links based on the expense of transferring data over the connections. The administrator uses the speed of the connection between sites to assign a cost to the communication link, and replication uses the cost to establish the least expensive route for replication traffic.

Site A and site B are connected by site link AB. Site A and site C are connected by site link AC, with the following costs:

Site link AB cost = 50.

Site link AC cost = 100.

The link between site A and site C has a much higher cost than the link between site A and site B. The administrator configured this cost based on the expensive Integrated Services Digital Network (ISDN) line that connects site A and site C, and the administrator would prefer that resources in site B be used when possible. The site coverage algorithm (described in the next sub-section) ensures that a domain controller in site B registers itself as a domain controller for site A. In this way, clients in Site A that are looking for a domain controller find one from site B, instead of possibly finding one from site C.

**Site Coverage Algorithm**

During registration of SRV records in DNS, the following algorithm determines if the domain controllers should register site SRV records to designate themselves as preferred domain controllers in Active Directory sites where no domain controller exists for a particular domain.

For every domain controller in the forest, this procedure is followed:

- Build a list of target sites — sites that have no domain controllers for this domain (the domain of the current domain controller).
- Build a list of candidate sites — sites that have domain controllers for this domain.
- For every target site, follow these steps:
    1. Build a list of candidate sites of which this domain is a member. (If none, do nothing.)
    2. Of these, build a list of sites that have the lowest site link cost to the target site. (If none, do nothing.)
    3. If more than one, break ties (reduce this list to one candidate site) by choosing the site with the largest number of domain controllers.
    4. If more than one, break ties by choosing the site that is first alphabetically.
    5. Register target-site-specific SRV records for the domain controllers for this domain in the selected site.

**Cache Time-out and Closest Site**

If a domain member computer requests a domain controller while all domain controllers in its site are offline, the Locator necessarily returns a domain controller in a different site. The location of this domain controller is stored in the client cache. The cache lifetime is controlled by the **CloseSiteTimeout** entry in the registry.

In addition, the domain controller performs authentication, and a secure channel is set up. On subsequent location attempts, the lifetime of the cache and the lifetime of the secure channel are secondary to the location of a domain controller in the closest site.

If the domain controller that is stored in the client cache is not in a site that is close to the client, Net Logon attempts to find a close domain controller when either of the following events occurs:

- An interactive logon process uses pass-through authentication on the secure channel.
- The value in the CloseSiteTimeout registry entry has elapsed since the last attempt, and any other attempt is made to use the secure channel (for example, pass-through authentication of network logons).

Thus, Net Logon attempts to find a close domain controller only on demand. The default value of the **CloseSiteTimeout**

period is 15 minutes; the maximum value is 49 days; the minimum value is 60 seconds. The implications of these settings are:

- If the time-out value is too large, a client never tries to find a close domain controller if there is not one available at startup.

- If the time-out value is too small, secure channel traffic is unnecessarily slowed down by discovery attempts.

**Clients with No Apparent Site**
Sometimes the client pings a domain controller and the client IP address cannot be found in the subnet-to-site mapping table. In this case, the domain controller returns a NULL site name, and the client uses the returned domain controller.

**Types of Locators**
On the basis of parameters passed to Net Logon in the DsGetDcName API, the process of locating a domain controller proceeds in one of two ways:

- The DNS-compatible Locator is used if the domain name passed to DsGetDcName is a DNS-compatible name. The Net Logon service on the client looks up the name in DNS (by calling DnsQuery) after it appends an appropriate string to the front of the domain name. The DNS service supports a query for determining the set of domain controllers. If the client site name is known, the client DNS query specifies the site. DNS returns the IP addresses of domain controllers that match the DNS query. The client Net Logon service sends an LDAP UDP message to one or more of the domain controllers that have been returned by DNS in order to determine whether any of the specified domain controllers are running and support the specified domain.

- The Windows NT 4.0–compatible Locator is used if the domain name passed to DsGetDcName is a NetBIOS name. The Net Logon service on the client sends a transport-specific logon request query to locate a domain controller in a particular domain and then sends a mailslot message to one or more of the domain controllers to determine whether any of the domain controllers it found are running and support the specified domain.

**DNS Client Service Configuration Elements**
The DNS configuration on Active Directory client computers follows a specific computer naming scheme and specifies how these clients will locate DNS servers. The following table lists the configurations for DNS configuration elements.

**DNS Configuration for Client Computers**

| DNS Configuration Element | Configuration |
|---|---|
| Computer naming | Use default naming. When a Windows 2000, Windows XP, or Windows Server 2003 or later computer joins a domain, the computer assigns itself a primary DNS name comprised of the host name of the computer and the name of the domain. |
| Client resolver configuration | Configure client computers to point to any DNS server on the network. |

**Note**

- Active Directory clients and domain controllers can dynamically register their DNS names using a DNS server that is not authoritative for the DNS name of the Active Directory domain. The DNS server used by these clients will refer the registration to the DNS server that is authoritative for the name of the Active Directory domain.

A computer might have an existing DNS name if the organization previously statically registered the computer in DNS or the organization previously deployed an integrated DHCP solution. If client computers already have a registered DNS name, when the domain to which they are joined is upgraded to Windows Server 2003 or later Active Directory, the client computers will have two names: the existing DNS name, and the new primary name.

Clients can be located by either name. Any existing DNS, DHCP, or integrated DNS/DHCP solution is left intact. The new primary names are created automatically and updated by means of dynamic update. The old names are cleaned up automatically by means of DNS scavenging.

To take advantage of Kerberos authentication when connecting to a server running Windows 2000, Windows XP, Windows

Server 2003 or later, the client must connect to the server by using the primary name.

**Network Ports Used by DNS in Support of Active Directory**

The network ports used by DNS are documented in the DNS Technical Reference. For more information, see "Network Ports used by DNS" in How DNS Works.

**Related Information**

The following resource contains additional information that is relevant to this section.

# DNS Support for Active Directory Tools and Settings

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**DNS Support for Active Directory Tools and Settings**

**In this section**

- DNS Support for Active Directory Tools
- DNS Support for Active Directory Registry Entries
- DNS Support for Active Directory Group Policy Settings
- DNS Support for Active Directory WMI Classes
- Related Information

**DNS Support for Active Directory Tools**

The following tools are associated with the Domain Name System (DNS) support for Active Directory. For more information about DNS tools and settings in a Windows Server 2003 network, see "DNS Tools and Settings" in DNS Technical Reference.

| Note |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to Active Directory Domain Services. |

**Dcdiag.exe: Domain Controller Diagnostic Tool**

**Category**

This tool is included in the Windows 2000 Server and later Support Tools.

**Version compatibility**

This tool runs on Windows XP, and the Windows 2000 Server and later operating systems.

You can use Domain Controller Diagnostic Tool to verify that there are sufficient resources for the DNS infrastructure when deploying the Windows 2000 Server or later Active Directory directory service. This tool analyzes the state of domain controllers in a forest or enterprise and reports any problems, to assist in troubleshooting. As an end-user reporting program, Domain Controller Diagnostic Tool queries the directory service infrastructure and uses the results to identify abnormal behavior in the system. Domain Controller Diagnostic Tool provides a framework for executing tests and a series of tests to verify different functional areas of the system. This framework selects which domain controllers are tested according to scope directives from the user, such as enterprise, site, or single server.

**Dnscmd.exe: Dnscmd**

**Category**

This tool is included in the Windows Server 2003 and later Support Tools.

**Version compatibility**

This tool runs on the Windows 2000 Server and later operating systems.

Dnscmd is used to view the properties of DNS servers, zones, and resource records. In addition, Dnscmd is used to modify all aspects of the DNS Server service, including creating and deleting zones and resource records, and forcing replication events between DNS server physical memory and DNS databases. Dnscmd can also be useful for developing scripts for configuring a DNS server.

**Dnslint.exe: DNSLint**

**Category**

This tool is available for download on the Microsoft Web site.

**Version compatibility**
This tool runs on Windows XP, and the Windows 2000 Server and later operating systems.

DNSLint is a Microsoft Windows utility that can be used to help diagnose common DNS name resolution issues. It can be targeted to look for specific DNS record sets and ensure that they are consistent across multiple DNS servers. It can also be used to verify that DNS records used specifically for Active Directory replication are correct.

**Dnsmgmt.msc: DNS console**

**Category**
This tool is included in the Windows 2000 Server and later operating systems, and is installed when the DNS Server service is installed. This tool is also installed with the Windows 2000 Server or later Administration Tools Pack (Adminpak.msi).

**Version compatibility**
This tool runs on the Windows 2000 Server and later operating systems. When installed from one of the administration tools packs, this tool can also run on Microsoft Windows 2000 Professional and Windows XP.

The DNS console is used to administer the DNS Server service. It can be used to modify all aspects of the DNS Server service, including creating and deleting zones and resource records, and forcing replication events between DNS server physical memory and DNS databases. The DNS console can also be used to perform diagnostics on the DNS infrastructure of a network.

**Eventvwr.exe: Event Viewer**

**Category**
This tool is included in all Windows server and client operating systems.

**Version compatibility**
This tool runs on Windows XP, and the Windows 2000 Server and later operating systems.

You can use Event Viewer to monitor events recorded in event logs. Typically, a computer stores the Application, Security, and System logs. It could also contain other logs, depending on the role of the computer and the applications that are installed on it. For example, DNS servers write DNS-related events (such as errors that occur when the DNS Server service is invoked) to log files which can be read by using Event Viewer.

**Ipconfig.exe: Ipconfig**

**Category**
This tool is included in all Windows server and client operating systems.

**Version compatibility**
This tool runs on all Windows server and client operating systems.

Ipconfig displays all current TCP/IP network configuration values and refreshes Dynamic Host Configuration Protocol (DHCP) and DNS settings. Used without parameters, Ipconfig displays IPv6 addresses or the IPv4 address, subnet mask, and default gateway for all adapters.

**Netdiag.exe: Network Connectivity Tester**

**Category**
This tool is included in the Windows 2000 and later Support Tools.

**Version compatibility**
This tool runs on Windows XP, and the Windows 2000 Server and later operating systems.

You can use Network Connectivity Tester to help isolate networking and connectivity problems, by performing a series of tests to determine the state of your network client, and whether it is functional. These tests, and the key network status information they expose, give network administrators and support personnel a more direct means of identifying and isolating network problems. Moreover, because this tool does not require that parameters or switches be specified, support personnel and network administrators can focus on analyzing the output rather than on training users how to use the tool.

**Netmon.exe: Network Monitor**

**Category**
This tool is installed with the Windows Server 2003 and later Administration Tools Pack.

**Version compatibility**
This tool runs on all Windows operating systems.

Network Monitor captures data about the packets on a network and logs them for subsequent analysis. The monitored data can be filtered using many criteria, including protocol, ports, physical addresses, and logical addresses. Network Monitor can be useful in many situations, such as when you are troubleshooting an environment that has a firewall between a DNS server and a client, or between two DNS servers.

There are two versions of Network Monitor: the Network Monitor that is provided as part of the Windows Server 2003 operating system, and the Network Monitor that is part of Microsoft Systems Management Server (SMS). The version of Network Monitor that is included with the Windows Server 2003 operating system captures only data about network packets that are sent to or from the server on which you run Network Monitor; it also captures data about network broadcasts that are received. The Network Monitor that is included with SMS can monitor all network packets on a network segment regardless of their source or destination.

**Nslookup.exe: Nslookup**

**Category**
This tool is included in all Windows server and client operating systems.

**Version compatibility**
This tool runs on all Windows server and client operating systems.

Nslookup is used to query DNS servers and to obtain detailed responses. The information obtained using Nslookup can be used to diagnose and solve name resolution problems, verify that resource records are added or updated correctly in a zone, and debug other server-related problems.

**DNS Support for Active Directory Registry Entries**
Active Directory uses DNS to enable client computers to locate domain controllers and to enable domain controllers to locate each other. Domain controllers register SRV records in DNS, and clients and other domain controllers query for these records. Which records are registered in DNS and how they are registered depends on settings in the Windows registry. The following registry entries are associated with DNS support for Active Directory.

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, modify settings though the use of policy settings or through dedicated management tools, such as the DNS snap-in for the Microsoft Management Console (MMC), to accomplish tasks, rather than editing the registry directly. If you must edit the registry, use extreme caution.

**DNS\Parameters**
The following registry entries are used to configure various DNS options that control how DNS interacts with the Active Directory environment.

**EnableDirectoryPartitions**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\DNS\Parameters

**Version**
Windows Server 2003 and later

If you do not want the default DNS application directory partitions to be created automatically, you must disable the **EnableDirectoryPartitions** registry key. The values for this key are **0x0** (disable) and **0x1** (enable).

For more information about this registry entry, see the "Registry Reference" in the Tools and Settings Collection.

**DnsAvoidRegisterRecords**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\Netlogon\Parameters

**Version**
Windows Server 2003 and later

Specifies the list of data corresponding to the DNS resource records that should not be registered for a domain controller by the Net Logon service. Restarting the Net Logon service is not required to make the changes to this value effective. If the

**DnsAvoidRegisterRecords** registry key is created or modified within the first 15 minutes after the Net Logon service is started, there might be a short delay before the appropriate DNS updates appear and are replicated to the other DNS servers. If the modifications are made while the Net Logon service is stopped there is a short delay before the DNS updates appear after the Net Logon service is restarted.

In this value, list the data corresponding to the DNS resource records that should not be registered for this domain controller by the Net Logon service. The list of data includes:

| Data Value | Resource Record Type | DNS Resource Record |
|---|---|---|
| LdapIpAddress | A | <*DnsDomainName*> |
| Ldap | SRV | _ldap._tcp.<*DnsDomainName*> |

**DNS Support for Active Directory Group Policy Settings**

Active Directory uses DNS to enable client computers to locate domain controllers and to enable domain controllers to locate each other. Domain controllers register SRV records in DNS, and clients and other domain controllers query for these records. Which records are registered in DNS and how they are registered depends on specific Group Policy settings The following tables list and describe the Group Policy settings that are associated with DNS support for Active Directory.

**Net Logon Group Policy Settings Associated with DNS Support for Active Directory**

| Group Policy Setting | Description |
|---|---|
| Site Name | Specifies the Active Directory site to which computers belong. An Active Directory site is one or more well-connected TCP/IP subnets that allow administrators to configure Active Directory access and replication. |

| | |
|---|---|
| Negative DC Discovery Cache Setting | Specifies the amount of time (in seconds) the DC locator retains that a domain controller (DC) could not be found in a domain. When a subsequent attempt to locate the DC occurs within the time set in this setting, DC Discovery immediately fails, without attempting to find the DC. |

**Domain Controller Locator Group Policy Settings Associated with DNS Support for Active Directory**

| Group Policy Setting | Description |
|---|---|
| Dynamic Registration of the DC Locator DNS Records | Determines if Dynamic Registration of the DC locator DNS resource records is enabled. These DNS records are dynamically registered by the Net Logon service and are used by the Locator algorithm to locate the DC. |
| DC Locator DNS records not registered by the DCs | Determines which DC Locator DNS records are not registered by the Netlogon service. |
| Refresh Interval of the DC Locator DNS Records | Specifies the Refresh Interval of the DC Locator DNS resource records for DCs to which this setting is applied. These DNS records are dynamically registered by the Net Logon service and are used by the Locator algorithm to locate the DC. This setting can be applied only to DCs by using dynamic update. |
| Weight Set in the DC Locator DNS SRV Records | Specifies the Weight field in the SRV resource records registered by the DCs to which this setting is applied. These DNS records are dynamically registered by the Net Logon service and are used to locate the DC. |
| Priority Set in the DC Locator DNS SRV Records | Specifies the Priority field in the SRV resource records registered by DCs to which this setting is applied. These DNS records are dynamically registered by the Net Logon service and are used to locate the DC. |
| TTL Set in the DC Locator DNS SRV Records | Specifies the value for the Time-To-Live (TTL) field in Net Logon registered SRV resource records. These DNS records are dynamically registered by the Net Logon service and are used to locate the domain controller (DC). |
| Automated Site Coverage by the DC Locator DNS SRV Records | Determines whether DCs dynamically register DC Locator site-specific SRV records for the closest sites where no DC for the same domain exists (or no Global Catalog (GC) for the same forest exists). These DNS records are dynamically registered by the Net Logon service and are used to locate the DC. |
| Sites Covered by the DC Locator DNS SRV Records | Specifies the sites for which the DCs register the following:<br>• Site-specific DC Locator DNS SRV resource records<br>• Site-specific SRV records registered for the site where the DC is located<br>• Records registered by a DC configured to register DC Locator DNS SRV records for those sites without a DC that are closest to it |
| Sites Covered by the GC Locator DNS SRV Records | Specifies the sites for which the GCs should register the following:<br>• Site-specific GC locator DNS SRV resource records<br>• Site-specific SRV records registered for the site where the GC is located<br>• Records registered by a GC configured to register GC Locator DNS SRV records for those sites without a GC that are closest to it |

| | |
|---|---|
| Sites Covered by the Application Directory Partition Locator DNS SRV Records | Specifies the sites for which the DCs hosting the application directory partition should register the following:<br>• Site-specific, application directory partition-specific DC Locator DNS SRV resource records<br>• Site-specific SRV records registered for the site where the DC is located<br>• Records registered by a DC configured to register DC Locator DNS SRV records for those sites without a DC that are closest to it. |
| Location of the DCs hosting a domain with a single label DNS name | Specifies whether the computers to which this setting is applied attempt DNS name resolution of single-label domain names. |

For more information about Group Policy settings, see the "Group Policy Settings Reference" in the Tools and Settings Collection.

**DNS Support for Active Directory WMI Classes**

The WMI classes that are associated with the DNS support for Active Directory are the DNS WMI classes. The following table lists and describes the WMI classes that are associated with the DNS Server service.

**WMI Classes Associated With DNS Server Service**

| Microsoft DNS WMI Class | Description |
|---|---|
| MicrosoftDNS_Server | Describes a DNS server. Every instance of this class might be associated with one instance of class MicrosoftDNS_Cache, one instance of class MicrosoftDNS_RootHints, and multiple instances of class MicrosoftDNS_Zone. |
| MicrosoftDNS_Domain | Represents a domain in a DNS hierarchy tree. |
| MicrosoftDNS_Zone | Describes a DNS zone. Every instance of the class MicrosoftDNS_Zone must be assigned to exactly one DNS Server. Zones might be associated with multiple instances of the classes MicrosoftDNS_Domain and MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_Cache | Describes a cache existing on a DNS server (do not confuse this with a cache file that contains root hints). This class simplifies visualizing the containment of DNS objects, rather than representing a real object. The class, MicrosoftDNS_Cache, is a container for the resource records cached by the DNS server.<br>Every instance of the class MicrosoftDNS_Cache must be assigned to exactly one DNS server. It might be associated with multiple instances of MicrosoftDNS_Domain and MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_RootHints | Describes the RootHints stored in a cache file on a DNS server. This class simplifies visualizing the containment of DNS objects, rather than representing a real object. Class MicrosoftDNS_RootHints is a container for the resource records stored by the DNS server in a cache file.<br>Every instance of the class MicrosoftDNS_RootHints must be assigned to exactly one DNS server. It might be associated with multiple instances of the MicrosoftDNS_ResourceRecord class. |
| MicrosoftDNS_Statistic | Represents a single DNS server statistic. |
| MicrosoftDNS_ServerDomainContainment | Every instance of the class MicrosoftDNS_ServerDomainContainment might contain multiple instances of the class MicrosoftDNS_Domain. |

| | |
|---|---|
| MicrosoftDNS_DomainDomainContainment | Every instance of the MicrosoftDNS_DomainDomainContainment class might contain multiple other instances of MicrosoftDNS_Domain. |
| MicrosoftDNS_DomainResourceRecordContainment | Every instance of the class MicrosoftDNS_DomainResourceRecordComtainment might contain multiple instances of the MicrosoftDNS_ResourceRecord class. |
| MicrosoftDNS_ResourceRecord | Represents the general properties of a DNS RR. |
| MicrosoftDNS_AAAAType | Represents an IPv6 Address (AAAA), often pronounced quad-A, RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_AFSDBType | Represents an Andrew File System Database Server (AFSDB) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_ATMAType | Represents an ATM Address-to-Name (ATMA) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_AType | Represents an Address (A) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_CNAMEType | Represents a Canonical Name (CNAME) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_HINFOType | Represents a Host Information (HINFO) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_ISDNType | Represents an ISDN RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_KEYType | Represents a KEY RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_MBType | Represents a Mailbox (MB) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_MDType | Represents a Mail Agent for Domain (MD) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_MFType | Represents a Mail Forwarding Agent for Domain (MF) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_MGType | Represents an MG RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_MINFOType | Represents an Mail Information (MINFO) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_MRType | Represents a Mailbox Rename (MR) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_MXType | Represents a Mail Exchanger (MX) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_NSType | Represents a Name Server (NS) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_NXTType | Represents a Next (NXT) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_PTRType | Represents a Pointer (PTR) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_RPType | Represents a Responsible Person (RP) RR. Subclass of MicrosoftDNS_ResourceRecord. |

| | |
|---|---|
| MicrosoftDNS_RTType | Represents a Route Through (RT) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_SIGType | Represents a Signature (SIG) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_SOAType | Represents a Start Of Authority (SOA) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_SRVType | Represents a Service (SRV) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_TXTType | Represents a Text (TXT) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_WINSRType | Represents a WINS-Reverse (WINSR) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_WINSType | Represents a WINS RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_WKSType | Represents a Well-Known Service (WKS) RR. Subclass of MicrosoftDNS_ResourceRecord. |
| MicrosoftDNS_X25Type | Represents an X.25 (X25) RR. Subclass of MicrosoftDNS_ResourceRecord. |

For more information about many WMI classes, see the WMI SDK documentation on MSDN.

**Related Information**

The following resources contain additional information that is relevant to this section.

- "Microsoft Platform SDK" on MSDN for more information about many WMI classes that are associated with the DNS Server service.
- "Group Policy Settings Reference" in the Tools and Settings Collection for information about Group Policy settings that are associated with the DNS Client service.
- "Registry Reference" in the Tools and Settings Collection for information about registry entries that are associated with DNS.

# Domain Controller Roles

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

A domain controller is a server that is running a version of the Windows Server® operating system and has Active Directory® Domain Services installed.

| **Note** |
| --- |
| In Windows Server 2003 and Microsoft Windows® 2000 Server, the directory service is named Active Directory. In Windows Server 2008 R2 and Windows Server 2008, the directory service is named Active Directory Domain Services. The rest of this topic refers to AD DS, but the information is also applicable to Active Directory. |

When you install Windows Server on a computer, you can choose to configure a specific server role for that computer. When you want to create a new forest, a new domain, or an additional domain controller in an existing domain, you configure the server with the role of domain controller by installing AD DS.

By default, a domain controller stores one domain directory partition consisting of information about the domain in which it is located, plus the schema and configuration directory partitions for the entire forest. A domain controller that runs Windows Server 2008 R2, Windows Server 2008, or Windows Server 2003 can also store one or more application directory partitions. There are also specialized domain controller roles that perform specific functions in an AD DS environment. These specialized roles include global catalog servers and operations masters.

**Global Catalog Servers**

Every domain controller stores the objects for the domain in which it is installed. However, a domain controller designated as a global catalog server stores the objects from all domains in the forest. For each object that is not in the domain for which the global catalog server is authoritative as a domain controller, a limited set of attributes is stored in a partial replica of the domain. Therefore, a global catalog server stores its own full, writable domain replica (all objects and all attributes) plus a partial, read-only replica of every other domain in the forest. The global catalog is built and updated automatically by the AD DS replication system. The object attributes that are replicated to global catalog servers are the attributes that are most likely to be used to search for the object in AD DS. The attributes that are replicated to the global catalog are identified in the schema as the partial attribute set (PAS) and are defined by default by Microsoft. However, to optimize searching, you can edit the schema by adding or removing attributes that are stored in the global catalog.

The global catalog makes it possible for clients to search AD DS without having to be referred from server to server until a domain controller that has the domain directory partition storing the requested object is found. By default, AD DS searches are directed to global catalog servers.

The first domain controller in a forest is automatically created as a global catalog server. Thereafter, you can designate other domain controllers to be global catalog servers if they are needed.

**Operations Masters**

Domain controllers that hold operations master roles are designated to perform specific tasks to ensure consistency and to eliminate the potential for conflicting entries in the Active Directory database. AD DS defines five operations master roles: the schema master, domain naming master, relative identifier (RID) master, primary domain controller (PDC) emulator, and infrastructure master.

The following operations masters perform operations that must occur on only one domain controller in the forest:

- Schema master
- Domain naming master

The following operations masters perform operations that must occur on only one domain controller in a domain:

- Primary Domain Controller (PDC) emulator
- Infrastructure master

- Relative ID (RID) master

# Global Catalog Technical Reference

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

The global catalog is a distributed data repository that facilitates searching and logons in an Active Directory® Domain Services (AD DS) directory service forest. The global catalog allows users and applications to locate objects in any domain in the forest by searching on an important attribute of the object (for example, search on the user's last name to locate the user object or search on a building name to find a printer in that building). The global catalog facilitates logons by ensuring that membership in universal groups from all domains are represented in the user's access credentials. One or more domain controllers are designated as global catalog servers because they host the global catalog, which is built automatically by the AD DS replication system.

# What Is the Global Catalog?

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Common Global Catalog Scenarios
- Global Catalog Dependencies and Interactions
- Related Information

The global catalog is a distributed data repository that contains a searchable, partial representation of every object in every domain in a multidomain Active Directory Domain Services (AD DS) forest. The global catalog is stored on domain controllers that have been designated as global catalog servers and is distributed through multimaster replication. Searches that are directed to the global catalog are faster because they do not involve referrals to different domain controllers.

| **Note** |
| --- |
| In Windows Server® 2003 and Microsoft Windows® 2000 Server, the directory service is named Active Directory. In Windows Server 2008 R2 and Windows Server 2008, the directory service is named Active Directory Domain Services. The rest of this topic refers to AD DS, but the information is also applicable to Active Directory. |

In addition to configuration and schema directory partition replicas, every domain controller in a forest stores a full, writable replica of a single domain directory partition. Therefore, a domain controller can locate only the objects in its domain. Locating an object in a different domain would require the user or application to provide the domain of the requested object.

The global catalog provides the ability to locate objects from any domain without having to know the domain name. A global catalog server is a domain controller that, in addition to its full, writable domain directory partition replica, also stores a partial, read-only replica of all other domain directory partitions in the forest. The additional domain directory partitions are partial because only a limited set of attributes is included for each object. By including only the attributes that are most used for searching, every object in every domain in even the largest forest can be represented in the database of a single global catalog server.

| **Note** |
| --- |
| A global catalog server can also store a full, writable replica of an application directory partition, but objects in application directory partitions are not replicated to the global catalog as partial, read-only directory partitions. |

The global catalog is built and updated automatically by the AD DS replication system. The attributes that are replicated to the global catalog are identified in the schema as the partial attribute set (PAS) and are defined by default by Microsoft. However, to optimize searching, you can edit the schema by adding or removing attributes that are stored in the global catalog.

In Windows 2000 Server environments, any change to the PAS results in full synchronization (update of all attributes) of the global catalog. Later versions of Windows Server reduce the impact of updating the global catalog by replicating only the attributes that change.

In a single-domain forest, a global catalog server stores a full, writable replica of the domain and does not store any partial replica. A global catalog server in a single-domain forest functions in the same manner as a non-global-catalog server except for the processing of forest-wide searches.

**Common Global Catalog Scenarios**

The following events require a global catalog server:

- **Forest-wide searches.** The global catalog provides a resource for searching an AD DS forest. Forest-wide searches are identified by the LDAP port that they use. If the search query uses port 3268, the query is sent to a global catalog server.
- **User logon.** In a forest that has more than one domain, two conditions require the global catalog during user

authentication:

- In a domain that operates at the Windows 2000 native domain functional level or higher, domain controllers must request universal group membership enumeration from a global catalog server.
- When a user principal name (UPN) is used at logon and the forest has more than one domain, a global catalog server is required to resolve the name.

- Universal Group Membership Caching: In a forest that has more than one domain, in sites that have domain users but no global catalog server, Universal Group Membership Caching can be used to enable caching of logon credentials so that the global catalog does not have to be contacted for subsequent user logons. This feature eliminates the need to retrieve universal group memberships across a WAN link from a global catalog server in a different site.

| **Note** |
| --- |
| Universal groups are available only in a domain that operates at the Windows 2000 native domain functional level or higher. |

- Exchange Address Book lookups. Servers running Microsoft Exchange Server rely on access to the global catalog for address information. Users use global catalog servers to access the global address list (GAL).

**Search Requests**
Because a domain controller that acts as a global catalog server stores objects for all domains in the forest, users and applications can use the global catalog to locate objects in any domain within a multidomain forest without a referral to a different server.

When a forest consists of a single domain, every domain controller has a full, writable copy of every object in the domain and forest. However, it is important to retain the global catalog on at least one domain controller because many applications use port 3268 for searching. For example, if you do not have any global catalog servers, the **Search** command on the **Start** menu cannot locate objects in AD DS.

The replicas that are replicated to the global catalog also include the access permissions for each object and attribute. If you are searching for an object that you do not have permission to access, you do not see the object in the list of search results. Users can find only objects to which they are allowed access.

**User Logon Support**
In addition to its role as a search provider, in a forest that has more than one domain, the global catalog has a role as an identity source during the user logon process. Universal groups can provide access to resources outside of the user's domain. User principal names (UPNs) can specify a domain other than the domain of the user. By making universal group membership and UPN domain-user mapping information available on all global catalog servers, the global catalog provides the definitive source for groups that are capable of providing access in more than one domain and names that do not unequivocally identify the domain of the user.

**Universal Group Membership**
During the domain logon process, the user must be authenticated. During the authentication process, the user is validated (the domain controller verifies the identity of the user) and the user receives authorization data for access to resources. To provide authorization data of a user, the authenticating domain controller retrieves the security identifiers (SIDs) for all security groups of which the user is a member and adds these SIDs to the user's access token. In a forest that has more than one domain, the global catalog is the only location where memberships of all universal groups in that forest can be ascertained. For this reason, access to a global catalog server is required for successful authentication in a domain that can have universal groups.

The global catalog stores the membership (the **member** attribute) of only universal groups. The membership of other groups can be ascertained at the domain level.

Because a universal group can have members from domains other than the domain where the group object is stored and can be used to provide access to resources in any domain, only a global catalog server is guaranteed to have all universal group memberships that are required for authentication.

For example, a user might be a member of a universal group that has its group object stored in a different domain but provides access to resources in the user's domain. To ensure that the user can be authorized to access resources appropriately in this domain, the domain controller must have access to the membership of all universal groups in the forest.

If a global catalog server is not available, the user logon fails.

**User Principal Name**
A user principal name (UPN) is a logon name that takes the form of an e-mail address. A UPN specifies the user ID followed by a DNS domain name, separated by an "@" character (for example, jsmith@contoso.com). UPNs allow administrative management of the UPN suffix to provide logon names that:

- Match the user's e-mail name.
- Do not reveal the domain structure of the forest.

When a user account is created, the UPN suffix is generated by default as *userName@ DnsDomainName*, but it can be changed administratively. For example, in a forest that has four domains, the UPN suffix might be configured to map to the external DNS name for the organization. The **userPrincipalName** attribute of the user account identifies the UPN and is replicated to the global catalog.

When you use a UPN to log on to a domain, your workstation contacts a global catalog server to resolve the name because the UPN suffix is not necessarily the domain for which the contacted domain controller is authoritative. If the DNS domain name in the UPN suffix is not a valid DNS domain, the logon fails. Assuming the UPN suffix is a valid DNS name, the global catalog server returns the name of the AD DS domain to your workstation, which then queries DNS for a domain controller in that domain.

If a company has more than one forest and uses trust relationships between the domains in the different forests, a UPN cannot be used to log on to a domain that is outside the user's forest because the UPN is resolved in the global catalog of the user's forest.

**Universal Group Membership Caching**
Universal Group Membership Caching eliminates the need for a domain controller in a multidomain forest to contact a global catalog server during the logon process in domains where universal groups are available. Caching group membership reduces WAN traffic, which helps in sites where updating the cached group membership of security principals, including user and computer accounts, generates less traffic than replicating the global catalog to the site.

Use the following criteria to determine if a site is a good candidate for Universal Group Membership Caching:

- Number of users and computers in the site: The site has less than 500 combined users and computers, including transient users who log on occasionally but not on a regular basis. The cache of a user who logs on once continues to be updated periodically for 180 days after the first logon. A general limit of 500 membership caches can be updated at a time. If greater than 500 security principals have cached group memberships, some caches might not be updated.
- Number of domain controllers: Each domain controller performs a refresh on every user in its site once every eight hours. Depending on the number of domains in the forest, 500 security principals and two domain controllers could generate more WAN traffic than placing a global catalog server in the site. Therefore, you need to rationalize the WAN costs when exceeding 500 security principals and two domain controllers.
- Tolerance for high latency in group updates. Because domain controllers in the site where Universal Group Membership Caching is enabled update the membership caches every eight hours, and because credentials are always taken from the cache, updates to group memberships are not reflected in the security principal's credentials for up to eight hours.

**Address Book Lookups**
Exchange Server uses the global catalog to store mail recipient data that enables clients in a forest to send and receive e-mail messages.

**Global Catalog Dependencies and Interactions**
Global catalog servers have the following dependencies and interactions with other Windows Server technologies:

- AD DS installation. When AD DS is installed on the first domain controller in a forest, the installation application creates that domain controller as a global catalog server.
- AD DS replication. The global catalog is built and maintained by AD DS replication:
    - Subsequent to forest creation, when a domain controller is designated as a global catalog server, AD DS

replication automatically transfers PAS replicas to the domain controller, including the partial replica of every domain in the forest other than the local domain.

    - To facilitate intersite replication of global catalog server updates, AD DS replication selects global catalog servers as bridgehead servers whenever a global catalog server is present in a site and domains that are not present in the site exist in other sites in the forest.

- Domain Name System (DNS). Global catalog server clients depend on DNS to provide the IP address of global catalog servers. DNS is required to advertise global catalog servers for domain controller location.

- Net Logon service. Global catalog advertisement in DNS depends on the Net Logon service to perform DNS registrations. When replication of the global catalog is complete, or when a global catalog server starts, the Net Logon service publishes service (SRV) resource records in DNS that specifically advertise the domain controller as a global catalog server.

- Domain controller Locator: When a global catalog server is requested (by a user or application that launches a search over port 3268, or by a domain controller that is authenticating a user logon), the domain controller Locator queries DNS for a global catalog server.

In the following diagram, global catalog interactions include tracking a global catalog server through the following interactions, which are indicated by boxes:

- **Active Directory installation of a new forest:** Global catalog creation occurs during AD DS installation of the first domain controller in the forest.

- **Net Logon registration:** Resource records are registered in DNS to advertise the domain controller as a global catalog server.

- **AD DS replication:**

    - When a new domain controller (DC2) is created and an administrator designates it as a global catalog server, replication of the PAS from DC1 occurs.

    - DC1 in DomainA replicates changes for DomainA to DC2, and DC2 replicates updates to data for DomainB to DC1.

- **DC location:** The dotted lines enclose the processes whereby two clients locate a global catalog server by querying DNS:

    - A through C: (A) ClientX sends a query to the global catalog, which prompts (B) a DNS query to locate the closest global catalog server, and then (C) the client contacts the returned global catalog server DC2 to resolve the query.

    - 1 through 5: (1) ClientY logs on to the domain, which prompts (2) a DNS query for the closest domain controllers. (3) ClientY contacts the returned domain controller DC3 for authentication. (4) DC3 queries DNS to find the closest global catalog server and then (5) contacts the returned global catalog server DC2 to retrieve the universal groups for the user.

**Interactions with Other Windows Technologies**

The global catalog solves the problem of how to locate domain data that is not stored on a domain controller in the domain of the client that requires the information. By using different ports for standard LDAP queries (port 389) and global catalog queries (port 3268), AD DS effectively separates forest-wide queries that require a global catalog server from local, domainwide queries that can be serviced by the domain controller in the user's domain.

# How the Global Catalog Works

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Global Catalog Architecture
- Global Catalog Protocols
- Global Catalog Interfaces
- Global Catalog Physical Structure
- Global Catalog Processes and Interactions
- Network Ports Used by the Global Catalog
- Related Information

In a multidomain Active Directory® Domain Services (AD DS) forest, the global catalog provides a central repository of domain information for the forest by storing partial replicas of all domain directory partitions. These partial replicas are distributed by multimaster replication to all global catalog servers in a forest.

| **Note** |
| --- |
| In Windows Server® 2003 and Microsoft Windows® 2000 Server, the directory service is named Active Directory. In Windows Server 2008 R2 and Windows Server 2008 and, the directory service is named Active Directory Domain Services . The rest of this topic refers to AD DS, but the information is also applicable to Active Directory. |

The global catalog makes the directory structure within a forest transparent to users who perform a search. For example, if you search for all printers in a forest, a global catalog server processes the query in the global catalog and then returns the results. Without a global catalog server, this query would require a search of every domain in the forest.

During an interactive domain logon, the domain controller authenticates the user by verifying the user's identity, and also provides authorization data for the user's access token by determining all groups of which the user is a member. Because the global catalog is the forestwide location of the membership of all universal groups, access to a global catalog server is a requirement for authentication in a multidomain forest. A global catalog server is also required for applications such as Microsoft Exchange Server.

For more information about other reasons why a global catalog server is required, see the FAQ on the Ask the Directory Services Team blog (http://blogs.technet.com/b/askds/archive/2011/09/30/friday-mail-sack-super-slo-mo-edition.aspx#gc).

An ideal distribution of the global catalog is to have at least one global catalog server in each AD DS site. When a global catalog server is available in a site, the authenticating domain controller is not required to communicate across a WAN link to retrieve global catalog information. It is recommended make all domain controllers be global catalog servers.

In branch office scenarios, it is often not feasible to deploy a global catalog server in every branch site. At the same time, it is not cost effective to contact a global catalog server over a WAN link for every logon that occurs in the site. On domain controllers that are running Windows Server 2003 or later, universal group membership can be cached so that the domain controller must connect to a global catalog server across a WAN link only for initial logons in the site; thereafter, universal group membership can be checked from a local cache. Search clients, however, must always connect to global catalog servers across the WAN if no global catalog server exists in the client's site.

This subject describes the functionality of the global catalog and the replication of objects to global catalog servers in an AD DS forest.

**Global Catalog Architecture**

Global catalog server architecture differs from non-global catalog server architecture in its use of the nonstandard LDAP port 3268, which directs queries to the global catalog. Queries over this port are formed the same way as any LDAP query, but AD DS varies the search behavior according to the port that is used: queries over port 3268 target the global catalog directory partitions (including the read-only domain directory partitions and the one writable domain directory partition for which the server is authoritative), and queries over port 389 target only the writable domain, configuration, application, and schema directory partition replicas stored by the global catalog server in its role as a domain controller. In addition, domain controllers use the proprietary replication interface when they contact global catalog servers to retrieve universal group membership during client logons.

Search clients include Exchange Address Book clients, which use the client MAPI provider Emsabp32.dll to look up e-mail addresses in the global catalog. The client-side MAPI provider communicates with the server through the proprietary Name Service Provider Interface (NSPI) RPC interface.

Windows NT clients use Net APIs to communicate with the Security Accounts Manager (SAM) on the primary domain controller (PDC) emulator. The PDC emulator, a domain controller operations master role in AD DS domains, manages search and replication communication with clients that are running Windows NT.

The relationships between these architectural components are shown in the following diagram. Descriptions for the major components are provided in the subsequent table.

**Global Catalog Architecture**

For a more detailed description of LDAP and replication client-server architecture, see "How the Active Directory Replication Model Works."

**Global Catalog Architecture Components**

| Component | Description |
|---|---|
| Clients | Global catalog clients, including search clients and Address Book clients, as well as domain controllers performing replication and universal group security identifier (SID) retrieval during logon in a multidomain forest. |
| Network | The physical IP network. |
| Interfaces | LDAP over port 389 for read and write operations and LDAP over port 3268 for global catalog search operations. NSPI and replication (REPL) use proprietary RPC protocols. Retrieval of universal group membership occurs over RPC as part of the replication RPC interface. Windows NT 4.0 clients and backup domain controllers (BDCs) communicate with AD DS through the Security Accounts Manager (SAM) interface. |
| Directory System Agent (DSA) | The directory service component that runs as Ntdsa.dll on each domain controller, providing the interfaces through which services and processes gain access to the directory database. |

| | |
|---|---|
| Extensible Storage Engine (ESE) | The directory service component that runs as Esent.dll. ESE manages the tables of records that comprise the directory database. |
| Ntds.dit database file | The AD DS data store. |

#### Global Catalog Protocols

The following diagram shows the four interfaces into AD DS and the protocols that package the data according to their specific applications. These protocols and interfaces are the same for all domain controllers and are not specific to global catalog servers. The significance for the global catalog server is that domain controllers use the proprietary RPC replication protocol not only for replication, but also to contact the global catalog server when retrieving universal group membership information and when updating the group membership cache when Universal Group Membership Caching is enabled.

**Global Catalog Protocols**

The protocols are described in the following table.

**Global Catalog Protocols**

| Protocol | Description |
|---|---|
| Lightweight directory access protocol (LDAP) | The primary directory service protocol that specifies directory communications. It runs directly over TCP/IP, and it can also run over User Datagram Protocol (UDP) connectionless transports (UDP access is primarily used by the domain controller Locator process and can also be used to query the rootDSE). Clients use LDAP to query, create, update, and delete information that is stored in a directory service over a TCP connection through the TCP default port 389. Global catalog clients can use LDAP to query AD DS over a TCP connection through the TCP port 3268. AD DS supports LDAP v2 (RFC 1777) and LDAP v3 (RFC 2251). LDAP v3 is an industry standard that can be used with any directory service that implements the LDAP protocol. LDAP is the preferred and most common way of interacting with AD DS. |
| Remote procedure call (RPC) | Protocol for replication (REPL) and domain controller management communications (including global catalog server interactions), NSPI address book communications, and SAM-related communications. RPC is a powerful, robust, efficient, and secure interprocess communication (IPC) mechanism that enables data exchange and invocation of functionality residing in a different process. That different process can be on the same computer, on the local area network (LAN), or across the Internet. |
| Simple mail transfer protocol (SMTP) | Protocol for replication communications when a permanent, "always on" network connection does not exist between two domain controllers. SMTP is used to transport and deliver messages based on specifications in Request for Comments (RFC) 821 and RFC 822. SMTP can replicate only the configuration and schema directory partitions and global catalog read-only replicas (not writable domain data). |

For more information about AD DS protocols, see "How the Data Store Works."

#### Global Catalog Interfaces

Interfaces for global catalog servers are the AD DS data store interfaces, shown in the previous figure and described in the following table.

**Global Catalog Data Store Interfaces**

| Interface | Description |
|---|---|

| | |
|---|---|
| LDAP | The primary interface for AD DS access. Directory clients use LDAP v3 to connect to the DSA through the LDAP interface. The LDAP interface is part of Wldap32.dll. LDAP v3 is backward compatible with LDAP v2. |
| REPL | The replication management interface that provides functionality for finding data about domain controllers, converting the names of network objects between different formats, manipulating service principal names (SPNs) and DSAs, and managing replication of servers. |
| NSPI/MAPI | Name Service Provider Interface (NSPI) by which Messaging API (MAPI) clients access AD DS. Messaging clients gain access to AD DS by using MAPI address book providers. For compatibility with existing messaging clients, AD DS supports the NSPI/RPC address book provider, which provides directory access, for example, to find the telephone number of a user. |
| SAM | Proprietary interface for connecting to the DSA on behalf of clients that run Windows NT 4.0 or earlier. These clients use Windows NT 4.0 networking APIs to connect to the DSA through SAM. Replication with Windows NT 4.0 backup domain controllers (BDCs) occurs through the SAM interface as well. |

**Note**

The NSPI (MAPI) interface is provided only for support of legacy Microsoft Outlook clients. Development against this interface is no longer supported.

For more information about AD DS data store interfaces, see "How the Data Store Works."

**Global Catalog Physical Structure**

AD DS is a distributed directory service in which data is stored as replicas on multiple domain controllers to provide a virtual database that maintains consistency through AD DS replication. Domain controllers provide the domainwide distribution of directory data. Global catalog servers provide the forestwide distribution of directory data in a multidomain forest.

**Global Catalog Partial Attribute Set**

In its role as a domain controller, a global catalog server stores one domain directory partition that has writable objects with a full complement of writable attributes. In its role as global catalog server, it also stores the objects of all other domain directory partitions in a multidomain forest as read-only objects with a partial set of attributes. The set of attributes that are marked for inclusion in the global catalog are called the partial attribute set (PAS). An attribute is marked for inclusion in the PAS as part of its schema definition.

Objects in the schema that define an attribute are **attributeSchema** objects, which themselves have an attribute **isMemberOfPartialAttributeSet**. If the value of that attribute is TRUE, the attribute is replicated to the global catalog. The replication topology for the global catalog is generated automatically by the Knowledge Consistency Checker (KCC), a built-in process that implements a replication topology that is guaranteed to deliver the contents of every directory partition to every global catalog server.

The attributes that are replicated to the global catalog by default include a base set that have been defined by Microsoft as the attributes that are most likely to be used in searches. Administrators can use the Microsoft Management Console (MMC) Active Directory Schema snap-in to specify additional attributes to meet the needs of their installation. In the Active Directory Schema snap-in, you can select the **Replicate this attribute to the global catalog** check box to designate an **attributeSchema** object as a member of the PAS, which sets the value of the **isMemberOfPartialAttributeSet** attribute to TRUE.

**Domain Controller and Global Catalog Server Structure**

The physical representation of global catalog data is the same as all domain controllers: the Ntds.dit database stores object attributes in a single file. On a domain controller that is not a global catalog server, the Ntds.dit file contains a full, writable replica of every object in one domain directory partition for its own domain, plus the writable configuration and schema directory partitions.

**Note**

The schema directory partition is writable only on the domain controller that is the schema operations master for the forest.

The following diagram shows the physical representations of the global catalog as a forestwide resource that is distributed as a database on global catalog servers.

**Global Catalog Physical Structure**

As shown in the preceding diagram, a global catalog server stores a replica of its own domain (full and writable) and a partial, read-only replica of all other domains in the forest. All directory partitions on a global catalog server, whether full or partial, are stored in the directory database file (Ntds.dit) on that server. That is, there is not a separate storage area for global catalog attributes; they are treated as additional information in the directory database of the global catalog server.

The following table describes the physical components of the diagram.

**Global Catalog Server Physical Components**

| Physical Component | Description |
|---|---|
| Active Directory forest | The set of domains that comprise the AD DS logical structure and that are searchable in the global catalog. |
| Domain controller | Server that stores one full, writable domain directory partition plus forestwide configuration and schema directory partitions. Global catalog servers are always domain controllers. |
| Global catalog server | Domain controller that stores one full, writable domain plus forestwide configuration and schema directory partitions, as well as a partial, read-only replica of all other domains in the forest. |
| Ntds.dit | Database file that stores replicas of the AD DS objects held by any domain controller, including global catalog servers. |

**Global Catalog Processes and Interactions**

In addition to its activities as a domain controller, the global catalog server supports the following special activities in the forest:

- User logon: In a multidomain forest, domain controllers must contact a global catalog server to retrieve any SIDs of universal groups that the user is a member of. Additionally, if the user specifies a logon name in the form of a UPN, the domain controller contacts a global catalog server to retrieve the domain of the user.

- Universal and global group caching and updates: In sites where Universal Group Membership Caching is enabled, domain controllers that are running Windows Server 2003 or later cache group memberships and keep the cache updated by contacting a global catalog server.

- Global catalog searches: Clients can search the global catalog by specifying port 3268 or by using search applications that use this port. Search activities include:

    - Validation of references to non-local directory objects. When a domain controller holds a directory object with an attribute that references an object in another domain, this reference is validated by contacting a global catalog server.

    - Exchange Address Book lookups: Exchange Server uses AD DS as the address book store. Outlook clients query the global catalog to locate Address Book information.

- Global catalog server creation and advertisement: Global catalog servers register global-catalog-specific service (SRV) resource records in DNS so that clients can locate them according to site. If no global catalog server is available in the site of the user, a global catalog server is located in the next closest site, according to the cost matrix that is generated by the KCC from site link cost settings.

- Global catalog replication: Global catalog servers must either have replication partners for all domains or be able to replicate with another global catalog server. When changes to the PAS occur on, and are replicated between, domain controllers that are running Windows Server 2003 or later, only the updated attributes are replicated. Changes to the PAS that occur on domain controllers that are running Windows 2000 Server prompt a full synchronization of the entire global catalog (all attributes in the PAS are replicated anew to all global catalog servers). For more information about PAS replication, see Global Catalog Replication.

**User Logon**

When a domain user logs on interactively to a domain, the contacted domain controller must retrieve information from a global catalog server under the following conditions:

- The user's domain is Windows 2000 native domain functional level or higher. In this case, the user might belong to a universal group whose object is stored in a different domain.

- The user's logon name is a user principal name (UPN), which has the format *sAMAccountName@DNSDomainName*. In this case, the DNS domain suffix is not necessarily the user's domain and the identity of the user's domain must be retrieved from a global catalog server.

**Universal Group SID Retrieval**

A universal group is a security group that is available at the Windows 2000 native domain functional level or higher. During interactive user logon, the authenticating domain controller retrieves the SIDs that the user's workstation requires to build the access token for the user. To retrieve the SIDs of all universal groups to which the user belongs, the authenticating domain controller must contact a global catalog server. If a global catalog server is not available in the site when a user logs on to a domain in which universal groups are available, the computer will use cached credentials to log the user on if the user has previously logged on to the domain from the same workstation. If the user has not previously logged on to the domain from the same computer, the user can log on to only the local computer.

Of the three group types that are used to allow access to resources in a forest (domain local, global, and universal), only universal groups have their membership replicated to the global catalog. The values of the **member** attribute of universal group objects that exist in all domains must be available to an authenticating domain controller because:

- Universal groups can contain members, including individual user accounts and global groups, from any domain in the forest. Therefore, the user who is logging on might have a membership in a universal group that exists in a different domain.

- Universal groups can be added to access control lists in any domain in the forest. Therefore, the user might have permissions on objects in this domain by virtue of membership in a universal group that exists in a different domain.

Contrast this requirement with the domain local group membership. Domain local groups can also have members from other domains; however, domain local groups can be added to access control lists in only the domain in which they are created. Therefore, a domain controller can always determine a user's membership in all domain local groups that are required for authorization in its own domain.

For global groups, although these groups can be added to access control lists in any domain, they can contain accounts from only the domain in which they are created. Therefore, the global group membership of the user who is logging on can always

be checked locally. However, global groups can be members of universal groups that exist in different domains. When group nesting is in effect (which has the same availability criteria as availability of universal groups), being a member of a global group that is itself a member of a universal group can give the user access to resources other than those allowed by membership in the global group alone.

During the logon process, the authenticating domain controller retrieves a list of global group SIDs from the user's domain. If universal groups are available in the user's domain, the domain controller passes the list of global group SIDs to the nearest global catalog server. The global catalog server responds as follows:

- Enumerates the **member** attribute of all universal groups in the forest and adds universal group SIDs to the user's SID list as follows:
    - All universal groups that contain the user's SID.
    - All universal groups that contain the SID of any of the global groups in the user's SID list.
- Returns the list, including both universal group SIDs and global group SIDs, to the domain controller.

The authenticating domain controller sends the list of SIDs that is returned from the global catalog server to the user's computer, along with domain local group SIDs from the user's domain. The user's local computer, which creates the access token for the user, adds the returned SIDs to the access token.

For more information about how domain controllers cache group membership, see Universal Group Membership Caching. For more information about how SIDs are retrieved and used in access tokens, see "How Access Tokens Work." For more information about the authentication process, see "How the Kerberos Version 5 Authentication Protocol Works." For more information about the logon process, see "How Interactive Logon Works."

**UPN Logon**

A global catalog server resolves UPNs when the authenticating domain controller does not have knowledge of the account. For example, if a users account is located in noam.corp.contoso.com and the user logs on with a UPN of JSmith@contoso.com, the domain name in the UPN suffix does not match the user's domain. In the Windows Server 2003 and Windows 2000 Server logon screen, you can either type your user name (**sAMAccountName**) and select the domain name from the drop-down list, or you can use a UPN. If you use a UPN, as soon as you type the @ sign, the domain list becomes unavailable. In this case, domain controllers running Windows Server 2003 or Windows 2000 Server take the domain name from the UPN suffix. The UPN suffix is often (usually) different from the home domain of the user. In this case, the responding domain controller must contact a global catalog server to determine the domain of the user.

The following diagram shows the general sequence that occurs when a user logs on to a domain by using a UPN.

**UPN Logon and Global Catalog Interaction**

1. Because the domain of the user is not necessarily the same as the UPN suffix, the domain controller Locator contacts the nearest domain controller according to the site of the client computer.
2. The contacted domain controller determines whether the DNS name in the UPN suffix is the domain for which the domain controller is authoritative.

- If the domain name in the UPN suffix matches the domain of the domain controller, the domain controller attempts to process the client authentication. If the user name is not found, the domain controller contacts a global catalog server.

- If the DNS name in the UPN suffix does not match the domain of the domain controller, the domain controller contacts a global catalog server.

3. The global catalog server uses the **userPrincipalName** attribute of the user object to look up the distinguished name of the user object, and returns this value to the domain controller.

4. The domain controller extracts the domain name from the distinguished name of the user and returns this value to the client.

5. The client requests a domain controller for its domain.

If a forest trust exists between two forests, the default form of a UPN (*sAMAccountName@DnsDomainName*) is used for authentication in a different forest. If you create a forest trust and the second-level DNS domain name (for example, contoso.com) exists in both forests, the New Trust Wizard detects the conflict and only one forest is authoritative for that name suffix.

If NTLM-based trust relationships are created between the domains in different forests—as is required for a trust relationship between a domain in an Active Directory forest and a Windows NT 4.0 domain, between domains in two Windows 2000 Server forests, or between a domain in a Windows 2000 Server forest and a domain in a Windows Server 2003 forest—a UPN cannot be used to log on to a trusting domain that is outside the forest because the UPN is resolved in the global catalog of only one forest.

**Logon Process in a Single-Domain Forest**
In a single-domain forest, all domain controllers can service all logon requests, including UPN logons, without requiring a global catalog server. However, only domain controllers that are configured as global catalog servers can respond to LDAP traffic over port 3268.

For more information about the logon process, see "Interactive Logon Technical Reference." For more information about forest trust relationships, see "Domain and Forest Trusts Technical Reference."

**Universal Group Membership Caching**
In multidomain forests where remote sites do not have a global catalog server, the need to contact a global catalog server over a potentially slow WAN connection can be problematic. On domain controllers that are running Windows Server 2003 or later, the Universal Group Membership Caching feature is available by default (does not require a specific functional level or domain mode), although it must be enabled on a per-site basis.

When enabled, this feature allows a domain controller to cache global group SIDs and universal group SIDs that it retrieves from a global catalog server so that future logons do not require contacting a global catalog server. This storage is referred to as "caching," but the memberships are actually stored in a non-volatile AD DS value. The memberships that are written to this value are not lost as a result of a restart or power outage. For the purposes of this discussion, the term "cache" refers to this value. Group membership is cached for user accounts and computer accounts.

Caching group memberships in branch site locations has the following potential benefits:

- Faster logon times because authenticating domain controllers no longer need to contact a global catalog server to obtain universal group membership.

- Higher availability because logon is still possible if the WAN link to the site of the global catalog server is unavailable.

- No need to upgrade the hardware of existing domain controllers to handle the extra system requirements necessary for hosting the global catalog.

- Minimized network bandwidth usage because a branch site domain controller does not have to replicate all of the objects located in the global catalog.

**Enabling Universal Group Membership Caching**

Universal Group Membership Caching can be enabled for a site by using the Active Directory Sites and Services MMC snap-in to edit the properties of the NTDS Site Settings object (CN=NTDS Site Settings,CN=*TargetSiteName*,CN=Sites,CN=Configuration,CN=*ForestRootDomain*). In Active Directory Sites and Services, if you click a site object, the NTDS Site Settings object for the site is visible in the details pane. Right-click the **NTDS Site Settings** object and then click **Properties**. In the **NTDS Site Settings Properties** dialog box, click **Enable Universal Group Membership Caching**.

| **Note** |
| --- |
| The **options** attribute of the NTDS Site Settings object, which controls this feature, has a default value of 0. When only the Universal Group Membership Caching option is enabled, the attribute value is 32. However, this attribute is a bit field, so its full functionality is derived from computing a bitwise AND of all of the bits that are set. |

When the feature is enabled for a site, domain controllers in the site cache both universal group membership and global group membership for first-time logons and keep the cache updated thereafter. The feature allows specifying the site from which to retrieve group membership. In the **NTDS Site Settings Properties** dialog box, you can use the **Refresh cache from** list to specify the site to use. The **msDS-Preferred-GC-Site** attribute stores the distinguished name of the specified site and controls this setting.

If no site is specified, the closest-site mechanism uses the cost setting on the site link to determine which site has the least-cost connection to contact a global catalog server.

If the user has not logged on to the domain previously and a global catalog server is not available, the user can log on to only the local computer.

| **Note** |
| --- |
| If a user is the Administrator in the domain (Builtin Administrator account), the user can always log on to the domain, even when a global catalog server is not available. |

For more information about closest-site mechanisms, see "How Active Directory Replication Topology Works" and "How DNS Support for Active Directory Works."

**Global Group and Universal Group SID List**

Although the feature is named Universal Group Membership Caching, in fact the domain controller caches both universal group SIDs and global group SIDs. As described in "Universal Group SID Retrieval" earlier in this subject, the authenticating domain controller retrieves the list of universal group SIDs from the global catalog server. The domain controller sends the list of global group SIDs to the global catalog server so that universal group membership can be ascertained for these groups as well as for the user or computer account itself. Therefore, both global group SIDs and universal group SIDs are included in the list of SIDs that is returned from the global catalog server. The domain controller caches the entire list of SIDs. When the account attempts subsequent logons in the site, the universal group and global group SIDs for the account are obtained from the cache. Domain local group SIDs are always obtained from the local directory database.

After a security principal has logged on in a site that has Universal Group Membership Caching enabled, the group cache for the account on the authenticating domain controller is immediately populated. However, it can take up to eight hours for other domain controllers in the same site to populate the group cache. During this time, if the account is authenticated by a domain controller that has not populated the account's cache, a global catalog server must be contacted for the logon to proceed. After eight hours, all domain controllers that are running Windows Server 2003 or later in the site can process all subsequent logons by using the cached membership.

**Group Cache Communication Between Domain Controllers**

Although the cache itself is not replicated between domain controllers, knowledge that an account has logged on in the site is replicated to all other domain controllers in the domain by means of a site affinity attribute (**msDS-Site-Affinity**) of the respective user or computer object. This multivalued attribute identifies the sites in which the account has logged on and includes a timestamp for each site. The domain controllers in the domain use the replicated site affinity attribute to determine which account memberships are cached for their site, and then independently populate their copy of each account's cache by contacting a global catalog server. For more information about how the cache is populated, see How the Cache is Populated at First Logon and How the Cache is Refreshed. For more information about how this attribute is updated, see Group Cache Storage.

**Cache Refresh and the Availability of Group Changes**

The caching of group SIDs in this way, including both universal group and global group SIDs, can lead to unexpected behavior when an administrator modifies the universal group or global group membership for an account and expects the change to be reflected on all domain controllers in the domain after the first replication cycle following the change. Even if the change is

made on the domain controller that authenticates the account or has been received through replication, the membership in the cache is used instead of the value of the object **member** attribute. By default, domain controllers update the membership cache for accounts in the site every eight hours. As a result, changes to the global group or universal group membership of an account can take up to eight hours to be reflected on domain controllers in a site where Universal Group Membership Caching is enabled.

To refresh the cache, domain controllers running Windows Server 2003 or later send a universal group membership confirmation request to a global catalog server. There is no limit to the number of accounts that can be cached, but a maximum of 500 account caches can be updated during any cache refresh.

| **Note** |
| --- |
| Universal Group Membership Caching can be enabled in a site that has domain controllers that are running Windows 2000 Server. If Universal Group Membership Caching is enabled in such a site, users might experience inconsistent group membership, depending on which domain controller authenticates them. For this reason, it is recommended that you either upgrade all domain controllers that are running Windows 2000 Server to Windows Server 2003 or later when group caching is enabled in a site, or remove them. |

Because the group memberships are cached, there is a period of latency before group membership changes are reflected in an account's access token. When group membership changes, the changes are not reflected in the access token until the following events have occurred (in order):

1. The changes are replicated to the global catalog server that is used for the refresh of the cache.

2. The cache on the domain controllers in the account's site is refreshed. Although the cache refresh is not a replication event, the process uses the site link schedule. Therefore, a closed site link schedule postpones the cache refresh until the schedule opens.

3. The user has logged off and back on again (user account is authenticated) or the computer has restarted (computer account is authenticated).

When an access token is created during logon, the token contents are static until that user logs off and logs on again. Furthermore, as long as Universal Group Membership Caching is enabled, an account's memberships are cached, and the cache entry has not expired, the cache entry is used during logon. If changes have been made to group membership and the refresh task has not run, the changes are not reflected until either the cache entry expires or the refresh task runs and processes the cache entry.

The length of the latency period depends on when the next refresh task is scheduled to run. The refresh task reschedules itself for its next refresh during each current refresh run, as follows:

- Beginning with the current time plus the registry-configured refresh interval, the domain controller consults the replication schedule on the site link that connects its site to the site of the closest (or designated) global catalog server.

- If the site link schedule allows replication at the projected time, the refresh task is scheduled to run at this time.

- If the site link schedule does not allow replication at the projected time, the scheduling algorithm steps forward one minimum replication interval (15 minutes) and checks the schedule again.

- This process is repeated until an open replication interval is found. If no open interval is found in the seven-day schedule, the refresh task is scheduled to run by using a time calculated as the current time plus the registry-configured refresh interval. In this case, event ID 1671 is logged as a warning message that indicates the group membership cache refresh task was unable to find the next available time slot of connectivity to the site of the global catalog server.

If faster updates are required, an administrator can initiate a cache refresh manually on the domain controllers in the user's site. For more information about refreshing the user cache, see Registry Settings that Affect Cache Refresh and Site Affinity Limits.

**Determining the Site to Use for Populating and Refreshing the Cache**

You can designate a site from which to initially populate and subsequently refresh the group membership cache. The Universal Group Membership Caching feature user interface (UI) contains an option to select a site from the list of existing sites. When a

site has been selected and the cache on a domain controller must be populated for the first time or updated, the domain controller contacts a global catalog server in the designated site. If no site is designated, site link costs are evaluated to determine the lowest-cost site that contains a global catalog server. The site link cost matrix is supplied by the Intersite Messenger (ISM) service.

The UI that you use to designate a preferred site for cache refresh does not check for the presence of a global catalog server in the selected site. Therefore, it is possible to designate a refresh site that does not contain a global catalog server. In this case, or in any case where a refresh site is designated but a global catalog server does not respond, the domain controller uses the site link cost matrix and logs event ID 1668 in the Directory Service log in Event Viewer, which indicates that the group membership cache refresh task did not locate a global catalog in the preferred site, but was able to find a global catalog in the following available site. The event lists the named preferred site and the actual site that was used.

**Group Cache Storage**

Cached group membership is stored as additional attributes of user and computer objects. Three **attributeSchema** objects in the AD DS schema for the **user** object class (and inherited by the **computer** object class) support this feature:

- **msDS-Cached-Membership**: (cached membership) A binary large object (BLOB) that contains both universal and global group memberships (the group SIDs) for the user. This attribute has the following characteristics:
    - Is single valued.
    - Is not indexed.
    - Can be deleted.
    - Cannot be written.
    - Is not replicated.
- **msDS-Cached-Membership-Time-Stamp**: (last refresh time) Contains the time that the cached membership was last updated, either by the first logon or by a refresh. This attribute is used for the “staleness” check. The maximum period that is tolerated when using a cached group membership is called the staleness interval. The staleness interval, set in the registry as 7 days, is measured against the current time and the last refresh time. If the timestamp indicates that the cache is older than the staleness interval allows, the cached membership is invalidated and a global catalog server is required for logon. This attribute has the following characteristics:
    - Is large integer, time valued.
    - Is indexed.
    - Can be deleted.
    - Cannot be written.
    - Is not replicated.
- **msDS-Site-Affinity**: Identifies the site(s) where the account has logged on plus a timestamp that indicates the start time for the cached logon in the respective site. Presence of a value in this attribute causes automatic population of group memberships and refresh at every refresh interval. When a domain controller refreshes its cached memberships (every 8 hours by default), the timestamp is used for removing accounts from the cache that have not logged on within the site affinity time limit (the cache expires). To avoid replication of this attribute every time the account logs on, the timestamp is updated only when the age exceeds 50 percent of the age limit that is set in the registry (180 days, by default) and one of the following actions occurs:
    - The account logs on and is authenticated by a domain controller.
    - A user changes his or her account password. This update ensures that users who go for extended periods without logging on have their site affinity values updated.

This attribute has the following characteristics:

- Is multivalued.
- Is indexed.
- Can be deleted.
- Can be written.
- Is replicated.

| Note |
| --- |
| You can use ADSI Edit in Windows Support Tools to clear the cached entries for an account by deleting the values in **msDS-Cached-Membership** and **msDS-Cached-Membership-Time-Stamp** from the user or computer object. The attribute values are repopulated at the next logon or cache refresh, whichever comes first. |

**Registry Settings that Affect Cache Refresh and Site Affinity Limits**

Registry settings on each domain controller determine the limits that are imposed on group membership caches. The entries in the following table are under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters**, unless otherwise noted, and they can be used to manage the cache.

Changes to these registry settings take effect the next time the refresh task runs.

| Note |
| --- |
| In the following table, some of the entry names contain the string "(minutes)". Note that this string is part of the entry name and must be included when creating the entry. For example:<br>• The value name **Cached Membership Refresh Interval (minutes)** is correct.<br>• The value name **Cached Membership Refresh Interval** is incorrect. |

- 
- 
- 

**Registry Entries Used to Configure Caching Behavior**

| Registry Entry | Type | Default Value | Notes |
| --- | --- | --- | --- |
| **Cached Membership Site Stickiness (minutes)** | DWORD | 172800<br><br>(Value is in minutes. This setting equals 180 days) | Defines how long the site affinity will remain in effect. The site affinity value is updated when half of the period defined by this value has expired. If an account has not logged on with a domain controller for a period of one half of this value or longer, the account is removed from the list of accounts whose memberships are being refreshed. The default value is recommended. |

| | | | |
|---|---|---|---|
| **Cached Membership Staleness (minutes)** | DWORD | 10080<br><br>(Value is in minutes. This setting equals 7 days) | Determines the maximum staleness value when using cached group membership. The account cannot log on if the cached membership list is older than the staleness value and if no global catalog server is available. The default value is recommended. |
| **Cached Membership Refresh Interval (minutes)** | DWORD | 480<br><br>(Value is in minutes. This setting equals 8 hours) | Defines the length of time between group membership cache refreshes. This value should be changed to synchronize once a day (1440 minutes). For dial-up connections, you might want a higher value than 24 hours. Lowering the value to increase the frequency of cache refresh is not recommended because it causes increased WAN traffic, potentially defeating the purpose of Universal Group Membership Caching. |
| **Cached Membership Refresh Limit** | DWORD | 500 | Defines the maximum number of user and computer accounts that are refreshed. Increase this setting only if event ID 1669 occurs in the event log or you have more than 500 users and computers in a branch. If the number of users and computers in a branch exceeds 500, a general recommendation is to either place a global catalog server in the branch or increase the Cached Membership Refresh Limit above 500. Be aware that increasing the limit might incur more WAN traffic than that caused by global catalog update traffic. |
| **SamNoGcLogonEnforceKerberosIpCheck**<br><br>This setting appears under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa**. | DWORD | 0 | By default, allows site affinity to be tracked for Kerberos logons that originate outside the site. A value of 1 configures SAM so it does not give site affinity to Kerberos logon requests that originate outside the current site. This option should be configured to 1 on domain controllers in the branch-sites to prevent logon requests from outside the site being given affinity for the local site. This setting prevents an account's affinity from being changed during the logon process when connecting to a Kerberos key distribution center (KDC) outside of the account's site. This setting applies only to Kerberos logons; it does not affect site affinity caching for NTLM logons from different sites. |

| | | | |
|---|---|---|---|
| **SamNoGcLogonEnforceNTLMCheck**<br><br>This setting appears under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa**. | DWORD | 0 | A value of 1 configures SAM to not give site affinity to NTLM logon requests that are network logon requests; it may not prevent caching for other logon types. This setting reduces the number of accounts with site affinity by excluding those that simply accessed network resources (by using NTLM). This option should not be enabled if you use older clients that must authenticate from outside the branch to local resources in the branch. |

**Note**

To minimize the probability that remote users will use the UGC-enabled branch domain controller for logon, remove the domain controller for site-less SRV records from DNS by using the **DnsAvoidRegisterRecords** parameter for **Netlogon**. For more information about using **DnsAvoidRegisterRecords**, see Microsoft Knowledge Base article 306602 (http://go.microsoft.com/fwlink/?LinkId=126645).

**Methods of Refreshing the Cached Memberships**

You can refresh cached memberships on a single domain controller.

For a one-time, immediate cache refresh:

- Use Ldp.exe to modify the operational attribute **updateCachedMemberships** on the rootDSE with a value of **1**. Adding a value of 1 to this attribute instructs the local domain controller to perform the update. If the site link schedule allows replication at the time you modify the attribute, this update occurs right away. This method is the preferred method for updating a single domain controller because it does not require restarting the domain controller. For information about using Ldp to modify this attribute, see the Note below. Ldp.exe can be installed from Windows Support Tools in Windows Server 2003 and Windows 2000 Server, and it is installed by default on domain controllers that run Windows Server 2008 and Windows Server 2008 R2.

  -or-

- Restart the domain controllers in the site to restart the cache refresh interval, which triggers a cache refresh.

- Use the following procedure to modify the **updateCachedMemberships** operational attribute. To perform this operation, the user needs the control access right "Refresh Group Cache for Logons" on the NTDS Settings object for the domain controller. Default access is granted to System, Domain Admins, and Enterprise Admins.

1. Start Ldp.exe and bind to the target domain controller where the cache reset is to be performed. (Do not select **Tree view** in the **View** menu.) When first binding to a domain controller with Ldp, the default location is rootDSE. You can view the attributes for rootDSE in the details pane. However, operational attributes are not listed.

2. On the **Browse** menu, click **Modify**.

3. In the **Modify** dialog box, in the **Edit Entry Attribute** box, type **updateCachedMemberships**. In the **Values** box, type **1**. Be sure to leave the **Dn** box blank.

4. Click **Enter**. The command should appear in the entry list.

5. Click **Run**. If the operation was successful, Ldp will report “Modified” in the output.

**Method of Clearing the Cached Memberships**

You can clear all cached memberships on all domain controllers in a site. However, doing so can affect performance. The need to clear the cached memberships might arise due to too many cached accounts, causing inability to refresh all account caches during a single cache refresh. For example, sites that have many transient accounts might exceed the 500-account refresh limit.

If you have more than 500 accounts cached and you want to clear them for all domain controllers in the site, you can do so by editing the registry.

| **Note** |
| --- |
| If you must edit the registry, use extreme caution and be sure that you back it up first. Registry information is provided here as a reference for use by only highly skilled directory service administrators. Do not directly edit the registry unless, as in this case, no Group Policy setting or other Windows tools can accomplish the task. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. Storage of incorrect values can result in unrecoverable errors in the system. |

On one domain controller, you can set the **Cached Membership Site Stickiness (minutes)** registry entry to 0 and then initiate a cache refresh by using the operational attribute method on that domain controller, as described in "Methods of Refreshing the Cached Memberships" earlier in this subject. The 0 value in the setting causes the cache to be purged—values in all three attributes (**msDS-Cached-Membership**, **msDS-Cached-Membership-Time-Stamp**, and **msDS-Site-Affinity**) are cleared. After the site stickiness attribute deletion has replicated within the site, you can then initiate cache refresh on the other domain controllers in the site. Remember to return the value in **Membership Site Stickiness (minutes)** to its default value of 180.

**Diagnostic Logging Levels and Events**

Diagnostic logging for Universal Group Membership Caching can be set in the registry entry **20 Group Caching** under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics**

Data type: REG_DWORD

Value range: 0-5

Default value: 0

Significant events are reported at logging level 2 with many additional events reported at logging level 5. For troubleshooting, set the logging level to 5.

**Sample Events at Logging Level 0**

Event ID 1667: The group membership cache refresh task detected that the following site in which a global catalog was found is not one of the cheapest sites, as indicated by the published site link information.

Event ID 1668: The group membership cache refresh task did not locate a global catalog server in the preferred site, but was able to find a global catalog server in the following available site. Preferred site: <site name> Available site: <site name>

Event ID 1669: The group membership cache refresh task has reached the maximum number of users for the local domain controller.

Event ID 1670: The group membership cache refresh task is behind schedule. Consider forcing a group membership cache update.

**Sample Events at Logging Level 2**

Event ID 1776 internal event: The group membership cache task is starting.

Event ID 1777 internal event: The group membership cache task has finished. The completion status was 0, and the exit Internal ID was ######.

Event ID 1779 internal event: The Global Catalog Domain Controller <dcname> in site <site name>, domain <domain name> will be used to update the group memberships.

Event ID 1781 internal event: By examining the published connectivity information, the group membership cache task has determined site <site name> is a site with a low network cost to contact. The task will schedule itself based on the schedule of network connectivity to this site.

Event ID 1782 internal event: By examining the published connectivity information, the group membership cache task cannot find an efficient site to obtain group membership information. The task will run using the global catalog server that is closest, as determined by the Net Logon locator, and will schedule itself based on a fixed period.

Event ID 1842 internal event: The following site link will be used to schedule the group membership cache refresh task. Site link: <distinguished name of site link>

**Sample Events at Logging Level 5**
Event ID 1778 internal event: The group membership cache task will run again in xx minutes.

Event ID 1784 internal event: The group membership cache task determined that site <distinguished name of site> does not have a global catalog server.

**How the Cache is Populated at First Logon**
By default, the caching attributes on the user and computer objects are not populated. The following diagram shows how the domain controller builds the list of SIDs to be cached and where in the process the caching attributes are populated during the user's first logon in the site. This example assumes that the user is in a site that has Universal Group Membership Caching enabled, the domain of the client workstation is the same as the domain of the user, and the domain has a functional level that allows universal groups.

**Universal Group Membership Caching Process at First Logon**

The following events occur at each step in the preceding diagram:

1. A user logs on in a site where Universal Group Membership Caching is enabled. The user is authenticated by the domain controller as being the requesting user.

2. The domain controller checks the values of the three caching attributes of the user object.

3. Finding that the attributes are not populated, the domain controller checks its local directory and retrieves the SID of the user (including SID history, if available) and the SIDs of all global groups to which the user belongs.

4. The domain controller sends this list of SIDs to the global catalog server. The global catalog server checks the universal group memberships of the user and all global groups in the list. The global catalog server returns the list of combined universal group and global group SIDs to the domain controller.

5. The user's cache attributes are populated as follows:

    a. The combined list of global group and universal group SIDs is recorded in the **msDS-Cached-Membership** attribute.

    b. The time is recorded in the **msDS-Cached-Membership-Time-Stamp** attribute (this time indicates the last time the cache was updated; on the first logon, it also happens to be the time the user logged on).

    c. If **SamNoGcLogonEnforceNTLMCheck** or **SamNoGcLogonEnforceKerberosIpCheck**, or both, are enabled on the domain controller, the **msDS-Site-Affinity** attribute is ignored.

    d. If the GUID for the local site exists in the **msDS-Site-Affinity** attribute and the settings in step c. are not enabled, the timestamp value in **msDS-Site-Affinity** is evaluated as follows: If the value indicates an age that is less than half the value in **Cached Membership Site Stickiness (minutes)**, the logon proceeds. If the timestamp indicates

an age that is greater than half the value in **Cached Membership Site Stickiness (minutes)**, or if the attribute is not populated, the site GUID and time are written to the **msDS-Site-Affinity** attribute, and the logon proceeds.

6. The domain controller checks its local directory for any domain local groups to which the user belongs and adds domain local group SIDs to its list of global group and universal group SIDs.

| **Note** |
| --- |
| The process for accomplishing Step 6 differs depending on whether the domain of the client computer is the same as the domain of the user and, if not, whether the client computer is joined to a domain that has a mixed domain mode or functional level, or a native domain mode or functional level. For more information about how SIDs are retrieved and added to access tokens, see "Access Tokens Technical Reference." |

7. The domain controller sends the entire list of SIDs to the client computer, where the LSA retrieves SIDs of the user's built-in group memberships and constructs the user's access token.

| **Note** |
| --- |
| Global catalog servers in a site where caching is enabled do not populate the **msDS-Cached-Membership** and **msDS-Cached-Membership-Time-Stamp** attributes of users they authenticate. Because global catalog servers are already aware of universal group memberships throughout the forest and global group memberships for the domain, there is no need for them to use these attributes. |

**How the Cache is Used for Subsequent Logons**

When Universal Group Membership Caching is enabled in the site, the following sequence occurs during account logon:

1. The account is authenticated by the contacted domain controller.

2. The domain controller checks for the presence of values in the caching attributes of the respective user or computer object. If the attribute values are present, the domain controller updates the values as follows:

   a. If the value in the **msDS-Cached-Membership-Time-Stamp** attribute indicates an age that is less than the staleness interval (**Cached Membership Staleness (minutes)**, default seven days), the domain controller reads the group SIDs from the **msDS-Cached-Membership** attribute and the logon proceeds.

   b. If the value in **msDS-Cached-Membership-Time-Stamp** indicates an age of greater than the staleness interval, the domain controller contacts a global catalog server to request the universal group membership. If a global catalog server cannot be contacted, the logon is denied.

   c. If the value in the timestamp in **msDS-Site-Affinity** is equal to or older than 50 percent of the site stickiness setting, the timestamp is updated with the current time.

3. The domain controller returns the group SIDs from the cache plus any domain local group SIDs to the client computer and the logon proceeds.

| **Note** |
| --- |
| At no time during a successful logon does the local domain controller check with a global catalog server to see if the account's group membership has changed. Changes to an account's group membership are not reflected in the account's access token until the local domain controller performs a cache refresh. The default amount of time between cache refreshes is eight hours. This interval could result in an inconsistent view of group membership if the account was authenticated by a domain controller in a different site. This discrepancy might also confuse administrators who are unfamiliar with how universal group membership caching works. |

**How the Cache is Refreshed**

The cache refresh process occurs automatically on every domain controller that is running Windows Server 2003 or later and has received replication of the **msDS-Site-Affinity** attribute update for a user or computer object or has already cached group

memberships. The refresh operation occurs differently depending on whether a site is selected for the preferred refresh site.

**Cache Refresh Process When a Preferred Refresh Site is Not Selected**

When the refresh interval expires, the domain controller proceeds as follows:

1. Lists all the site links that connect the domain controller's site to a site that hosts a global catalog server in increasing order of cost values on the site link objects.

2. Selects the lowest-cost site link and schedules the refresh by using the site link schedule. If no site link schedule is set, then replication is always available. Depending on the schedule, the refresh proceeds as follows:

   - If the schedule currently allows replication, the domain controller begins the refresh.

   - If the schedule does not currently allow replication, the domain controller schedules the refresh to begin when the schedule allows replication.

     | **Note** |
     | --- |
     | When the refresh is postponed according to the site link schedule, a random stagger in the range of 0-15 minutes is added to the computed start time. Schedule staggering has the effect of ensuring that domain controllers begin their refresh at slightly different times, thereby improving load balancing on the global catalog server. |

   - When the schedule allows replication, begins the refresh by locating and binding to a global catalog server in the next closest site.

   - Removes accounts that have a populated cache but no site affinity. Cached entries that do not include a populated **msDS-Site-Affinity** value are purged at this time. A maximum of 64 entries are removed at a time. If more entries need to be removed, they are removed during subsequent refreshes.

   - Removes any account whose site affinity matches the local site, but whose site affinity time period has expired. In this case, the values in the three cache attributes are deleted and this account no longer has a group membership cache on the domain controller.

   - Builds a list of accounts by querying the global catalog for all accounts that have GUIDs in their **msDS-Site-Affinity** attribute that match the GUID of the domain controller's site.

   - Updates cache attributes of the accounts in the list by querying the global catalog for each account's group membership, as follows:

     - Update the **msDS-Cached-Membership** attribute with the account's group membership SIDs.

     - Update the **msDS-Cached-Membership-Time-Stamp** attribute with the time of refresh.

   - Repeats the process for each account until all accounts are updated or until the refresh limit of 500 accounts is reached. If the refresh limit is reached, the domain controller logs event ID 1669 in the Directory Service event log, and the refresh stops.

   - Checks to ensure that the refresh task has not fallen behind in terms of the maximum period allowed for an account's cached membership list to be valid for logons. This step is accomplished by locating the record with the oldest **msDS-Cached-Membership-Time-Stamp** value and comparing the timestamp value to the staleness interval (seven days by default). If the entry is more than seven days old, the domain controller logs event ID 1670, indicating that the refresh task has fallen behind.

     | **Note** |
     | --- |

When the domain controller encounters the refresh limit, it stops updating cache entries. Because the order in which the updates occur cannot be predicted, there is no way to ensure that the caches of the most recent accounts are updated. The staleness check in step 9 checks all cached entries, even those excluded due to exceeding the refresh limit. After about one week, the non-updated cache entries will become stale and cause the falling behind error to be reported in the event log.

**Note**

- When the domain controller encounters the refresh limit, it stops updating cache entries. Because the order in which the updates occur cannot be predicted, there is no way to ensure that the caches of the most recent accounts are updated. The staleness check in step 9 checks all cached entries, even those excluded due to exceeding the refresh limit. After about one week, the non-updated cache entries will become stale and cause the falling behind error to be reported in the event log.

**Cache Refresh Process When A Preferred Refresh Site is Selected**

When a site is selected to always be used for refreshing the group membership cache, the domain controller does not need to order the site links according to cost, but simply contacts a global catalog server in the specified site. However, if no global catalog server is available at the time the refresh is attempted, the domain controller logs event ID 1782, indicating that a domain controller could not be found in the preferred site, and uses the site link cost to locate a global catalog server in the next closest site.

**Inconsistent Access to Domain-Based Objects on Global Catalog Servers**

When specifying Read or List permissions for domain data that is also replicated to the global catalog, use global groups rather than domain local groups because the access token that is created for the user by the global catalog server does not necessarily contain information about domain local groups to which the user belongs.

When a user connects to a global catalog server, an access token is created for the user that is used in subsequent access decisions on the server. If the user is a member of a domain other than the domain of the global catalog server, the global catalog server contacts a domain controller in the user's domain to authenticate the user and retrieve authorization data. The domain controller returns information about the user, including the SIDs of global groups in the user's domain to which the user belongs. The domain controller from the user's domain *does not return domain local group SIDs to the global catalog server*.

Universal group membership is retrieved from the global catalog, and the global catalog server looks to its own domain (which is not necessarily the domain of the user) for any domain local groups to which the user belongs. Thus the access token for the user on the global catalog server contains the global groups and universal groups to which the user belongs, as well as any domain local groups to which the user belongs in the domain of the global catalog server.

The effect of a missing domain local group SID in the user's access token is that the user's access to global catalog data is unpredictable. For example, if access to the **homePhone** attribute of a user object is restricted by a domain local group in the user's domain, and the user is a member of that group, the user is able to view that attribute in the global catalog when both of the following conditions are true:

- The **homePhone** attribute is replicated to the global catalog.
- The global catalog server to which the user connects does not host a writable copy of the user's domain.

Similarly, if the user is a member of a domain local group in a domain other than the domain hosted by the global catalog server, and that group is granted read access to the **homePhone** attribute, the user cannot view that attribute in the global catalog.

**Global Catalog Searches**

The location of an object in AD DS is provided by the distinguished name of the object, which includes the full path to a replica of the object, culminating in the directory partition that holds the object. However, the user or application does not always have the distinguished name of the target object, or even the domain of the object. To locate objects without knowing the domain, the most commonly used attributes of the object are replicated to the global catalog. By using these object attributes and directing the search to the global catalog, requesters can find objects of interest without having to know their directory location. For example, to locate a printer, you can search according to the building of the printer. To locate a person, you can provide the name of the person. To locate all people who are managed by someone, you can provide the manager's name.

**LDAP Search Ports**
AD DS uses the Lightweight Directory Access Protocol (LDAP) as its access protocol. LDAP search requests can be sent and received by AD DS on port 389 (the default LDAP access port) and port 3268 (the default global catalog port). LDAP traffic that uses the Secure Sockets Layer (SSL) authentication protocol accesses ports 636 and 3269, respectively. In this discussion, search behavior that applies to ports 389 and 3268 also apply to the respective behavior of LDAP queries over ports 636 and 3269.

When a search request is sent to port 389, the search is conducted on a single domain directory partition. If the object is not found in that domain or the schema or configuration directory partitions, the domain controller refers the request to a domain controller in the domain that is indicated in the distinguished name of the object.

When a search request is sent to port 3268, the search includes all directory partitions in the forest — that is, the search is processed by a global catalog server. If the request specifies attributes that are part of the PAS, the global catalog can return results for objects in any domain without generating a referral to a domain controller in a different domain. Only global catalog servers receive LDAP requests through port 3268. Certain LDAP client applications are programmed to use port 3268. Even if the data that satisfies a search request is available on a regular domain controller, if the application launching the search uses port 3268, the search necessarily goes to a global catalog server.

**Search Criteria That Target the Global Catalog**
Searches are directed to a global catalog server under the following conditions:

- You specify port 3268 or 3269 in an LDAP search tool.
- You select **Entire Directory** in a search-scope list in an AD DS snap-in or search tool, such as Active Directory Users and Computers or the **Search** command on the **Start** menu.
- You write the distinguished name as an attribute value, where the distinguished name represents a nonlocal object. For example, if you are adding a member to a group and the member that you are adding is from a different domain, a global catalog server verifies that the user object represented by the distinguished name exists and obtains its GUID.

**Characteristics of a Global Catalog Search**
The following characteristics differentiate a global catalog search from a standard LDAP search:

- Global catalog queries are directed to port 3268, which explicitly indicates that global catalog semantics are required. By default, ordinary LDAP searches are received through port 389. If you bind to port 389, even if you bind to a global catalog server, your search includes a single domain directory partition. If you bind to port 3268, your search includes all directory partitions in the forest. If the server you attempt to bind to over port 3268 is not a global catalog server, the server refuses the bind.
- Global catalog searches can specify a non-instantiated search base, indicated as "com" or " " (blank search base).
- Global catalog searches cross directory partition boundaries. The extent of the standard LDAP search is the directory partition.
- Global catalog searches do not return subordinate referrals. If you use port 3268 to request an attribute that is not in the global catalog, you do not receive a referral to it. Subordinate referrals are an LDAP response; when you query over port 3268, you receive global catalog responses, which are based solely on the contents of the global catalog. If you query the same server by using port 389, you receive referrals for objects that are in the forest but whose attributes are not referenced in the global catalog.

| **Note** |
| --- |
| A referral to a directory that is external to AD DS can be returned by the global catalog if a base-level search for an external directory is submitted and if the distinguished name of the external directory uses the domain component (dc=) naming attribute. This referral is returned according to the ability of AD DS to construct a Domain Name System (DNS) name from the domain components of the distinguished name and is not based on the presence of any cross-reference object. The same referral is returned by using the LDAP port; it is not specific to the global catalog. |

Because the **member** attribute is not replicated to the global catalog for all group types, and because the **memberOf** attribute derives its value by referencing the **member** attribute (called back links and forward links, respectively), the results of searches

for members of groups and groups of which a member belongs can vary, depending on whether you search the global catalog (port 3268) or the domain (port 389), the kind of groups that the user belongs to (global groups or domain local groups), and whether the user belongs to universal groups outside the local domain.

For more information about global catalog searches and the implications of searching on back links and forward links, see "How Active Directory Searches Work."

**The Infrastructure Master and Phantom Records**

An attribute that has a distinguished name as a value references (points to) the named object. When the referenced object does not actually exist in the local directory database because it is in a different domain, a placeholder record called a phantom is created in that database as the object reference. Because there is a reference to it, the referenced object must exist in some form, either as the full object (if the domain controller stores the respective domain directory partition) or as an object reference (when the domain controller does not store that domain).

The infrastructure master is a single domain controller in each domain that tracks name changes of referenced objects and updates the references on the referencing object. When a referenced object is moved to a different domain (which effectively renames the object), the infrastructure master updates the distinguished name of the phantom. The infrastructure master finds phantom records by using a database index that is created only on domain controllers that hold the infrastructure operations master role. When the reference count of the phantom falls to zero (no objects are referencing the object that the phantom represents), garbage collection on each domain controller removes the phantom.

Because objects can reference objects in different domains, the infrastructure operations master role is not compatible with global catalog server status if more than one domain is in the forest. If a global catalog server holds the infrastructure operations master role, phantom records are never created because the referenced object is always located in the directory database on the global catalog server.

For more information about the infrastructure operations master role, see "How Operations Masters Work."

**Exchange Address Book Lookups**

The Exchange Server directory service is integrated with AD DS. When mail users want to find a person within their organization, they usually search the global address book (GAL), which is an aggregation of all messaging recipients in the enterprise, including mailbox-enabled users, mail-enabled users, groups, and contacts. The GAL is a virtual linked list of pointers to the mail recipient objects that comprise it. Mail recipients can be user accounts (both enabled and disabled accounts), contacts, distribution lists, security groups, and folders. The GAL is automatically populated by a service on the Exchange Server, and user's can create customized address lists. Exchange Server uses the global catalog to generate the GAL.

Every Outlook client is configured with the name of an Exchange server. Exchange servers use AD DS and DNS to locate a global catalog server. When an Outlook client user opens the Address Book, or when a user composes a message and types a name or an address in the To: field, the Outlook client uses the global catalog server that is specified by its Exchange server to search the contents of the GAL or other address lists.

For more information about how Outlook clients locate address information in the global catalog, see "How Active Directory Searches Work."

**Global Catalog Server Creation and Advertisement**

You can designate a domain controller as a global catalog server by simply selecting the **Global catalog** check box in the properties of the NTDS Settings object, located beneath each server object in Active Directory Sites and Services. On servers that run Windows Server 2008 R2 or Windows Server 2008, you can also designate a domain controller as a global catalog server during AD DS installation. However, for search clients and other domain controllers in the forest to locate it, the global catalog server must register itself in DNS.

The Net Logon service on a domain controller registers service (SRV) resource records in DNS that identify the domain controller so that it can be located. In the case of a global catalog server, additional SRV resource records are registered to identify the server as a global catalog server. These SRV resource records contain the server name, the forest name, and the site name for the global catalog server. DNS queries for these records return all global catalog servers in the requested site. When a client requests a global catalog server by launching an LDAP search over port 3268, the domain controller Locator on the client queries DNS for a domain controller that hosts the global catalog. For more information about how domain controllers and global catalog servers are located, see "How DNS Support for Active Directory Works."

By default, before a domain controller advertises itself as a global catalog server in DNS, the global catalog contents must be replicated to the server. This process involves replication of a partial, read-only replica of every domain in the forest except for the domain for which the new global catalog server is authoritative. The duration of this process depends on how many domains the forest contains, the size of the domains, and the relative locations of source and destination domain controllers. If multiple domains are in the forest and if source domain controllers are located only in distant sites, the process takes longer than if all domains are in the same site or in only a few sites. When replication must occur between sites to create the global

catalog, replication occurs according to the site link schedule.

When creating a new global catalog server, the process can be delayed by several conditions, including the following:

- The KCC could not reach a source domain controller from which to replicate a directory partition.
- Replication cannot begin until the scheduled time.
- Replication of the directory partition is in progress but has not yet completed. This delay might occur if the directory partition is very large. In addition, the replication priority queue prioritizes addition of new directory partitions at a lower priority than incremental replication of existing partitions.
- The source domain controller for a directory partition has gone offline or is unavailable due to network problems.

These conditions are logged in the Directory Service log when the logging level is set to 0 (the default setting) in the **Global Catalog** entry under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics**. If you want to receive more information, you can increase the logging level by editing this entry.

| **Warning** |
| --- |
| If you must edit the registry, use extreme caution and be sure that you back it up first. Registry information is provided here as a reference for use by only highly skilled directory service administrators. Do not directly edit the registry unless, as in this case, no Group Policy setting or other Windows tools can accomplish the task. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. Storage of incorrect values can result in unrecoverable errors in the system. |

**Requirements for Global Catalog Readiness**

By default, a global catalog server is not considered "ready" (the server advertises itself in DNS as a global catalog server) until all read-only directory partitions have been fully replicated to the new global catalog server. The **Global Catalog Partition Occupancy** registry entry under **HKEY_Local_Machine\System\CurrentControlSet\Services\NTDS\Parameters** determines the requirements for how many read-only directory partitions must be present on a domain controller for it to be considered a global catalog server, from no partitions (0) to all partitions (6).

For domain controllers that run Windows Server 2003 or later, the default occupancy value requires that all read-only directory partitions be replicated to the global catalog server before the Net Logon service registers SRV resource records in DNS. For most conditions, this default provides the best option for ensuring that a global catalog server provides a consistent view of the directory. In less common circumstances, however, it might be useful to make the global catalog server available with an incomplete set of partial domain directory partitions—for example, when delay of replication of a domain that is not required by users is jeopardizing their ability to log on.

The **Global Catalog Partition Occupancy** entry can have the values shown in the following table.

**Global Catalog Partition Occupancy Level Values**

| Value | Description |
| --- | --- |
| 0 | No occupancy requirement. Removing the occupancy level requirement might be useful in a scenario where domain controllers are being staged for deployment but are not yet in production. |
| 1 | At least one read-only directory partition in the site has been added by the KCC. This level, as well as level 3 and level 5, provide the ability to distinguish between a source for the directory partition being reachable (at least one object has been returned) and the entire directory partition having been replicated (as in levels 2, 4, and 6).<br><br>When the KCC can reach the first object, it can create a replica link, which is the agreement between the source and destination domain controllers to replicate to the destination. If the KCC cannot reach a source, the KCC logs event ID 1558 in the Directory Service log, which indicates the distinguished name of the directory partition that has not been fully synchronized. In this case, the KCC continues to try to replicate the partition each time it runs (every 15 minutes by default).<br><br>When the KCC succeeds in creating the replica link, it passes responsibility for retrying and completing the synchronization to the replication engine. The KCC then stops logging events, after which the replication status can be checked by using the **repadmin/showrepl** command. |

| | |
|---|---|
| 2 | At least one read-only directory partition in the site has been fully synchronized. |
| 3 | All read-only directory partitions in the site have been added by the KCC (at least one has been fully synchronized). In this case, the KCC has been able to contact one source for every directory partition in the site. This level is useful when you want to advertise a global catalog server as soon as possible with a high likelihood of success. |
| 4 | All read-only directory partitions in the site have been fully synchronized. With this setting, if a source for any directory partition is not available, DNS registrations cannot occur. On domain controllers that are running Windows 2000 Server with Service Pack 1 (SP1) or Windows 2000 Server with Service Pack 2 (SP2), this occupancy level is the default requirement before the global catalog server is advertised in DNS. |
| 5 | All read-only directory partitions in the forest have been added by the KCC (at least one has been fully synchronized). |
| 6 | All read-only directory partitions in the forest have been fully synchronized. On domain controllers that are running Windows Server 2003 or Windows 2000 Server with SP3 or later, this occupancy level is the default requirement before the global catalog server is advertised in DNS. This setting ensures the highest level of consistency. |

Event ID 1578 reports the level that is required and the level that the domain controller has achieved.

**Advertising a Global Catalog Server Prior to Full Synchronization**

By default, a domain controller checks every 30 minutes to see whether it has received all of the read-only directory partitions that are required to be present before the server advertises itself in DNS as a global catalog server. Event ID 1110 indicates that the promotion is being delayed because the required directory partitions have not all been synchronized.

This delay is controlled by the **Global Catalog Delay Advertisement (sec)** registry entry under **HKEY_Local_Machine\System\CurrentControlSet\Services\NTDS\Parameters**. If you set a value for **Global Catalog Delay Advertisement (sec)**, it overrides the requirements set in **Global Catalog Partition Occupancy** and allows global catalog advertisement without requiring full synchronization of all read-only directory partitions.

When conditions preclude the successful synchronization of the new global catalog server, you can force advertisement of the global catalog server and then remove the global catalog from the server. Until the global catalog server is successfully advertised, you are unable to remove it.

**Replication Process for Global Catalog Creation**

When you designate a domain controller to be a global catalog server, the Knowledge Consistency Checker (KCC) on the domain controller runs immediately and updates the replication topology. When the KCC runs, it checks to see whether the Global Catalog option is selected for any domain controllers, and creates the replication topology accordingly. The KCC configures the newly selected global catalog server to be the destination server for a read-only replica of every domain directory partition in the forest except for the writable domain directory partition that the server already holds. The KCC on the global catalog server must be able to reach a server that will be the source of each read-only directory partition.

When the KCC locates an available source domain controller, it creates an inbound connection on the new global catalog server and replication of that read-only partition takes place. If the source is within the site, replication begins immediately. If the source is in a different site, replication begins when it is next scheduled. Replication of all objects in the partial directory partition must complete successfully before the directory partition is considered to be present on the global catalog server.

**Successful Completion of Global Catalog Creation**

When all directory partitions are present, the domain controller sets its rootDSE **isGlobalCatalogReady** attribute to TRUE and the Net Logon service on the domain controller registers SRV resource records that specifically advertise the global catalog server in DNS. At this point, the global catalog is considered to be available, and event ID 1119 is logged in the Directory Service log.

**Global Catalog Replication**

Although read-only directory partitions on global catalog servers cannot be updated directly by administrative LDAP writes, they are updated through AD DS replication when changes occur to their respective writable replicas.

The following diagram represents the AD DS database on a global catalog server in the corp.contoso.com forest root domain. A global catalog server has a single directory database. However, to represent the different logical directory partitions in the forest, the diagram shows database divided into segments. The top three segments represent directory partitions that are writable replicas for the domain controller (the domain, configuration, and schema directory partitions). The bottom three segments represent directory partitions that are read-only replicas of the other domains in the forest.

**Writable and read-only replicas in the AD DS database on a global catalog server**

The source domain controller for replication of a given directory partition to a global catalog server can be either a non-global catalog domain controller or another global catalog server. In the following diagram, each directory partition on the global catalog server is being updated by a non-global catalog domain controller. The writable replicas on the global catalog server are updated by a domain controller that is authoritative for the same domain, Corp.contoso.com. The replication for the Corp.contoso.com domain and the configuration and schema directory partitions is two-way because the replicas are all writable.

Each of the read-only replicas is updated by a source domain controller that is authoritative for the respective directory partition. The replication is one-way because read-only replicas never update writable replicas.

**Direction of directory partition replica updates between a global catalog server and other domain controllers**

**Replication Between Global Catalog Servers**

As is true for all domain controllers, a global catalog server uses a single topology to replicate the schema and configuration directory partitions, and it uses a separate topology, if needed, for each domain directory partition. However, when a two-way connection exists between the servers, either for replication of the schema and configuration directory partitions or for replication in opposite directions of the two writable domain directory partitions, all replicas on each global catalog server use the same connection to update their common replicas when changes are available.

The diagram below shows the directions of replication between directory partitions on two global catalog servers that are in different sites and are authoritative for different domains. The writable replicas of soam.corp.contoso.com and corp.contoso.com update the respective read-only replicas in one direction only (a writable replica is never updated by a read-only replica). Because neither domain controller is authoritative for the noam.corp.contoso.com and eur.corp.contoso.com domain replicas, the global catalog servers can be sources for replication of these partial read-only replicas. This replication is shown as two-way because a two-way connection already exists and these replicas are each capable of updating the other.

**Direction of directory partition replica updates between two global catalog servers in different domains**

In the preceding diagram, the read-only replicas can also be updated from other domain controllers. Unless the forest functional level is Windows 2000 Server, the intersite KCC algorithm avoids creating redundant connection objects by implementing one-way replication where possible. For example, if the schema and configuration writable replicas and the Corp and Eur read-only domain replicas on GC1 are all updated by a domain controller other than GC2, replication of the Corp and Eur read-only replicas from GC1 to GC2 occurs in one direction if it occurs. In this case, GC1 might not generate a connection object for replication from GC2.

**Global Catalog Replication of Additions to the Partial Attribute Set**

Each global catalog server in an AD DS forest hosts a copy of every existing object in that forest. For the objects of its own domain, a global catalog server has information related to all attributes that are associated with those objects. For the objects in domains other than its own, a global catalog server has only information that is related to the set of attributes that are marked in the AD DS schema to be included in the partial attribute set (PAS). As described earlier, the PAS is defined by

Microsoft as those attributes that are most likely to be used for searches. These attributes are replicated to every global catalog server in an AD DS forest.

If you want to add an attribute to the PAS, you can mark the attribute by using the Active Directory Schema snap-in to edit the **isMemberOfPartialAttributeSet** value on the respective **attributeSchema** object. You mark the attribute by placing a checkmark next to **isMemberOfPartialAttributeSet**. If the **isMemberOfPartialAttributeSet** value is checked (set to TRUE), the attribute is replicated to the global catalog. If the value is not checked (set to FALSE), the attribute is not replicated to the global catalog.

When the PAS is updated on the domain controller that has the schema operations master role, the writable schema directory partition replicates normally to all domain controllers. When a global catalog server attempts to update its read-only directory partition from a source replication partner whose schema has been udpated with the PAS change, the destination global catalog server receives the information that the PAS has been updated.

Depending on the version of Windows that is running on the replication partners, a global catalog server responds to an update to the PAS either by initiating replication of all attributes in the read-only directory partitions in the global catalog (full synchronization), or only the attributes that were added to the PAS (updates only), as follows:

- **Updates only—both replication partners are running Windows Server 2003 or later:** Only the added attributes are replicated and there is no replication impact. In this case, when the **isMemberOfPartialAttributeSet** value of a new **attributeSchema** object in the schema directory partition is set to TRUE and this change is either made on a global catalog server or replicated in by a global catalog server, the global catalog server records unique NTDS Replication informational events in the Directory Service log for each read-only directory partition that it hosts, as follows:

    - Event ID 1704, stating that in response to addition of one or more attributes to the PAS, the global catalog server has initiated replication of the PAS for the specified directory partition from the specified domain controller.

    - Event ID 1702, stating that synchronization of the PAS has completed successfully.

- **Full synchronization—both replication partners are running Windows 2000 Server:** The global catalog server initiates replication of all PAS attributes of all objects in all read-only domain directory partitions. In this case, all replication partner metadata and up-to-dateness metadata for the directory partition is discarded and the global catalog server builds a new list of replication partners and up-to-dateness information relative to those partners. Building its partner information anew, it requests replication of all attributes, filtering out any attribute that is not marked for inclusion in the PAS. If the attributes can be replicated over an RPC connection, the domain controller attempts a full replication over the RPC connection before it uses a configured SMTP connection. If full replication is completed, the up-to-dateness vector that is created ensures that later replication requests on other connections do not include data that has been received during the initial full replication.

  Full replication of all attributes in the PAS to bring all global catalog servers up-to-date causes increased network traffic while it is in progress and can take from several minutes to hours, depending on the size of the directory. Although interruption of service does not occur, this replication causes higher bandwidth consumption than is required for usual day-to-day replication. The resulting bandwidth consumption for each global catalog server is equivalent to that caused by assigning the global catalog role to a domain controller.

  In this case, when the **isMemberOfPartialAttributeSet** value of an additional **attributeSchema** object in the schema directory partition is set to TRUE and this change is either made on a global catalog server or replicated in by a global catalog server, a unique NTDS Replication informational event ID 1575 is recorded in the Directory Service log for each read-only directory partition that is hosted by the global catalog server. Event ID 1575 states that one or more new attributes has been added to the PAS for the specified directory partition and that full synchronization of all objects and all attributes in the specified directory partition will be performed from the source domain controller on the next replication cycle.

- **Full synchronization—a global catalog server that is running Windows Server 2003 or later sources replication of a partial, read-only directory partition from a global catalog server or domain controller that is running Windows 2000 Server:** The global catalog server that is running Windows Server 2003 or later reverts to Windows 2000 Server behavior and, as described above, initiates full replication of all objects and their attributes in all read-only directory partitions. For each read-only directory partition that it hosts, the global catalog server that is running Windows Server 2003 or alter records unique NTDS Replication informational events in the Directory Service log, as follows:

- Event ID 1575, stating that full synchronization of the PAS will be initiated on the next replication cycle.
- Event ID 1703, stating that synchronization of the PAS has been initiated.
- Event ID 1702, stating that synchronization of the PAS has completed successfully.

| **Note** |
| --- |
| The AD DS schema in Windows Server 2003 and later contains attributes that are marked for inclusion in the PAS as soon as the forest functional level is raised to Windows Server 2003 or higher. Replication of the additions to the PAS to global catalog servers is triggered by raising the forest functional level to Windows Server 2003 or higher. Therefore, upgrading the schema has no impact on Windows 2000–based global catalog servers because the global catalog is updated only when all domain controllers are running Windows Server 2003 or later (the requirement for raising the forest functional level to at least Windows Server 2003). For more information about functional levels, see "How Active Directory Functional Levels Work." |

For more information about replication metadata, including up-to-dateness vector, see "How the Active Directory Replication Model Works."

**Global Catalog Response to Deletions from the Partial Attribute Set**
Removing an attribute from the PAS does not involve replication of a deletion, but is handled locally. If you set the **isMemberOfPartialAttributeSet** value to FALSE in the schema, the attribute is removed from the directory of each global catalog server immediately after receiving the schema update. This behavior is the same on global catalog servers running any version of Windows Server.

**Removing the Global Catalog from a Domain Controller**
When you add the global catalog to a domain controller, a partial replica of each domain directory partition, other than the domain for which the domain controller is authoritative, is copied to the domain controller as described in Replication Process for Global Catalog Creation. This replication occurs immediately within a site or at the next scheduled replication between sites. However, when you remove the global catalog from a domain controller, the KCC begins removing the read-only replicas one at a time by means of an asynchronous process that removes objects gradually over time until no read-only objects remain.

The Windows 2000 KCC removes approximately 500 objects per attempt. Each time the KCC runs (every 15 minutes by default), it attempts the removal of the read-only replica until there are no remaining objects. At an estimated 2000 objects per hour, complete removal of the global catalog from the domain controller can take from several hours to days, depending on the size of the directory.

The KCC in Windows Server 2003 or later initially instructs the directory to remove each replica, but once the instruction is received, the directory itself keeps track of the progress of replica removal and reschedules the work accordingly. Rather than removing a fixed number of objects per removal attempt, AD DS continues removing objects until either the replica is gone or a higher priority replication operation is in the queue. Read-only replica removal receives the lowest possible priority, meaning that any other replication work will interrupt it. Thus, removal work is pre-empted for the other work and then resumed later. On domain controllers running Windows Server 2003 or later, event log messages record when removal of a partial replica is starting, being resumed, and finishing.

KCC events that are logged in the Directory Service log during global catalog removal include:

- Event ID 1744: Local domain controller is no longer a global catalog server.
- Event ID 1659: Removal of a directory partition from the local database has been resumed, including the approximate number of objects remaining to be removed and number of link values of attributes remaining to be removed.
- Event ID 1660: A specified directory partition has been removed from the local domain controller.

For a normally-to-lightly loaded system, read-only replica removal occurs as fast as possible in the background. On a server that is very busy with replication (for example, a hub domain controller), estimating the time required for global catalog removal is difficult.

As soon as you set the domain controller to not be a global catalog server by clearing the **Global Catalog** check box on the NTDS Settings object properties page, Net Logon deregisters the SRV resource records that specifically advertise the global

catalog server in DNS. Therefore, although the read-only domain replicas might take hours or days to remove, the domain controller immediately stops advertising itself as a global catalog server in DNS and immediately stops accepting LDAP requests over port 3268.

| **Note** |
| --- |
| On a domain controller running Windows 2000 Server, if you check the **Global Catalog** box again before a partial replica has been completely removed, the KCC begins the process of replicating in the read-only replicas as follows: If a given replica is completely gone, the KCC adds the replica back. If the replica is still in the process of being removed, the KCC does not add it again until the initial removal is complete. Thus, during the removal period, there can conceivably be a mix of new replicas from the most recent global catalog instance, and some old replicas in the process of being removed from the previous instance. This condition is temporary and of no consequence to users because the domain controller is not being advertised as a global catalog server. |

**Network Ports Used by the Global Catalog**

The following ports are used by global catalog servers:

**Port Assignments for Global Catalog Servers**

| Service Name | UDP | TCP |
| --- | --- | --- |
| LDAP | | 3268 (global catalog) |
| LDAP | | 3269 (global catalog Secure Sockets Layer [SSL]) |
| LDAP | 389 | 389 |
| LDAP | | 636 (SSL) |
| RPC/REPL | | 135 (endpoint mapper) |
| Kerberos | 88 | 88 |
| DNS | 53 | 53 |
| SMB over IP | 445 | 445 |

# Global Catalog Tools and Settings

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Global Catalog Tools
- Global Catalog Registry Entries
- Global Catalog Group Policy Settings
- Network Ports Used by Global Catalog Servers
- Related Information

**Global Catalog Tools**
Tools that are associated with a global catalog server are the same tools that you use to manage any domain controller.

The following tools have commands that are specific to managing global catalog servers.

**Adsiedit.msc: ADSI Edit**

**Category**
A Microsoft Management Console (MMC) snap-in that is available in Windows Support Tools in Windows Server® 2003 and Microsoft Windows® 2000 Server. It is built into Windows Server 2008 R2 and Windows Server 2008 and available if you have the Active Directory® Domain Services (AD DS) or the Active Directory Lightweight Directory Services (AD LDS) server role installed. It is also available if you install the Active Directory Domain Services Tools that are part of the Remote Server Administration Tools (RSAT). For more information, see How to Administer Microsoft Windows Client and Server Computers Locally and Remotely (http://go.microsoft.com/fwlink/?LinkID=177813).

| **Note** |
| --- |
| In Windows Server 2003 and Windows 2000 Server, the directory service is named Active Directory. In Windows Server 2008 R2 and Windows Server 2008, the directory service is named Active Directory Domain Services. The rest of this topic refers to AD DS, but the information is also applicable to Active Directory. |

| Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows 7 with Remote Server Administration Tools (RSAT) installed.<br>• Windows Vista with Remote Server Administration Tools (RSAT) installed.<br>• Windows XP Professional with Adminpak.msi installed | Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Active Directory Sites and Services to create, modify, and delete site configuration objects in Active Directory, including sites, subnets, connection objects, and site links. You can also use Active Directory Sites and Services to create the intersite topology, including mapping subnet addresses to sites, creating and configuring site links, creating manual connection objects, forcing replication over a connection, setting a domain controller to be a global catalog server, and selecting preferred bridgehead servers.

**Repadmin.exe: Repadmin**

**Category**
Windows Support Tools, command-line

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows 7 with Remote Server Administration Tools (RSAT) installed.<br>• Windows Vista with Remote Server Administration Tools (RSAT) installed.<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

Repadmin is used to view the replication information on domain controllers. You can determine the last successful replication of all directory partitions, identify inbound and outbound replication partners, identify the current bridgehead servers, view object metadata, and generally manage Active Directory replication topology. You can use Repadmin to force replication of an entire directory partition or of a single object. You can also list domain controllers in a site.

Repadmin is extended in Windows Server 2003 to enable commands to target sets of domain controllers. For example, you can target all domain controllers in a site or domain, or all domain controllers that are global catalog servers. In Windows 2000 Server, Repadmin can report information about only one domain controller at a time.

For more information about Repadmin, see "Support Tools Help" in Tools and Settings Collection.

**Ldp.exe: Ldp**

**Category**
Windows Support Tools, GUI

**Version compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows 7 with Remote Server Administration Tools (RSAT) installed.<br>• Windows Vista with Remote Server Administration Tools (RSAT) installed.<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

Ldp is a Lightweight Directory Access Protocol (LDAP) graphical user interface (GUI) tool that you can use to perform operations such as connect, bind, search, modify, add, and delete against any LDAP-compatible directory, such as AD DS. You can also use Ldp to view objects that are stored in AD DS, along with their metadata, for example, security descriptors and replication metadata.

You can use Ldp to view and edit the **updateCachedMemberships** operational attribute on the **rootDSE**.

For more information about Ldp, see "Support Tools Help" in Tools and Settings Collection.

**Global Catalog Registry Entries**

The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

The following registry entries are associated with the global catalog.

**NTDS Parameters**

The following registry entries under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters** control or contain information about the configuration of the global catalog.

**Global Catalog Promotion Complete**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2003:

Used for Install From Media. This entry is set in conjunction with the domain controller setting its rootDSE attribute **isGlobalCatalogReady** to TRUE, the Net Logon service on the domain controller registering SRV resource records that specifically advertise the global catalog in DNS, and the domain controller beginning to listen on port 3268.

**Global Catalog Partition Occupancy**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, and Windows Server 2003:

The requirement for read-only replicas that must be added (replication partner established) or synchronized (replication completed), or both, on the global catalog server before the server is advertised in DNS. Lower occupancy levels specify varying levels of replication completeness, including advertising in DNS when all read-only replicas of only those domains represented in the domain controller's site are synchronized.

**Version**
Windows 2000 Server with SP3 and later:

The occupancy level requires full synchronization of all read-only replicas.

**Version**
Windows 2000 Server with Service Pack (SP) 2 and earlier:

The occupancy level requires only the replicas of domains in the site.

**Global Catalog Delay Advertisement**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters**

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server

Overrides the requirements set in **Global Catalog Partition Occupancy** entry and allows global catalog advertisement without requiring full synchronization of all read-only replicas. If you do not set this value, checking for synchronized read-only partitions continues to occur at 30-minute intervals until the requirements are met.

**Cached Membership Site Stickiness (minutes)**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters**

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003

The maximum time during which an account's cached membership can be refreshed automatically without the account having to log on in this site. The default value is one-half the value of the account's site affinity setting, which is 180 days by default. If the account has not logged on in more than 90 days, the account's group membership cache expires and must be reinstated at the next logon by contacting a global catalog server.

**Cached Membership Staleness (minutes)**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters**

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003

The maximum staleness to tolerate when using a cached group membership. The default value is one week. If the cached membership age is greater than this interval and no global catalog server is available, the logon fails. If no value is present, the

default value is used.

**Cached Membership Refresh Interval (minutes)**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters**

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003

The frequency of automatic cache refresh. The default value is eight hours. If no value is present, the default value is used.

**Cached Membership Refresh Limit**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters**

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003

The maximum number of user and computer accounts that are refreshed during a group membership cache refresh.

**SamNoGcLogonEnforceKerberosIpCheck**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa**

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003

By default, allows site affinity to be tracked for Kerberos logons that originate outside the site. This setting only applies to Kerberos logons; it will not affect site affinity caching for NTLM logons from different sites.

**SamNoGcLogonEnforceNTLMCheck**

**Registry path**
**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Lsa**

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003

A value of 1 configures Security Accounts Manager (SAM) to not give site affinity to NTLM logon requests that are network logon requests; it may not prevent caching for other logon types.

**NTDS Diagnostics**
The following registry entry under **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics** control the logging level for the component or process that is specified in the entry name.

**Global Catalog**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server

The logging level for the global catalog on the domain controller. The value is set to an integer from 0 (no logging) through 5 (most verbose logging).

**20 Group Caching**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Diagnostics

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003

The logging level for Universal Group Membership Caching on a domain controller in a site where this feature is enabled. The value is set to an integer from 0 (no logging) through 5 (most verbose logging). Significant events are reported at logging level

2. with many additional events reported at logging level 5.

**Global Catalog Group Policy Settings**

The following table lists and describes the Group Policy settings that are associated with global catalog servers.

**Group Policy Settings Associated with the Global Catalog**

| Group Policy Setting | Description |
|---|---|
| Automated Site Coverage by the DC Locator DNS SRV Records | Determines whether domain controllers will dynamically register DC Locator site-specific SRV resource records for the closest sites where no domain controller for the same domain exists (or no global catalog server for the same forest exists). These DNS records are dynamically registered by the Net Logon service, and they are used to locate domain controllers. |
| Sites Covered by the GC Locator DNS SRV Records | Specifies the sites for which the global catalog servers should register the site-specific GC Locator SRV resource records in DNS. These records are registered in addition to the site-specific SRV resource records registered for the site where the global catalog server resides and, if the global catalog server is appropriately configured, for the sites without a global catalog server in the same forest for which this global catalog server is the closest global catalog server. These records are registered by Net Logon service.<br><br>If this policy is not configured, then it is not applied to any global catalog servers and global catalog servers use their local configuration. |

**Network Ports Used by Global Catalog Servers**

The following table shows the network ports that are used by global catalog servers.

**Port Assignments for Global Catalog Servers**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | | 3268 (global catalog) |
| LDAP | | 3269 (global catalog Secure Sockets Layer [SSL]) |
| LDAP | 389 | 389 |
| LDAP | | 636 (SSL) |
| RPC/REPL | | 135 (endpoint mapper) |
| Kerberos | 88 | 88 |
| DNS | 53 | 53 |
| SMB over IP | 445 | 445 |

# Operations Masters Technical Reference

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**Operations Masters Technical Reference**

Operations masters prevent conflicting updates from being made to the Active Directory® Domain Services (AD DS) directory service database by performing specific tasks that no other domain controllers are permitted to perform. Most updates can be made to AD DS on any domain controller and because they are replicated by using a multimaster replication model, all other domain controllers receive the updates.

| **Note** |
| --- |
| In Windows Server® 2003 and Microsoft Windows® 2000 Server, the directory service is named Active Directory. In Windows Server 2008 R2 and Windows Server 2008 , the directory service is named Active Directory Domain Services. The rest of this topic refers to AD DS, but the information is also applicable to Active Directory. |

However, specific updates, such as password changes, the addition or deletion of a domain or application directory partition, or writing to the AD DS schema, are performed on domain controllers that hold one of five operations master roles to prevent database inconsistencies.

When you install AD DS on the first domain controller in a forest, it automatically assigns five operations master roles to that domain controller. Each of the roles can be transferred to another domain controller at any time.

This subject explains what operations masters are, and how each operations master role functions in Active Directory.

# What are Operations Masters?

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Operations Master Roles
- Operations Master Dependencies
- Related Information

Active Directory Domain Services (AD DS) defines five operations master roles: the schema master, domain naming master, relative identifier (RID) master, primary domain controller (PDC) emulator, and infrastructure master. The domain controllers that hold operations master roles are designated to perform specific tasks to ensure consistency and to eliminate the potential for conflicting entries in the AD DS database.

| **Note** |
| --- |
| In Windows Server® 2003 and Microsoft Windows® 2000 Server, the directory service is named Active Directory. In Windows Server 2008 R2 and Windows Server 2008 , the directory service is named Active Directory Domain Services. The rest of this topic refers to AD DS, but the information is also applicable to Active Directory. |

AD DS is a multimaster enabled database, which provides the flexibility of allowing changes to occur at any domain controller in the forest. However, because it is multimaster enabled, it can also allow conflicting updates that can potentially lead to problems when data is replicated throughout the domain or forest.

The general approach to resolving AD DS replication conflicts is to order all update operations (Add, Modify, Move, and Delete) by assigning a globally unique stamp to the originating update. Each replicated attribute value (or multivalue) is stamped during the originating update and this stamp is replicated with the value. The stamp that is applied during an originating write consists of a version number, a time stamp of when the originating write occurred, and the originating domain controller. Conflicts are resolved by comparing the version number. If two stamps have the same version number, the originating time almost always breaks the tie. In the extremely rare event that the same attribute is updated on two different domain controllers during the same second, the originating domain controller breaks the tie in an arbitrary fashion.

Although this resolution method is acceptable, some changes are too difficult to resolve by using the stamp of the originating update. In such cases, it is best to prevent the conflict from occurring rather than to try to resolve it after it has occurred.

When changes such as the addition or removal of domains to a forest or password changes are made, AD DS performs them in a single-master fashion to prevent conflicting updates from occurring. In a single-master update model, only one domain controller in the entire directory is allowed to process the update. This is similar to the role of a Windows NT PDC, in which the PDC is responsible for processing all updates in a given domain.

AD DS extends the single-master model to include multiple roles that are responsible for different types of updates. AD DS also provides the ability to transfer an operations master role to another domain controller.

- By designating a single domain controller to manage specific tasks, AD DS enhances your ability to avoid conflicts in the directory, ensure consistency of the schema, and to add a domain to, or remove a domain from a forest. Operations masters also maintain interaction between earlier versions of Windows operating systems that do not include AD DS or Active Directory and they maintain consistent group-to-user references across domains.

**Operations Master Roles**

The five operations master roles are assigned automatically when the first domain controller in a given domain is created. Two forest-level roles are assigned to the first domain controller created in a forest and three domain-level roles are assigned to the first domain controller created in a domain.

**Forestwide Operations Master Roles**

The schema master and domain naming master are forestwide roles, meaning that there is only one schema master and one

domain naming master in the entire forest.

**Schema Master**
The schema master is responsible for performing updates to the AD DS schema. The schema master is the only domain controller that can perform write operations to the directory schema. Those schema updates are replicated from the schema master to all other domain controllers in the forest. Having only one schema master for each forest prevents any conflicts that would result if two or more domain controllers attempt to concurrently update the schema.

**Domain Naming Master**
The domain naming master manages the addition and removal of all domains and directory partitions, regardless of domain, in the forest hierarchy. The domain controller that has the domain naming master role must be available in order to perform the following actions:

- Add new domains or application directory partitions to the forest.
- Remove existing domains or application directory partitions from the forest.
- Add replicas of existing application directory partitions to additional domain controllers.
- Add or remove cross-reference objects to or from external directories.
- Prepare the forest for a domain rename operation.

**Domainwide Operations Master Roles**
The other operations master roles are domainwide roles, meaning that each domain in a forest has its own RID master, PDC emulator, and infrastructure master.

**RID Master**
The relative identifier (RID) operations master allocates blocks of RIDs to each domain controller in the domain. Whenever a domain controller creates a new security principal, such as a user, group, or computer object, it assigns the object a unique security identifier (SID). This SID consists of a domain SID, which is the same for all security principals created in the domain, and a RID, which uniquely identifies each security principal created in the domain.

**PDC Emulator**
**The primary domain controller (PDC) emulator operations master**. The PDC emulator receives preferential replication of password changes that are performed by other domain controllers in the domain, and it is the source for the latest password information whenever a logon attempt fails as a result of a bad password. It is a preferred point of administration for services (examples are Group Policy and Distributed File System, DFS). For this reason, of all operations master roles, the PDC emulator operations master role has the highest impact on the performance of the domain controller that hosts that role. The PDC emulator in the forest root domain is also the default Windows Time service (W32time) time source for the forest.

The PDC emulator operations master also processes all replication requests from Windows NT Server 4.0 backup domain controllers (BDCs). It processes all password updates for clients not running Active Directory–enabled client software, plus any other directory write operations.

**Infrastructure Master**
The infrastructure operations master is responsible for updating object references in its domain that point to the object in another domain. The infrastructure master updates object references locally and uses replication to bring all other replicas of the domain up to date. The object reference contains the object's globally unique identifier (GUID), distinguished name and possibly a SID. The distinguished name and SID on the object reference are periodically updated to reflect changes made to the actual object. These changes include moves within and between domains as well as the deletion of the object. If the infrastructure master is unavailable, updates to object references are delayed until it comes back online.

**Operations Master Dependencies**
Domain controllers designated as operations masters have the following dependencies:

**Operations master placement**
Because operations masters are critical to the long-term performance of the directory, they must be available to all domain controllers and desktop clients that require their services. Careful placement of your operations masters becomes more important as you add more domains and sites to build your forest.

By improperly placing operations master role holders, you might prevent clients running Windows NT Workstation 4.0, Windows 95, or Windows 98 without the Active Directory client installed from changing their passwords, or be unable to add

domains and new objects, such as users and groups. You might also be unable to make changes to the schema. In addition, name changes might not properly appear within group memberships that are displayed in the user interface.

As your environment changes, you must avoid the problems associated with improperly placed operations master role holders. Eventually, you might need to reassign the roles to other domain controllers.

Although you can assign the operations master roles to any domain controller, follow these guidelines to minimize administrative overhead and ensure the performance of Active Directory:

- Leave the two forestwide roles on a domain controller in the forest root domain.
- Place the two forestwide roles on a global catalog server.
- Place the three domainwide roles on the same domain controller.
- In a forest that contains multiple domains, do not place the domainwide roles on a global catalog server unless all domain controllers in the domain are also global catalog servers.
- Place the domainwide roles on a higher performance domain controller.
- Adjust the workload of the operations master role holder, if necessary.

**Active Directory replication**
Operations masters replicate changes made on them throughout the domain or forest, depending on whether they hold a domain or forest role. AD DS replication must be working properly in order for the other domain controllers to receive these changes.

**Domain Name System (DNS)**
AD DS requires that DNS is properly designed and deployed so that domain controllers can correctly resolve DNS names of replication partners. If DNS is not working properly, operations masters cannot be contacted to perform their specific domain or forest functions.

**Security**
User rights for designating operations master roles can be set for groups or users in a forest. This allows you to limit or add to the group of default users that can change operations master role holders in a forest or domain. The following user rights are required to change operations master role holders:

- The **Change Schema Master** right is required to transfer or seize the schema master. By default, only members of the Schema Administrators group are assigned this right.
- The **Change Domain Master** right is required to transfer or seize the domain naming master role. Be default, only members of the Enterprise Admins group are assigned this right.
- The **Change PDC** right is required to transfer or seize the PDC emulator role. By default, only members of the Domain Admins group are assigned this right.
- The **Change Infrastructure Master** right is required to transfer or seize the infrastructure master. By default, only members of the Domain Admins group are assigned this right.
- The **Change RID Master** right is required to transfer or seize the RID master role. By default, only members of the Domain Admins group are assigned this right.

# How Operations Masters Work

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Operations Master Protocols
- Operations Master Roles and Functionality
- Role Transfer and Seizure
- Network Ports Used by Operations Masters
- Related Information

Active Directory Domain Services (AD DS) is a multimaster enabled database, which provides the flexibility of allowing changes to the directory to occur at any domain controller. However, some changes, if performed in a multimaster fashion, can cause errors in the AD DS database. For these changes, one domain controller, called an operations master, is assigned to accept requests for such changes. Operations masters perform updates to the directory in a single-master fashion, meaning that only the domain controller assigned to hold the operations master role is allowed to process the update. This single-master update model prevents conflicting updates from being made to the AD DS database.

| **Note** |
| --- |
| In Windows Server® 2003 and Microsoft Windows® 2000 Server, the directory service is named Active Directory. In Windows Server 2008 R2 and Windows Server 2008 , the directory service is named Active Directory Domain Services. The rest of this topic refers to AD DS, but the information is also applicable to Active Directory. |

Five operations masters are assigned to perform specific tasks in an AD DS environment. The schema master and the domain naming master are forestwide roles, meaning that only one of each of these types of operations masters is in a forest. The relative identifier (RID) master, infrastructure master, and primary domain controller (PDC) emulator master are domainwide roles, meaning one of each of these types of operations masters is in each domain in a forest.

Because operation masters are used to perform specific tasks and are important to the performance of the directory, they must be available to all domain controllers and directory clients that require their services.

This section describes the functionality and interactions of each operations master.

**Operations Master Protocols**

Operations masters use the same protocols as other domain controllers. The protocols that package the data sent to and from a domain controller are described in the following table.

**Operations Master Protocols**

| Protocol | Description |
| --- | --- |
| Lightweight directory access protocol (LDAP) | The primary directory service protocol that specifies directory communications. It runs directly over TCP/IP, and it can also run over UDP connectionless transports (UDP access is primarily used by the domain controller Locator process). Clients use LDAP to query, create, update, and delete information that is stored in a directory service over a TCP connection through the TCP port 389. AD DS supports LDAP v2 (RFC 1777) and LDAP v3 (RFC 2251). LDAP v3 is an industry standard that can be used with any directory service that implements the LDAP protocol. LDAP is the preferred and most common way of interacting with AD DS. |

| | |
|---|---|
| Remote procedure call (RPC) | Protocol for replication (REPL), domain controller management communications, and SAM-related communications. RPC is a powerful, robust, efficient, and secure interprocess communication (IPC) mechanism that enables data exchange and invocation of functionality residing in a different process. That different process can be on the same computer, on the local area network (LAN), or across the Internet. |
| Simple mail transfer protocol (SMTP) | Protocol for replication communications when a permanent, "always on" network connection does not exist between two domain controllers. SMTP is used to transport and deliver messages based on specifications in Request for Comments (RFC) 821 and RFC 822. SMTP can replicate configuration, schema, and global catalog replicas only (not writable domain data). |

For more information about AD DS protocols, see "How the Data Store Works."

**Operations Master Roles and Functionality**

Five operations master roles manage single-master operations in AD DS.

Two operations master roles exist in each forest:

- **The schema master**, which governs all changes to the schema.
- **The domain naming master**, which adds and removes domains to and from the forest.

In addition to the two forestwide operations master roles, three operations master roles exist in each domain:

- **The primary domain controller (PDC) emulator**. The PDC emulator processes all replication requests from Microsoft Windows NT 4.0 backup domain controllers and processes all password updates for clients that are not running Active Directory–enabled client software.
- **The relative identifier (RID) master**. The RID master allocates RIDs to all domain controllers to ensure that all security principals have a unique identifier.
- **The infrastructure master**. The infrastructure master for a given domain maintains a list of the security principals from other domains that are members of groups within its domain.

**Schema Master**

The schema master controls all originating updates to the schema. The schema contains the master list of object classes and attributes that are used to create all AD DS objects, such as computers, users, and printers. The domain controller that holds the schema master role is the only domain controller that can perform write operations to the directory schema. These schema updates are replicated from the schema operations master to all other domain controllers in the forest.

**Domain Naming Master**

The domain naming master is a forestwide operations master role because it manages the addition and removal of all directory partitions, regardless of domain, in the forest hierarchy. The domain controller that has the domain naming master role must be available in order to perform the following actions:

- Add or remove domains.
- Add or remove application directory partitions.
- Add or remove cross-reference objects.
- Validate domain rename instructions.

**Add or Remove Domains**

Only the domain controller holding the domain naming master role has the authority to add a new domain. The domain naming master manages this process, preventing multiple domains from joining the forest with the same domain name. When you use the Active Directory Domain Services Installation Wizard to create or remove a child domain, it contacts the domain naming master and requests the addition or deletion. The domain naming master is responsible for ensuring that domain names are unique. If the domain naming master is unavailable, you cannot add domains or remove them from the forest.

**Add or Remove Application Directory Partitions**

Application directory partitions are special partitions that can be created on domain controllers running Windows Server 2003 or later to provide LDAP storage for dynamic data. In Windows 2000 Server, nondomain data is limited to configuration and schema data, which is replicated to every domain controller in the forest. For domain controllers that run Windows Server 2003 or later, application directory partitions provide storage for nondomain, application-specific data that can be replicated to any arbitrary set of domain controllers in the forest — as few or as many as needed by the application that uses the data.

The Domain Name System (DNS) creates and uses application directory partitions by default when it is installed in a forest with domain controllers that run Windows Server 2003 or later. DNS automatically creates two default DNS application directory partitions below the forest root domain in the domain hierarchy, one for the forest (ForestDnsZones) and one for the domain (DomainDnsZones). Thereafter, when you install AD DS to create a new domain in the forest and configure that server to be a DNS server, DNS creates one default application directory partition below the new domain directory partition in the domain hierarchy.

If the domain controller hosting the domain naming operations master role is not running Windows Server 2003 or later, or if it is unavailable, you cannot add or remove application directory partitions from the forest.

**Add or Remove Cross-Reference Objects**

When AD DS is installed to create the first domain controller in a new forest, the schema, configuration, and domain directory partitions are created on the domain controller. At this time, a cross-reference object (class **crossRef**) is created for each directory partition in the Partitions container in the configuration directory partition (CN=partitions,CN=configuration,DC=*forestRootDomain*). Creation of each subsequent directory partition in the forest, either by installing AD DS to create a new domain or by creating a new application directory partition on an existing domain controller, initiates the creation of an associated cross-reference object in the Partitions container.

| **Note** |
| --- |
| You can also manually create a cross-reference object for an application directory partition. |

A cross-reference object identifies the name and server location of each directory partition in the forest. The replication system uses this information to identify servers that store the same directory partitions. LDAP queries use cross-reference objects to create referrals to different domains. If the domain naming master is unavailable, you cannot add or remove cross-reference objects.

**Validate Domain Rename Instructions**

When you use the domain rename tool, rendom.exe, to rename an AD DS domain, the tool must be able to access the domain naming operations master. The domain naming master is the domain controller responsible for validating the instructions that the domain rename tool has generated for the new forest.

Certain changes occur on the domain naming master in preparation for the actual execution of a domain rename. On the domain naming master, the XML-encoded script containing the domain rename instructions is written to the **msDS-UpdateScript** attribute on the Partitions container object (cn=partitions,cn=configuration,dc=*ForestRootDomain*) in the configuration directory partition. The Partitions container can only be updated on the domain controller holding the domain naming operations master role for the forest. Therefore, the **msDS-UpdateScript** attribute must be changed on the domain naming master.

In addition to the **msDS-UpdateScript** attribute value being written to the Partitions container, the new DNS name of each domain being renamed is also written by rendom.exe to the **msDS-DnsRootAlias** attribute on the cross-reference object (class **crossRef**) corresponding to that domain. Again, because cross-reference objects are stored in the Partitions container and the Partitions container can only be updated on the domain naming master, the **msDS-DnsRootAlias** attribute can only be changed on the domain naming operations master.

The domain naming master replicates the script stored in the **msDS-UpdateScript**attribute and the DNS name in the **msDS-DnsRootAlias** attribute to all domain controllers in the forest through scheduled replication of the configuration directory partition.

In preparation of a domain rename operation; rendom.exe uses the domain naming operations master to:

- Retrieve all information needed to compute the list of rename instructions for updating the configuration and schema directory partitions.
- Write the resulting script to the **msDS-UpdateScript** attribute of the Partitions container.
- Change the **msDS-DnsRootAlias** attribute of all cross-reference objects for domains that are being renamed.

- Validate the forest description against the current state of the forest. If any of these validity checks fails, the command fails. The following requirements are verified:
    - Each existing domain is part of the new forest.
    - The new forest is well formed.
    - The new forest does not re-assign domain names that are being relinquished as part of the current domain rename operation.

For more information about domain rename, see "Domain Rename Technical Reference."

**Relative Identifier Master**

The relative identifier (RID) master is a domainwide operations master role. The RID master is responsible for allocating sequences of unique RIDs to each domain controller in its domain and for moving objects from one domain to another.

You can create a new security principal object (user, group, or computer) on any domain controller. When you create a security principal object, the domain controller attaches a unique Security ID (SID) to the object. There are four elements of a domain SID, one of which is the RID for the domain.

The following table describes the elements of the domain **SID: S-1-5-Y1-Y2-Y3-Y4**.

**Elements of a Security Identifier (SID)**

| SID element | Description |
|---|---|
| S-1 | Indicates a revision 1 SID. At this time 1 is the only SID revision in use. |
| 5 | Indicates the issuing agency or issuing authority. A 5 always indicates Windows NT or AD DS domains. Note that a well-known SID may use a 1 or 0 as the issuing identity to signify that it is a well known SID. |
| Y1-Y2-Y3 | The domain identifier portion of the SID. This is the same for every security principal object created in that domain. |
| Y4 | The relative ID (RID) for the domain, which represents a user name or group. This is obtained from the RID pool on a domain controller at the time the object is created. |

**RID Allocation**

Domain controllers running AD DS have a shared RID pool. The RID operations master is responsible for maintaining a pool of RIDs to be used by the domain controllers in its domain and for providing groups of RIDs to each domain controller when necessary. When a new AD DS domain controller is added to the domain, the RID master allocates a batch of approximately 500 RIDs from the domain RID pool to that domain controller. Each time a new security principal is created on a domain controller, the domain controller draws from its local pool of RIDs and assigns one to the new object. When the number of RIDs in a domain controller's RID pool falls below approximately 100, that domain controller submits background requests (by means of RPC) for additional RIDs from the domain's RID master. The RID master allocates a block of approximately 500 RIDs from the domain's RID pool to the pool of the requesting domain controller.

The RID master does not actually maintain a pool of numbers. Rather, it maintains the highest value of the last range it allocated. When a new request is received, it increments that value by one to establish the low value in the new RID pool and then adds four hundred and ninety nine to establish the new maximum value. It sends these two values to the requesting domain controller to use as its next allocation of RIDs.

If a domain controller's local RID pool is empty, and it cannot contact the domain's RID master to request additional RIDs, the domain controller will log event ID 16645, indicating that the maximum account identifier allocated to the domain controller has been assigned and the domain controller has failed to obtain a new identifier pool from the RID master. Likewise, when attempting to add new objects in AD DS, such as users, computers, or domain controllers, you might notice event ID 16650 in the System log indicating that the object cannot be created because the directory service was unable to allocate a relative identifier. Network connectivity to the RID master might have been lost or the RID master might have been removed from the network. In any case, you cannot create new security principal objects on the domain controller until RID pool acquisition is successful.

**Cross-Domain Moves**
Migrating AD DS objects from one domain to another requires the availability of the RID master. You can only move an object out of its domain if the domain's RID master can be contacted. Requiring that objects be moved from one domain to another by using the RID master prevents AD DS from creating two objects in different domains with the same unique identifier. This might happen if one object is moved from two domain controllers simultaneously to two different domains.

You can use the Active Directory Migration Tool (ADMT) to perform intraforest migrations of domain objects from one domain (the source domain) to another (the target domain). The RID master must be online and available in the source domain for ADMT to migrate successfully. If the RID master is unavailable, cross-domain migration of AD DS objects will fail.

**RID Attributes in AD DS**
The following are RID-related attributes in AD DS:

**FsmoRoleOwner**
DN path: CN=RID Manager$,CN=System,DC=<domain>,DC=com

This attribute points to the Domain Name path for the current RID master's NTDS Settings object according to the domain controller that is being queried.

**RidAvailablePool**
DN path: CN=RID Manager$,CN=System,DC=<domain>,DC=com

This attribute defines the global RID space from which RID pools are allocated to the RID master.

**RidAllocationPool**
DN Path: CN=Rid Set,CN=<computername>,OU=domain controllers,DC=<domain>,DC=com

Each domain controller has two RID pools: the one that they are currently allocating from, and the pool that they will use next. This attribute defines the RID pool that will be used in the domain when the current RID pool is exhausted.

**RidNextRid**
DN Path: CN=Rid Set,CN=<computername>,OU=domain controllers,DC=<domain>,DC=com

This attribute defines the next free RID in the current allocation pool that is assigned to the next security principal created on the local domain controller. **RidNextRid** is a non-replicated value in AD DS.

**RidPreviousAllocationPool**
DN Path: CN=Rid Set,CN=<computername>,OU=domain controllers,DC=<domain>,DC=com

This attribute defines the RID pool from which the RID master actually allocates from. The value for **RidNextRid** is implicitly a member of this pool.

**RidUsedPool**
DN Path: CN=Rid Set,CN=<computername>,OU=domain controllers,DC=<domain>,DC=com

This attributed defines the RID pools that have been used by a domain controller.

**NextRid**
DN Path: DC=<domain>,DC=com

This attribute defines the next RID field used by the RID master.

**Primary Domain Controller (PDC) Emulator**
The PDC emulator serves as primary domain controller for compatibility with earlier Windows operating systems. Windows 2000 Server and Windows Server 2003 interoperate with Windows NT workstations, member servers, and backup domain controllers. Windows Server 2008 R2 and Windows Server 2008 domain controllers cannot interoperate with Windows NT domain controllers.

The primary domain controller (PDC) in a Windows NT 3.51 or Windows NT 4.0 domain is responsible for the following:

- Processing password changes from both users and computers
- Replicating updates to backup domain controllers
- Running the Domain Master Browser

Active Directory uses multimaster replication for most directory updates, including password changes. Therefore, if the PDC emulator becomes unavailable, the impact is small. However, in a mixed environment with Windows NT–based domain controllers and Active Directory, the unavailability of the PDC emulator has the following impact:

- When a user of a computer running Windows NT Workstation 4.0, Windows 95, or Windows 98 without the Active Directory client installed attempts a password change, the user sees a message similar to the following: "Unable to change password on this account. Please contact your system administrator."

- In a mixed domain, the event logs of Windows NT 4.0 BDCs contain entries showing failed replication attempts.

- In a mixed domain, when a user tries to start User Manager on a Windows NT 4.0 backup domain controller, it results in a "domain unavailable" error message. If User Manager is already running, you will see an "RPC server unavailable" message. Attempting to create an account by using the **net user /add** command results in a "could not find domain controller for this domain" message. When you run Server Manager, you will see a message similar to the following: "Cannot find the primary domain controller for <*domain name*>. You may administer this domain, but certain domain-wide operations will be disabled."

As operating systems are upgraded, either to Windows 7, Windows Vista, Windows XP, Windows 2000, Windows Server 2003, or (for Windows NT Workstation 4.0, Windows 95, and Windows 98) by installing the Active Directory client, they cease to rely on the PDC and, instead, behave in the following manner:

- Clients do not make password changes at the PDC emulator. Instead, clients update passwords at any domain controller in the domain.

- The PDC emulator does not receive Windows NT 4.0 replication requests after all Windows NT 4.0 BDCs in a domain are upgraded to AD DS.

- Clients use Active Directory to locate network resources. They do not require the Computer Browser service.

In addition, the domain controller holding the PDC emulator role performs the following functions:

- When password changes are performed by other domain controllers in the domain, they are sent to the PDC emulator by using higher priority replication.

- When an authentication fails with an invalid password at other domain controllers in the domain, the authentication request is retried at the PDC emulator before failing. If a recent password update has reached the PDC emulator, the retried authentication request should succeed.

- When an authentication succeeds for an account for which the most recent authentication attempt at the domain controller failed, the domain controller communicates this fact ("zero lockout count") to the PDC emulator. This resets the lockout counter at the PDC emulator in case another client attempts to validate the same account by using a different domain controller.

Therefore, when the PDC emulator is unavailable, you might experience an increase in support requests regarding password difficulties. However, unlike the Windows NT 4.0 environment, where the PDC was the only computer that wrote the updated password to the domain, in AD DS, any domain controller can write the password update to the directory and normal replication will ensure that all domain controllers in the domain eventually become aware of the change. This will occur even if the PDC emulator operations master remains unavailable.

**Windows Server 2003 Well Known Security Principals**

The PDC emulator operations master is responsible for managing well-known security principals. For more information about well-known security principals that are added in Windows Server 2008, see Appendix A: Background Information for Upgrading Active Directory Domains (http://go.microsoft.com/fwlink/?LinkId=192800). The rest of this section covers information about well-known security principals that are added in Windows Server 2003.

When you upgrade your environment from Windows 2000 Server, it is important that you upgrade the PDC emulator early in the upgrade process so that the "CN=WellKnown Security Principals,CN=Configuration,DC=<YourDomain>" container is updated with the well-known security principals that are introduced in Windows Server 2003.

After upgrading the Windows 2000–based domain controller holding the role of the PDC emulator in each domain in the forest to Windows Server 2003, several new well-known and built-in groups are created and some new group memberships are established. If you transfer the PDC emulator role to a Windows Server 2003–based domain controller instead of upgrading it, these groups will be created when the role is transferred. The new well-known and built-in groups are:

- Builtin\Remote Desktop Users
- Builtin\Network Configuration Operators
- Performance Monitor Users
- Performance Log Users
- Builtin\Incoming Forest Trust Builders
- Builtin\Performance Monitoring Users
- Builtin\Performance Logging Users
- Builtin\Windows Authorization Access Group
- Builtin\Terminal Service License Server

The newly established group memberships are:

- If the Everyone group is in the Pre-Windows 2000 Compatible Access group, the Anonymous Logon group and Authenticated Users group are also added to the Pre-Windows 2000 Compatible Access group.
- The Network Servers group is added to the Performance Monitoring Users group.
- The Enterprise Domain Controllers group is added to the Windows Authorization Access group.

In addition, when upgrading the Windows 2000–based domain controller that holds the role of the PDC emulator in the forest root domain, the following additional security principals are created:

- LocalService
- NetworkService
- NTLM Authentication
- Other Organization
- Remote Interactive Logon
- SChannel Authentication
- This Organization

**AdminSDHolder**

The Administrator security descriptor holder protects administrative groups through a background task that computes the set of memberships and checks whether their security descriptors are well-known protected security descriptors. If the security descriptor of any administrative account does not match that of AdminSDHolder, the security descriptor is overwritten with the security descriptor of AdminSDHolder. This task is executed only on the domain controller that holds the primary domain controller (PDC) emulator operations master role.

**DNS and the PDC**

The first domain controller deployed in every domain is automatically assigned the PDC emulator role. During the AD DS installation on this server, Net Logon registers the _ldap._tcp.pdc._msdcs.DnsDomainName DNS SRV resource record that enables clients to locate the PDC emulator. Only the PDC emulator of the domain registers this SRV resource record.

**DFS and the PDC**

When a change is made to a Distributed File System (DFS) domain-based namespace, the change is made on the domain controller that acts as the PDC emulator master. DFS root servers that host domain-based namespaces poll the PDC emulator periodically to obtain an updated version of the DFS metadata, and then they store this metadata in memory. Therefore, if the domain controller that holds the PDC emulator role is not available, DFS will not function properly.

For more information about DFS and the role of the PDC emulator, see "How DFS Works" on the Microsoft Web site at http://go.microsoft.com/fwlink/?LinkId=48186.

**Raising the Domain Functional Level**

The functional level of a domain or forest defines the set of advanced AD DS features that are available in that domain or forest. The functional level of a domain or forest also defines the set of Windows Server operating systems that can run on the domain controllers in that domain or forest.

The PDC emulator is the domain controller targeted when you raise the domain functional level. Therefore, the PDC emulator must be available to raise the domain functional level. For more information domain and forest functional levels, see "Active Directory Functional Levels Technical Reference."

**Infrastructure Master**

The infrastructure master is responsible for updating the group-to-user references whenever the members of groups are renamed or changed within a domain.

For example, suppose you use Active Directory Users and Computers to add a user to a group within a single domain. While still connected to the same domain controller, you can view the group's membership and see the user you just added. If you then rename the user object (that is, change its **CN** attribute) and then display the group membership, you instantly see the user's new name in the list of group members.

However, when the user and group are in different domains, there is a lag between the time when you rename a user object and when a group containing that user displays the user's new name. This time lag is inevitable in a distributed system where sites function independently and must rely on replication for changes to be distributed to all sites.

The domain controller holding the infrastructure master role for the group's domain is responsible for updating the cross-domain group-to-user reference to reflect the user's new name. Periodically, the infrastructure master scans the domain accounts and verifies the membership of the groups. If a user account is moved to a new domain, the infrastructure master identifies the user account's new domain and updates the group accordingly. After the infrastructure master updates these references locally, it uses replication to update all other replicas of the domain. If the infrastructure master is unavailable, these updates are delayed.

**Phantom Records**

Whenever a domain controller contains a reference to an object in another domain, the domain controller's local database contains a phantom record for that object. Within the local database, a reference to the object is represented as the database pointer to (in fact the primary key of) the phantom record.

For example, if a user in domain A is a member of a group in domain B, the local database of a domain controller in domain B, holding the group, contains a phantom record for that user. The group references the user by pointing to the phantom. The infrastructure master is responsible for updating the phantom records in its local database. If the distinguished name of the user in domain A changes, the infrastructure master in domain B is responsible for updating its reference to the user.

Each phantom record in the database contains the referenced object's GUID, its SID (for references to security principals), and its distinguished name. If the referenced object is renamed or moved, its GUID does not change; its SID changes if the move is cross-domain, and its distinguished name always changes.

The infrastructure master periodically examines the phantom records in its local database. It compares the data in a phantom record to the corresponding data on the replica of the referenced object contained in the global catalog. Because global catalog servers receive regular updates for all objects in the forest through replication, the global catalog's data is – allowing for replication latency – always up to date. If the SID or the distinguished name in a phantom record does not match the SID or the distinguished name of the object in the global catalog, then the infrastructure master updates its local database with the values from the global catalog. The infrastructure master then replicates the new values to the other domain controllers in its domain.

A global catalog server holds a complete replica of its own domain and a partial replica of every other domain in the forest. The complete replica of its own domain includes the GUID, SID, and distinguished name of the domain's objects. The partial replica of another domain includes the GUIDs, SIDs, and distinguished names of all the objects in that domain. Because this data exists

in the global catalog server's local database, there are no phantom records representing cross-domain object references on a global catalog server.

Cross-domain object references on a global catalog server are represented in the same way as intradomain references on any domain controller – that is, as a direct pointer to the referenced object. Therefore, if the infrastructure master is running on a global catalog server, it never finds any phantom records representing cross-domain references in its local database. Consequently, the infrastructure master is unable to replicate any updated references to cross-domain objects to any other domain controller in its domain. For this reason, the infrastructure master should never run on a global catalog server in a forest that contains multiple domains.

If every domain controller in a domain is a global catalog server, then no domain controller in the domain has any phantom records that need to be updated. In this case, the infrastructure master has no work to do and remains in a dormant state.

For more information about phantom records, see "How the Data Store Works" in this collection.

**Role Transfer and Seizure**

You can reassign an operations master role by transfer or, as a last resort, by seizure.

Role transfer is the preferred method to move an operations master role from one domain controller to another. When an operations master role is transferred, the previous role holder replicates its most recent updates to the new role holder to ensure that no information is lost. After the transfer completes, the previous role holder reconfigures itself so that it no longer attempts to perform as the operations master while the new domain controller assumes those duties. This prevents the possibility of duplicate operations masters existing on the network at the same time, which can lead to inconsistencies in the directory.

Role seizure should be used only as a last resort to forcibly remove an operations master role from one domain controller and assign the role to a different domain controller. Use this process only when the previous operations master fails and remains out of service for an extended period of time. For more information about the ramifications of roles seizure, see Seizing Operations Master Roles.

During a role seizure, the domain controller that assumes the operations master role does not verify that replication is updated, so recent changes can be lost. Because the previous role holder is unavailable during the role seizure, it cannot know that a new role holder exists. If the previous role holder comes back online, it assumes that it is still the operations master. This can result in duplicate operations master roles on the network, which can lead to corruption of data in the directory.

**Transferring Operations Master Roles**

To transfer a role to a new domain controller, ensure that replication is up to date and functioning properly between the domain controller you are transferring the role from and the domain controller assuming the new role. This minimizes the time required to complete the role transfer. If replication is sufficiently out of date, the transfer process will take longer.

When an operations master role is transferred from one domain controller to another, the original role holder checks that all recent updates have been replicated to the new role holder. In the event that you must transfer an operations master role, it is best to transfer the role to a domain controller located in the same site as the original role holder. Changes made by the original role holder will replicate during the next replication cycle. Therefore, domain controllers located in the same site are likely to have the most recent information from the original operations master role holder.

If the new role holder is not located in the same site, changes might still need to replicate before the role transfer completes (this occurs during the role transfer process). If the new role holder is in the same site, it is more likely that the changes are already replicated, eliminating the need to replicate a large amount of changes during the role transfer process. This can significantly decrease the time required to transfer the role.

**Operational Attributes Used to Transfer Roles**

Not all attribute values are stored in a directory service. Instead, attribute values that are not contained in the directory can be calculated when a request for the attribute is made. This type of attribute is called an operational attribute. Note that this type of attribute is defined in the schema but it does not contain a value in the directory. Instead, the domain controller that processes a request for an operational attribute calculates the attribute's value to answer the client request.

The following operational attributes are used to transfer operations master roles and are located on the rootDSE (or root DSA-specific entry, the root of the AD DS tree for a given domain controller where specific information about the domain controller is kept):

- becomeRidMaster
- becomeSchemaMaster

- becomeDomainMaster
- becomePDC
- becomeInfrastructureMaster

During the operation of writing to the appropriate operational attribute on the domain controller that is receiving the operations master role, the role is removed from the old domain controller and is assigned to the new domain controller automatically. No manual intervention is required.

**Decommissioning a Role Holder**
When you use the Active Directory Domain Services Installation Wizard to decommission a domain controller that currently holds one or more operations master roles, the wizard reassigns the roles to a different domain controller. When the wizard is run, it determines whether the domain controller currently holds any operations master roles. If it detects any operations master roles, it queries the directory for other eligible domain controllers and transfers the roles to a new domain controller. A domain controller is eligible to hold a domainwide role if it is a member of the same domain. A domain controller is eligible to hold a forestwide role if it is a member of the same forest.

You cannot control which domain controller the wizard chooses and the wizard does not indicate which domain controller receives the roles. Because of this behavior, it is best to transfer the roles prior to decommissioning the role holder so that you have control over which new domain controller will hold the role.

**Operational Attributes Used to Decommission a Role Holder**
If you do not transfer operations master roles before demoting a domain controller, the **GiveAwayAllFsmoRoles** operational attribute is written, which triggers the domain controller to locate other domain controllers to transfer any roles it currently owns. AD DS determines which roles the domain controller being decommissioned currently owns and locates a suitable domain controller to assume these roles by following these rules:

- Locate a server in the same site
- Locate a server to which there is RPC connectivity
- Use a server over an asynchronous transport such as SMTP

In all role transfers, if the role is a domain-specific role, the role can be moved only to another domain controller in the same domain. Otherwise, any domain controller in the forest is a candidate.

**Seizing Operations Master Roles**
Role seizure is the act of assigning an operations master role to a new domain controller without the cooperation of the current role holder. During role seizure, a new domain controller assumes the operations master role without communicating with the current role holder. Because this can adversely affect your AD DS environment, seize operations master roles only as a last resort and if the current role owner is offline and unlikely to return to service.

Role seizure can create two conditions that can cause problems in the directory. First, the new role holder starts performing its duties based on the data located in its current directory partition. If replication did not complete prior to the time when the original role holder went offline, the new role holder might not receive changes that were made to the previous role holder. This can cause data loss or data inconsistency in the directory database.

To minimize the risk of losing data to incomplete replication, do not perform a role seizure until enough time has passed to complete at least one complete end-to-end replication cycle across your network. Allowing enough time for complete end-to-end replication ensures that the domain controller that assumes the role is as up-to-date as possible.

Second, the original role holder is not informed that it is no longer the operations master role holder, which is not a problem if the original role holder stays offline. However, if it comes back online (for example, if the hardware is repaired or the server is restored from a backup), it might try to perform the operations master role that it previously owned. This can result in two domain controllers performing the same operations master role simultaneously. Depending on the role that was seized, the severity of duplicate operations master roles varies from no visible effect to potential corruption of the AD DS database. Seize the operations master role to a domain controller that has the most recent updates from the current role holder to minimize the impact of the role seizure.

In Windows 2000 Server with Service Pack 3 (SP3) or later and Windows Server 2003 or later, if an operations master that has been taken offline is intentionally or unintentionally returned to service, it must successfully replicate inbound changes on the

directory partition that replicates and maintains that operations master state before resuming its previously held role. The directory partitions that maintain each operations master are defined in the following table.

**Operations Masters and Corresponding Directory Partitions**

| Operations Master Role | Directory Partition |
|---|---|
| Schema Master | Schema partition |
| Domain Naming Master | Configuration partition |
| Primary Domain Controller (PDC) Emulator | Domain partition for the operations master role owner's domain |
| RID Master | Domain partition for the operations master role owner's domain |
| Infrastructure Master | Domain partition for the operations master role owner's domain |

By waiting a full replication cycle, the domain controller can determine if another operations master exists before it brings itself back online. Successful replication must occur before dependent operations can be performed. When the previous role holder receives the current environmental state from another replica through inbound replication, it will update its copy of the database so that it no longer hosts the role in question. This is to prevent more than one domain controller from holding the same operations master role in each domain or forest.

Operations master roles that are hosted by a single domain controller in that role's domainwide or forestwide replication scope do not have to satisfy the initial synchronization requirement because the domain controller has no replication partners. Initial synchronization requirements only exist when a current operations master role owner's **hasMasterNC** attribute contains references to more than one domain controller. The **hasMasterNC** attribute is part of a domain controller's NTDS settings object in the CN=configuration partition of an operations master.

**Ramifications of Role Seizure**

If a role is seized, the new role holder is configured to host the operations master role with the assumption that you do not intend to return the previous role holder to service. Use role seizure only when the previous role holder is not available and you need the operations master role to keep the directory functioning. Because the previous role holder is not available during a seizure, you cannot reconfigure the previous role holder and inform it that another domain controller is now hosting the operations master role.

To reduce risk, perform a role seizure only if the missing operations master role unacceptably affects performance of the directory. Calculate the effect by comparing the impact of the missing service provided by the operations master to the amount of work that is needed to bring the previous role holder safely back online after you perform the role seizure.

AD DS continues to function when the operations master roles are not available. If the role holder is offline only for a short period, you might not need to seize the role to a new domain controller. Remember that returning an operation master to service after the role is seized can have dire consequences if it is not done properly. The following table shows the consequences of an unavailable operations master role and restoring a role holder after the role has been seized.

**Operations Master Role Functionality Risk Assessment**

| Operations Master Role | Consequences if Role is Unavailable | Risk of Improper Restoration | Recommendation for Returning to Service After Seizure |
|---|---|---|---|
| Schema master | You cannot make changes to the schema. | Conflicting changes can be introduced to the schema if both schema masters attempt to modify the schema at the same time. This can result in a fragmented schema. | Not recommended. Can lead to a corrupted forest. |
| Domain naming master | You cannot add or remove domains from the forest, add or remove application directory partitions, or perform domain rename operations. | You cannot add or remove domains or application directory partitions, or clean-up metadata. Domains and application directory partitions might appear as though they are still in the forest even though they are not. | Not recommended. Can lead to data corruption. |

| | | | |
|---|---|---|---|
| PDC emulator | You cannot change passwords on clients that do not have Active Directory client software installed. No replication to Windows NT 4.0 backup domain controllers. | Password validation can randomly pass or fail. Password changes take much longer to replicate throughout the domain. | Allowed. User authentication can be erratic for a time, but no permanent damage occurs. |
| Infrastructure master | Delays displaying updated group membership lists in the user interface when you move users from one group to another within a single domain. | Displays incorrect user names in group membership lists in the user interface after you move users from one group to another. | Allowed. May impact the performance of the domain controller hosting the role, but no damage occurs to the directory. |
| RID master | Eventually, domain controllers cannot create new directory objects as each of their individual RID pools is depleted. | Duplicate RID pools can be allocated to domain controllers, resulting in data corruption in the directory. This can lead to security risks and unauthorized access. | Not recommended. Can lead to data corruption. |

**Operational Attributes Used to Seize Roles**

When you seize an operations master role from an existing computer, the **fsmoRoleOwner** attribute is modified on the object that represents the root of the data directly, bypassing synchronization of the data and graceful transfer of the role.

The **fsmoRoleOwner** attribute of each of the following objects is written with the distinguished name of the NTDS Settings object (the data in AD DS that defines a computer as a domain controller) of the domain controller that is taking owner'ship of that role:

**Schema master**

LDAP://CN=Schema,CN=Configuration,DC=Contoso,DC=Com

**Domain naming master**

LDAP://CN=Partitions,CN=Configuration,DC=Contoso,DC=Com

**RID master**

LDAP://CN=Rid Manager$,CN=System,DC=Contoso,DC=Com

**PDC emulator**

LDAP://DC=Contoso,DC=Com

**Infrastructure master**

LDAP://CN=Infrastructure,DC=Contoso,DC=Com

As replication of this change starts to spread, other domain controllers learn of the operations master role change.

For example, if Server1 is the PDC emulator in the Contoso.com domain and is decommissioned and the administrator is unable to decommission the computer properly, Server2 needs to be forcibly assigned the PDC emulator role. After the role is seized, the value

CN=NTDS Settings,CN=Server2,CN=Servers,CN=Default-First-Site-Name,CN=Sites,CN=Configuration,DC=Contoso,DC=Com

is present on the LDAP://DC=Contoso,DC=com object.

**Network Ports Used by Operations Masters**

The following ports are used by all domain controllers.

### Port Assignments for Operations Masters

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |
| LDAP | | 686 (Secure Sockets Layer [SSL]) |
| RPC/REPL | | 135 (endpoint mapper) |
| NetLogon | | 137 |

| | | |
|---|---|---|
| Kerberos | 88 | 88 |
| DNS | 53 | 53 |
| SMB over IP | 445 | 445 |

- Network Ports Used by Operations Masters
- Related Information

**Operations Masters Tools**

Tools that are associated with operations masters are the same tools that you use to manage any domain controller.

The following tools have commands that are specific to managing operations masters.

**Domain.msc: Active Directory Domains and Trusts**

**Category**

An Active Directory Domain Services (AD DS) Administrative Tools Microsoft Management Console (MMC) snap-in that is automatically installed on all domain controllers running Windows Server 2008 R2, Windows Server 2008, and Windows Server 2003. It is also available if you install the Active Directory Domain Services Tools that are part of the Remote Server Administration Tools (RSAT). For more information, see How to Administer Microsoft Windows Client and Server Computers Locally and Remotely (http://go.microsoft.com/fwlink/?LinkID=177813).

| **Note** |
| --- |
| In Windows Server® 2003 and Microsoft Windows® 2000 Server, the directory service is named Active Directory. In Windows Server 2008 R2 and Windows Server 2008, the directory service is named Active Directory Domain Services. The rest of this topic refers to AD DS, but the information is also applicable to Active Directory. |

**Version compatibility**

| Can Be Run From | Can Be Run Against |

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows 7 with Remote Server Administration Tools (RSAT) installed.<br>• Windows Vista with Remote Server Administration Tools (RSAT) installed.<br>• Windows XP Professional with Adminpak.msi installed[1] | Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

1. To run the Windows Server 2003 Administration Tools Pack (Adminpak.msi) on a computer that is running Windows XP Professional, Windows XP Home Edition, or Windows XP 64-Bit Edition Version 2003, Windows XP Service Pack 1 (SP1) must be installed.

Active Directory Domains and Trusts provides a graphical interface in which you can view and manage all domains in the forest.

Use this tool to transfer the role of the domain naming master to another computer in the forest. You must be a member of the Domain Admins group (in the forest root domain) or the Enterprise Admins group, or you must have been delegated the appropriate authority to transfer this operations master role. For more information about the specific rights that are required to transfer specific operations master roles, see "What are Operations Masters?."

**Dsa.msc: Active Directory Users and Computers**

**Category**
An Active Directory Administrative Tools Microsoft Management Console (MMC) snap-in that is automatically installed on all domain controllers running Windows Server 2008 R2, Windows Server 2008, and Windows Server 2003. It is also available if you install the Active Directory Domain Services Tools that are part of the Remote Server Administration Tools (RSAT). For more information, see How to Administer Microsoft Windows Client and Server Computers Locally and Remotely (http://go.microsoft.com/fwlink/?LinkID=177813).

1. To run the Windows Server 2003 Administration Tools Pack (Adminpak.msi) on a computer that is running Windows XP Professional, Windows XP Home Edition, or Windows XP 64-Bit Edition Version 2003, Windows XP Service Pack 1 (SP1) must be installed.

Active Directory Users and Computers provides a graphical user interface that can be used to manage users and computers in AD DS domains.

Use this tool to transfer the role of the RID master, the PDC emulator, and the Infrastructure master to another computer in the domain. You must be a member of the Domain Admins group or the Enterprise Admins group, or you must have been delegated the appropriate authority to transfer these operations master roles. For more information about the specific rights that are required to transfer specific operations master roles, see "What are Operations Masters?."

**schmmgmt.msc: Active Directory Schema**

**Category**
An Active Directory Administrative Tools Microsoft Management Console (MMC) snap-in that is automatically installed on all domain controllers running Windows Server 2008 R2, Windows Server 2008, and Windows Server 2003. It is also available if you install the Active Directory Domain Services Tools that are part of the Remote Server Administration Tools (RSAT). For more information, see How to Administer Microsoft Windows Client and Server Computers Locally and Remotely (http://go.microsoft.com/fwlink/?LinkID=177813).

# Active Directory Replication Technologies

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

Active Directory is a distributed directory service that stores objects that represent real-world entities such as users, computers, services, and network resources. Objects in the directory are distributed among all domain controllers in a forest, and all domain controllers can be updated directly. Active Directory replication is the process by which the changes that originate on one domain controller are automatically transferred to other domain controllers that store the same data.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

**Active Directory Replication Model**

The replication model comprises the mechanisms that support the multimaster update capabilities of Active Directory domain controllers. To ensure that replication data is transferred efficiently in the multimaster system, domain controllers track the changes that they have received and request only the updates that have occurred since the last replication. The update tracking is based on the state of the data as it exists on a replicating pair of domain controllers at the time of replication. Update tracking ensures that:

- Only changes that have not been received are replicated to a destination.
- Conflicts are resolved according to the last change that occurred, even when individual domain controller clocks are not synchronized or when administrators at different domain controllers make changes to the same object.

The replication model also accommodates multimaster updates by enabling replicated changes to be stored on destination domain controllers and forwarded to other domain controllers. This store-and-forward capability removes the need for every domain controller on which updates originate to contact every other domain controller that requires the updates.

**Active Directory Replication Topology**

The replication topology is the current set of Active Directory connections by which domain controllers in a forest communicate over local area networks (LANs) and wide area networks (WANs) to synchronize the directory partition replicas that they have in common. The replication topology ensures the transfer of changes to all directory partition replicas in the forest without redundancy. Replication topology generation is dynamic and adapts to network conditions and availability of domain controllers.

To ensure a consistent replication topology, domain controllers use global configuration data to arrive at the same view of domain controller data. They apply the same algorithm to this data to arrive at an identical replication topology. Operating independently, each domain controller contributes to a uniform and efficient replication topology.

Replication topology generation is optimized for speed within sites and for cost between sites. Replication between domain controllers in the same site occurs automatically in response to changes and does not require administrative management. Replication within a site is sent uncompressed to reduce processing time. Replication between domain controllers in different sites can be managed to control the scheduling and routing of replication over WAN links. Replication between sites is compressed so that it uses less bandwidth when sent across WAN links, thereby reducing the cost.

# Active Directory Replication Model Technical Reference

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**Active Directory Replication Model Technical Reference**

The Active Directory directory service replication model ensures that Active Directory data on one domain controller is consistent with the replica of the same data on other domain controllers in the same domain. The Active Directory replication model determines how changes to Active Directory data are propagated and tracked automatically between domain controllers. The replication model allows directory data on each domain controller to be updated directly. Each domain controller maintains replication metadata that indicates the update status both for itself and relative to other domain controllers. In addition, the replication model allows each domain controller to request (pull) only changes that need to be replicated and to forward changes to other domain controllers that need them.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

# What Is the Active Directory Replication Model?

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**What Is the Active Directory Replication Model?**

**In this section**

- Replication Model Components
- Technologies Related to Active Directory Replication
- Active Directory Replication Dependencies
- Related Information

Active Directory replication is the means by which changes to directory data are transferred between domain controllers in an Active Directory forest. The Active Directory replication model defines the mechanisms that allow directory updates to be transferred automatically between domain controllers to provide a seamless replication solution for the Active Directory distributed directory service.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

**Note**

- This discussion of the replication model and related mechanisms for transferring directory data between domain controllers does not include the topic of replication topology. Replication topology is the set of connections that are generated by the Knowledge Consistency Checker (KCC) to enable replication to take place between domain controllers.

Active Directory is distributed by means of directory partitions. In addition to directory partitions that store forest-wide data, each domain controller stores a replica of a single domain directory partition, which contains data that is specific to one or more closely aligned business units—the users, computers, organizational units, and network resources that are managed by the same set of service and data administrators. Because each domain controller stores only one domain directory partition, Active Directory can scale to hundreds or thousands of domains storing millions of objects.

To efficiently synchronize data between domain controllers that store the same domain, Active Directory replication transfers updates according to directory partition. Each domain controller receives directory updates to the data that is stored in its domain only, as well as updates that are stored in the two directory partitions that store configuration and schema data for the forest.

**Note**

- In Windows Server 2003 forests, domain controllers can also store application directory partitions, which store application data that can be replicated to only the domain controllers that store the directory partition, irrespective of domain.

Active Directory replication manages the transfer of these updates to the appropriate domain controllers automatically, keeping domain data up-to-date among all domain controllers in the domain, regardless of location. In the process, all domain controllers in the forest are also updated with changes to forest-wide data.

**Replication Model Components**

To globally distribute the directory service, the Active Directory replication model incorporates the components in the following table.

**Replication Model Components and Advantages**

| Component | Description | Advantage |
|---|---|---|
| Multimaster replication | Every domain controller can receive originating updates to data for which it is authoritative, rather than having a single domain controller that receives all original updates (single-master replication, such as Windows NT 4.0 replication). | Provides fault tolerance, eliminating the dependency on a single domain controller to maintain directory operations. |
| Pull replication | Domain controllers request (pull) changes rather than send (push) changes that might not be needed. | Reduces unnecessary network traffic. |
| Store-and-forward replication | Each domain controller communicates with a subset of domain controllers to transfer replication changes, rather than one domain controller being responsible for communicating with every other domain controller that requires the change. | Balances the replication load among many domain controllers. |
| State-based replication | Each domain controller tracks the state of replication updates. | Conflicts and unnecessary replication are reduced. |

The Active Directory replication model ensures:

- **Domain controller availability.** Multimaster replication ensures that all domain controllers are available for updates, eliminating the potential for slow service if only a single updatable domain controller were available.

- **Efficient transfer of data.** State-based and pull replication ensures the minimum replication traffic and the maximum efficiency to retrieve only the changes that are needed.

- **Reliable consistency.** Directory consistency is guaranteed within the same period of replication latency.

- **Conflict resolution.** Even if two administrators change the same attribute on different domain controllers at the same time, conflict resolution ensures that only one of the values is replicated to all domain controllers.

**Replication Latency**

Multimaster replication involves *latency* — the period of time for an update that occurs on the originating domain controller to reach all other domain controllers that need it. To address replication latency, multimaster replication ensures *loose consistency* with *convergence*, as follows:

- *Loose consistency* means that the replicas are not guaranteed to be consistent with each other at any particular point in time because changes can originate from any replica at any time.

- *Convergence* means that if the system is allowed to reach a steady state in which no new updates are occurring and all previous updates have been completely replicated, all replicas of the same directory partition are guaranteed to converge on the same set of values.

With multimaster replication, it is not necessary for every domain controller to replicate with every other domain controller. Instead, the system implements a robust set of connections that determines which domain controllers replicate to which other domain controllers to ensure that networks are not overloaded with replication traffic and that replication latency is not so long that it inconveniences users. The set of connections through which changes are replicated to domain controllers in an enterprise is called the *replication topology*.

Although it involves latency, multimaster update capability provides high availability of write access to directory objects because several servers can contain writable copies of an object. Each domain controller in the domain can accept updates independently, without communicating with other domain controllers. Active Directory replication resolves any conflicts that occur when multiple updates are made to a single directory object.

**State-based Vs. Log-based Replication**

In state-based replication, each domain controller (master) in the multimaster system applies updates to its replica as they arrive, without maintaining a change log file. In a typical log-based replication system (also called “change-based”), each master keeps a log of the updates that it originated and communicates its log to every other replica. After a log has arrived at a replica, the replica applies the log, bringing itself more up-to-date. In this process, the destination receives and stores a record

of all changes, not just the changes it needs.

Active Directory replication relies on the current "state" (the current values of all objects) of the source replica instead of logs. The current state includes metadata that is used to resolve conflicts and to avoid sending the full replica on each replication cycle.

Generally speaking, a directory partition replica maintains all of its objects in a list ordered by last modification. This list is a log of sorts, but one whose size is a tiny fraction of the size of the replica itself. A typical replication request can be satisfied by examining only the last few objects on the list because the replication destination server is aware of how much of its replication source's list of changes have already been processed.

**Multimaster Vs. Single-master Replication**
Although a single-master model is adequate for a directory that has a small number of replicas and for an environment where all of the changes can be applied centrally, this approach does not scale beyond small organizations nor does it address the needs of decentralized organizations.

Multimaster replication provides the following advantages over single-master replication:

- If one domain controller becomes inoperable, other domain controllers can continue to update the directory. In single-master replication, if the master becomes inoperable, directory updates cannot take place. For example, if the failed server holds your password and your password has expired, you cannot reset your password and therefore you cannot log on to the domain.

- Servers that are capable of making changes to the directory can be distributed across the network and can be deployed in multiple locations.

- By creating multiple replicas of the directory and keeping the replicas consistent, the directory service can handle more queries per second. Directory services must handle a large number of queries compared to the number of updates they must process. A typical ratio of queries to updates is 99:1.

**Pull Vs. Push Replication**
In push replication, a source domain controller sends unsolicited information to update a destination domain controller. Push replication is problematic because it is difficult for the source to know what information the destination needs. The destination can receive the same information from another source. Therefore, a source can send unnecessary information to a destination.

**Technologies Related to Active Directory Replication**
File Replication service (FRS) is related to Active Directory replication because it requires the Active Directory replication topology. FRS is a multimaster replication service that is used to replicate files and folders in the System Volume (SYSVOL) shared folder on domain controllers and in Distributed File System (DFS) shared folders. FRS works by detecting changes to files and folders and then replicating the updated files and folders to other replica members, which are connected in a replication topology.

FRS uses the replication topology that is generated by the KCC to replicate the SYSVOL files to all domain controllers in the domain. SYSVOL files are required by all domain controllers for Active Directory to function. For more information about FRS and how it uses the Active Directory replication topology, see "FRS Technical Reference." For more information about SYSVOL, see "Data Store Technical Reference." For more information about DFS, see "DFS Technical Reference."

**Active Directory Replication Dependencies**
Active Directory replication has the following dependencies:

- **DNS**. The Domain Name System (DNS) that resolves DNS names to IP addresses. Active Directory requires that DNS is properly designed and deployed so that domain controllers can correctly resolve DNS names of replication partners.

- **Remote procedure call (RPC)**. Active Directory replication requires IP connectivity and the Remote Procedure Call (RPC) to transfer updates between replication partners.

- **Kerberos v5 authentication**. The authentication protocol for both authentication and encryption that is required for all Active Directory RPC replication.

- **LDAP protocol**. The primary access protocol for Active Directory. Replication of an entire replica of an Active Directory domain, as occurs when Active Directory is installed on an additional domain controller in an existing domain, uses LDAP communication rather than RPC.

The following diagram shows the interaction of these components within the replication process.

**Replication Interactions with Other Technologies**

# How the Active Directory Replication Model Works

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**How the Active Directory Replication Model Works**

**In this section**

- Active Directory Replication Model Architecture
- Active Directory Replication Model Physical Structure
- Active Directory Data Updates
- Domain Controller Notification of Changes
- Identifying and Locating Replication Partners
- Urgent Replication
- Network Ports Used by Active Directory Replication
- Related Information

Active Directory data takes the form of objects that have properties, or attributes. Each object is an instance of an object class, and object classes and their respective attributes are defined in the Active Directory schema. The values of the attributes define the object, and a change to a value of an attribute must be transferred from the domain controller on which it occurs to every other domain controller that stores a replica of that object.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

Thus, Active Directory replicates directory data updates at the attribute level. In addition, updates from the same directory partition are replicated as a unit to the corresponding replica on the destination domain controller over the same connection to optimize network usage.

The information in this section applies to organizations that are designing, deploying, or operating an Active Directory infrastructure that satisfies the following requirements:

- A Domain Name System (DNS) infrastructure is in place that manages the name resolution for domain controllers in the forest. Active Directory-integrated DNS is assumed, wherein DNS zone data is stored in Active Directory and is replicated to all domain controllers that are DNS servers.
- All Active Directory sites have local area network (LAN) connectivity.
- IP connectivity is available between all datacenter locations and branch sites.

The limits for data that can be replicated in one replication cycle are as follows:

- Values that can be transferred in one replication cycle (replication of the current set of updates between a source and destination domain controller): no limit.
- Values that can be transferred in one replication packet: approximately 100. Replication exchanges continue during the

course of one replication cycle until no values are left to send.

- Values that can be written in a single database transaction: 5,000. The effect of this limit depends on the forest functional level:

    - Windows 2000 forest functional level: The minimum unit of replication at this level is the entire attribute. Therefore, changes to any value in the linked, multivalued **member** attribute results in replicating the entire attribute. For this reason, the supported size of group membership is limited to 5,000.

    - Windows Server 2003 or Windows Server 2003 interim forest functional level: The minimum unit of replication is a single value of a linked, multivalued attribute. Therefore, the limitation on group membership is effectively removed.

This section covers the interactions that take place between individual domain controllers to synchronize directory data in an Active Directory forest.

**Active Directory Replication Model Architecture**
Active Directory replication operates within the directory service component of the security subsystem. The directory service component, Ntdsa.dll, is accessed through the Lightweight Directory Access Protocol (LDAP) network protocol and LDAP C application programming interface (API) for directory service updates, as implemented in Wldap32.dll. The updates are transported over Internet Protocol (IP) as packaged by the replication remote procedure call (RPC) protocol. Simple Mail Transfer Protocol (SMTP) can also be used to prepare non-domain updates for Transmission Control Protocol (TCP) transport over IP.

The Directory Replication System (DRS) client and server components interact to transfer and apply Active Directory updates between domain controllers.

When SMTP is used for the replication transport, Ismserv.exe on the source domain controller uses the Collaborative Data Object (CDO) library to build an SMTP file on disk with the replication data as the attached mail message. The message file is placed in a queue directory. When the mail is scheduled for transfer by the mail server application, the SMTP service (Smtpsvc) delivers the mail message to the destination domain controller over TCP/IP and places the file in the drop directory on the destination domain controller. Ismserv.exe applies the updates on the destination.

The following diagram shows the client-server architecture for replication clients and LDAP clients.

**Replication and LDAP Client-Server Architecture**

The following table describes the replication architecture components.

**Replication Architecture Components**

| Component | Description |
|---|---|
| Ntdsapi.dll | Manages communication with the directory service over RPC. |
| Private DRS client | Private version of Ntdsapi.dll that runs on domain controllers to make RPC calls for replication. |
| Wldap32.dll | Client library with APIs for access to directory service. |
| Asn.1 | Encodes and decodes LDAP requests for transport over TCP/IP or UDP/IP. |
| Drs.idl | Set of functions for replication (for example, Get-Changes) and maintenance (for example, Get replication status) |
| MAPI (address book) | Entry protocol for address book applications such as Microsoft Outlook. |
| Domain rename | Carries out domain rename instructions. |
| Ntdsa.dll | The directory service module, which supports the Windows Server 2003 and Windows 2000 replication protocol and LDAP, and manages partitions of data. |
| ISMServ.exe | Prepares replication data in e-mail message format for SMTP protocol transport. |
| CDO library | Used by Ismserv.exe to package replication data into a mail message. |
| Smtpsvc | SMTP service. |

**Note**

- If Windows NT 4.0 backup domain controllers (BDCs) are operating in the forest, Windows NT4 Net APIs provide an entry to the security accounts manager (SAM) on the primary domain controller (PDC) emulator.

The protocols that are used by Active Directory replication are described in the following table. RPC and SMTP are the replication transport protocols. LDAP is a directory access protocol, and IP is a network wire protocol.

**Active Directory Access and Replication Protocols**

| Protocol | Description |
|---|---|
| LDAP | The primary directory access protocol for Active Directory. Windows Server 2003 family, Windows XP, Windows 2000 Server family, and Windows 2000 Professional clients, as well as Windows 98, Windows 95, and Windows NT 4.0 clients that have the Active Directory client components installed, use LDAP v3 to connect to Active Directory. |
| IP | Routable protocol that is responsible for the addressing, routing, and fragmenting of packets by the sending node. IP is required for Active Directory replication. |
| Replication RPC | The Directory Replication Service (Drsuapi) RPC protocol, used in the enabling of administration and monitoring of Active Directory replication, to communicate replication status and topology and network topology from a client running administrative tools to a domain controller. RPC is required by Active Directory replication. |
| Replication Simple Mail Transfer Protocol (SMTP) | Replication protocol that can be used by Active Directory replication over IP network transport for message-based replication between sites only and for non-domain replication only. |

**Replication Subsystem**

Within the directory service component of the Active Directory architecture, the replication subsystem interacts with the operational layer to implement replication changes on the destination domain controller. The replication subsystem also determines the changes that a replication partner already has or those that are needed.

The database layer manages the database capability of the directory service. The extensible storage engine (Esent.dll) communicates directly with individual records in the directory data store.

The following diagram shows the replication subsystem components.

**Replication Subsystem Components**

The components of the replication subsystem are described in the following table.

**Replication Subsystem Components**

| Component | Description |
|---|---|
| Ntdsa.dll | Directory system agent (DSA), which provides the interfaces through which directory clients and other directory servers gain access to the directory database. |
| Replication | Directory Replication System (DRS) interface, which communicates with the database through RPC. |
| Operational layer | Performs low-level operations on the database without regard for protocol. |
| Database layer | API that resides within Ntdsa.dll and provides an interface between applications and the directory database to protect the database from direct interaction with applications. |

| | |
|---|---|
| Extensible storage engine (ESE) | Manages the tables of records, each with one or more columns that comprise the directory database. |
| Ntds.dit | The directory database file. |

**Active Directory Replication Model Physical Structure**

The Active Directory replication model components that determine how Active Directory replication functions between domain controllers are associated with mechanisms that effect automatic transfer of changes between replicating domain controllers, as described in the following table.

**Active Directory Replication Model Components and Related Mechanisms**

| Component | Description | Related Mechanisms |
|---|---|---|
| Multimaster replication | All domain controllers accept LDAP requests for changes to attributes of Active Directory objects for which they are authoritative, subject to security constraints that are in place. Each originating update is replicated to one or more other domain controllers, which record it as a replicated update. | LDAP update<br><br>Directory partitions<br><br>Change notification<br><br>Change tracking<br><br>Conflict resolution |
| Pull replication | When an update occurs on a domain controller, it notifies its replication partner. The partner domain controller responds by requesting (pulling) the changes from the source domain controller. | DNS name resolution<br><br>Kerberos authentication<br><br>Change tracking<br><br>Change notification<br><br>Change request |
| Store-and-forward replication | Domain controllers store changes received from replication partners and forward the changes to other domain controllers so that the originating domain controller for each change is not required to transfer changes to every other domain controller that requires the change. | Change tracking<br><br>Kerberos authentication<br><br>DNS name resolution<br><br>Change notification<br><br>Change request |

| | | |
|---|---|---|
| State-based replication | Active Directory replication is driven by the difference between the current "state" (the current values of all attributes) of the directory partition replica on the source and destination domain controllers. This state includes metadata that is used to resolve conflicts and to avoid sending the full replica on each replication cycle. | Change-tracking metadata:<br>• Update sequence number (USN) counter<br>• Up-to-dateness vector<br>• High-watermark |

These mechanisms are implemented by the replication system in a sequence of events that occurs between two domain controllers.

The following diagram shows a simplified version of the sequence between source and destination domain controllers when the source initiates replication by sending a change notification.

**Replication Sequence**

**Active Directory Data Updates**

When a change is made to an object in a directory partition, the value of the changed attribute or attributes must be updated on all domain controllers that store a replica of the same directory partition. Domain controllers communicate data updates automatically through Active Directory replication. Their communication about updates is always specific to a single directory partition at a time.

Active Directory data is logically partitioned so that all domain controllers in the forest do not store all objects in the directory. Active Directory objects are instances of schema-defined classes, which consist of named sets of attributes. Schema definitions determine whether an attribute can be administratively changed. Attributes that cannot be changed are never updated and therefore never replicated. However, most Active Directory objects have attribute values that can be updated.

Different categories of data are stored in replicas of different directory partitions, as follows:

- Domain data that is stored in domain directory partitions:
    - Every domain controller stores one writable domain directory partition.
    - A domain controller that is a global catalog server stores one writable domain directory partition and a partial, read-only replica of every other domain in the forest. Global catalog read-only replicas contain a partial set of attributes for every object in the domain.
- Configuration data: Every domain controller stores one writable configuration directory partition that stores forest-wide data controlling site and replication operations.
- Schema data: Every domain controller stores one writable schema partition that stores schema definitions for the forest. Although the schema directory partition is writable, schema updates are allowed on only the domain controller that holds the role of schema operations master.
- Application data: Domain controllers that are running Windows Server 2003 can store directory partitions that store application data. Application directory partition replicas can be replicated to any set of domain controllers in a forest, irrespective of domain.

**Changes to Attributes**

Active Directory updates originate on one domain controller (originating updates) and the same update is subsequently made on other domain controllers during the replication process (replicated updates).

Object update behavior is consistent and predictable: when a set of changes is made to a specific directory partition replica, those changes will be propagated to all other domain controllers that store replicas of the directory partition. How soon the changes are applied depends on the distance between the domain controllers and whether the change must be sent to other sites.

The following key points are central to understanding the behavior of Active Directory updates:

- Changes occur at the attribute level; only the changed attribute value is replicated, not the entire object.
- At the time of replication, only the current value of an attribute that has changed is replicated. If an attribute value has changed multiple times between replication cycles (for example, between scheduled occurrences of intersite replication), only the current value is replicated.
- The smallest change that can be replicated in Windows 2000 Active Directory is an entire attribute; even if the attribute is linked and multivalued, all values replicate as a single change. The smallest change that can be replicated in Windows Server 2003 Active Directory is a separate value in a multivalued attribute that is linked. This Windows Server 2003 feature is called linked-value replication.
- The individual values of a multivalued attribute are replicated separately under the following conditions:
    - The forest functional level is Windows Server 2003 interim or Windows Server 2003.
    - The attribute is linked. Linked attributes have the following characteristics:

      The attribute has distinguished name syntax.

      The attribute is marked as linked in the schema.
- An attribute is available for replication as soon as it is written.
- Replication is store-and-forward and moves sequentially through a set of connected domain controllers that host directory partition replicas.
- Multimaster conflict resolution is effective without depending on clock synchronization.

- Originating updates to a single object are written to the database in the same transaction, so partially written objects are not possible and a consistent view of the object is maintained.

- For replicated updates to large numbers of values in linked multivalued attributes, such as the **member** attribute of a group, updates are not always guaranteed to be applied in the same transaction. In this case, the updates are guaranteed to be applied in one or more subsequent transactions in the same replication cycle (all updates from one source are applied at the destination).

- After a replication cycle is initiated, all available changes to a directory partition on the source domain controller are sent to the destination domain controller, including changes that occur while the replication cycle is in progress.

**Effect of Schema Changes on Replication**

Attribute definitions are stored in **attributeSchema** objects in the schema directory partition. Changes to **attributeSchema** objects block other replication until the schema changes are performed. During replication of any directory partition other than the schema directory partition, the replication system first checks to see whether the schema versions of the source and the destination domain controllers are in agreement. If the versions are not the same, the replication of the other directory partition is rescheduled until the schema directory partition is synchronized.

Prior to upgrading a domain controller from Windows 2000 Server to Windows Server 2003, you must update the schema to be compatible with Windows Server 2003. When you run Adprep.exe, Windows Server 2003 schema is installed in the forest. This process upgrades the schema on each Windows 2000–based domain controller. Thereafter, you can begin upgrading domain controllers to Windows Server 2003.

### Note

- The Windows Server 2003 schema update adds 25 indexed attributes to the schema directory partition. An update of this size can cause replication delays in a large database. For this reason, domain controllers that are running Windows 2000 Server must be running at a minimum Windows 2000 Service Pack 2 (SP2) plus all additional Windows updates. However, it is highly recommended that you install Windows 2000 Service Pack 3 (SP3) on all domain controllers prior to preparing your infrastructure for upgrade to the Windows Server 2003 operating system.

**Effect of Raising the Forest Functional Level on Existing Linked, Multivalued Attributes**

Existing linked, multivalued attributes are not directly affected when you raise the forest functional level to enable linked-value replication. These attribute values are converted to replicate as single values only when they are modified. This design avoids the performance effects that would potentially result from rewriting the existing **member** attribute values of all group objects in the forest at the same time.

Because the **member** attribute is not converted until it is modified, a group that exceeded the 5,000-member limit in Windows 2000 continues to represent a replication issue because the original set of members continues to replicate as a unit under the new forest functional level. New members that are added and any member values that are updated replicate separately thereafter. Therefore, if the groups that were created in Windows 2000 do not exceed the 5,000-member limit, no replication issues are associated with the group.

Raising the forest functional level does affect the ability of an authoritative restore process to restore the back-links of a restored object that has one or more single-valued or multivalued linked attributes. The version of Ntdsutil that is included with Windows Server 2003 provides this functionality automatically when the forest has a functional level of Windows Server 2003 interim or Windows Server 2003. The version of Ntdsutil that is included with Windows Server 2003 SP1 also provides the ability to restore back-links that were created before the forest functional level was raised to Windows Server 2003 interim or Windows Server 2003. For more information about restoring back-linked attribute values, see "Authoritative Restore" later in this section.

For more information about how linked, multivalued attributes are stored, see "How the Data Store Works."

**Originating Updates: Initiating Changes**

As a Lightweight Directory Access Protocol (LDAP) directory service, Active Directory supports the following four types of update requests:

- Add an object to the directory.

- Modify (add, delete, or replace) attribute values of an object in the directory.

- Move an object by changing the name or parent of the object.

- Delete an object from the directory.

Each LDAP request generates a separate write transaction. An LDAP directory service processes each write request as an atomic transaction; that is, the transaction is either completed in full or not applied at all. The practical limit to the number of values that can be written in one LDAP transaction is approximately 5,000 values added, modified, or deleted at the same time.

A write request either commits and all its effects are durable, or it fails before completion and has no effect. A write request that commits is called an originating update. An originating update is initiated and committed at a specific replica. The absolute success or failure of an update applies even for requests that might affect several attributes of a single object, such as Add or Modify. In this case, if one attribute update fails, they all fail and the object is not updated.

An originating update enforces schema restrictions, including allowable parent object types and syntax for mandatory and optional attributes for an object. The restrictions are enforced according to the schema that exists on the domain controller at the moment of the update.

**Originating Add**
An Add request makes a new object with a unique **objectGUID** attribute. The values of all replicated attributes that are set by the Add request are stamped Version = 1.

The Add request fails immediately if the parent object does not exist or if the originating domain controller does not contain a writable replica of the parent object's directory partition.

**Originating Modify**
All Modify operations replace the current value of an attribute with a new value. A modify request can specify one of the following:

- That an attribute be deleted from the object. Attribute deletion is best thought of as replacing the attribute value with NULL. The NULL value occupies no storage of its own but does carry a stamp, as does any value that is stored as a directory attribute.

- That a value be added to the current value of an attribute, as when modifying an attribute that can have multiple values. The effect is to replace the current values with the current values plus the added value.

For each attribute in the request, a Modify request compares the new value in the request with the existing value. If the values are the same, the request to modify that attribute is ignored. If the resulting Modify request does not change any attributes of the object, the entire request is ignored.

Otherwise, a Modify request computes a stamp in the metadata for each new replicated attribute value by reading the version from the existing value (version=0 for an attribute that has never been written) and then adding 1 to this value. The Modify request replaces the old stamp values with new stamp values.

**Originating Move**
A Move request is essentially a special Modify request for a single attribute, the **name** attribute. The operation proceeds as described for the Modify request.

**Originating Delete**
A Delete request is essentially a special Modify request that does the following series of operations:

1. Sets the **isDeleted** attribute to TRUE, which marks the object as a tombstone (an object that has been deleted but not fully removed from the directory).

2. Changes the relative distinguished name of the object to a value that cannot be set by an LDAP application (a value that is impossible).

3. Strips all attributes that are not needed by Active Directory. A few important attributes (including **objectGUID**, **objectSid**, **distinguishedName**, **nTSecurityDescriptor**, and **uSNChanged**) are preserved on the tombstone.

   **Note**

- Because these attributes are preserved, tombstones can be restored (reanimated) by applications that use the LDAP API for undeleting an object.

- On domain controllers running Windows Server 2003 with SP1, the **sIDHistory** attribute is also retained on tombstone objects.

4. Moves the tombstone to the Deleted Objects container, which is a hidden container within those directory partitions that allow deletions.

On domain controllers running Windows Server 2003, you can restore tombstones in the Deleted Objects container to an active state.

**Configuration Objects Protected from Deletion**
Certain objects in the configuration directory partition are critical to the functioning of a domain controller. These objects and their child objects are protected from deletion.

**Reanimination of Protected Objects**
Each domain controller protects the following objects from deletion:

- The cross-reference (class **crossRef**) objects that represent the writable directory partitions that are stored on the domain controller.

- The RID object for the domain controller.

These objects are protected at that domain controller, as follows:

- The domain controller rejects an originating deletion of a protected object.

- The domain controller does not carry out a replicated deletion of a protected object. Instead, the threatened protected object is revived by updating its replication metadata as if each attribute had just been updated. The update is then replicated out, thereby reanimating the deleted object.

**Reanimation of the NTDS Settings Object**
The NTDS Settings (class **nTDSDSA**) object is also protected from deletion. On domain controllers running Windows 2000 Server or Windows Server 2003 with no service pack installed, the NTDS Settings object is reanimated and partner domain controllers continue to attempt to replicate with it. However, because the NTDS Settings object represents a domain controller in the replication topology, preserving it as a replication source when a domain controller has been removed from service is counterproductive and represents a security risk. For example, if a domain controller is demoted (that is, Active Directory is removed by running Dcpromo.exe), another server with the same name can be installed and mistaken by a replication partner for the demoted domain controller. To eliminate the possibility of improper replication attempts, domain controllers running Windows Server 2003 with SP1 disable the ability of the preserved NTDS Settings object to receive replication requests. Although the object is preserved on the domain controller that deleted it, replication attempts with the server that is represented by the deleted NTDS Settings object are discontinued. For information about how NTDS Settings replication metadata is preserved, see "Preservation of Replication Metadata" later in this section.

**Replicated Update Tracking by Domain Controllers**
A replicated update is performed on one domain controller as a result of receiving replication of an originating update that was performed at another domain controller. There is not necessarily a one-to-one correspondence between originating and replicated updates. A single replicated update might reflect a set of originating updates (even updates originating at different domain controllers) to the same object.

For example, the manager of a user object can be changed at one domain controller at the same time the address of the same user is changed at another domain controller. A third domain controller might receive these changes separately to the user object and in turn replicate the changes to a fourth domain controller in a single replicated update.

To avoid endless replication of the same update and reapplication of an update that is received from different replication partners, a domain controller must be able to recognize replicated updates that it has already received as opposed to those that it has not. Some directory services use timestamps to determine what changes need to be propagated, on the basis of preserving the last write. But keeping time closely synchronized in a large network is difficult. When the latest time of a directory write is the only means of determining which of two changes is recorded and replicated, skewed time on a domain

controller can result in data loss or directory corruption.

Active Directory replication does not primarily depend on time to determine what changes need to be propagated. Instead it uses update sequence numbers (USNs) that are assigned by a counter that is local to each domain controller. Because these USN counters are local, it is easy to ensure that they are reliable and never run backward (that is, they cannot decrease in value).

**Note**

- Replication uses Kerberos v 5 authentication protocol for security, which does require that the time services on domain controllers are synchronized.

When a conflict occurs, instead of using timestamps as the primary mechanism to determine what updates are preserved, Active Directory uses volatility (number of changes) as the first element of the per-attribute stamps that are compared during conflict resolution. The second element is a timestamp. Therefore, if an attribute is updated once on domain controller A and once on domain controller B, the last writer's update is preserved. But if the attribute is updated on domain controller A, then on domain controller B, and then again on domain controller A, the update of domain controller A is preserved even if the clock of domain controller B is set forward from that of domain controller A. With Active Directory, clock skew can never prevent a value from being overwritten.

Domain controllers use USNs to simplify recovery after a failure. When a domain controller is restored following a failure, it queries its replication partners for changes with USNs greater than the USN of the last change it received from each partner.

You do not need to be concerned with USNs and their implications unless you experience problems with replication that require troubleshooting.

**Server Object GUID (DSA GUID) and Server Database GUID (Invocation ID)**

The server object that represents a domain controller in the Sites container of the configuration directory partition has a globally unique identifier (GUID) that identifies it to the replication system as a domain controller. This GUID, called the DSA (Directory System Agent) GUID, is used in USNs to track originating updates. It is also used by domain controllers to locate replication partners. The DSA GUID is the GUID of the NTDS Settings object (class **nTDSDSA**), which is a child object of the server object. Its value is stored in the **objectGUID** attribute of the NTDS Settings object.

The DSA GUID is created when Active Directory is initially installed on the domain controller and destroyed only if Active Directory is removed from the domain controller. The DSA GUID ensures that the DSA remains recognizable when a domain controller is renamed. The DSA GUID is not affected by the Active Directory restore process.

The Active Directory database has its own GUID, which the DSA uses to identify the database instance (version of the database). The database GUID is stored in the **invocationId** attribute on the NTDS Settings object. Unlike the DSA GUID, which never changes for the lifetime of the domain controller, the invocation ID is changed during an Active Directory restore process to ensure replication consistency. For more information about replication following a restore process, see "Active Directory Replication on a Restored Domain Controller" later in this section.

On domain controllers that are running Windows Server 2003, the invocation ID also changes when an application directory partition is removed from or added to the domain controller.

**Determining Changes to Replicate: Update Sequence Numbers**

A source domain controller uses USNs to determine what changes have already been received by a destination domain controller that is requesting changes. The destination domain controller uses USNs to determine what changes it needs to request.

The current USN is a 64-bit counter that is maintained by each Active Directory domain controller as the **highestCommittedUsn** attribute on the rootDSE object. At the start of each update transaction (originating or replicated), the domain controller increments its current USN and associates this new value with the update request.

**Note**

- The rootDSE (DSA-specific Entry) represents the top of the logical namespace for one domain controller. RootDSE has no hierarchical name or schema class, but it does have a set of attributes that identify the contents of a given domain controller.

The current USN value is stored on an updated object as follows:

- Local USN: The USN for the update is stored in the metadata of each attribute that is changed by the update as the local

USN of that attribute (originating and replicated writes). As the name implies, this value is local to the domain controller where the change occurs.

- **uSNChanged**: The maximum local USN among all of an object's attributes is stored as the object's **uSNChanged** attribute (originating and replicated writes). The **uSNChanged** attribute is indexed, which allows objects to be enumerated efficiently in the order of their most recent attribute write.

  **Note**

  - When the forest functional level is Windows Server 2003 or Windows Server 2003 interim, discrete values of linked multivalued attributes can be updated individually. In this case, there is a **uSNChanged** associated with each link in addition to the **uSNChanged** associated with each object. Therefore, updates to individual values of linked multivalued attributes do not affect the local USN, only the **uSNChanged** attribute on the object.

- Originating USN: For an originating write only, the update's USN value is stored with each updated attribute as the originating USN of that attribute. Unlike the local USN and **uSNChanged**, the originating USN is replicated with the attribute's value.

**Tracking Object Creation, Replication, and Change**

The following series of diagrams illustrates the replication-related data for a single object and one of its attributes as it goes from creation through replication.

The following diagram shows the replication-related data for the user object when it is first created on domain controller DC1. Before the user object is created, the current USN for the domain controller is 4710. When the object is created, the local USN of 4711 is assigned to each attribute of the user object, and the current USN for the domain controller increments from 4710 to 4711. Because the object has not yet changed, the value of its **uSNChanged** attribute is the same as its **uSNCreated** attribute 4711.

### 1. Replication-related Data on DC1 When a User Object is Created

| Property | Value | Local USN | Version | Originating Time | Originating DC | Originating USN |
|---|---|---|---|---|---|---|
| cn | Jeff Smith | 4711 | 1 | 2003-09-10 10:49.03 | <DC1_GUID> | 4711 |
| userPassword | 6Be8W5q- | 4711 | 1 | 2003-09-10 10:49.03 | <DC1_GUID> | 4711 |
| sAMAccountName | JSmith | 4711 | 1 | 2003-09-10 10:49.03 | <DC1_GUID> | 4711 |
| userPrincipalName | JSmith@contoso.com | 4711 | 1 | 2003-09-10 10:49.03 | <DC1_GUID> | 4711 |

The next diagram shows the change to the destination domain controller when the new user object is replicated. The object is created as a replicated update on DC2. Notice that the per-attribute originating USN and stamp (version, originating time, originating DC) are replicated from DC1 to DC2, but the per-attribute local USN and per-object **uSNChanged** are unique to DC2.

### 2. Replication-related Data on DC2 When a New User Object is Replicated From DC1

| Property | Value | Local USN | Version | Originating Time | Originating DC | Originating USN |
|---|---|---|---|---|---|---|
| cn | Jeff Smith | 1746 | 1 | 2003-09-10 10:49.03 | <DC1_GUID> | 4711 |
| userPassword | 6Be8W5q- | 1746 | 1 | 2003-09-10 10:49.03 | <DC1_GUID> | 4711 |
| sAMAccountName | JSmith | 1746 | 1 | 2003-09-10 10:49.03 | <DC1_GUID> | 4711 |
| userPrincipalName | JSmith@contoso.com | 1746 | 1 | 2003-09-10 10:49.03 | <DC1_GUID> | 4711 |

The following information is transferred in the metadata of an updated attribute value from the source domain controller to the destination domain controller:

- The originating USN value for the updated attribute, which is the USN assigned by the domain controller on which the update was made.

- The stamp, which is used to resolve conflicts.

The next diagram illustrates the change in the replicated object on DC2 when someone changes the password (the **userPassword** property in the diagram) of the object on that domain controller. By this time, the current USN on DC2 has increased from 1746 to 2453. The update request changes the password and increments the current USN to 2453 on DC2. The request also sets the password attribute's originating USN and local USN to 2453 and creates a new stamp for the password value. The version number of this password's stamp is 2, which is one version number higher than the version of the previous password.

**3. Replication-related Data on DC2 After the User Password Value Has Been Changed on DC2**

| Property | Value | Local USN | Version | Originating Time | Originating DC | Originating USN |
|---|---|---|---|---|---|---|
| cn | Jeff Smith | 1746 | 1 | 2003-09-10 10:49.03 | <DC1_GUID> | 4711 |
| userPassword | sEP3569?@2 | 2453 | 2 | 2003-09-10 11:53.29 | <DC2_GUID> | 2453 |
| sAMAccountName | JSmith | 1746 | 1 | 2003-09-10 10:49.03 | <DC1_GUID> | 4711 |
| userPrincipalName | JSmith@contoso.com | 1746 | 1 | 2003-09-10 10:49.03 | <DC1_GUID> | 4711 |

In the next diagram, the changed password is now replicated back to the original domain controller, whose current USN has increased to 5039. The replicated update increments the current USN of DC1 to 5040. The per-attribute originating USN and stamp (version, originating time, originating DC) are replicated from DC2 to DC1, and the per-attribute local USN and per-object **uSNChanged** values are set to 5040.

**4. Replication-related Data on DC1 After the Password Change Has Replicated to DC1**

| Property | Value | Local USN | Version | Originating Time | Originating DC | Originating USN |
|---|---|---|---|---|---|---|
| cn | Jeff Smith | 4711 | 1 | 2003-09-10 10:49.03 | <DC1_GUID> | 4711 |
| userPassword | sEP3569?@2 | 5040 | 2 | 2003-09-10 11:53.29 | <DC2_GUID> | 2453 |
| sAMAccountName | JSmith | 4711 | 1 | 2003-09-10 10:49.03 | <DC1_GUID> | 4711 |
| userPrincipalName | JSmith@contoso.com | 4711 | 1 | 2003-09-10 10:49.03 | <DC1_GUID> | 4711 |

**Replication Request Filtering**

Destination domain controllers use the originating USN to track changes they have received from other domain controllers with which they replicate. When requesting changes from a source domain controller, the destination informs the source of the updates it has already received so that the source never replicates changes that the destination does not need.

Two values are used by source and destination domain controllers to filter updates when the destination requests changes from the source replication partner:

- **Up-to-dateness vector**. The current status of the latest originating updates to occur on all domain controllers that store a replica of a specific directory partition.

- **High-watermark (direct up-to-dateness vector)**. The latest update (originating or replicated) to a specific directory partition that has been received by a destination from a specific source replication partner during the current replication cycle.

Both of these values specify the invocation ID of the source domain controller.

**Attributes to Send for Replication: Up-to-Dateness Vector**

The up-to-dateness vector is a value that the destination domain controller maintains for tracking the originating updates that are received from all source domain controllers. When a destination domain controller requests changes for a directory partition, it provides its up-to-dateness vector to the source domain controller. The source domain controller uses this value to reduce the set of attributes that it sends to the destination domain controller.

The up-to-dateness vector contains an entry for each domain controller that holds a full replica of the directory partition. The up-to-dateness vector values include the database GUID (invocation ID) of the source domain controller and the highest originating write (based on the USN) received from the source domain controller. If the up-to-dateness entry that corresponds to source domain controller X contains the USN *n*, the destination domain controller guarantees that it holds all updates to a specific directory partition that originated at domain controller X and that have an originating USN value of less than or equal

to *n*.

If the destination already has an up-to-date value, the source domain controller does not send that attribute. If the source has no attributes to send for an object, it sends no information at all about that object.

At the completion of a successful replication cycle between two replication partners, the source domain controller returns its up-to-dateness vector to the destination, including the highest originating USN on the source domain controller. The destination merges this information into its up-to-dateness vector. In this way, the destination tracks the latest originating update it has received from each partner, as well as the status of every other domain controller that stores a replica of the directory partition.

**Timestamp on Up-to-Dateness Vector in Windows Server 2003**
On domain controllers that are running Windows Server 2003, the up-to-dateness vector includes a timestamp that represents the last time the local (destination) domain controller has completed a full replication cycle with the source domain controller. The replication cycle may have occurred directly (direct replication partner) or indirectly (transitive replication partner). The timestamp is recorded whether or not the local domain controller actually received any changes from the partner.

By examining the timestamps, a domain controller can quickly identify other domain controllers that are not replicating. Warning messages are posted to the event log on each domain controller when non-replicating partners are discovered (Event ID 1864 in the Directory Service event log).

**Objects to Consider for Replication: High-Watermark (Direct Up-to-Dateness Vector)**
The high-watermark, or direct up-to-dateness vector, is a value that the destination domain controller maintains during replication to keep track of the most recent attribute change that it has received from a specific source domain controller for an object in a specific directory partition. When sending changes to a destination domain controller, the source domain controller provides the changes in increasing order of **uSNChanged**. Although the **uSNChanged** values from the source domain controller are not stored on objects at the destination domain controller, the destination domain controller keeps track of the **uSNChanged** value of the most recent object that was successfully updated from the source domain controller for a specific directory partition. This USN is called the destination's high-watermark with respect to the directory partition and the source domain controller.

When requesting changes during a replication cycle, the destination provides the high-watermark value with each request to the source domain controller, which in turn uses this value to filter the objects that it considers for continuing replication to the destination. If the **uSNChanged** value of an object on the source domain controller is less than or equal to the high-watermark value of the destination domain controller, the object update has already been received by the destination domain controller and is therefore not replicated. The high-watermark serves to decrease the CPU time and number of disk I/O operations that would otherwise be required.

The up-to-dateness vector and the high-watermark are complementary filter mechanisms that work together to decrease replication latency. Whereas the high-watermark prevents irrelevant objects from being considered by the source domain controller with respect to a single destination, the up-to-dateness vector helps the source domain controller to filter irrelevant attributes (and entire objects if all attributes are filtered) on the basis of the relationships between all sources of originating updates and a single destination.

For a specific directory partition, a domain controller maintains a high-watermark value for only those domain controllers from which it requests changes, but it maintains an up-to-dateness vector entry for every domain controller that has ever performed an originating update, which is typically every domain controller that holds a full replica of the directory partition.

**Multiple Paths Without Redundant Replication**
Multiple replication paths can exist between a pair of domain controllers. Multiple paths provide fault tolerance and can reduce latency. However, when multiple paths exist, you might expect the same change to be sent along each path to a specific domain controller or that a change might replicate in an endless loop. Active Directory prevents these potential problems with multiple paths by using the up-to-dateness vector. The ability to eliminate redundancy is called "propagation dampening."

The following is an example of how replication ordinarily occurs:

1. DC A updates a password attribute. In this example, the originating USN of the attribute is set to 3.

2. Destination DC B requests changes from source DC A and sends its high-watermark and up-to-dateness vector to DC A.

3. According to the high-watermark that was passed by DC B, source DC A examines one or more objects, one of which contains the changed password. When DC A encounters the changed password attribute, it proceeds as follows:

    a. First, DC A finds that the originating directory system agent (DSA) of the password attribute is DC A.

| Note |
| --- |
| The DSA is the server-side process that creates an instance of a directory service. The DSA provides access to the physical store of directory information located on a hard disk. |

b. Therefore, DC A reads the up-to-dateness vector supplied by DC B and finds that DC B is guaranteed to be up-to-date with updates that originated at DC A and that have an originating USN of less than or equal to 2.

c. DC A then finds that the originating USN of the password attribute is 3.

d. Because 3 is greater than 2, DC A sends the changed password attribute to DC B.

To illustrate propagation dampening, suppose that DC B had already received the password update from DC C, which had received it from DC A. In this case, the entry in the up-to-dateness vector of DC B for DC A would contain the USN value 3, not 2. Therefore, DC A would not send the changed password to DC B.

For information about viewing the replication metadata, see "Active Directory Replication Tools and Settings".

**Multimaster Conflict Resolution Policy**
Active Directory must ensure that all domain controllers agree on the value of the updated attribute after replication occurs. The general approach to resolving conflicts is to order all update operations (Add, Modify, Move, and Delete) by assigning a globally unique (per-object and per-attribute) stamp to the originating update. Thus each replicated attribute value (or multivalue) is stamped during the originating update and this stamp is replicated with the value.

**Conflict Resolution Stamp**
The stamp that is applied during an originating write has the following three components:

- The version is a number that is incremented for each originating write. The version of the first originating write is 1. The version of each successive originating write is increased by 1.
- The originating time is the time of the originating write, to a one-second resolution, according to the system clock of the domain controller that performed the write.
- The originating DC is the invocationID of the domain controller that performed the originating write.

When stamps are compared, the version is the most significant, followed by the originating time and then the originating DC. If two stamps have the same version, the originating time almost always breaks the tie. In the extremely rare event that the same attribute is updated on two different domain controllers during the same second, the originating DC breaks the tie in an arbitrary fashion.

Two different originating writes of a specific attribute of a particular object cannot assign the same stamp because each originating write advances the version at a specified originating domain controller. The originating time does not contribute to uniqueness. Replicated writes cannot decrease the version because values with smaller versions lose during conflict resolution. You can see all three components of the stamp in the output of the **repadmin /showobjmeta** command.

In the case of a conflict, the ordering of stamps allows a consistent resolution, as described in the following table.

**Replication Conflict Resolution**

| Replication Conflict | Description | Resolution |
| --- | --- | --- |
| Attribute value conflict | A Modify operation sets the value of an attribute. Concurrently, at another domain controller, a Modify operation sets the value of the same attribute to a different value. | The attribute value at all domain controllers is the value with the larger version number in its stamp. |

| | | |
|---|---|---|
| Add or Move under deleted parent, Delete non-leaf object | An Add or Move operation makes an object a child of parent object. Concurrently, at another domain controller, a Delete operation deletes the parent object. | At all domain controllers, the parent object is deleted and the child object is a child of the special LostAndFound container in the directory partition. Stamps are not involved in the resolution. |
| Relative distinguished name conflict | An Add or Move operation names a child object below a parent object. Concurrently, at another domain controller, an Add or Move operation names a different child of the same parent with the same child name, resulting in two child objects with identical relative distinguished name values below the same parent object. | The child object whose naming attribute has the larger version number in its stamp keeps its given name. The child object whose relative distinguished name attribute (for example, CN for most objects, OU for organizational units, DC for domain components) has the smaller version number in its stamp is named by the following convention: At all domain controllers, a system-assigned value that is unique to the conflicting name and cannot conflict with any client-assigned value is assigned to the child object. For example, if the relative distinguished name of a child object was "CN=ABC" before conflict resolution, its relative distinguished name after resolution is "CN=ABC*CNF:<*GUID*>," where "*" represents a reserved character, "CNF" is a constant that indicates a conflict resolution, and "<*GUID*>" represents a printable representation of the **objectGUID** attribute value. |

**Preservation of Replication Metadata**

On domain controllers running Windows Server 2003 with no service pack installed, replication metadata of the NTDS Settings object is maintained by default after Active Directory is removed from a domain controller. The mechanism for preserving replication metadata is disabled in Windows Server 2003 SP1.

**How Replication Metadata is Preserved in Windows Server 2003**

The period of time during which the replication metadata of the NTDS Settings object is maintained after Active Directory is removed from the respective domain controller is determined by an attribute of the Directory Service object (cn=Directory Service,cn=Windows NT,cn=Services,cn=Configuration,dc=*ForestRootDomainName*). This attribute, **replTopologyStayOfExecution**, has a default value of 14 days and a maximum value of half the tombstone lifetime.

For example, if you set the tombstone lifetime to 30 days and the **replTopologyStayOfExecution** value to 20 days, the actual stay-of-execution value is 15 days.

The root object of each directory partition replica has a multivalued attribute **repsFrom** that contains configuration and persistent state information associated with inbound replication from each source replica of that directory partition. A destination domain controller uses this information to poll source domain controllers for replication changes. The Knowledge Consistency Checker (KCC) is the replication topology component that manages creation of connection objects. When the KCC detects a **repsFrom** value with no corresponding connection object, as is the case when the NTDS Settings object has been deleted, the KCC checks the tombstone for the NTDS Settings object for the time it was deleted and compares that time to the interval in **replTopologyStayOfExecution**. If the NTDS Settings object has been deleted for a time that is equal to or greater than the value in **replTopologyStayOfExecution**, then the KCC removes the **repsFrom** value and replication is no longer attempted with the deleted server. For more information about the data that is stored in **repsFrom**, see "Destination Identification of Source Replication Partners" later in this section.

Prior to the stay-of-execution lifetime, you can see evidence of failed replication attempts in the Directory Service event log and in the output of Windows Support tools such as Repadmin.exe. When replication attempts are from a server designated as <unknown>, they are likely due to the stay-of-execution mechanism.

**Disabled replTopologyStayOfExecution in Windows Server 2003 SP1**

On domain controllers running Windows Server 2003 with SP1, the stay-of-execution mechanism is disabled so that replication attempts do not continue after a domain controller is demoted. Without the **repsFrom** metadata, destination domain controllers no longer poll for replication from the deleted source. Eliminating this mechanism ensures that computers attempting to maliciously spoof the deleted domain controller cannot respond to polling for replication changes. However, if you provide a value for **replTopologyStayOfExecution**, the stay-of-execution mechanism takes effect according to that value.

**Replication of Linked and Nonlinked Attributes**

Attributes are replicated differently depending on whether they are linked or nonlinked. Understanding the differences in how these attributes operate is helpful to understanding their effect on replication.

**Linked Attributes**

A linked attribute represents an interobject, distinguished-name reference. Linked attributes occur in pairs — forward link and backward link (back-link). The forward link is the linked attribute on the source object (for example, the **member** attribute on

the group object), while the backward link is the linked attribute on the target object (for example, the **memberOf** attribute on the user object). A back-link value on any object instance consists of the distinguished names of all the objects that have the object's distinguished name set in their corresponding forward link. For example, **manager** and **directReports** are a pair of linked attributes, where **manager** is the forward link and **directReports** is the back-link. If Bill is Joe's manager and the distinguished name of Bill's user object is stored in the **manager** attribute of Joe's user object, then the distinguished name of Joe's user object appears in the **directReports** attribute of Bill's user object.

A linked attribute can have either single or multiple values. For example, the **manager** attribute identifies the distinguished name of a single manager of the object or objects that are managed. The **directReports** attribute of a user object can have multiple values of user names.

The relationships between linked attributes are stored in a separate table in the directory database as link pairs. The matching pair of Link IDs (defined as any two numbers 2N and 2N+1) tie the attributes together. For example, the **member** attribute has a link ID of 2 and the **memberOf** attribute has a link ID of 3. Because the **member** and the **memberOf** attributes are linked in the database and indexed for searching, the directory can be examined for all records in which the link pair is **member**/**memberOf** and the **memberOf** attribute identifies the group (for example, "What user objects have group X as a value in their **memberOf** attribute?").

Attributes are marked in the schema as being linked. Attributes with the distinguished name syntax **Object(DS-DN)**, **Object(DN-String)**, or **Object(DN-Binary)** can be linked, but not all such attributes are linked.

**Nonlinked Attributes**

Nonlinked, distinguished-name attributes reference other objects in the same way as linked attributes do except that their behavior is different when a referred-to object is deleted, as described in "Replication of Deletion Updates" later in this section. In addition, nonlinked, multivalued attributes have an approximate limit of 1200 values (increased from the Windows 2000 Server limit of approximately 800 values). This limit is based on an approximate maximum page size of 8 kilobytes. For attributes of this maximum size, there are no storage or replication drawbacks or limitations. For more information about data size requirements, see "How the Data Store Works."

**USNs and Database Transactions**

Originating and local USNs effectively identify the database transactions that record originating and replicated changes. Local USNs represent a local database transaction. Therefore, local USNs that are the same represent the same database transaction. For example, when two updates to the same object originate on different systems, they are assigned different originating GUIDs and originating USN values. By definition, the local USN for each originating change is the same as the respective originating USN. Then, these changes replicate to a third domain controller independently. The originating USNs stay the same, but the local USNs now change to reflect the two separate transactions. When this set of changes replicates to a fourth domain controller, the two changes travel together. When they are applied at the fourth system, the originating USNs are still different, but the local USNs are now the same, reflecting their application in the same transaction.

Individual values of a multivalued attribute have slightly different rules. On origination, each unique value is assigned its own originating USN. The values replicate out independently, in roughly increasing USN order; however, atomicity between values is not guaranteed. When a set of values is applied on the destination domain controller, they are applied in batches to the same object. The batch size is approximately 100 multivalues. Therefore, when they are written on the destination domain controller, their originating USNs are still different, but the values on the same object, in groups of 100, have the same local USN.

**Atomicity of Linked and Nonlinked Attributes**

Atomicity is a guarantee by a database system that a grouping is applied in a single transaction. "Atomic" can be defined as "indivisible." Atomicity of a transaction means that the transaction occurs in total, or not at all. This guarantee ensures that objects are always in a complete state of either pre- or post-update. Nothing in between is possible.

As evidenced by the application of the local USN, write transactions are performed according to the way replication data is packaged and received. Rules that affect whether attribute values replicate together or separately differ for linked and nonlinked attributes.

- Nonlinked attributes: All changes to nonlinked attributes of an object replicate together and are assigned the same local USN. Therefore, they are committed to the database in the same write transaction.

- Linked attributes: Changes to linked attributes are not guaranteed to replicate together. Therefore, they are not guaranteed to be written in the same database transaction.

The issue for an update transaction, then, is at what points in the replication stream the application of an update can be interrupted and the effect of interruption on the end state. For inbound replication, the unit of transaction is the entire object for nonlinked attributes. For linked attributes, the unit of transaction is the batch of values for the same object. Therefore, it is

possible for a replicated update to a single object that has linked values to occur in more than one transaction. However, transactions to apply all updates to the same object are guaranteed to occur during the same replication cycle.

Atomicity provides the following assurances:

- Inferences can be based on the relationships of multiple attributes: If you always update attribute 1 and attribute 2 together and you see attribute 1, you know that you can make a decision based on attribute 2.

- Even if the system crashes in the middle of applying the replicated update, the database system guarantees that all changes are applied or that no changes are applied, and nothing in between.

**Replication Order of Linked and Nonlinked Attribute Updates**
To accommodate the guarantee that changes that are committed together on the originating domain controller appear in the same write transaction on the destination domain controller, updates to nonlinked attributes are prioritized more highly than updates to linked attributes. For this reason, although originating USNs are applied as they occur in order of the update and outbound replication changes are assembled in this update order, nonlinked updates are packaged for transmission ahead of linked updates. Therefore, when an object is updated and some of the updated attributes are linked and some are not linked, the replication packet orders the nonlinked values first, splitting the order of values between linked and nonlinked. For example, if two objects (obj1 and obj2) receive updates simultaneously to one linked attribute and one nonlinked attribute on each object, the order of the attribute values in the replication data packet are as follows:

obj1.nonlinked; obj2.nonlinked; obj1.linked; obj2.linked

Now, suppose that the number of nonlinked changes is sufficiently large that the values fill an entire replication packet. When both linked and nonlinked attributes are replicated, this scenario results in a set of changes that are made to one of the objects spanning multiple replication packets. All nonlinked values for a single object are included in one packet, but linked values for the same object can span multiple packets. Therefore, the write transaction at the destination can occur out of update order, and replicated updates to a single object can require multiple transactions.

**Transaction Order of Linked and Nonlinked Attribute Updates**
For linked attributes, although objects are transmitted in increasing USN order, object transactions might be applied out of order as a result of parent-child relationships. This condition guarantees that object creation precedes the application of any links to that object.

In addition, when the object already exists at the destination, although replication of nonlinked attributes occurs first, transaction of nonlinked attribute updates before linked attribute updates is not guaranteed. However, nonlinked updates are generally applied before linked updates at the destination.

For applications that depend on updates being written in update order, the prioritized implementation of replicated linked and nonlinked attribute updates can occasionally result in unexpected behavior.

**Group Membership and Linked-Value Replication**
The replication of linked, multivalued attributes is especially important for group objects. Potentially, the linked, multivalued **member** attribute of a group object can have thousands of values. Linked-value replication in Windows Server 2003 enables individual values to replicate separately. Linked-value replication requires a forest functional level of Windows Server 2003 or Windows Server 2003 interim. When it is in effect, linked-value replication solves the problem of replication delays that are due to the inability to write an entire **member** attribute in a single database transaction. Linked-value replication also makes restoring group membership back-links possible when a user or group object is authoritatively restored.

**Group Membership Replication in Windows 2000 Forests**
Linked-value replication is not available in Windows 2000 Server forests. Because an originating update must be written in a single database transaction, and because the practical limit for a single transaction is 5,000 values, membership of more than 5,000 values is not supported in Windows 2000 Server Active Directory. A group of this size represents a limitation both in terms of the database write operation that is required to record a change to an attribute of that size and the transfer of that much data over the network.

These conditions have the following impacts on replication, most notably for group and distribution list objects:

- Lost changes: If values of the same multivalued attribute are updated on two different domain controllers during a period of replication latency, the most recently changed replica of the attribute with all its multiple values is replicated and any earlier changes are lost. Changes to the separate values are not merged.

  **Note**

    - Because all changes to an object must be written in the same database transaction, multiple changes to a single group object can take a relatively long time to be written, which increases the likelihood of another change occurring to the same object prior to the completion of the original write.

- Excessive network bandwidth consumption: For example, when one member is added to a group of 3,000 members, the **member** attribute with all 3,001 values is transmitted between domain controllers. Transmission of all values to apply a change to only the updated value or values is inefficient use of network resources.

These limitations are effectively removed in a forest that has a forest functional level of Windows Server 2003 or Windows Server 2003 interim. At these levels, linked-value replication accommodates replication of individually updated **member** values.

**Group Membership Replication in Windows Server 2003 Forests**
In a Windows Server 2003 forest that has a forest functional level of Windows Server 2003 or Windows Server 2003 interim, linked-value replication provides the following benefits:

- Removed likelihood of losing entire sets of changes to the same group membership made on different domain controllers.

- Greatly reduced likelihood of update collisions, where the same **member** value is changed on different domain controllers at the same time and one update is lost.

- Improved network efficiency by transmitting only updated values and not the entire set of attribute values, which can include many thousands of values.

Although replication of many thousands of individual membership updates can be accommodated in a Windows Server 2003 forest, LDAP writes have a practical limit of approximately 5,000 updates in a single transaction. Because originating updates are required to complete in a single transaction, a practical limit of approximately 5,000 updates to a single object is recommended.

**Note**

- Only originating updates must be applied in the same database transaction. Replicated updates can be applied in more than one database transaction.

**Replication of Deletion Updates**
Object deletions are replicated by replicating tombstones. After an object is deleted but before it is removed from the directory, object references that formerly referred to the object now refer to the deleted object's tombstone. The **isDeleted** attribute, which has a value of TRUE when an object is a tombstone, indicates the object deletion to other domain controllers. Deleted objects are stored in the Deleted Objects hidden container. Every directory partition has a Deleted Objects container.

**Note**

- Objects are moved to the Deleted Objects container according to system flags. Certain protected configuration objects, such as NTDS Settings, do not move to the Deleted Objects container when they are deleted. In addition, dynamic objects that are deleted are removed from Active Directory according to a Time-to-Live (TTL) setting. They are not moved to the Deleted Objects container as tombstones. DNS resource records that are removed by scavenging are also not stored as tombstones when DNS is Active Directory–integrated. For more information about storage of object deletions and dynamic data, see "Storage and Removal of Object Deletions" and "Dynamic Data," respectively, in How the Data Store Works. For more information about how DNS data is removed from Active Directory, see "Understanding Aging and Scavenging" in How DNS Works.

By default, tombstones have a lifetime of 60 days (180 days in a forest that was created on a server running Windows Server 2003 with SP1), after which they are permanently removed from the directory database through a process called garbage collection.

The tombstone lifetime can be changed, but it is important to ensure that the tombstone lifetime is larger than the worst possible replication latency for any directory partition so that a tombstone cannot be deleted before it has replicated to every

directory partition replica. In addition, Active Directory does not allow data to be restored from a backup image that is older than the tombstone lifetime.

**Note**

- A tombstone is invisible to normal LDAP searches. However, a tombstone is visible to searches that use the special LDAP control 1.2.840.113556.1.4.417.

**Effect of Deletion on Linked Values**

When an object is deleted, two types of automatic cleanup occur with regard to linked values:

- All of the forward links that are held by the deleted object are removed; that is, if a group object is deleted, all of the **member** links on the group object are removed. The target of each link (for example, the user object that is named in the **member** attribute) is not affected by the removal of the group and its forward link, except that its **memberOf** back-link attribute loses the value that corresponds to the deleted group.

- All the back-links that are held by the deleted object are removed; that is, if a user is deleted, its back-links include all the group objects that have forward links to the user object. For example, if a user is a member of multiple groups and the user is deleted, the user's distinguished name value is removed from the **member** attributes of each group object that is named in the **memberOf** attribute of the deleted user. The group object is not changed in any way other than its membership.

During replication, if a linked value replicates to a domain controller, the linked value is silently dropped (that is, it disappears from the database with no history) under the following conditions:

- The forward link holder object that is referenced by the link value has been deleted.

- The backward link holder that is referenced by the link value (the target of the back-link) has been deleted.

When a target and source object are authoritatively restored together on a domain controller running Windows Server 2003, whether the links are restored on the destination domain controller depends on which restored object replicates out first:

- If the restored group object replicates to a destination domain controller before the restored user object, the group membership of the user is not restored because the user object does not exist on the destination.

- If the user object replicates out ahead of the group object and if the functional level of the forest was Windows Server 2003 or Windows Server 2003 interim when the back-link was created (that is, when the user was added to the group), the group membership of the user is restored in the **member** and **memberOf** attributes on the respective objects.

For more information about restoring back-links on authoritatively restored objects, see "Authoritative Restore" later in this section.

**Replication of Absent Linked Object References**

A different condition occurs when the object that the link refers to is simply removed as a referent, as it is when a user is removed from a group.

In a Windows 2000 forest, this condition results in replication of the entire linked attribute. In a forest with a functional level of Windows Server 2003 or Windows Server 2003 interim, this condition is replicated on a per-value basis. For example, if a user is removed from a group, the user value in the **member** attribute is marked “absent” in the database so that its condition can be replicated, much like a tombstone.

The deletion of the user object from the group replicates as an absent value in the **member** attribute of the group. After a tombstone lifetime, absent values are physically removed from the database. Until that time, the link value remains in the database. Such absent values can be restored prior to the end of the tombstone lifetime. If you add the user back to the group prior to the end of a tombstone lifetime, the link value is restored in the database by the value being marked "present."

**Deleting Group Objects in a Windows Server 2003 Forest**

In a forest that has a forest functional level of Windows Server 2003 or Windows Server 2003 interim, you can delete a group object of any size and its multivalued **member** attribute values are cleaned up in the background. For this reason, it is not

required for the deletion to complete in one transaction, as it is in a Windows 2000 forest. However, if you delete more than 5,000 members in the same transaction without deleting the group itself, the same long-running transaction conditions can occur as described in “Group Membership Replication in Windows 2000 Forests” earlier in this section.

Therefore, if you must add, modify, or delete more than 5,000 members of the same group, do so in blocks of less than 5,000 members to avoid long-running transactions and excessive network bandwidth consumption.

For more information about linked and nonlinked values, garbage collection, and tombstones, see "Storage and Removal of Object Deletions" in How the Data Store Works.

**Deletions on Nonreplicating Domain Controllers**

If a domain controller fails to replicate for a number of days that exceeds the tombstone lifetime, replicas of objects that have been deleted from a writable partition might remain in that domain controller’s directory. Because the tombstones of the deleted objects are permanently removed from the directory at the end of the tombstone lifetime, a domain controller that fails to replicate changes for tombstoned objects never deletes them.

This condition can occur for a variety of reasons, including:

- Prolonged misconfigurations.
- Prolonged errors in name resolution, authentication, or the replication engine that block inbound replication.
- Turning on a domain controller that has been offline for longer than the tombstone lifetime.
- Advancing system time or reducing tombstone lifetime values in an attempt to accelerate garbage collection before end-to-end replication has taken place for all directory partitions in the forest.

The condition of outdated objects can also occur due to hardware and software problems that render the domain controller unreachable. Regardless of the reason, a deleted object can remain on a domain controller any time the domain controller goes offline before receiving a deletion and remains offline for longer than the tombstone lifetime of that deletion.

These outdated objects, called lingering objects, create inconsistency in the directory. If a change is made to an outdated object on the reconnected domain controller, it is possible for the object to be recreated in the directory under certain conditions. To avoid this situation, replication of an outdated object is prohibited by default in newly created Windows Server 2003 forests.

**Backup Latency Interval**

On domain controllers running Windows Server 2003 with SP1, a new NTDS Replication event provides a warning to administrators when a domain controller has not been backed up. Event ID 2089 provides the backup status of each directory partition that a domain controller stores, including application directory partitions. Specifically, event ID 2089 is logged in the Directory Service event log when partitions in the Active Directory forest are not backed up within a backup latency interval. The value for the backup latency interval is stored as a **REG_DWORD** value in the **Backup Latency Threshold (days)** entry in **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters**.

By default, the value of **Backup Latency Threshold (days)** is half the value of the tombstone lifetime of the forest. If halfway through the tombstone lifetime a directory partition has not been backed up, event ID 2089 is logged in the Directory Service event log and continues daily until the directory partition is backed up.

This event serves as a warning to administrators and monitoring applications to make sure that domain controllers are backed up before the tombstone lifetime expires. However, it is recommended that you take backups at a much higher frequency than the default value of **Backup Latency Threshold (days)**.

**Replication Consistency Setting**

If the attributes on a lingering object never change, the object is never considered for replication. However, if an attribute changes, the attribute is considered for outbound replication. Because the destination domain controller does not hold the object for the attribute that is being replicated, an update cannot be performed. How this condition is resolved depends on the replication consistency setting on the domain controller.

A registry setting on domain controllers that are running Windows Server 2003 or Windows 2000 Server with SP3 provides a consistency value that determines whether a domain controller replicates and reanimates an updated object that has been deleted from all other replicas, or whether replication of such objects is blocked. The default settings are different on domain controllers that are running Windows 2000 Server with SP3 and Windows Server 2003.

**Strict Replication Consistency**

To avoid problems with reanimating objects that have been deleted, a domain controller that is running Windows Server 2003

in a newly created (not upgraded) Windows Server 2003 forest blocks inbound replication by default when it receives an update to an object that it does not have.

**Note**

- Active Directory replication uses update tracking to differentiate between replicating a newly created object and updating an attribute for an existing object. Replication of a lingering object is an attempt to update an attribute or attributes of an object that the destination domain controller cannot update because the object does not exist.

Replication is halted in the directory partition for the object until the lingering object is removed from the source domain controller or the strict replication consistency setting is disabled. For information about how lingering objects are removed, see "Lingering Object Removal" later in this section.

#### Loose Replication Consistency

When strict replication consistency is disabled, the effect is called "loose" consistency. By using "loose" consistency, the destination domain controller detects that it does not have the object for the attribute that is being replicated. The destination domain controller requests the entire object from the source partner, and thereby reanimates the object in its copy of the directory. The same process repeats on all domain controllers that do not have a copy of the object.

This mechanism can be used to cause lingering objects to be reanimated across the entire forest. If a lingering object is discovered and its presence is intended, then perform any update to the object. As long as replication consistency is set to loose (strict replication consistency is disabled) on all domain controllers, the object will be reanimated as it replicates around the forest.

Loose replication consistency is the default setting for domain controllers that are running Windows 2000 Server with SP3 or later. The Windows 2000 Server default is not changed by upgrading to Windows Server 2003; strict replication consistency remains disabled and replication is allowed to proceed. Keeping the Windows 2000 Server setting is required to ensure that the upgraded domain and forest are consistent with Windows 2000 Server functionality. You must change the setting manually following the upgrade.

#### Storage for Consistency Setting

The setting for replication consistency is in the registry on each domain controller.

The value for the consistency setting is stored in the **Strict Replication Consistency** entry in **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters**.

The values are as follows:

- Value: **1** (Set to **0** to disable)
- Default: **1** (enabled) in a new Windows Server 2003 forest, otherwise **0**.
- Data type: **REG_DWORD**

**Note**

- Having **Strict Replication Consistency** set to **0** or unset is equivalent to the Windows 2000 Server setting applied by the **Correct Missing Objects** registry entry. However, the semantics for **Correct Missing Objects** are the opposite of **Strict Replication Consistency**: **Correct Missing Objects**=1 is equivalent to **Strict Replication Consistency**=0 or unset.

#### Lingering Object Removal

On domain controllers that are running Windows Server 2003, you can use Repadmin to analyze and remove lingering objects from a domain controller that you suspect or know has not replicated for a tombstone lifetime or longer. If strict replication consistency is in effect and replication fails on the destination domain controller, event ID 1988 is logged in the Directory Service event log on the destination domain controller. Event ID 1988 indicates that the local domain controller has attempted to replicate an object from the source domain controller and the object is not present on the local domain controller because it might have been deleted and its tombstone already garbage collected. Event ID 1988 provides the GUID-based distinguished name of the source domain controller as well as the distinguished name and GUID of the outdated object. Replication of the directory partition containing the outdated object does not continue with the source domain controller until the situation has been resolved.

In this event, you can use an up-to-date domain controller as the authority against which to compare the objects on the source replication partner suspected of harboring lingering objects. This domain controller acts as the authoritative directory replica to reveal outdated objects in the suspect directory database on the destination.

In the Repadmin command-line arguments that remove lingering objects, the roles of source and destination are switched. The **repadmin /removelingeringobjects** command compares the directories of two domain controllers, as follows:

- A "source" domain controller that you designate as the authoritative reference server.
- A "destination" domain controller, which is the source replication partner that has attempted to replicate an outdated object.

To use the **repadmin /removelingeringobjects** command, both source and destination domain controllers must be running Windows Server 2003.

If the comparison reveals any mismatched objects, Repadmin either displays or removes the objects that are found on the destination but not on the source, depending on the arguments that you use. The advisory mode argument allows you to view the results of the command before you take action to remove any objects from the directory.

**Repadmin /RemoveLingeringObjects Command Syntax**

The command **repadmin /removelingeringobjects** has the following syntax:

```
                /removelingeringobjects <Dest_DC_LIST> <Source DC GUID> <NC>
[/ADVISORY_MODE]
```

where

- <Dest_DC_List> is the DNS or NetBIOS name of one or more domain controllers that you suspect of harboring lingering objects. <DC_List> provides the ability to target specific domain controllers, such as all domain controllers in a site, all global catalog servers, or domain controllers that hold specific operations master roles. To see the syntax for DC_List, type **repadmin /listhelp** at the command prompt.
- <Source DC GUID> is the GUID you obtained by running **repadmin /showrepl** against the source domain controller that you are using as the authoritative server.
- <NC> is the distinguished name of the directory partition that contains the lingering object.
- [/ADVISORY_MODE] is an optional switch that specifies that no deletions are performed on the destination domain controller, but are displayed (logged) only. Using this switch is recommended prior to allowing Repadmin to remove any objects.

To use this command, you must first obtain the GUID of the authoritative source domain controller by running **repadmin /showrepl <source_server>**, where <source_server> is the name of the domain controller that has a writable copy of the directory partition that will serve as the authoritative replica. The output of this command provides the "DC GUID," which the **/removelingeringobjects** command requires to identify the authoritative source.

**RemoveLingeringObjects Implementation**

When you run **repadmin /removelingeringobjects**, the tool performs the following steps to compare the directories of the source and destination domain controllers and log (or remove) any found lingering objects:

1. Check to ensure that the directory partition and the source domain controller are valid.
2. Verify that the user has the DS-Replication-Manage-Topology extended right on the directory partition container object specified in <NC>. This extended right is required to verify object state between two domain controllers. Members of the Domain Admins group have this right by default.
3. Ensure that both source and destination use the same objects for comparison by merging the up-to-dateness vectors to filter out any objects that have not replicated from the source to the destination or from the destination to the source. This check rules out a lingering object on the destination if the destination has not received the tombstone from the

source, and vice versa. Any such nonreplicated objects are removed from the comparison.

4. Create the list of object GUIDs for each domain controller to be compared. Examine the metadata of each object and use the merged up-to-dateness vector to determine whether the object should be present on both source and destination.

5. For each GUID that is in the list for the destination, determine if it is in the list of GUIDs for the source.

6. If a GUID is not found on the source, the object is identified to be outdated on the destination and is either displayed or deleted on the destination server. If advisory mode has been specified, the GUID is displayed only.

For more information about up-to-dateness vectors, see "Replicated Update Tracking by Domain Controllers" later in this section. For more information about removing lingering objects, see "Troubleshooting Active Directory Replication Problems" in the Active Directory Operations Guide.

**Active Directory Replication on a Restored Domain Controller**
All domain controllers must be backed up routinely to ensure directory integrity. In case of failure on a domain controller, the backup media can be used to restore the domain controller to its state at the time of the backup. When a domain controller is restored from a backup, it can then be brought up-to-date by normal replication.

There are two general methods for restoring Active Directory from backup media, each of which has different replication consequences:

- Nonauthoritative restore. Replication brings the domain controller up-to-date from its state at the time of backup, including updating deletions that have occurred since the time of the backup.

- Authoritative restore. Objects that were deleted can be reinstated.

**Nonauthoritative Restore**
Nonauthoritative restore is the default method of performing a restore of Active Directory, and it is used in the majority of restore situations, such as domain controller hard disk failure. Nonauthoritative restore is performed by using the backup tool that you used to create the backup file. A nonauthoritative restore returns Active Directory on the domain controller to a state that is consistent with the time that the backup was taken. When the domain controller restarts following the restore process, it requests changes from its replication partners. Through the normal replication process, the restored domain controller receives any directory changes that have occurred since the time of the backup.

Because the restore process does not restore any previously deleted data to Active Directory, it is described as nonauthoritative.

The following example illustrates the process of replication between a set of domain controllers before and after nonauthoritative restore, including the metadata changes that determine the effect of the restore operation. In this example, three domain controllers (DC1, DC2, and DC3) exist as part of the Active Directory replication topology. The scenario includes the following steps:

**Step 1**
Prior to backup, DC1 maintains replication information about itself and its replication partners:

- Its own invocation ID (database GUID)

- Highest USN that it has committed for changes to the local database.

- Replication metadata for its two replication partners, DC2 and DC3:

    - Invocation ID of the local Active Directory database of each domain controller.

    - The up-to-dateness vector, as shown in the table below.

**Step 2**
Some changes have been made to the Active Directory database on DC1 since Step 1, which result in advancing the current USN on DC1 to 35. At this point, DC1 is backed up.

**Step 3**
A total of 14 additional change changes have been made to the local Active Directory database on DC1, advancing the highest committed USN on DC1 to 49. DC1 now begins replicating these changes to DC2. After replicating 12 of the 14 changes to DC2, DC1 becomes unavailable due to hard drive corruption. As a result, DC2 has USN 47 as the last change it received from DC1. At this point, the up-to-dateness vector on DC2 shows a highest committed USN of 47 for DC1.

**Step 4**
A nonauthoritative restore has been completed and DC1 is restarted. During the restore process a new invocation ID has been assigned to the local Active Directory database on DC1. For replication purposes, DC1 adds its old invocation ID (GUID1) and highest committed USN of 35 to its up-to-dateness vector, effectively restoring it to its state as of Step 2.

**Step 5**
DC1 replicates in the 12 changes that were saved to DC2 before the restore (which corresponds to Step 3 in the following table). The last two changes that occurred as originating updates on DC1 prior to going offline are lost.

**DC1 Replication Metadata Values Pre- and Post-Nonauthoritative Restore**

| | **Step 1: Prior to backup** | **Step2: Immediately post-backup** | **Step 3: Offline status before restore** | **Step 4: Immediately post-Restore** | **Step 5: After post-restore replication** |
|---|---|---|---|---|---|
| **Invocation ID of DC1** | DC1-GUID1 | DC1-GUID1 | DC1-GUID1 | DC1-GUID4 | DC1-GUID4 |
| **Highest committed USN on DC1** | 20 | 35 | 49 | 35 | 47 |
| **Up-to-dateness vector on DC1** | DC2-GUID2, USN=10;<br>DC3-GUID3, USN=45 | DC2-GUID2, USN=25;<br>DC3-GUID3, USN=60 | DC2-GUID2, USN=37;<br>DC3-GUID3, USN=60 | DC2-GUID2, USN=25;<br>DC3-GUID3, USN=60;<br>DC1-GUID1, USN=35 | DC2-GUID2, USN=37;<br>DC3-GUID3, USN=60;<br>DC1-GUID1, USN=47 |

**Authoritative Restore**
The primary purpose of an authoritative restore is to reinstate objects that were deleted from Active Directory. To reinstate objects that were intentionally or accidentally deleted, a nonauthoritative restore must be completed and followed by an authoritative restore. Authoritative restore is performed by using Ntdsutil.exe.

The nonauthoritative restore process cannot reinstate deleted objects from a backup image because the backup media that was used to restore the domain controller contains an image of Active Directory that was created before the objects were deleted. In this case, the deletions would simply be replicated in from the up-to-date replication partner and applied by the restored domain controller. To reinstate a deleted object, an authoritative restore is required.

The authoritative restore process works as follows:

1. The domain controller is restarted in Directory Services Restore Mode, and a nonauthoritative restore of Active Directory is performed by using backup media that was created before the object was deleted.

2. Following the nonauthoritative restore but prior to restarting, the object metadata is altered by Ntdsutil.exe so that it has a higher USN than any other possible version of the object (by default, the version number is increased by 100,000). The effect is to render the object or objects as authoritative and reinstates them in Active Directory.

The authoritative restore process results in a merge of authoritatively restored objects and attributes and existing objects and attributes. The authoritative restore process does not affect objects that were created after the backup was created. This merge functionality applies to objects with linked attributes and nonlinked attributes alike. For example, if you are restoring an object that has attribute A and attribute B in the backup version and has attributes A′, B′, and C in the current directory, attribute C is retained after authoritative restore. Therefore, a group object that has the **member** value of User1 in the backup and has both User1 and User2 in the current directory includes both of those memberships after authoritative restore of the group object. Any post-backup **memberOf** or **member** attribute values that were added to a user or group, respectively, are not affected by replication updates after the restore procedure.

**Note**

- Only the domain and configuration directory partitions can be marked as authoritative. The schema directory partition cannot be authoritatively restored.

**Restoring Back-links for Authoritatively Restored Objects**

When authoritative restore is performed on domain controllers running Windows Server 2000, the procedure recovers objects that have been deleted, but it does not restore the back-links for any objects that have linked attributes. The effect of not restoring back-links for the restored objects is particularly problematic for group memberships, which must be restored manually.

In a forest that has a forest functional level of Windows Server 2003 or Windows Server 2003 interim, the procedure for performing authoritative restore automatically restores back-links for multivalued, linked attributes. For example, the **member** attribute of groups to which a restored user object belongs are updated. This restoration applies to only those links that were created after the functional level was raised. For example, if you added a user to a group before raising the forest functional level, the user's membership in that group is not restored if you delete the user and then authoritatively restore the user. Automatic restore of back-links requires the raised forest functional level because link restoration is made possible by linked-value replication.

**Restoring Back-links Created Before Linked-Value Replication**

An updated version of Ntdsutil that is included with Windows Server 2003 SP1 makes it possible to also restore back-links that were created before implementation of linked-value replication. On domain controllers that have this updated version of Ntdsutil, the **authoritative restore** option generates an LDAP Data Interchange Format (LDIF) file that can be used to restore any back-links that are not restored automatically. In addition, Ntdsutil generates a text file that you can use to create an LDIF file for restoring back-links for groups in other domains. The LDIF file can be used to restore back-links on domain controllers running Windows 2000 Server or Windows Server 2003, and it does not depend on forest functional level. This method also resolves the problem of links not being restored if linked user and group objects are authoritatively restored together and the restored group object replicates out before the restored user object. For more information about restoring back-links, see "Managing Active Directory Backup and Restore" in the Active Directory Operations Guide.

**Domain Controller Notification of Changes**

Replication within a site occurs as a response to changes. On its NTDS Settings object, the source domain controller stores a **repsTo** attribute that lists all servers in the same site that pull replication from it. When a change occurs on a source domain controller, it notifies its destination replication partner, prompting the destination domain controller to request the changes from the source domain controller. The source domain controller either responds to the change request with a replication operation or places the request in a queue if requests are already pending. Replication occurs one request at a time until all requests in the queue are processed.

| **Note** |
| --- |
| Replication between sites occurs according to a schedule, where the destination requests changes at the specified time. By default, change notification is not enabled on site links. |

**Notification Delay Values**

When a change occurs on a domain controller within a site, two configurable intervals determine the delay between the change and subsequent events:

- **Initial notification delay**. The delay between the change to an attribute and notification of the first partner. This interval serves to stagger network traffic caused by intrasite replication. When a domain controller makes a change (originating or replicated) to a directory partition, it starts the timer for the interval; when the timer expires, the domain controller begins to notify its replication partners (for that directory partition and within its site) that it has changes.

- **Subsequent notification delay**. The delay between notification of the first partner and notification of each subsequent partner. A domain controller does not notify all of its replication partners at one time. By delaying between notifications, the domain controller distributes the load of responding to replication requests from its partners.

The storage location and default values for the initial and subsequent notification delay intervals vary depending on the version of the operating system (Windows Server 2003 or Windows 2000 Server) that is running on the domain controller and whether the domain controller has been upgraded. Application of notification delay values is also potentially affected by their default status and by the forest functional level.

**Storage of Intrasite Notification Delay Values**
On a domain controller that is running Windows Server 2003, intrasite notification delay values are specific to each directory partition and are stored in two attributes of the cross-reference object for each directory partition.

**Windows Server 2003 Storage of Notification Delay Values**
On domain controllers that are running Windows Server 2003, the attributes that store the change notification values are located on each cross-reference object in the Partitions container within the configuration directory partition:

- The value for initial change notification delay is stored in the **msDS-Replication-Notify-First-DSA-Delay** attribute.

  The default value is 15 seconds.

- The value for subsequent notification delay is stored in the **msDS-Replication-Notify-Subsequent-DSA-Delay** attribute.

  The default value is 3 seconds.

These attributes do not exist in Windows 2000 Server.

Although the attribute values are present on all domain controllers that are running Windows Server 2003, the default values of 15 seconds for initial notification delay and 3 seconds for subsequent notification delay are in effect only under the conditions described in "Application of Notification Delay Values by Domain Controllers" later in this section.

**Windows 2000 Server Storage of Notification Delay Values**
On domain controllers that are running Windows 2000 Server, intrasite notification delay values affect all directory partitions and are stored in registry entries on each domain controller. The registry entries are as follows:

- The value for the delay before the first change notification is stored in the **Replicator notify pause after modify (secs)** entry in HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters.

  The default value is 300 seconds.

- The value for the delay before each subsequent change notification is stored in the **Replicator notify pause between DSAs (secs)** entry in HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters.

  The default value is 30 seconds.

**Effect of Upgrade and Forest Functional Level on Registry Notification Delay Values**
Notification delay values for first and subsequent change notification are preserved as registry settings during upgrades from Windows 2000 Server to Windows Server 2003.

Raising the forest functional level to Windows Server 2003 Interim or Windows Server 2003 affects notification delay values for first and subsequent change notification, as follows:

- If a registry entry has the Windows 2000 Server default value of 300 seconds for initial notification delay or 30 seconds for subsequent notification delay at the time the forest functional level is raised, the registry entry that has the default value is removed and the Windows Server 2003 default value takes effect on the respective attribute of each cross-reference object.

- If a registry entry has a nondefault value, the registry value is preserved.

| **Note** |
| --- |
| One or both notification delay registry entries can be added to the registry to override the cross-reference values, if needed, to control notification by a specific domain controller running Windows Server 2003. |

**Application of Notification Delay Values by Domain Controllers**
To accommodate both the registry and cross-reference object locations of notification delay information, the process that is used to determine which change notification delay values to apply favors the settings in the registry if any exist. When replication partners send notification of changes, notification delay values are checked according to the operating systems that

are running on the partners, as follows:

- Windows Server 2003 only:
    - Check the registry for the presence of initial and subsequent notification delay values and use those values if they exist.
    - If no registry values exist, check the cross-reference object for the directory partition to which the change has occurred. If values are set, use those values.
    - Otherwise, use the default values of 15 seconds for initial notification delay and 3 seconds for subsequent notification delay.
- Windows Server 2003 and Windows 2000 Server:
    - Check the registry for the presence of registry values. If a value is set for an entry, use the value that is set for all relevant directory partitions.
    - If no value is set on a registry entry (the default is in effect), use the respective default values of 300 seconds for initial notification delay and 30 seconds for subsequent notification delay.

**Identifying and Locating Replication Partners**
Replication occurs in one direction between two domain controllers at a time. The replication topology determines the replication partnerships between source and destination domain controllers. As a replication source, the domain controller must determine the replication partners it must notify when changes occur. As a replication destination, the domain controller participates in replication either by responding to notification of changes from a source, or by requesting changes to initiate replication when it starts up or in response to a schedule.

**Destination Identification of Source Replication Partners**
When the KCC creates the replication topology, it creates connection objects on destination domain controllers that represent the inbound connection from the replication source domain controller. For each source domain controller that is represented by an inbound connection object, the KCC writes information to the **repsFrom** attribute of the directory partition object for each directory partition that the destination domain controller has in common with the source domain controller. This information is local to the destination domain controller and is not replicated. For a destination domain controller, the **repsFrom** attribute contains the following information about each source domain controller:

- Directory partition name.
- NTDS Settings object distinguished name.
- GUID-based DNS name (CNAME alias).
- Whether replication is intrasite, intersite using IP (RPC), or intersite using SMTP.
- Flags that govern the options, which indicate whether notification is allowed (no value is present) or not allowed (NEVER_NOTIFY is present).
- Invocation ID, for the purpose of detecting a change due to a restore from backup.
- Direct USN vector (high-watermark), which is the USN pair of object USN (OU) and property USN (PU).
- Time of last attempt and time of last success.
- Last error code.
- Count of consecutive failures, if any.

If notification is enabled on the destination domain controller, the destination responds to notification messages from source domain controllers by sending a request for changes. If notification is not enabled, the destination responds to notification requests with an error.

Notification is enabled on a destination domain controller except under the following conditions, in which the KCC sets the option NEVER_NOTIFY in **repsFrom**:

- The connection object that the KCC creates is inbound from a server in a different site. Such a destination is designated as a bridgehead server for the directory partition. Bridgehead servers pull replication according to a schedule on the site link object.

- The connection object is created to identify the source from which this domain controller replicates to add Active Directory as a new domain controller.

#### Source Identification of Destination Replication Partners

The source domain controller keeps track of the replication partners that pull changes from it and uses the information to locate partners for change notification. This information is not provided by the KCC, but rather by the source domain controller itself during a replication cycle. The first time a domain controller receives a request for changes from a new destination, the source creates an entry for the destination in the **repsTo** attribute on the respective directory partition object.

Whenever the source has changes, it sends a notification to all replication partners that are identified in the **repsTo** value for the respective directory partition. Like the **repsFrom** data, this information is stored locally on the domain controller and is not replicated. When updates occur, the source domain controller checks the **repsTo** attribute to determine the identities of its destination replication partners. The source domain controller notifies them one by one that changes are available.

### Note

- The output of the command **repadmin /showrepl /v /all** shows the contents of the **repsFrom** value (INBOUND NEIGHBORS) and the **repsTo** value (OUTBOUND NEIGHBORS).

If a destination domain controller has the NEVER_NOTIFY option set, the destination responds to a notification message with an error. When the error is received by the source domain controller, it removes the entry for that destination from its **repsTo** data.

If a destination domain controller moves to a different site, the KCC adjusts the notify setting to indicate that notification is not needed.

#### Locating Replication Partners

The partner that initiates replication locates its partner by querying DNS to look up the IP address of the partner according to the GUID of the NTDS Settings object (class **nTDSDSA**). The NTDS Settings object represents the directory system agent (DSA) on the domain controller. Its GUID uniquely identifies the domain controller and is guaranteed to find the correct server, even if the name of the server has been changed.

The GUID of the NTDS Settings object is stored in the **objectGUID** attribute. The DSA GUID is created when Active Directory is installed on the domain controller, and is destroyed only if Active Directory is removed from the domain controller to create a member server.

### Note

- The Active Directory database also has a GUID, which is used by the DSA to identify the specific versions of the database when a database has been restored. This GUID is stored in the **invocationId** attribute on the NTDS Settings object.

As part of the DNS registration process, the Net Logon service on every domain controller registers a canonical name (CNAME) resource record, or alias record, which is constructed using the DSA GUID as the alias and maps to the DNS fully qualified domain name (FQDN) of the respective domain controller. The format of CNAME alias is:

*DsaGuid*._msdcs.*DNSForestName*.

To initiate replication, the domain controller retrieves the GUID-based DNS name that is stored in **repsTo** (for a source domain controller that is sending a change notification) and **repsFrom** (for a destination domain controller that is initiating replication) and queries DNS for the CNAME resource record. DNS responds by returning both the CNAME resource record and the host (A) resource record, which contains the IP address of the destination domain controller. The domain controller uses

information in the CNAME resource record to authenticate to the replication partner. Therefore, by using the CNAME and A resource record data, the domain controller can initiate replication.

**Note**

- The _msdcs.*DnsForestName* DNS zone contains a variety of forest-wide service (SRV) resource records that are used to locate special servers, such as domain controllers and global catalog servers, and to facilitate replication. In the context of this discussion, it is important to note that if a DNS server that is authoritative for the _msdcs.*DnsForestName* zone is not available, replication between domain controllers cannot occur.

For more information about the DSA and application directory partitions, see "How the Data Store Works." For more information about SRV resource records and the _msdcs subdomain, see "DNS Support for Active Directory Technical Reference".

**Urgent Replication**

Certain important events trigger replication immediately, overriding existing change notification. Urgent replication is implemented immediately by using RPC/IP to notify replication partners that changes have occurred on a source domain controller. Urgent replication uses regular change notification between destination and source domain controller pairs that otherwise use change notification, but notification is sent immediately in response to urgent events instead of waiting the default period of 15 seconds (or 300 seconds on domain controllers that are running Windows 2000).

**Events That Trigger Urgent Replication**

Urgent Active Directory replication is always triggered by certain events on all domain controllers within the same site, regardless of what operating system is running on the domain controller. When you have enabled change notification between sites, these triggering events also replicate immediately between sites.

Between domain controllers in the same site, immediate notification is caused by the following events:

- Assigning an account lockout, which a domain controller performs to prohibit a user from logging on after a certain number of failed attempts.

  | **Note** |
  | --- |
  | An account unlock is not urgently replicated. |

- Changing the account lockout policy.
- Changing the domain password policy.
- Changing a Local Security Authority (LSA) secret, which is a secure form in which private data is stored by the LSA (for example, the password for a trust relationship).
- Changing the password on a domain controller computer account.
- Changing the relative identifier (known as a "RID") master role owner, which is the single domain controller in a domain that assigns relative identifiers to all domain controllers in that domain.

**Urgent Replication of Account Lockout Changes**

Account lockout is a security feature that sets a limit on the number of failed authentication attempts that are allowed before the account is "locked out" from a further attempt to log on, in addition to a time limit for how long the lockout is in effect.

The PDC emulator receives urgent replication of account lockouts. In Active Directory domains, a single domain controller in each domain holds the role of PDC emulator, which simulates the behavior of a Windows NT version 3.*x*–based or Windows NT 4.0–based PDC. In Windows NT domains, the only domain controller that can accept updates is the PDC. If authentication fails at a BDC, the authentication request is passed immediately to the PDC, which is guaranteed to have the current password.

| **Note** |
| --- |

Because Active Directory Lightweight Directory Services (AD LDS) does not have a PDC emulator, urgent replication of account lockouts does not occur. An account lockout is replicated according to the replication frequency schedule. In order to ensure account lockouts are replicated as soon as possible in AD LDS, configure the replication frequency for every 15 minutes, or to another value that is suitable to your environment. The lowest value that can be set is 15 minutes. For more information, see Setting replication frequency (http://go.microsoft.com/fwlink/?LinkId=212626).

An account lockout is urgently replicated to the PDC emulator and is then urgently replicated to the following:

- Domain controllers in the same domain that are located in the same site as the PDC emulator.
- Domain controllers in the same domain that are located in the same site as the domain controller that handled the account lockout.
- Domain controllers in the same domain that are located in sites that have been configured to allow change notification between sites (and, therefore, urgent replication) with the site that contains the PDC emulator or with the site where the account lockout was handled. These sites include any site that is included in the same site link as the site that contains the PDC emulator or in the same site link as the site that contains the domain controller that handled the account lockout.

In addition, when authentication fails at a domain controller other than the PDC emulator, the authentication is retried at the PDC emulator. For this reason, the PDC emulator locks the account before the domain controller that handled the failed-password attempt if the bad-password-attempt threshold is reached.

**Note**

- When a bad password is used in an attempt to change a password, the lockout count is incremented on that domain controller only and is not replicated. As such, an attacker could try (# of domain controllers)*(lockout threshold -1) + 1 guesses before the account is locked out. Although this scenario has a relatively small impact on account lockout security, domains with an exceptionally high number of domain controllers represent a significant increase in the total number of guesses available to an attacker. Because a user cannot specify the domain controller on which the password change is attempted, an attack of this type requires an advanced tool.

**Replication of Password Changes**

Password changes are replicated differently than both normal (non-urgent) replication and urgent replication. Changes to security account passwords present a replication latency problem wherein a user's password is changed on domain controller A and the user subsequently attempts to log on, being authenticated by domain controller B. If the password has not replicated from A to B, the attempt to log on fails. Active Directory replication remedies this situation by forwarding password changes immediately to a single domain controller in the domain, the PDC emulator.

In Active Directory, when a user password is changed at a domain controller, that domain controller attempts to update the respective replica at the domain controller that holds the PDC emulator role. Update of the PDC emulator occurs immediately, without respect to schedules on site links. The updated password is propagated to other domain controllers by normal replication within a site.

When the user logs on to a domain and is authenticated by a domain controller that does not have the updated password, the domain controller refers to the PDC emulator to check the credentials of the user name and password rather than denying authentication based on an invalid password. Therefore, the user can log on successfully even when the authenticating domain controller has not yet received the updated password. On domain controllers that are running Windows Server 2003 or Windows 2000 Server with SP4, if the authentication is successful at the PDC emulator, the PDC emulator replicates the password immediately to the requesting domain controller to prevent that domain controller from having to check the PDC emulator again.

If the update at the PDC emulator fails for any reason, the password change is replicated non-urgently by normal replication.

For clients that are running Windows NT 4.0 or clients that are running Windows 95 or Windows 98 without the Directory Service Client Pack, the client attempts to contact the PDC emulator. If the client has the Directory Service Client Pack installed, the client contacts any domain controller and the contacted domain controller then attempts to contact the PDC emulator.

**Note**

- The Group Policy setting "Contact PDC on logon failure" can be disabled to keep a domain controller from contacting the

PDC emulator if the PDC emulator role owner is not in the current site. If this setting is disabled, the password change reaches the PDC emulator non-urgently through normal replication.

**Network Ports Used by Active Directory Replication**

By default, RPC-based replication uses dynamic port mapping. When connecting to an RPC endpoint during Active Directory replication, the RPC run time on the client contacts the RPC endpoint mapper on the server at a well-known port (port 135). The server queries the RPC endpoint mapper on this port to determine what port has been assigned for Active Directory replication on the server. This query occurs whether the port assignment is dynamic (the default) or fixed. The client never needs to know which port to use for Active Directory replication.

For more information about how to restrict Active Directory replication traffic and RPC traffic to a specific port, see article 224196 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkId=111871).

**Note**

- An endpoint comprises the protocol, local address, and port address.

In addition to the dynamic port 135, other ports that are required for replication to occur are listed in the following table.

**Port Assignments for Active Directory Replication**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |
| LDAP | | 636 (Secure Sockets Layer [SSL]) |
| LDAP | | 3268 (global catalog) |
| Kerberos | 88 | 88 |
| DNS | 53 | 53 |

Replication within a domain also requires File Replication Service (FRS) using a dynamic RPC port. For more information about how to restrict FRS replication to a specific port, see article 319553 in the Microsoft Knowledge Base (http://go.microsoft.com/fwlink/?LinkId=111872).

# Active Directory Replication Tools and Settings

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**Active Directory Replication Tools and Settings**

**In this section**

- Active Directory Replication Tools
- Active Directory Replication Registry Entries
- Active Directory Replication Group Policy Settings
- Active Directory Replication WMI Classes
- Network Ports Used by Active Directory Replication
- Related Information

**Active Directory Replication Tools**

The following tools are associated with Active Directory replication.

| Note |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

**Dssite.msc: Active Directory Sites and Services**

**Category**

Active Directory Administrative Tools Microsoft Management Console (MMC) snap-in. This tool is installed automatically when you install Active Directory, and is available on the Start menu under Programs\Administrative Tools. This tool also ships with the Administration Tools Pack (Adminpak.msi).

**Version compatibility**

Active Directory Sites and Services provides a view into the Sites container of the configuration directory partition. Use Active Directory Sites and Services to manage Active Directory replication topology. The following objects and their properties can be managed by using this tool:

- Sites container: Add new sites.
- Site objects: Add new servers to a site.
- NTDS Site Settings object: For each site, view the connection object schedule and enable Universal group membership caching.
- Server object: View the NTDS Settings object and designate the server as a bridgehead server.
- NTDS Settings object: View inbound connections for the server. View the connection object schedule and change the source server for the connection.
- Inter-Site Transports container: Manage IP and SMTP site links.
- Site link objects: Manage the site link properties for a set of sites.

- Subnets container: Add, remove, and configure subnets with IP addresses. Associate subnets with sites.

**Repadmin.exe: Repadmin**

**Category**
Command-line tool.

**Version compatibility**
Repadmin is used to view the replication information on domain controllers. You can determine the last successful replication of all directory partitions, identify inbound and outbound replication partners, identify the current bridgehead servers, view object metadata, and generally manage Active Directory replication topology. You can use Repadmin to force replication of an entire directory partition or of a single object. You can also list domain controllers in a site.

Repadmin is extended to enable commands to target sets of domain controllers. For example, you can target all domain controllers in a site or domain, or all domain controllers that are global catalog servers.

Repadmin also includes the **RemoveLingeringObjects** command, which removes objects that are outdated (do not exist in a replica of the same directory partition on the source domain controller).

For more information about removing lingering objects, see "Fixing Replication Lingering Object Problems (Event IDs 1388, 1988, 2042)" in the Windows Server 2003 Operations Guide at http://go.microsoft.com/fwlink/?LinkId=44131. For more information about Repadmin, see Repadmin Overview.

**Ntdsutil.exe: Ntdsutil**

**Category**
Command-line tool.

**Version compatibility**
Ntdsutil.exe provides management capabilities for Active Directory. You can use Ntdsutil.exe to perform Active Directory database maintenance, manage and control single-master operations, and remove replication metadata left behind by domain controllers that are removed from the network without uninstalling Active Directory. The version of Ntdsutil that is included with Windows Server 2003 SP1 removes File Replication service (FRS) metadata in addition to Active Directory replication metadata. You can also use Ntdsutil to create application directory partitions and perform authoritative restore operations. This tool is intended for use by experienced administrators.

**Active Directory Replication Registry Entries**
The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

The following registry settings cannot be modified by using Group Policy or other Windows tools.

**NTDS Parameters Registry Settings**
The following registry entries are associated with Active Directory replication.

**Replicator notify pause after modify (secs)**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows 2000 Server.

**Default value**
Windows 2000 Server: 300 seconds.

The value for the delay between an originating update on a domain controller and the first change notification. On domain controllers running Windows Server 2003 or higher, the value for initial change notification delay is stored in the **msDSReplicationNotifyFirstDSADelay** attribute on the cross-reference object for each directory partition in the Configuration container. The default value in Windows Server 2003 and higher operating systems is decreased to 15 seconds

when the forest functional level is Windows Server 2003 or higher.

**Replicator notify pause between DSAs (secs)**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows 2000 Server.

**Default value**
Windows 2000 Server: 30 seconds

The value for the delay before each subsequent change notification. On domain controllers running Windows Server 2003, the value for subsequent notification delay is stored in the **msDSReplicationNotifySubsequentDSADelay** attribute on the cross-reference object for each directory partition in the Configuration container. The default value in Windows Server 2003 is decreased to 3 seconds when the forest functional level is Windows Server 2003.

**RPC Replication Timeout (mins)**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
Windows 2000 Server: 45 minutes; Windows Server 2003 and higher server operating systems: 5 minutes.

The number of minutes between initiation of Active Directory replication and the RPC timeout. The domain controller must be restarted before the change takes effect.

**Strict replication consistency**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008 R2, Windows Server 2003, Windows 2000 Server with SP3.

**Default value**
Windows 2000 Server with SP3: off (0); Windows Server 2003 and higher server operating systems: on (1)

The value that determines the treatment of replication of outdated objects that exist on reconnected domain controllers that have not replicated in longer than a tombstone lifetime. If the destination domain controller has strict replication consistency enabled, inbound replication of an outdated object is blocked. If the destination domain controller has strict replication disabled, inbound replication of the full object occurs.

**Replicator intra site packet size (objects)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
1/1,000,000th the size of RAM, with a minimum of 100 objects and a maximum of 1,000 objects.

The maximum number of objects per packet for RPC replication within a site.

**Replicator intra site packet size (bytes)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
1/100th the size of RAM, with a minimum of 1 megabyte (MB) and a maximum of 10 MB.

The maximum size of objects per packet for RPC replication within a site.

**Replicator inter site packet size (objects)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008 R2, Windows Server 2003, Windows 2000 Server.

**Default value**
1/1,000,000th the size of RAM, with a minimum of 100 objects and a maximum of 1,000 objects.

The maximum number of objects per packet for RPC replication between sites.

**Replicator inter site packet size (bytes)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

The maximum size of objects per packet for RPC replication between sites.

**Default value**
1/100th the size of RAM, with a minimum of 1 MB and a maximum of 10 MB.

**Replicator async inter site packet size (objects)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008, Windows Server 2008 R2, Windows Server 2003, Windows 2000 Server.

**Default value**
1/1,000,000th the size of RAM, with a minimum of 100 objects and a maximum of 1,000 objects.

The maximum number of objects per packet for SMTP replication between sites.

**Replicator async inter site packet size (bytes)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
1 MB.

The maximum size of objects per packet for SMTP replication between sites.

**Replicator compression algorithm**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003.

**Default value**
For Windows 2000 Server compression, change the value to 2.

Determines the compression algorithm that is used on a site link

**Repl topology update delay (secs)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
300 seconds.

Number of seconds to wait between the time Active Directory starts and the KCC performs the first topology check.

To find more information about **Repl topology update delay (secs)**, see "Registry Reference" in Tools and Settings Collection.

**Repl topology update period (secs)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008, Windows Server 2008 R2, Windows Server 2003, Windows 2000 Server.

**Default value**
900 seconds.

Interval between KCC replication topology checks.

To find more information about **Repl topology update period (secs)**, see "Registry Reference" in Tools and Settings Collection.

**IntersiteFailuresAllowed**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
1.

Number of failed replication attempts prior to excluding nonresponding servers from the intersite topology.

**MaxFailureTimeForIntersiteLink (sec)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
7200 seconds (2 hours).

Time in seconds that must elapse prior to excluding nonresponding servers from the intersite topology.

**NonCriticalLinkFailuresAllowed**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
1.

Number of failed replication attempts prior to excluding nonresponding servers from the intrasite topology.

**MaxFailureTimeForNonCriticalLink (sec)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008, Windows Server 2008 R2, Windows Server 2003, Windows 2000 Server.

**Default value**
43200 seconds (12 hours).

Time in seconds that must elapse prior to excluding nonresponding servers from the intrasite topology.

**CriticalLinkFailuresAllowed**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
0.

Number of failed replication attempts prior to excluding nonresponding servers for immediate neighbor connections within a site.

**MaxFailureTimeForCriticalLink (sec)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
7200 seconds (2 hours).

Time in seconds that must elapse prior to excluding nonresponding servers for immediate neighbor connections within a site.

**TCP/IP Port**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
135.

TCP port that the directory service uses instead of using dynamic port 135. The domain controller must be restarted before the change takes effect.

**Backup Latency Threshold (days)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003 with SP 1

**Default value**
Half the value of the tombstone lifetime of the forest.

When the value is reached, logs event ID 2089 in the Directory Service event log, warning administrators and monitoring applications to make sure that domain controllers are backed up before the tombstone lifetime expires.

**Active Directory Replication Group Policy Settings**

The following table lists and describes the Group Policy settings that are associated with Active Directory replication updates.

**Group Policy Settings Associated with Active Directory Replication**

| Group Policy Setting | Description |
|---|---|
| Account Lockout Policy:<br>• Account lockout duration<br>• Account lockout threshold<br>• Reset account lockout counter after | Changes to these settings in the Domain Security Policy trigger urgent replication. |
| Password Policy:<br>• Enforce password history<br>• Maximum password age<br>• Minimum password age<br>• Minimum password length<br>• Password must meet complexity requirements<br>• Store passwords using reversible encryption | Changes to these settings in the Domain Security Policy trigger urgent replication. |
| Contact PDC on logon failure | Account lockout and domain password changes rely on contacting the primary domain controller (PDC) emulator urgently to update the PDC emulator with the change. If Contact PDC on logon failure is disabled, replication of password changes to the PDC emulator occurs non-urgently. |

To find more information about these Group Policy settings, see “Group Policy Settings Reference” in Tools and Settings

Collection.

**Active Directory Replication WMI Classes**

The following table lists and describes the WMI classes that are associated with Active Directory replication. These classes are shipped with Windows Server 2003 or later server operating systems, but are also compatible with Windows 2000 Server.

**WMI Classes Associated with Active Directory Replication**

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| MSAD_DomainController | \\root\MicrosoftActiveDirectory | Windows Server 2008 R2<br>Windows Server 2008<br>Windows Server 2003<br>Windows 2000 Server |
| MSAD_NamingContext | \\root\MicrosoftActiveDirectory | Windows Server 2008 R2<br>Windows Server 2008<br>Windows Server 2003<br>Windows 2000 Server |
| MSAD_ReplNeighbor | \\root\MicrosoftActiveDirectory | Windows Server 2008 R2<br>Windows Server 2008<br>Windows Server 2003<br>Windows 2000 Server |
| MSAD_ReplCursor | \\root\MicrosoftActiveDirectory | Windows Server 2008 R2<br>Windows Server 2008<br>Windows Server 2003<br>Windows 2000 Server |
| MSAD_ReplPendingOp | \\root\MicrosoftActiveDirectory | Windows Server 2008 R2<br>Windows Server 2008<br>Windows Server 2003<br>Windows 2000 Server |

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

**Network Ports Used by Active Directory Replication**

By default, RPC-based replication uses dynamic port mapping. When connecting to an RPC endpoint during Active Directory replication, the RPC run time on the client contacts the RPC endpoint mapper on the server at a well-known port (port 135). The server queries the RPC endpoint mapper on this port to determine what port has been assigned for Active Directory replication on the server. This query occurs whether the port assignment is dynamic (the default) or fixed. The client never needs to know which port to use for Active Directory replication.

**Note**

- An endpoint comprises the protocol, local address, and port address.

In addition to the dynamic port 135, other ports that are required for replication to occur are listed in the following table.

**Port Assignments for Active Directory Replication**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |
| LDAP | | 636 (Secure Sockets Layer [SSL]) |
| LDAP | | 3268 (global catalog) |
| Kerberos | 88 | 88 |
| DNS | 53 | 53 |
| SMB over IP | 445 | 445 |

Replication within a domain also requires FRS using a dynamic RPC port.

# Active Directory Replication Topology Technical Reference

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**Active Directory Replication Topology Technical Reference**

The replication topology of Active Directory directory service provides the network of connections between domain controllers in a forest according to their location in Active Directory sites. A site is an Active Directory object that you create and configure to represent an area of good network connectivity, typically corresponding to a local area network (LAN). The site object is associated with a set of one or more subnets, which are objects that identify a range of IP addresses. Each domain controller has an IP address that maps to a subnet, and that mapping in turn identifies the site of the domain controller. By recognizing domain controllers according to site locations, the replication system ensures that each domain controller is updated with directory changes in the most efficient and timely manner possible, given network conditions and directory service configuration. The replication topology is generated automatically at regular intervals to accommodate network and configuration changes, and is designed to ensure that all domain controllers are connected without redundancy and with minimum cost.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

# What Is Active Directory Replication Topology?

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**What Is Active Directory Replication Topology?**

**In this section**

- Replication Within and Between Sites
- Technologies Related to Active Directory Replication Topology
- Active Directory Replication Topology Dependencies
- Related Information

Replication of updates to Active Directory objects are transmitted between multiple domain controllers to keep replicas of directory partitions synchronized. Multiple domains are common in large organizations, as are multiple sites in disparate locations. In addition, domain controllers for the same domain are commonly placed in more than one site.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

Therefore, replication must often occur both within sites and between sites to keep domain and forest data consistent among domain controllers that store the same directory partitions. Site objects can be configured to include a set of subnets that provide local area network (LAN) network speeds. As such, replication within sites generally occurs at high speeds between domain controllers that are on the same network segment. Similarly, site link objects can be configured to represent the wide area network (WAN) links that connect LANs. Replication between sites usually occurs over these WAN links, which might be costly in terms of bandwidth. To accommodate the differences in distance and cost of replication within a site and replication between sites, the intrasite replication topology is created to optimize speed, and the intersite replication topology is created to minimize cost.

The Knowledge Consistency Checker (KCC) is a distributed application that runs on every domain controller and is responsible for creating the connections between domain controllers that collectively form the replication topology. The KCC uses Active Directory data to determine where (from what source domain controller to what destination domain controller) to create these connections.

**Replication Within and Between Sites**

The KCC creates separate replication topologies to transfer Active Directory updates within a site and between all configured sites in the forest. The connections that are used for replication within sites are created automatically with no additional configuration. Intrasite replication takes advantage of LAN network speeds by providing replication as soon as changes occur, without the overhead of data compression, thus maximizing CPU efficiency. Intrasite replication connections form a ring topology with extra shortcut connections where needed to decrease latency. The fast replication of updates within sites facilitates timely updates of domain data. In deployments where large datacenters constitute hub sites for the centralization of mission-critical operations, directory consistency is critical.

Replication between sites is made possible by user-defined site and site link objects that are created in Active Directory to represent the physical LAN and WAN network infrastructure. When Active Directory sites and site links are configured, the KCC creates an intersite topology so that replication flows between domain controllers across WAN links. Intersite replication occurs according to a site link schedule so that WAN usage can be controlled, and is compressed to reduce network bandwidth requirements. Site link settings can be managed to optimize replication routing over WAN links. The connections that are created between sites form a spanning tree for each directory partition in the forest, merging where common directory partitions can be replicated over the same connection.

In remote branch locations, replication of updates from the hub sites is optimized for network availability. Thus, because intrasite replication is optimized for speed, branch locations across WAN links can be assured of receiving data from hub sites

that is up-to-date and reliable; but because intersite replication is scheduled, branch sites receive this replication only at intervals that are deemed appropriate and cost-effective for remote operations.

#### Technologies Related to Active Directory Replication Topology

The following technologies interact with Active Directory replication.

#### File Replication Service

File Replication service (FRS) is related to Active Directory replication because it requires the Active Directory replication topology. FRS is a multimaster replication service that is used to replicate files and folders in the system volume (SYSVOL) shared folder on domain controllers and in Distributed File System (DFS) shared folders. FRS works by detecting changes to files and folders and then replicating the updated files and folders to other replica members, which are connected in a replication topology.

FRS uses the replication topology that is generated by the KCC to replicate the SYSVOL files to all domain controllers in the domain. SYSVOL files are required by all domain controllers for Active Directory to function. For more information about FRS and how it uses the Active Directory replication topology, see "FRS Technical Reference". For more information about SYSVOL, see "Data Store Technical Reference."

#### SMTP

Simple Mail Transfer Protocol (SMTP) is a packaging protocol that can be used as an alternative to the remote procedure call (RPC) replication transport. SMTP can be used to transport nondomain replication over IP networks in mail-message format. Where networks are not fully routed, e-mail is sometimes the only transport method available.

#### Active Directory Replication Topology Dependencies

Active Directory replication topology has the following dependencies:

- **Routable IP infrastructure**. The replication topology is dependent upon a routable IP infrastructure from which you can map IP subnet address ranges to site objects. This mapping generates the information that is used by client workstations to communicate with domain controllers that are close by, when there is a choice, rather than those that are located across WAN links.

- **DNS**. The Domain Name System (DNS) resolves DNS names to IP addresses. Active Directory replication topology requires that DNS is properly designed and deployed so that domain controllers can correctly resolve the DNS names of replication partners.

  DNS also stores service (SRV) resource records that provide site affinity information to clients searching for domain controllers, including domain controllers that are searching for replication partners. Every domain controller registers these records so that they can be located according to site.

- **Net Logon service**. Net Logon is required for DNS registrations.

- **RPC**. Active Directory replication requires IP connectivity and RPC to transfer updates between replication partners within sites. RPC is required for replication between two sites containing domain controllers in the same domain, but SMTP is an alternative where RPC cannot be used and domain controllers for the same domain are all located in one site so that intersite replication of domain data is not required.

- **Intersite Messaging**. Intersite Messaging is required for SMTP intersite replication and for site coverage calculations. If the forest functional level is Windows 2000, Intersite Messaging is also required for intersite topology generation.

The following diagram shows the interaction of these technologies with the replication topology, which is indicated by the two-way connections between each set of domain controllers.

# How Active Directory Replication Topology Works

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**How Active Directory Replication Topology Works**

**In this section**

- Active Directory KCC Architecture and Processes
- Replication Topology Physical Structure
- Performance Limits for Replication Topology Generation
- Goals of Replication Topology
- Topology-Related Objects in Active Directory
- Replication Transports
- Replication Between Sites
- KCC and Topology Generation
- Network Ports Used by Replication Topology
- Related Information

Active Directory implements a replication topology that takes advantage of the network speeds within sites, which are ideally configured to be equivalent to local area network (LAN) connectivity (network speed of 10 megabits per second [Mbps] or higher). The replication topology also minimizes the use of potentially slow or expensive wide area network (WAN) links between sites.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

When you create a site object in Active Directory, you associate one or more Internet Protocol (IP) subnets with the site. Each domain controller in a forest is associated with an Active Directory site. A client workstation is associated with a site according to its IP address; that is, each IP address maps to one subnet, which in turn maps to one site.

Active Directory uses sites to:

- Optimize replication for speed and bandwidth consumption between domain controllers.
- Locate the closest domain controller for client logon, services, and directory searches.
- Direct a Distributed File System (DFS) client to the server that is hosting the requested data within the site.
- Replicate the system volume (SYSVOL), a collection of folders in the file system that exists on each domain controller in a domain and is required for implementation of Group Policy.

The ideal environment for replication topology generation is a forest that has a forest functional level of at least Windows

Server 2003. In this case, replication topology generation is faster and can accommodate more sites and domains than occurs when the forest has a forest functional level of Windows 2000. When at least one domain controller in each site is running Windows Server 2003, more domain controllers in each site can be used to replicate changes between sites than when all domain controllers are running Windows 2000 Server.

In addition, replication topology generation requires the following conditions:

- A Domain Name System (DNS) infrastructure that manages the name resolution for domain controllers in the forest. Active Directory–integrated DNS is assumed, wherein DNS zone data is stored in Active Directory and is replicated to all domain controllers that are DNS servers.
- All physical locations that are represented as site objects in Active Directory have LAN connectivity.
- IP connectivity is available between each site and all sites in the same forest that host operations master roles.
- Domain controllers meet the hardware requirements for Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Standard Edition; Windows Server 2003, Enterprise Edition; and Windows Server 2003, Datacenter Edition.
- The appropriate number of domain controllers is deployed for each domain that is represented in each site.

This section covers the replication components that create the replication topology and how they work together, plus the mechanisms and rationale for routing replication traffic between domain controllers in the same site and in different sites.

**Active Directory KCC Architecture and Processes**

The replication topology is generated by the Knowledge Consistency Checker (KCC), a replication component that runs as an application on every domain controller and communicates through the distributed Active Directory database. The KCC functions locally by reading, creating, and deleting Active Directory data. Specifically, the KCC reads configuration data and reads and writes connection objects. The KCC also writes local, nonreplicated attribute values that indicate the replication partners from which to request replication.

For most of its operation, the KCC that runs on one domain controller does not communicate directly with the KCC on any other domain controller. Rather, all KCCs use the knowledge of the common, global data that is stored in the configuration directory partition as input to the topology generation algorithm to converge on the same view of the replication topology.

Each KCC uses its in-memory view of the topology to create inbound connections locally, manifesting only those results that apply to itself. The KCC communicates with other KCCs only to make a remote procedure call (RPC) request for replication error information. The KCC uses the error information to identify gaps in the replication topology. A request for replication error information occurs only between domain controllers in the same site.

**Note**

- The KCC uses only RPC to communicate with the directory service. The KCC does not use Lightweight Directory Access Protocol (LDAP).

One domain controller in each site is selected as the Intersite Topology Generator (ISTG). To enable replication across site links, the ISTG automatically designates one or more servers to perform site-to-site replication. These servers are called bridgehead servers. A bridgehead is a point where a connection leaves or enters a site.

The ISTG creates a view of the replication topology for all sites, including existing connection objects between all domain controllers that are acting as bridgehead servers. The ISTG then creates inbound connection objects for servers in its site that it determines will act as bridgehead servers and for which connection objects do not already exist. Thus, the scope of operation for the KCC is the local server only, and the scope of operation for the ISTG is a single site.

Each KCC has the following global knowledge about objects in the forest, which it gets by reading objects in the Sites container of the configuration directory partition and which it uses to generate a view of the replication topology:

- Sites
- Servers
- Site affiliation of each server

- Global catalog servers
- Directory partitions stored by each server
- Site links
- Site link bridges

Detailed information about these configuration components and their functionality is provided later in this section.

The following diagram shows the KCC architecture on servers in the same forest in two sites.

**KCC Architecture and Processes**

The architecture and process components in the preceding diagram are described in the following table.

**KCC Architecture and Process Components**

| Component | Description |
|---|---|
| Knowledge Consistency Checker (KCC) | The application running on each domain controller that communicates directly with the Ntdsa.dll to read and write replication objects. |
| Directory System Agent (DSA) | The directory service component that runs as Ntdsa.dll on each domain controller, providing the interfaces through which services and processes such as the KCC gain access to the directory database. |
| Extensible Storage Engine (ESE) | The directory service component that runs as Esent.dll. ESE manages the tables of records, each with one or more columns. The tables of records comprise the directory database. |
| Remote procedure call (RPC) | The Directory Replication Service (Drsuapi) RPC protocol, used to communicate replication status and topology to a domain controller. The KCC also uses this protocol to communicate with other KCCs to request error information when building the replication topology. |

| | |
|---|---|
| Intersite Topology Generator (ISTG) | The single KCC in a site that manages intersite connection objects for the site. |

The four servers in the preceding diagram create identical views of the servers in their site and generate connection objects on the basis of the current state of Active Directory data in the configuration directory partition. In addition to creating its view of the servers in its respective site, the KCC that operates as the ISTG in each site also creates a view of all servers in all sites in the forest. From this view, the ISTG determines the connections to create on the bridgehead servers in its own site.

**Note**

- A connection requires two endpoints: one for the destination domain controller and one for the source domain controller. Domain controllers creating an intrasite topology always use themselves as the destination end point and must consider only the endpoint for the source domain controller. The ISTG, however, must identify both endpoints in order to create connection objects between two other servers.

Thus, the KCC creates two types of topologies: intrasite and intersite. Within a site, the KCC creates a ring topology by using all servers in the site. To create the intersite topology, the ISTG in each site uses a view of all bridgehead servers in all sites in the forest. The following diagram shows a high-level generalization of the view that the KCC sees of an intrasite ring topology and the view that the ISTG sees of the intersite topology. Lines between domain controllers within a site represent inbound and outbound connections between the servers. The lines between sites represent configured site links. Bridgehead servers are represented as BH.

**KCC and ISTG Views of Intrasite and Intersite Topology**

**Replication Topology Physical Structure**

The Active Directory replication topology can use many different components. Some components are required and others are not required but are available for optimization. The following diagram illustrates most replication topology components and their place in a sample Active Directory multisite and multidomain forest. The depiction of the intersite topology that uses multiple bridgehead servers for each domain assumes that at least one domain controller in each site is running at least Windows Server 2003. All components of this diagram and their interactions are explained in detail later in this section.

**Replication Topology Physical Structure**

In the preceding diagram, all servers are domain controllers. They independently use global knowledge of configuration data to generate one-way, inbound connection objects. The KCCs in a site collectively create an intrasite topology for all domain controllers in the site. The ISTGs from all sites collectively create an intersite topology. Within sites, one-way arrows indicate the inbound connections by which each domain controller replicates changes from its partner in the ring. For intersite replication, one-way arrows represent inbound connections that are created by the ISTG of each site from bridgehead servers (BH) for the same domain (or from a global catalog server [GC] acting as a bridgehead if the domain is not present in the site) in other sites that share a site link. Domains are indicated as D1, D2, D3, and D4.

Each site in the diagram represents a physical LAN in the network, and each LAN is represented as a site object in Active Directory. Heavy solid lines between sites indicate WAN links over which two-way replication can occur, and each WAN link is represented in Active Directory as a site link object. Site link objects allow connections to be created between bridgehead servers in each site that is connected by the site link.

Not shown in the diagram is that where TCP/IP WAN links are available, replication between sites uses the RPC replication transport. RPC is always used within sites. The site link between Site A and Site D uses the SMTP protocol for the replication transport to replicate the configuration and schema directory partitions and global catalog partial, read-only directory partitions. Although the SMTP transport cannot be used to replicate writable domain directory partitions, this transport is required because a TCP/IP connection is not available between Site A and Site D. This configuration is acceptable for replication because Site D does not host domain controllers for any domains that must be replicated over the site link A-D.

By default, site links A-B and A-C are transitive (bridged), which means that replication of domain D2 is possible between Site B and Site C, although no site link connects the two sites. The cost values on site links A-B and A-C are site link settings that determine the routing preference for replication, which is based on the aggregated cost of available site links. The cost of a direct connection between Site C and Site B is the sum of costs on site links A-B and A-C. For this reason, replication between Site B and Site C is automatically routed through Site A to avoid the more expensive, transitive route. Connections are created between Site B and Site C only if replication through Site A becomes impossible due to network or bridgehead server conditions.

**Performance Limits for Replication Topology Generation**

Active Directory topology generation performance is limited primarily by the memory on the domain controller. KCC performance degrades at the physical memory limit. In most deployments, topology size will be limited by the amount of domain controller memory rather than CPU utilization required by the KCC.

Scaling of sites and domains is improved in Windows Server 2003 by improving the algorithm that the KCC uses to generate

the intersite replication topology. Because all domain controllers must use the same algorithm to arrive at a consistent view of the replication topology, the improved algorithm has a forest functional level requirement of Windows Server 2003 or Windows Server 2003 interim.

KCC scalability was tested on domain controllers with 1.8 GHz processor speed, 512 megabytes (MB) RAM, and small computer system interface (SCSI) disks. KCC performance results at forest functional levels that are at least Windows Server 2003 are described in the following table. The times shown are for the KCC to run where all new connections are needed (maximum) and where no new connections are needed (minimum). Because most organizations add domain controllers in increments, the minimum generation times shown are closest to the actual runtimes that can be expected in deployments of comparable sizes. The CPU and memory usage values for the Local Security Authority (LSA) process (Lsass.exe) indicate the more significant impact of memory versus percent of CPU usage when the KCC runs.

**Note**

- Active Directory runs as part of the LSA, which manages authentication packages and authenticates users and services.

**Minimum and Maximum KCC Generation Times for Domain-Site Combinations**

| Domains | Sites | Connections | KCC Generation Time (seconds) | Lsass.exe Memory Usage (MB) | Lsass.exe CPU Usage (%) |
|---|---|---|---|---|---|
| **1** | 500 | Maximum | 43 | 100 | 39 |
| | | Minimum | 1 | 100 | 29 |
| | 1,000 | Maximum | 49 | 149 | 43 |
| | | Minimum | 2 | 149 | 28 |
| | 3,000 | Maximum | 69 | 236 | 46 |
| | | Minimum | 2 | 236 | 63 |
| **5** | 500 | Maximum | 70 | 125 | 29 |
| | | Minimum | 2 | 126 | 71 |
| | 1,000 | Maximum | 77 | 237 | 28 |
| | | Minimum | 3 | 237 | 78 |
| | 2,000 | Maximum | 78 | 325 | 43 |
| | | Minimum | 5 | 325 | 77 |
| | 3,000 | Maximum | 85 | 449 | 52 |
| | | Minimum | 6 | 449 | 75 |
| | 4,000 | Maximum | 555 | 624 | 46 |
| | | Minimum | 34 | 624 | 69 |
| **20** | 1,000 | Maximum | 48 | 423 | 65 |
| | | Minimum | 5 | 423 | 81 |
| **40** | 1,000 | Maximum | 93 | 799 | 56 |
| | | Minimum | 12 | 799 | 96 |
| | 2,000 | Minimum | 38 | 874 | 71 |

These numbers cannot be used as the sole guidelines for forest and domain design. Other limitations might affect performance and scalability. A limitation of note is that when FRS is deployed, a limit of 1,200 domain controllers per domain is recommended to ensure reliable recovery of SYSVOL.

For more information about FRS limitations, see "FRS Technical Reference." For more information about the functional level requirements for the intersite topology generation algorithm, see "Automated Intersite Topology Generation" later in this section.

**Goals of Replication Topology**
The KCC generates a replication topology that achieves the following goals:

- Connect every directory partition replica that must be replicated.
- Control replication latency and cost.
- Route replication between sites.
- Effect client affinity.

By default, the replication topology is managed automatically and optimizes existing connections. However, manual connections created by an administrator are not modified or optimized.

**Connect Directory Partition Replicas**
The total replication topology is actually composed of several underlying topologies, one for each directory partition. In the case of the schema and configuration directory partitions, a single topology is created. The underlying topologies are merged to form the minimum number of connections that are required to replicate each directory partition between all domain controllers that store replicas. Where the connections for directory partitions are identical between domain controllers — for example, two domain controllers store the same domain directory partition — a single connection can be used for replication of updates to the domain, schema, and configuration directory partitions.

A separate replication topology is also created for application directory partitions. However, in the same manner as schema and configuration directory partitions, application directory partitions can use the same topology as domain directory partitions. When application and domain directory partitions are common to the source and destination domain controllers, the KCC does not create a separate connection for the application directory partition.

A separate topology is not created for the partial replicas that are stored on global catalog servers. The connections that are needed by a global catalog server to replicate each partial replica of a domain are part of the topology that is created for each domain.

The routes for the following directory partitions or combinations of directory partitions are aggregated to arrive at the overall topology:

- Configuration and schema within a site.
- Each writable domain directory partition within a site.
- Each application directory partition within a site.
- Global catalog read-only, partial domain directory partitions within a site.
- Configuration and schema between sites.
- Each writable domain directory partition between sites.
- Each application directory partition between sites.
- Global catalog read-only, partial domain directory partitions between sites.

Replication transport protocols determine the manner in which replication data is transferred over the network media. Your network environment and server configuration dictates the transports that you can use. For more information about transports, see "Replication Transports" later in this section.

**Control Replication Latency and Cost**
Replication latency is inherent in a multimaster directory service. A period of replication latency begins when a directory

update occurs on an originating domain controller and ends when replication of the change is received on the last domain controller in the forest that requires the change. Generally, the latency that is inherent in a WAN link is relative to a combination of the speed of the connection and the available bandwidth. Replication cost is an administrative value that can be used to indicate the latency that is associated with different replication routes between sites. A lower-cost route is preferred by the ISTG when generating the replication topology.

Site topology is the topology as represented by the physical network: the LANs and WANs that connect domain controllers in a forest. The replication topology is built to use the site topology. The site topology is represented in Active Directory by site objects and site link objects. These objects influence Active Directory replication to achieve the best balance between replication speed and the cost of bandwidth utilization by distinguishing between replication that occurs within a site and replication that must span sites. When the KCC creates replication connections between domain controllers to generate the replication topology, it creates more connections between domain controllers in the same site than between domain controllers in different sites. The results are lower replication latency within a site and less replication bandwidth utilization between sites.

Within sites, replication is optimized for speed as follows:

- Connections between domain controllers in the same site are always arranged in a ring, with possible additional connections to reduce latency.
- Replication within a site is triggered by a change notification mechanism when an update occurs, moderated by a short, configurable delay (because groups of updates frequently occur together).
- Data is sent uncompressed, and thus without the processing overhead of data compression.

Between sites, replication is optimized for minimal bandwidth usage (cost) as follows:

- Replication data is compressed to minimize bandwidth consumption over WAN links.
- Store-and-forward replication makes efficient use of WAN links — each update crosses an expensive link only once.
- Replication occurs at intervals that you can schedule so that use of expensive WAN links is managed.
- The intersite topology is a layering of spanning trees (one intersite connection between any two sites for each directory partition) and generally does not contain redundant connections.

**Route Replication Between Sites**

The KCC uses the information in Active Directory to identify the least-cost routes for replication between sites. If a domain controller is unavailable at the time the replication topology is created, making replication through that site impossible, the next least-cost route is used. This rerouting is automatic when site links are bridged (transitive), which is the default setting.

Replication is automatically routed around network failures and offline domain controllers.

**Effect Client Affinity**

Active Directory clients locate domain controllers according to their site affiliation. Domain controllers register SRV resource records in the DNS database that map the domain controller to a site. When a client requests a connection to a domain controller (for example, when logging on to a domain computer), the domain controller Locator uses the site SRV resource record to locate a domain controller with good connectivity whenever possible. In this way, a client locates a domain controller within the same site, thereby avoiding communications over WAN links.

Sites can also be used by certain applications, such as DFS, to ensure that clients locate servers that are within the site or, if none is available, a server in the next closest site. If the ISTG is running Windows Server 2003 or later server operating systems, you can specify an alternate site based on connection cost if no same-site servers are available. This DFS feature, called "site costing," is new in Windows Server 2003.

For more information about the domain controller Locator, see "DNS Support for Active Directory Technical Reference." For more information about DFS site costing, see "DFS Technical Reference."

**Topology-Related Objects in Active Directory**

Active Directory stores replication topology information in the configuration directory partition. Several configuration objects define the components that are required by the KCC to establish and implement the replication topology.

Active Directory Sites and Services is the Microsoft Management Console (MMC) snap-in that you can use to view and manage the hierarchy of objects that are used by the KCC to construct the replication topology. The hierarchy is displayed as the contents of the Sites container, which is a child object of the Configuration container. The Configuration container is not identified in the Active Directory Sites and Services UI. The Sites container contains an object for each site in the forest. In addition, Sites contains the Subnets container, which contains subnet definitions in the form of subnet objects.

The following figure shows a sample hierarchy, including two sites: Default-First-Site-Name and Site A. The selected NTDS Settings object of the server MHDC3 in the site Default-First-Site-Name displays the inbound connections from MHDC4 in the same site and from A-DC-01 in Site A. In addition to showing that MHDC3 and MHDC4 perform intrasite replication, this configuration indicates that MHDC3 and A-DC-01 are bridgehead servers that are replicating the same domain between Site A and Default-First-Site-Name.

**Sites Container Hierarchy**

**Site and Subnet Objects**

Sites are effective because they map to specific ranges of subnet addresses, as identified in Active Directory by subnet objects. The relationship between sites and subnets is integral to Active Directory replication.

**Site Objects**

A site object (class **site**) corresponds to a set of one or more IP subnets that have LAN connectivity. Thus, by virtue of their subnet associations, domain controllers that are in the same site are well connected in terms of speed. Each site object has a child NTDS Site Settings object and a Servers container. The distinguished name of the Sites container is CN=Sites,CN=Configuration,DC=*ForestRootDomainName*. The Configuration container is the topmost object in the configuration directory partition and the Sites container is the topmost object in the hierarchy of objects that are used to manage and implement Active Directory replication.

When you install Active Directory on the first domain controller in the forest, a site object named Default-First-Site-Name is created in the Sites container in Active Directory.

**Subnet Objects**

Subnet objects (class **subnet**) define network subnets in Active Directory. A network subnet is a segment of a TCP/IP network to which a set of logical IP addresses is assigned. Subnets group computers in a way that identifies their physical proximity on the network. Subnet objects in Active Directory are used to map computers to sites. Each subnet object has a **siteObject** attribute that links it to a site object.

**Subnet-to-Site Mapping**

You associate a set of IP subnets with a site if they have high-bandwidth LAN connectivity, possibly involving hops through high-performance routers.

**Note**

- LAN connectivity assumes high-speed, inexpensive bandwidth that allows similar and reliable network performance, regardless of which two computers in the site are communicating. This quality of connectivity does not indicate that all servers in the site must be on the same network segment or that hop counts between all servers must be identical. Rather, it is the measure by which you know that if a large amount of data needs to be copied from one server to another, it does not matter which servers are involved. If you find that you are concerned about such situations, consider creating another site.

When you create subnet objects in Active Directory, you associate them with site objects so that IP addresses can be localized according to sites. During the process of domain controller location, subnet information is used to find a domain controller in the same site as, or the site closest to, the client computer. The Net Logon service on a domain controller is able to identify the site of a client by mapping the client's IP address to a subnet object in Active Directory. Likewise, when a domain controller is installed, its server object is created in the site that contains the subnet that maps to its IP address.

You can use Active Directory Sites and Services to define subnets, and then create a site and associate the subnets with the site. By default, only members of the Enterprise Admins group have the right to create new sites, although this right can be delegated.

In a default Active Directory installation, there is no default subnet object, so potentially a computer can be in the forest but have an IP subnet that is not contained in any site. For private networks, you can specify the network addresses that are provided by the Internet Assigned Numbers Authority (IANA). By definition, that range covers all of the subnets for the organization. However, where several class B or class C addresses are assigned, there would necessarily be multiple subnet objects that all mapped to the same default site.

To accommodate this situation, use the following subnets:

- For class B addresses, subnet 128.0.0.0/2 covers all class B addresses.

- For class C addresses, subnet 192.0.0.0/3 covers all class C addresses.

**Note**

- The Active Directory Sites and Services MMC snap-in neither checks nor enforces IP address mapping when you move a server object to a different site. You must manually change the IP address on the domain controller to ensure proper mapping of the IP address to a subnet in the appropriate site.

**Server Objects**

Server objects (class **server**) represent server computers, including domain controllers, in the configuration directory partition. When you install Active Directory, the installation process creates a server object in the Servers container within the site to which the IP address of the domain controller maps. There is one server object for each domain controller in the site.

A server object is distinct from the computer object that represents the computer as a security principal. These objects are in separate directory partitions and have separate globally unique identifiers (GUIDs). The computer object represents the domain controller in the domain directory partition; the server object represents the domain controller in the configuration directory partition. The server object contains a reference to the associated computer object.

The server object for the first domain controller in the forest is created in the Default-First-Site-Name site. When you install Active Directory on subsequent servers, if no other sites are defined, server objects are created in Default-First-Site-Name. If other sites have been defined and subnet objects have been associated with these sites, server objects are created as follows:

- If additional sites have been defined in Active Directory and the IP address of the installation computer matches an existing subnet in a defined site, the domain controller is added to that site.

- If additional sites have been defined in Active Directory and the new domain controller's IP address does not match an existing subnet in one of the defined sites, the new domain controller's server object is created in the site of the source domain controller from which the new domain controller receives its initial replication.

When Active Directory is removed from a server, its NTDS Settings object is deleted from Active Directory, but its server object remains because the server object might contain objects other than NTDS Settings. For example, when Microsoft Operations Manager or Message Queuing is running on a domain controller, these applications create child objects beneath the server object.

**NTDS Settings Objects**
The NTDS Settings object (class **nTDSDSA**) represents an instantiation of Active Directory on that server and distinguishes a domain controller from other types of servers in the site or from decommissioned domain controllers. For a specific server object, the NTDS Settings object contains the individual connection objects that represent the inbound connections from other domain controllers in the forest that are currently available to send changes to this domain controller.

### Note

- The NTDS Settings object should not be manually deleted.

The **hasMasterNCs** multivalued attribute (where "NC" stands for "naming context," a synonym for "directory partition") of an NTDS Settings object contains the distinguished names for the set of writable (non-global-catalog) directory partitions that are located on that domain controller, as follows:

- DC=Configuration,DC=*ForestRootDomainName*
- DC=Schema,DC=Configuration,DC=*ForestRootDomainName*
- DC=*DomainName*,DC=*ForestRootDomainName*

The **msDSHasMasterNCs** attribute is new attribute introduced in Windows Server 2003, and this attribute of the NTDS Settings object contains values for the above-named directory partitions as well as any application directory partitions that are stored by the domain controller. Therefore, on domain controllers that are DNS servers and use Active Directory–integrated DNS zones, the following values appear in addition to the default directory partitions:

- DC=ForestDNSZones,DC=*ForestRootDomainName* (domain controllers in the forest root domain only)
- DC=DomainDNSZones,DC=*DomainName*,DC=*ForestRootDomainName* (all domain controllers)

Applications that need to retrieve the list of all directory partitions that are hosted by a domain controller can be updated or written to use the **msDSHasMasterNCs** attribute. Applications that need to retrieve only domain directory partitions can continue to use the **hasMasterNCs** attribute.

For more information about these attributes, see Active Directory in the Microsoft Platform SDK on MSDN.

**Connection Objects**
A connection object (class **nTDSConnection**) defines a one-way, inbound route from one domain controller (the source) to the domain controller that stores the connection object (the destination). The KCC uses information in cross-reference objects to create the appropriate connection objects, which enable domain controllers that store the same directory partitions to replicate with each other. The KCC creates connections for every server object in the Sites container that has an NTDS Settings object.

The connection object is a child of the replication destination's NTDS Settings object, and the connection object references the replication source domain controller in the **fromServer** attribute on the connection object — that is, it represents the inbound half of a connection. The connection object contains a replication schedule and specifies a replication transport. The connection object schedule is derived from the site link schedule for intersite connections. For more information about intersite connection schedules, see "Connection Object Schedule" later in this section.

A connection is unidirectional; a bidirectional replication connection is represented as two inbound connection objects. The KCC creates one connection object under the NTDS Settings object of each server that is used as an endpoint for the connection.

Connection objects are created in two ways:

- Automatically by the KCC.
- Manually by a directory administrator by using Active Directory Sites and Services, ADSI Edit, or scripts.

Intersite connection objects are created by the KCC that has the role of intersite topology generator (ISTG) in the site. One domain controller in each site has this role, and the ISTG role owners in all sites use the same algorithm to collectively generate

the intersite replication topology.

**Ownership of Connection Objects**

Connections that are created automatically by the KCC are "owned" by the KCC. If you create a new connection manually, the connection is not owned by the KCC. If a connection object is not owned by the KCC, the KCC does not modify it or delete it.

**Note**

- One exception to this modification rule is that the KCC automatically changes the transport type of an administrator-owned connection if the **transportType** attribute is set incorrectly (see "Transport Type" later in this section).

However, if you modify a connection object that is owned by the KCC (for example, you change the connection object schedule), the ownership of the connection depends on the application that you use to make the change:

- If you use an LDAP editor such as Ldp.exe or Adsiedit.msc to change a connection object property, the KCC reverses the change the next time it runs.

- If you use Active Directory Sites and Services to change a connection object property, the object is changed from automatic to manual and the KCC no longer owns it. The UI indicates the ownership status of each connection object.

In most Active Directory deployments, manual connection objects are not needed.

If you create a connection object, it remains until you delete it, but the KCC will automatically delete duplicate KCC-owned objects if they exist and will continue to create needed connections. Ownership of a connection object does not affect security access to the object; it determines only whether the KCC can modify or delete the object.

**Note**

- If you create a new connection object that duplicates one that the KCC has already created, your duplicate object is created and the KCC-created object is deleted by the KCC the next time it runs.

**ISTG and Modified Connections**

Because connection objects are stored in the configuration directory partition, it is possible for an intersite connection object to be modified by an administrator on one domain controller and, prior to replication of the initial change being received, to be modified by the KCC on another domain controller. Overwriting such a change can occur within the local site or when a connection object changes in a remote site.

By default, the KCC runs every 15 minutes. If the administrative connection object change is not received by the destination domain controller before the ISTG in the destination site runs, the ISTG in the destination site might modify the same connection object. In this case, ownership of the connection object belongs to the KCC because the latest write to the connection object is the write that is applied.

**Manual Connection Objects**

The KCC is designed to produce a replication topology that provides low replication latency, that adapts to failures, and that does not need modification. It is usually not necessary to create connection objects when the KCC is being used to generate automatic connections. The KCC automatically reconfigures connections as conditions change. Adding manual connections when the KCC is employed potentially increases replication traffic by adding redundant connections to the optimal set chosen by the KCC. When manually generated connections exist, the KCC uses them wherever possible.

*Adding extra connections does not necessarily reduce replication latency*. Within a site, latency issues are usually related to factors other than the replication topology that is generated by the KCC. Factors that affect latency include the following:

- Interruption of the service of key domain controllers, such as the primary domain controller (PDC) emulator, global catalog servers, or bridgehead servers.

- Domain controllers that are too busy to replicate in a timely manner (too few domain controllers).

- Network connectivity issues.

- DNS server problems.

- Inordinate amounts of directory updates.

For problems such as these, creating a manual connection does not improve replication latency. Adjusting the scheduling and costs that are assigned to the site link is the best way to influence intersite topology.

**Site Link Objects**
For a connection object to be created on a destination domain controller in one site that specifies a source domain controller in another site, you must manually create a site link object (class **siteLink**) that connects the two sites. Site link objects identify the transport protocol and scheduling required to replicate between two or more sites. You can use Active Directory Sites and Services to create the site links. The KCC uses the information stored in the properties of these site links to create the intersite topology connections.

A site link is associated with a network transport by creating the site link object in the appropriate transport container (either IP or SMTP). All intersite domain replication must use IP site links. The Simple Mail Transfer Protocol (SMTP) transport can be used for replication between sites that contain domain controllers that do not host any common domain directory partition replicas.

**Site Link Properties**
A site link specifies the following:

- Two or more sites that are permitted to replicate with each other.
- An administrator-defined cost value associated with that replication path. The cost value controls the route that replication takes, and thus the remote sites that are used as sources of replication information.
- A schedule during which replication is permitted to occur.
- An interval that determines how frequently replication occurs over this site link during the times when the schedule allows replication.

For more information about site link properties, see "Site Link Settings and Their Effects on Intersite Replication" later in this section.

**Default Site Link**
When you install Active Directory on the first domain controller in the forest, an object named DEFAULTIPSITELINK is created in the Sites container (in the IP container within the Inter-Site Transports container). This site link contains only one site, Default-First-Site-Name.

**Site Link Bridging**
By default, site links for the same IP transport that have sites in common are bridged, which enables the KCC to treat the set of associated site links as a single route. If you categorically do not want the KCC to consider some routes, or if your network is not fully routed, you can disable automatic bridging of all site links. When this bridging is disabled, you can create site link bridge objects and manually add site links to a bridge. For more information about using site link bridges, see "Bridging Site Links Manually" later in this section.

**NTDS Site Settings Object**
NTDS Site Settings objects (class **nTDSSiteSettings**) identify site-wide settings in Active Directory. There is one NTDS Site Settings object per site in the Sites container. NTDS Site Settings attributes control the following features and conditions:

- The identity of the ISTG role owner for the site. The KCC on this domain controller is responsible for identifying bridgehead servers. For more information about this role, see "Automated Intersite Topology Generation" later in this section.
- Whether domain controllers in the site cache membership of universal groups and the site in which to find a global catalog server for creating the cache.
- The default schedule that applies to connection objects. For more information about this schedule, see "Connection Object Schedule" later in this section.

**Note**

- To allow for the possibility of network failure, which might cause one or more notifications to be missed, a default schedule of once per hour is applied to replication within a site. You do not need to manage this schedule.

**Cross-Reference Objects**

Cross-reference objects (class **crossRef**) store the location of directory partitions in the Partitions container (CN=Partitions,CN=Configuration,DC=*ForestRootDomainName*). The contents of the Partitions container are not visible by using Active Directory Sites and Services, but can be viewed by using Adsiedit.msc to view the Configuration directory partition.

Active Directory replication uses cross-reference objects to locate the domain controllers that store each directory partition. A cross-reference object is created during Active Directory installation to identify each new directory partition that is added to the forest. Cross-reference objects store the identity (**nCName**, the distinguished name of the directory partition where "NC" stands for "naming context," a synonym for "directory partition") and location (**dNSRoot**, the DNS domain where servers that store the particular directory partition can be reached) of each directory partition.

### Note

- Starting in Windows Server 2003 Active Directory, a special attribute of the cross-reference object, **msDS-NC-Replica-Locations**, identifies application directory partitions to the replication system. For more information about how application directory partitions are replicated, see "Topology Generation Phases" later in this section.

**Replication Transports**

Replication transports provide the wire protocols that are required for data transfer. There are three levels of connectivity for replication of Active Directory information:

- Uniform high-speed, synchronous RPC over IP within a site.
- Point-to-point, synchronous, low-speed RPC over IP between sites.
- Low-speed, asynchronous SMTP between sites.

The following rules apply to the replication transports:

- Replication within a site always uses RPC over IP.
- Replication between sites can use either RPC over IP or SMTP over IP.
- Replication between sites over SMTP is supported for only domain controllers of different domains. Domain controllers of the same domain must replicate by using the RPC over IP transport. Therefore, replication between sites over SMTP is supported for only schema, configuration, and global catalog replication, which means that domains can span sites only when point-to-point, synchronous RPC is available between sites.

The Inter-Site Transports container provides the means for mapping site links to the transport that the link uses. When you create a site link object, you create it in either the IP container (which associates the site link with the RPC over IP transport) or the SMTP container (which associates the site link with the SMTP transport).

For the IP transport, a typical site link connects only two sites and corresponds to an actual WAN link. An IP site link connecting more than two sites might correspond to an asynchronous transfer mode (ATM) backbone that connects, for example, more than two clusters of buildings on a large campus or connects several offices in a large metropolitan area that are connected by leased lines and IP routers.

**Synchronous and Asynchronous Communication**

The RPC intersite and intrasite transport (RCP over IP within sites and between sites) and the SMTP intersite transport (SMTP over IP between sites only) correspond to synchronous and asynchronous communication methods, respectively. Synchronous communication favors fast, available connections, while asynchronous communication is better suited for slow or intermittent connections.

**Synchronous Replication Over IP**

The IP transport (RPC over IP) provides synchronous inbound replication. In the context of Active Directory replication, synchronous communication implies that after the destination domain controller sends the request for data, it waits for the

source domain controller to receive the request, construct the reply, and send the reply before it requests changes from any other domain controllers; that is, inbound replication is sequential. Thus in synchronous transmission, the reply is received within a short time. The IP transport is appropriate for linking sites in fully routed networks.

**Asynchronous Replication Over SMTP**
The SMTP transport (SMTP over IP) provides asynchronous replication. In asynchronous replication, the destination domain controller does not wait for the reply and it can have multiple asynchronous requests outstanding at any particular time. Thus in asynchronous transmission, the reply is not necessarily received within a short time. Asynchronous transport is appropriate for linking sites in networks that are not fully routed and have particularly slow WAN links.

### Note

- Although asynchronous replication can send multiple replication requests in parallel, the received replication packets are queued on the destination domain controller and the changes applied for only one partner and directory partition at a time.

**Replication Queue**
Suppose a domain controller has five inbound replication connections. As the domain controller formulates change requests, either by a schedule being reached or from a notification, it adds a work item for each request to the end of the queue of pending synchronization requests. Each pending synchronization request represents one <source domain controller, directory partition> pair, such as "synchronize the schema directory partition from DC1," or "delete the ApplicationX directory partition."

When a work item has been received into the queue, notification and polling intervals do not apply — the domain controller processes the item (begins synchronizing from that source) as soon as the item reaches the front of the queue, and continues until either the destination is fully synchronized with the source domain controller, an error occurs, or the synchronization is pre-empted by a higher-priority operation.

**SMTP Intersite Replication**
When sites are on opposite ends of a WAN link (or the Internet), it is not always desirable — or even possible — to perform synchronous, RPC-based directory replication. In some cases, the only method of communication between two sites is e-mail. When connectivity is intermittent or when end-to-end IP connectivity is not available (an intermediate site does not support RPC/IP replication), replication must be possible across asynchronous, store-and-forward transports such as SMTP.

In addition, where bandwidth is limited, it can be disadvantageous to force an entire replication cycle of request for changes and transfer of changes between two domain controllers to complete before another can begin (that is, to use synchronous replication). With SMTP, several cycles can be processing simultaneously so that each cycle is being processed to some degree most of the time, as opposed to receiving no attention for prolonged periods, which can result in RPC time-outs.

For intersite replication, SMTP replication substitutes mail messaging for the RPC transport. The message syntax is the same as for RPC-based replication. There is no change notification for SMTP–based replication, and scheduling information for the site link object is used as follows:

- By default, SMTP replication ignores the **Replication Available** and **Replication Not Available** settings on the site link schedule in Active Directory Sites and Services (the information that indicates when these sites are connected). Replication occurs according to the messaging system schedule.

- Within the scope of the messaging system schedule, SMTP replication uses the replication interval that is set on the SMTP site link to indicate how often the server requests changes. The interval (**Replicate every ____ minutes**) is set in 15-minute increments on the **General** tab in site link **Properties** in Active Directory Sites and Services.

The underlying SMTP messaging system is responsible for message routing between SMTP servers.

**SMTP Replication and Intersite Messaging**
Intersite Messaging is a component that is enabled when Active Directory is installed. Intersite Messaging allows for multiple transports to be used as add-ins to the Intersite Messaging architecture. Intersite Messaging enables messaging communication that can use SMTP servers other than those that are dedicated to processing e-mail applications.

When the forest has a functional level of at least Windows 2000, Intersite Messaging also provides services to the KCC in the form of querying the available replication paths. In addition, Net Logon queries the connectivity data in Intersite Messaging when calculating site coverage. By default, Intersite Messaging rebuilds its database once a day, or when required by a site link change.

When the forest has a functional level of at least Windows Server 2003, the KCC does not use Intersite Messaging for

calculating the topology. However, regardless of forest functional level, Intersite Messaging is still required for SMTP replication, DFS, universal group membership caching, and Net Logon automatic site coverage calculations. Therefore, if any of these features are in use, do not stop Intersite Messaging.

For more information about site coverage and how automatic site coverage is calculated, see "How DNS Support for Active Directory Works." For more information about DFS, see "DFS Technical Reference."

**Requirements for SMTP Replication**

The KCC does not create connections that use SMTP until the following requirements are met:

- Internet Information Services (IIS) is installed on both bridgehead servers.
- An enterprise certification authority (CA) is installed and configured on your network. The CA signs and encrypts SMTP messages that are exchanged between domain controllers, ensuring the authenticity of directory updates. Specifically, a domain controller certificate must be present on the replicating domain controllers. The replication request message, which contains no directory data, is not encrypted. The replication reply message, which does contain directory data, is encrypted using a key length of 128 bits.
- The sites are connected by SMTP site links.
- The site link path between the sites has a lower cost than any IP/RPC site link that can reach the SMTP site.
- You are not attempting to replicate writable replicas of the same domain (although replication of global catalog partial replicas is supported).
- Each domain controller is configured to receive mail.

You must also determine if mail routing is necessary. If the two replicating domain controllers have direct IP connectivity and can send mail to each other, no further configuration is required. However, if the two domain controllers must go through mail gateways to deliver mail to each other, you must configure the domain controller to use the mail gateway.

**Note**

- RPC is required for replicating the domain to a new domain controller and for installing certificates. If RPC is not available to the remote site, the domain must be replicated and certificates must be installed over RPC in a hub site and the domain controller then shipped to the remote site.

**Comparison of SMTP and RPC Replication**

The following characteristics apply to both SMTP and RPC with respect to Active Directory replication:

- For replication between sites, data that is replicated through either transport is compressed.
- Active Directory can respond with only a fixed (maximum) number of changes per change request, based on the size of the replication packet. The size of the replication packet is configurable. For information about configuring the replication packet size, see "Replication Packet Size" later in this section.
- Active Directory can apply a single set of changes at a time for a specific directory partition and replication partner.
- The response data (changes) are transported in one or many frames, based on the total number of changed or new values.
- TCP transports the data portion by using the same algorithm for both SMTP and RPC.
- If transmission of the data portion fails, complete retransmission is necessary.

Point-to-point synchronous RPC replication is available between sites to allow the flexibility of having domains that span multiple sites. RPC is best used between sites that are connected by WAN links because it involves lower latency. SMTP is best used between sites where RPC over IP is not possible. For example, SMTP can be used by companies that have a network

backbone that is not based on TCP/IP, such as companies that use an X.400 backbone.

Active Directory replication uses both transports to implement a request-response mechanism. Active Directory issues requests for changes and replies to requests for changes. RPC maps these requests into RPC requests and RPC replies. SMTP, on the other hand, actually uses long-lived TCP connections (or X.400-based message transfer agents in non-TCP/IP networks) to deliver streams of mail in each direction. Thus, RPC transport expects a response to any request immediately and can have a maximum of one active inbound RPC connection to a directory partition replica at a time. The SMTP transport expects much longer delays between a request and a response. As a result, multiple inbound SMTP connections to a directory partition replica can be active at the same time, provided the requests are all for a different source domain controller or, for the same source domain controller, a different directory partition. For more information, see "Synchronous and Asynchronous Communication" earlier in this section.

**Replication Packet Size**

Replication packet sizes are computed on the basis of memory size unless you have more than 1 gigabyte (GB). By default, the system limits the packet size as follows:

- The packet size in bytes is 1/100th the size of RAM, with a minimum of 1 MB and a maximum of 10 MB.
- The packet size in objects is 1/1,000,000th the size of RAM, with a minimum of 100 objects and a maximum of 1,000 objects. For general estimates when this entry is not set, assume an approximate packet size of 100 objects.

There is one exception: the value of the **Replicator async inter site packet size (bytes)** registry entry is always 1 MB if it is not set (that is, when the default value is in effect). Many mail systems limit the amount of data that can be sent in a mail message (2 MB to 4 MB is common), although most Windows-based mail systems can handle large 10-MB mail messages.

Overriding these memory-based values might be beneficial in advanced bandwidth management scenarios. You can edit the registry to set the maximum packet size.

**Note**

- If you must edit the registry, use extreme caution. Registry information is provided here as a reference for use by only highly skilled directory service administrators. It is recommended that you do not directly edit the registry unless, as in this case, there is no Group Policy or other Windows tools to accomplish the task. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. Storage of incorrect values can result in unrecoverable errors in the system.

Setting the maximum packet size requires adding or modifying entries in the following registry path with the REG_DWORD data type: HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters. These entries can be used to determine the maximum number of objects per packet and maximum size of the packets. The minimum values are indicated as the lowest value in the range.

- For RPC replication within a site:
    - **Replicator intra site packet size (objects)**

      Range: >=2
    - **Replicator intra site packet size (bytes)**

      Range: >=10 KB
- For RPC replication between sites:
    - **Replicator inter site packet size (objects)**

      Range: >=2
    - **Replicator inter site packet size (bytes)**

      Range: >=10 KB

- For SMTP replication between sites:

    - **Replicator async inter site packet size (objects)**

      Range: >=2

    - **Replicator async inter site packet size (bytes)**

      Range: >=10 KB

**Transport Type**
The **transportType** attribute of a connection object specifies which network transport is used when the connection is used for replication. The transport type receives its value from the distinguished name of the container in the configuration directory partition that contains the site link over which the connection occurs, as follows:

- Connection objects that use TCP/IP have the **transportType** value of CN=IP,CN=Inter-Site Transports,CN=IP,DC=Configuration,DC=*ForestRootDomainName*.

- Connection objects that use SMTP/IP have the **transportType** value of CN=SMTP,CN=Inter-Site Transports,CN=IP,DC=Configuration,DC=*ForestRootDomainName*.

- For intrasite connections, **transportType** has no value; Active Directory Sites and Services shows the transport of "RPC" for connections that are from servers in the same site.

If you move a domain controller to a different site, the connection objects from servers in the site from which it was moved remain, but the transport type is blank because it was an intrasite connection. Because the connection has an endpoint outside of the site, the local KCC in the server's new site does not manage the connection. When the ISTG runs, if a blank transport type is found for a connection that is from a server in a different site, the **transportType** value is automatically changed to IP. The ISTG in the site determines whether to delete the connection object or to retain it, in which case the server becomes a bridgehead server in its new site.

**Replication Between Sites**
Replication between sites transfers domain updates when domain controllers for a domain are located in more than one site. Intersite replication of configuration and schema changes is always required when more than one site is configured in a forest. Replication between sites is accomplished by bridgehead servers, which replicate changes according to site link settings.

**Bridgehead Servers**
When domain controllers for the same domain are located in different sites, at least one bridgehead server per directory partition and per transport (IP or SMTP) replicates changes from one site to a bridgehead server in another site. A single bridgehead server can serve multiple partitions per transport and multiple transports. Replication within the site allows updates to flow between the bridgehead servers and the other domain controllers in the site. Bridgehead servers help to ensure that the data replicated across WAN links is not stale or redundant.

Any server that has a connection object with a "from" server in another site is acting as a destination bridgehead. Any server that is acting as a source for a connection to another site acts as a source bridgehead.

### Note

- You can identify a KCC-selected bridgehead server in Active Directory Sites and Services by viewing connection objects for the server (select the NTDS Settings object below the server object); if there are connections from servers in a different site or sites, the server represented by the selected NTDS Settings object is a bridgehead server. If you have Windows Support Tools installed, you can see all bridgehead servers by using the command **repadmin /bridgeheads**.

KCC selection of bridgehead servers guarantees bridgehead servers that are capable of replicating all directory partitions that are needed in the site, including partial global catalog partitions. By default, bridgehead servers are selected automatically by the KCC on the domain controller that holds the ISTG role in each site. If you want to identify the domain controllers that can act as bridgehead servers, you can designate preferred bridgehead servers, from which the ISTG selects all bridgehead servers. Alternatively, if the ISTG is not used to generate the intersite topology, you can create manual intersite connection objects on

domain controllers to designate bridgehead servers.

In sites that have at least one domain controller that is running Windows Server 2003, the ISTG can select bridgehead servers from all eligible domain controllers for each directory partition that is represented in the site. For example, if three domain controllers in a site store replicas of the same domain and domain controllers for this domain are also located in three or more other sites, the ISTG can spread the inbound connection objects from those sites among all three domain controllers, including those that are running Windows 2000 Server.

In Windows 2000 forests, a single bridgehead server per directory partition and per transport is designated as the bridgehead server that is responsible for intersite replication of that directory partition. Therefore, for the preceding example, only one of the three domain controllers would be designated by the ISTG as a bridgehead server for the domain, and all four connection objects from the four other sites would be created on the single bridgehead server. In large hub sites, a single domain controller might not be able to adequately respond to the volume of replication requests from perhaps thousands of branch sites.

For more information about how the KCC selects bridgehead servers, see “Bridgehead Server Selection” later in this section.

**Compression of Replication Data**
Intersite replication is compressed by default. Compressing replication data allows the data to be transferred over WAN links more quickly, thereby conserving network bandwidth. The cost of this benefit is an increase in CPU utilization on bridgehead servers.

By default, replication data is compressed under the following conditions:

- Replication of updates between domain controllers in different sites.
- Replication of Active Directory to a newly created domain controller.

A new compression algorithm is employed by bridgehead servers that are running at least Windows Server 2003. The new algorithm improves replication speed by operating between two and ten times faster than the Windows 2000 Server algorithm.

**Windows 2000 Server Compression**
The compression algorithm that is used by domain controllers that are running Windows 2000 Server achieves a compression ratio of approximately 75% to 85%. The cost of this compression in terms of CPU utilization can be as high as 50% for intersite Active Directory replication. In some cases, the CPUs on bridgehead servers that are running Windows 2000 Server can become overwhelmed with compression requests, compounded by the need to service outbound replication partners. In a worst case scenario, the bridgehead server becomes so overloaded that it cannot keep up with outbound replication. This scenario is usually coupled with a replication topology issue where a domain controller has more outbound partners than necessary or the replication schedule was overly aggressive for the number of direct replication partners.

### Note

- If a bridgehead server has too many replication partners, the KCC logs event ID 1870 in the Directory Service log, indicating the current number of partners and the recommended number of partners for the domain controller.

**Windows Server 2003 Compression**
On domain controllers that are running Windows Server 2003, compression quality is comparable to Windows 2000 but the processing burden is greatly decreased. The Windows Server 2003 algorithm produces a compression ratio of approximately 60%, which is slightly less compression than is achieved by the Windows 2000 Server ratio, but which significantly reduces the processing load on bridgehead servers. The new compression algorithm provides a good compromise by significantly reducing the CPU load on bridgehead servers, while only slightly increasing the WAN traffic. The new algorithm reduces the time taken by compression from approximately 60% of replication time to 20%.

The Windows Server 2003 compression algorithm is used only when both bridgehead servers are running Windows Server 2003. If a bridgehead server that is running Windows Server 2003 replicates with a bridgehead server that is running Windows 2000 Server, then the Windows 2000 compression algorithm is used.

**Reverting to Windows 2000 Compression**
For slow WAN links (for example, 64 KB or less), if more compression is preferable to a decrease in computation time, you can change the compression algorithm to the Windows 2000 algorithm. The compression algorithm is controlled by the REG_DWORD registry entry HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters**Replicator compression algorithm**. By editing this registry entry, you can change the algorithm that is used for compression to the

Windows 2000 algorithm.

**Note**

- If you must edit the registry, use extreme caution. Registry information is provided here as a reference for use by only highly skilled directory service administrators. It is recommended that you do not directly edit the registry unless, as in this case, there is no Group Policy or other Windows tools to accomplish the task. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. Storage of incorrect values can result in unrecoverable errors in the system.

The default value is 3, which indicates that the Windows Server 2003 algorithm is in effect. By changing the value to 2, the Windows 2000 algorithm is used for compression. However, switching to the Windows 2000 algorithm is not recommended unless both bridgehead domain controllers serve relatively few branches and have ample CPU (for example, > dual processor 850 megahertz [MHz]).

**Site Link Settings and Their Effects on Intersite Replication**

In Active Directory Sites and Services, the **General** tab of the site link **Properties** contains the following options for configuring site links to control the replication topology:

- A list of two or more sites to be connected.

- A single numeric cost that is associated with communication over the link. The default cost is 100, but you can assign higher cost values to represent more expensive transmission. For example, sites that are connected by low-speed or dial-up connections would have high-cost site links between them. Sites that are well connected through backbone lines would have low-cost site links. Where multiple routes or transports exist between two sites, the least expensive route and transport combination is used.

- A schedule that determines days and hours during which replication can occur over the link (the link is available). For example, you might use the default (100 percent available) schedule on most links, but block replication traffic during peak business hours on links to certain branches. By blocking replication, you give priority to other traffic, but you also increase replication latency.

  **Note**

  - Scheduling information is ignored by site links that use SMTP transports; the mail is stockpiled and then exchanged at the times that are configured for your mail infrastructure.

- An interval in minutes that determines how often replication can occur (default is every 180 minutes, or 3 hours). The minimum interval is 15 minutes. If the interval exceeds the time allowed by the schedule, replication occurs once at the scheduled time.

A site can be connected to other sites by any number of site links. For example, a hub site has site links to each of its branch sites. Each site that contains a domain controller in a multisite directory must be connected to at least one other site by at least one site link; otherwise, it cannot replicate with domain controllers in any other site.

The following diagram shows two sites that are connected by a site link. Domain controllers DC1 and DC2 belong to the same domain and are acting as partner bridgehead servers. When topology generation occurs, the ISTG in each site creates an inbound connection object on the bridgehead server in its site from the bridgehead server in the opposite site. With these objects in place, replication can occur according to the settings on the SB site link.

**Connections Between Domain Controllers in Two Sites that Are Connected by a Site Link**

**Site Link Cost**

The ISTG uses the cost settings on site links to determine the route of replication between three or more sites that replicate the same directory partition. The default cost value on a site link object is 100. You can assign lower or higher cost values to site links to favor inexpensive connections over expensive connections, respectively. Certain applications and services, such as

domain controller Locator and DFS, also use site link cost information to locate nearest resources. For example, site link cost can be used to determine which domain controller is contacted by clients located in a site that does not include a domain controller for the specified domain. The client contacts the domain controller in a different site according to the site link that has the lowest cost assigned to it.

Cost is usually assigned not only on the basis of the total bandwidth of the link, but also on the availability, latency, and monetary cost of the link. For example, a 128-kilobits per second (Kbps) permanent link might be assigned a lower cost than a dial-up 128-Kbps dual ISDN link because the dial-up ISDN link has replication latency-producing delay that occurs as the links are being established or removed. Furthermore, in this example, the permanent link might have a fixed monthly cost, whereas the ISDN line is charged according to actual usage. Because the company is paying up-front for the permanent link, the administrator might assign a lower cost to the permanent link to avoid the extra monetary cost of the ISDN connections.

The method used by the ISTG to determine the least-cost path from each site to every other site for each directory partition is more efficient when the forest has a functional level of at least Windows Server 2003 than it is at other levels. For more information about how the KCC computes replication routes, see "Automated Intersite Topology Generation" later in this section. For more information about domain controller location, see "How DNS Support for Active Directory Works."

**Transitivity and Automatic Site Link Bridging**

By default, site links are transitive, or "bridged." If site A has a common site link with site B, site B also has a common site link with Site C, and the two site links are bridged, domain controllers in site A can replicate directly with domain controllers in site C under certain conditions, even though there is no site link between site A and site C. In other words, the effect of bridged site links is that replication between sites in the bridge is transitive.

The setting that implements automatic site link bridges is **Bridge all site links**, which is found in Active Directory Sites and Services in the properties of the IP or SMTP intersite transport containers. The default bridging of site links occurs automatically and no directory object represents the default bridge. Therefore, in the common case of a fully routed IP network, you do not need to create any site link bridge objects.

**Transitivity and Rerouting**

For a set of bridged site links, where replication schedules in the respective site links overlap (replication is available on the site links during the same time period), connection objects can be automatically created, if needed, between sites that do not have site links that connect them directly. All site links for a specific transport implicitly belong to a single site link bridge for that transport.

Site link transitivity enables the KCC to re-route replication when necessary. In the next diagram, a domain controller that can replicate the domain is not available in Seattle. In this case, because the site links are transitive (bridged) and the schedules on the two site links allow replication at the same time, the KCC can re-route replication by creating connections between DC3 in Portland and DC2 in Boston. Connections between domain controllers in Portland and Boston might also be created when a domain controller in Portland is a global catalog server, but no global catalog server exists in the Seattle site and the Boston site hosts a domain that is not present in the Seattle site. In this case, connections can be created between Portland and Boston to replicate the global catalog partial, read-only replica.

### Note

- Overlapping schedules are required for site link transitivity, even when **Bridge all site links** is enabled. In the example, if the site link schedules for SB and PS do not overlap, no connections are possible between Boston and Portland.

**Transitive Replication when Site Links Are Bridged, Schedules Overlap, and Replication Must Be Rerouted**

In the preceding diagram, creating a third site link to connect the Boston and Portland sites is unnecessary and counterproductive because of the way that the KCC uses cost to route replication. In the configuration that is shown, the KCC uses cost to choose either the route between Portland and Seattle or the route between Portland and Boston. If you wanted the KCC to use the route between Portland and Boston, you would create a site link between Portland and Boston instead of the site link between Portland and Seattle.

**Aggregated Site Link Cost and Routing**
When site links are bridged, the cost of replication from a domain controller at one end of the bridge to a domain controller at the other end is the sum of the costs on each of the intervening site links. For this reason, if a domain controller in an interim site stores the directory partition that is being replicated, the KCC will route replication to the domain controller in the interim site rather than to the more distant site. The domain controller in the more distant site in turn receives replication from the interim site (store-and-forward replication). If the schedules of the two site links overlap, this replication occurs in the same period of replication latency.

The following diagram illustrates an example where two site links connecting three sites that host the same domain are bridged automatically (**Bridge all site links** is enabled). The aggregated cost of directly replicating between Portland and Boston illustrates why the KCC routes replication from Portland to Seattle and from Seattle to Boston in a store-and-forward manner. Given the choice between replicating at a cost of 4 from Seattle or a cost of 7 from Boston, the ISTG in Portland chooses the lower cost and creates the connection object on DC3 from DC1 in Seattle.

**Bridged Site Links Routing Replication Between Three Sites According to Cost**

In the preceding diagram, if DC3 in Portland needs to replicate a directory partition that is hosted on DC2 in Boston but not by any domain controller in Seattle, or if the directory partition is hosted in Seattle but the Seattle site cannot be reached, the ISTG creates the connection object from DC2 to DC3.

**Significance of Overlapping Schedules**
In the preceding diagram, to replicate the same domain that is hosted in all three sites, the Portland site replicates directly with Seattle and Seattle replicates directly with Boston, transferring Portland's changes to Boston, and vice versa, through store-and-forward replication. Whether the schedules overlap has the following effects:

- PS and SB site link schedules have replication available during at least one common hour of the schedule:
    - Replication between these two sites occurs in the same period of replication latency, being routed through Seattle.
    - If Seattle is unavailable, connections can be created between Portland and Boston.
- PS and SB site link schedules have no common time:
    - Replication of changes between Portland and Boston reach their destination in the next period of replication latency after reaching Seattle.
    - If Seattle is unavailable, no connections are possible between Portland and Boston.

    **Note**

If **Bridge all site links** is disabled, a connection is never created between Boston and Portland, regardless of schedule overlap, unless you manually create a site link bridge.

**Site Link Changes and Replication Path**
The path that replication takes between sites is computed from the information that is stored in the properties of the site link objects. When a change is made to a site link setting, the following events must occur before the change takes effect:

- The site link change must replicate to the ISTG of each site by using the previous replication topology.

- The KCC must run on each ISTG.

As the path of connections is transitively figured through a set of site links, the attributes (settings) of the site link objects are combined along the path as follows:

- Costs are added together.
- The replication interval is the maximum of the intervals that are set for the site links along the path.
- The options, if any are set, are computed by using the AND operation.

  **Note**

  - Options are the values of the **options** attribute on the site link object. The value of this attribute determines special behavior of the site link, such as reciprocal replication and intersite change notification.

Thus the site link schedule is the overlap of all of the schedules of the subpaths. If none of the schedules overlap, the path is not used.

**Bridging Site Links Manually**

If your IP network is composed of IP segments that are not fully routed, you can disable **Bridge all site links** for the IP transport. In this case, all IP site links are considered nontransitive, and you can create and configure site link bridge objects to model the actual routing behavior of your network. A site link bridge has the effect of providing routing for a disjoint network (networks that are separate and unaware of each other). When you add site links to a site link bridge, all site links within the bridge can route transitively.

A site link bridge object represents a set of site links, all of whose sites can communicate through some transport. Site link bridges are necessary if both of the following conditions are true:

- A site contains a domain controller that hosts a domain directory partition that is not hosted by a domain controller in an adjacent site (a site that is in the same site link).
- That domain directory partition is hosted on a domain controller in at least one other site in the forest.

**Note**

- Site link bridge objects are used by the KCC only when the **Bridge all site links** setting is disabled. Otherwise, site link bridge objects are ignored.

Site link bridges can also be used to diminish potentially high CPU overhead of generating a large transitive replication topology. In very large networks, transitive site links can be an issue because the KCC considers every possible connection in the bridged network, and selects only one. Therefore, in a Windows 2000 forest that has a very large network or a Windows Server 2003 or higher forest that consists of an extremely large hub-and-spoke topology, you can reduce KCC-related CPU utilization and run time by turning off **Bridge all site links** and creating manual site link bridges only where they are required.

**Note**

- Turning off **Bridge all site links** affects the ability of DFS clients to locate DFS servers in the closest site. If the ISTG is running at least Windows Server 2003, the **Bridge all site links** must be enabled to generate the intersite cost matrix that DFS requires for its site-costing functionality. If the ISTG is running at least Windows Server 2003 with Service Pack 1 (SP1), you can enable **Bridge all site links** and then run the **repadmin /siteoptions W2K3_BRIDGES_REQUIRED** command on each site where you need to accommodate the DFS site-costing functionality. This command disables automatic site link bridging for the KCC but allows default Intersite Messaging options to enable the site-costing calculation to occur for DFS. For more information about turning off this functionality while accommodating DFS, see "DFS Site Costing and Windows Server 2003 SP1 Site Options" later in this section. For more information about site link cost and DFS, see "DFS Technical Reference."

You create a site link bridge object for a specific transport by specifying two or more site links for the specified transport.

**Requirements for manual site link bridges**
Each site link in a manual site link bridge must have at least one site in common with another site link in the bridge. Otherwise, the bridge cannot compute the cost from sites in one link to the sites in other links of the bridge. If bridgehead servers that are capable of the transport that is used by the site link bridge are not available in two linked sites, a route is not available.

**Manual site link bridge behavior**
Separate site link bridges, even for the same transport, are independent. To illustrate this independence, consider the following conditions:

- Four sites have domain controllers for the same domain: Portland, Seattle, Detroit, and Boston.
- Three site links are configured: Portland-Seattle (PS), Seattle-Detroit (SD), and Detroit-Boston (DB).
- Two separate manual site link bridges link the outer site links PS and DB with the inner site link SD.

The presence of the PS-SD site link bridge means that an IP message can be sent transitively from the Portland site to the Detroit site with cost 4 + 3 = 7. The presence of the SD-DB site link bridge means that an IP message can be sent transitively from Seattle to Boston at a cost of 3 + 2 = 5. However, because there is no transitivity between the PS-SB and SB-DB site link bridges, an IP message cannot be sent between Portland and Boston with cost 4 + 3 + 2 = 9, or at any cost.

In the following diagram, the two manual site link bridges means that Boston is able to replicate directly only with Detroit and Seattle, and Portland is able to replicate directly only with Seattle and Detroit.

**Note**

- If you need direct replication between Portland and Detroit, you can create the PS-SB-DB site link bridge. By excluding the PS site link, you ensure that connections are neither created nor considered by the KCC between Portland and Detroit.

**Two Site Link Bridges that Are Not Transitive**

In the diagram, connection objects are not possible between DC4 in Detroit and DC3 in Portland because two site link bridges are not transitive. For connection objects to be possible between DC3 and DC4, the site link DB must be added to the PS-SB site link bridge. In this case, the cost of replication between DC3 and DC4 is 9.

**Note**

- Cost is applied differently to a site link bridge than to a site link that contains more than two sites. To use the preceding example, if Seattle, Boston, and Portland are all in the same site link, the cost of replication between any of the two sites is the same.

Bridging site links manually is generally recommended for only large branch office deployments. For more information about using manual site link bridging, see the "Windows Server 2003 Active Directory Branch Office Deployment Guide."

**Site Link Schedule**
Replication using the RPC transport between sites is scheduled. The schedule specifies one or many time periods during which replication can occur. For example, you might schedule a site link for a dial-up line to be available during off-peak hours (when telephone rates are low) and unavailable during high-cost regular business hours. The **schedule** attribute of the site link object specifies the availability of the site link. The default setting is that replication is always available.

**Note**

- The **Ignore schedules** setting on the IP container is equivalent to replication being always available. If **Ignore schedules** is selected, replication occurs at the designated intervals but ignores any schedule.

If replication goes through multiple site links, there must be at least one common time period (overlap) during which replication is available; otherwise, the connection is treated as not available. For example, if site link AB has a schedule of 18:00 hours to 24:00 hours and site link BC has a schedule of 17:00 hours to 20:00 hours, the resulting overlap is 18:00 hours through 20:00 hours, which is the intersection of the schedules for site link AB and site link BC. During the time in which the schedules overlap, replication can occur from site A to site C even if a domain controller in the intermediate site B is not available. If the schedules do not overlap, replication from the intermediate site to the distant site continues when the next replication schedule opens on the respective site link.

**Note**

- Cost considerations also affect whether connections are created. However, if the site link schedules do not overlap, the cost is irrelevant.

**Scheduling across time zones**

When scheduling replication across time zones, consider the time difference to ensure that replication does not interfere with peak production times in the destination site.

Domain controllers store time in Coordinated Universal Time (UTC). When viewed through the Active Directory Sites and Services snap-in, time settings in site link object schedules are displayed according to the local time of the computer on which the snap-in is being run. However, replication occurs according to UTC.

For example, suppose Seattle adheres to Pacific Standard Time (PST) and Japan adheres to Japan Standard Time (JST), which is 17 hours later. If a schedule is set on a domain controller in Seattle and the site link on which the schedule is set connects Seattle and Tokyo, the actual time of replication in Tokyo is 17 hours later.

If the schedule is set to begin replication at 10:00 PM PST in Seattle, the conversion can be computed as follows:

- Convert 10:00 PM PST to 22:00 PST military time.
- Add 8 hours to arrive at 06:00 UTC, the following day.
- Add 9 hours to arrive at 15:00 JST.
- 15:00 JST converts to 3:00 PM.

Thus, when replication begins at 10:00 o'clock at night in Seattle, it is occurring in Tokyo at 3:00 o'clock in the afternoon the following day. By scheduling replication a few hours later in Seattle, you can avoid replication occurring during working hours in Japan.

**Schedule implementation**

The times that you can set in the **Schedule** setting on the site link are in one-hour increments. For example, you can schedule replication to occur between 00:00 hours and 01:00 hours, between 01:00 hours and 02:00 hours, and so forth. However, each block in the actual connection schedule is 15 minutes. For this reason, when you set a schedule of 01:00 hours to 02:00 hours, you can assume that replication is queued at some point between 01:00 hours and 01:14:59 hours.

**Note**

- RPC synchronous inbound replication is serialized so that if the server is busy replicating this directory partition from another source, replication from a different source does not begin until the first synchronization is complete. SMTP asynchronous replication is processed serially by order of arrival, with multiple replication requests queued simultaneously.

Specifically, a replication event is queued at time $t + n$, where $t$ is the replication interval that is applied across the schedule and $n$ is a pseudo-random number from 1 minute through 15 minutes. For example, if the site link indicates that replication can occur from 02:00 hours through 07:00 hours, and the replication interval is 2 hours (120 minutes), $t$ is 02:00 hours, 04:00 hours, and 06:00 hours. A replication event is queued on the destination domain controller between 02:00 hours and 02:14:59 hours, and another replication event is queued between 04:00 hours and 04:14:59 hours. Assuming that the first

replication event that was queued is complete, another replication event is queued between 06:00 hours and 06:14:59 hours. If the synchronization took longer than two hours, the second synchronization would be ignored because an event is already in the queue.

Replication can extend beyond the end of the schedule. A period of replication latency that starts before the end of the schedule runs until completion, even if the period is still running when the schedule no longer allows replication to be available.

**Note**

- The replication queue is shared with other events, and the time at which replication takes place is approximate. Duplicate replication events are not queued for the same directory partition and transport.

**Connection object schedule**

Each connection object has a schedule that controls when (during what hours) and how frequently (how many times per hour) replication can occur:

- None (no replication)
- Once per hour (the default setting)
- Twice per hour
- Four times per hour

The connection object schedule and interval are derived from one of two locations, depending on whether it is an intrasite or intersite connection:

- Intrasite connections inherit a default schedule from the **schedule** attribute of the NTDS Site Settings object. By default, this schedule is always available and has an interval of one hour.
- Intersite connections inherit the schedule and interval from the site link.

Although intrasite replication is prompted by changes, intrasite connection objects inherit a default schedule so that replication occurs periodically, regardless of whether change notification has been received. The connection object schedule ensures that intrasite replication occurs if a notification message is lost, or if notification does not take place, due to network problems or a domain controller becomes unavailable. The NTDS Site Settings schedule has a minimum replication interval of 15 minutes. This minimum replication interval is not configurable and determines the smallest interval that is possible for both intrasite and intersite replication (on a connection object or a site link, respectively).

For intersite replication, the schedule is configured on the site link object, but the connection object schedule actually determines replication; that is, the connection object schedule for an intersite connection is derived from the site link schedule, which is applied through the connection object schedule. Scheduled replication occurs independently of change notification.

**Note**

- You do not need to configure the connection object schedule unless you are creating a manual intersite replication topology that does not use the KCC automatic connection objects.

The KCC uses a two-step process to compute the schedule of an intersite connection.

1. The schedules of the site links traversed by a connection are merged together.
2. This merged schedule is modified so that it is available at only certain periods. The length of those periods is equal to the maximum replication interval of the site links traversed by this connection.

By using Active Directory Sites and Services, you can manually revise the schedule on a connection object, but such an override is effective for only administrator-owned connection objects.

**Replication Interval**
For each site link object, you can specify a value for the replication interval (frequency), which determines how often replication occurs over the site link during the time that the schedule allows. For example, if the schedule allows replication between 02:00 hours and 04:00 hours, and the replication interval is set for 30 minutes, replication can occur up to four times during the scheduled time.

The default replication interval is 180 minutes, or 3 hours. When the KCC creates a connection between a domain controller in one site and a domain controller in another site, the replication interval of the connection is the maximum interval along the minimum-cost path of site link objects from one end of the connection to the other.

**Interaction of Replication Schedule and Interval**
When multiple site links are required to complete replication for all sites, the replication interval settings on each site link combine to affect the entire length of the connection between sites. In addition, when schedules on each site link are not identical, replication can occur only when the schedules overlap.

Suppose that site A and site B have site link AB, and site B and site C have site link BC. When a domain controller in site A replicates with a domain controller in site C, it can do so only as often as the maximum interval that is set for site link AB and site link BC allows. The following table shows the site link settings that determine how often and during what times replication can occur between domain controllers in site A, site B, and site C.

**Replication Interval and Schedule Settings for Two Site Links**

| Site Link | Replication Interval | Schedule |
|---|---|---|
| AB | 30 minutes | 12:00 hours to 04:00 hours |
| BC | 60 minutes | 01:00 hours to 05:00 hours |

Given these settings, a domain controller in site A can replicate with a domain controller in site B according to the AB site link schedule and interval, which is once every 30 minutes between the hours of 12:00 and 04:00. However, assuming that there is no site link AC, a domain controller in site A can replicate with a domain controller in site C between the hours of 01:00 and 04:00, which is where the schedules on the two site links intersect. Within that timespan, they can replicate once every 60 minutes, which is the greater of the two replication intervals.

**KCC and Topology Generation**
The Knowledge Consistency Checker (KCC) is a dynamic-link library (DLL) that runs as a distributed application on every domain controller. The KCC on each domain controller modifies data in its local instance of the directory in response to forest-wide changes, which are made known to the KCC by changes to data in the configuration directory partition.

The KCC generates and maintains the replication topology for replication within sites and between sites by converting KCC-defined and administrator-defined (if any) connection objects into a configuration that is understood by the directory replication engine. By default, the KCC reviews and makes modifications to the Active Directory replication topology every 15 minutes to ensure propagation of data, either directly or transitively, by creating and deleting connection objects as needed. The KCC recognizes changes that occur in the environment and ensures that domain controllers are not orphaned in the replication topology.

Operating independently, the KCC on each domain controller uses its own view of the local replica of the configuration directory partition to arrive at the same intrasite topology. One KCC per site, the ISTG, determines the intersite replication topology for the site. Like the KCC that runs on each domain controller within a site, the instances of the ISTG in different sites do not communicate with each other. They independently use the same algorithm to produce a consistent, well-formed spanning tree of connections. Each site constructs its own part of the tree and, when all have run, a working replication topology exists across the enterprise.

The predictability of all KCCs allows scalability by reducing communication requirements between KCC instances. All KCCs agree on where connections will be formed, ensuring that redundant replication does not occur and that all parts of the enterprise are connected.

The KCC performs two major functions:

- Configures appropriate replication connections (connection objects) on the basis of the existing cross-reference, server, NTDS settings, site, site link, and site link bridge objects and the current status of replication.

- Converts the connection objects that represent inbound replication to the local domain controller into the replication agreements that are actually used by the replication engine. These agreements, called replica links, accommodate replication of a single directory partition from the source to the destination domain controller.

#### Intervals at Which the KCC Runs

By default, the KCC runs its first replication topology check five minutes after the domain controller starts. The domain controller then attempts initial replication with its intrasite replication partners. If a domain controller is being used for multiple other services, such as DNS, WINS, or DHCP, extending the replication topology check interval can ensure that all services have started before the KCC begins using CPU resources.

You can edit the registry to modify the interval between startup and the time the domain controller first checks the replication topology.

**Note**

- If you must edit the registry, use extreme caution. Registry information is provided here as a reference for use by only highly skilled directory service administrators. It is recommended that you do not directly edit the registry unless, as in this case, there is no Group Policy or other Windows tools to accomplish the task. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. Storage of incorrect values can result in unrecoverable errors in the system.

Modifying the interval between startup and the time the domain controller first checks the replication topology requires changing the **Repl topology update delay (secs)** entry in HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters as appropriate:

- **Value:** Number of seconds to wait between the time Active Directory starts and the KCC runs for the first time.
- **Default:** 300 seconds (5 minutes)
- **Data type:** REG_DWORD

Thereafter, as long as services are running, the KCC on each domain controller checks the replication topology every 15 minutes and makes changes as necessary.

Modifying the interval at which the KCC performs topology review requires changing the **Repl topology update period (secs)** entry in HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters as appropriate:

- **Value:** Number of seconds between KCC topology updates
- **Default:** 900 seconds (15 minutes)
- **Data type:** REG_DWORD

#### Objects that the KCC Requires to Build the Replication Topology

The following objects, which are stored in the configuration directory partition, provide the information required by the KCC to create the replication topology:

- **Cross-reference.** Each directory partition in the forest is identified in the Partitions container by a cross-reference object. The attributes of this object are used by the replication system to locate the domain controllers that store each directory partition.
- **Server.** Each domain controller in the forest is identified as a server object in the Sites container.
- **NTDS Settings.** Each server object that represents a domain controller has a child NTDS Settings object. Its presence identifies the server as having Active Directory installed. The NTDS Settings object must be present for the server to be considered by the KCC for inclusion in the replication topology.
- **Site.** The presence of the above objects also indicates to the KCC the site in which each domain controller is located for replication. For example, the distinguished name of the NTDS Settings object contains the name of the site in which the server object that represents the domain controller exists.

- **Site link.** A site link must be available between any set of sites and its schedule and cost properties evaluated for routing decisions.

- **Site link bridge.** If they exist, site link bridge objects and properties are evaluated for routing decisions.

If the domain controller is physically located in one site but its server object is configured in a different site, the domain controller will attempt intrasite replication with a replication partner that is in the site of its server object. In this scenario, the improper configuration of servers in sites can affect network bandwidth.

If a site object exists for a site that has no domain controllers, the KCC does not consider the site when generating the replication topology.

**Topology Generation Phases**

The KCC generates the replication topology in two phases:

- **Evaluation.** During the evaluation phase, the KCC evaluates the current topology, determines whether replication failures have occurred with the existing connections, and constructs whatever new connection objects are required to complete the replication topology.

- **Translation.** During the translation phase, the KCC implements, or "translates," the decisions that were made during the evaluation phase into agreements between the replication partners. During this phase, the KCC writes to the **repsFrom** attribute on the local domain controller (for intrasite topology) or on all bridgehead servers in a site (for intersite topology) to identify the replication partners from which each domain controller pulls replication. For more information about the information in the replication agreement, see "How the Active Directory Replication Model Works."

**KCC Modes and Scopes**

Because individual KCCs do not communicate directly to generate the replication topology, topology generation occurs within the scope of either a single domain controller or a single site. In performing the two topology generation phases, the KCC has three modes of operation. The following table identifies the modes and scope for each mode.

**Modes and Scopes of KCC Topology Generation**

| KCC Mode | Performing Domain Controllers | Scope | Description |
|---|---|---|---|
| Intrasite | All | Local server | Evaluate all servers in a site and create connection objects locally on this server from servers in the same site that are adjacent to this server in the ring topology. |
| Intersite | One domain controller per site that has the ISTG role | Local site | Evaluate the servers in all sites and create connection objects both locally and on other servers in the site from servers in different sites. |
| Link translation | All | Local server | Translate connection objects into replica links (partnerships) for each server relative to each directory partition that it holds. |

**Topology Evaluation and Connection Object Generation**

The KCC on a destination domain controller evaluates the topology by reading the existing connection objects. For each connection object, the KCC reads attribute values of the NTDS Settings object (class **nTDSDSA**) of the source domain controller (indicated by the **fromServer** value on the connection object) to determine what directory partitions its destination domain controller has in common with the source domain controller.

**Topology evaluation for all domain controllers**

To determine the connection objects that need to be generated, the KCC uses information stored in the attributes of the NTDS Settings object that is associated with each server object, as follows:

- For all directory partitions, the multivalued attribute **hasMasterNCs** stores the distinguished names of all directory partitions that are stored on that domain controller.

- For all domain controllers, the value of the **options** attribute indicates whether that domain controller is configured to host the global catalog.

- The **hasPartialReplicaNCs** attribute contains the set of partial-replica directory partitions (global catalog read-only

domain partitions) that are located on the domain controller that is represented by the server object.

**Topology evaluation for domain controllers running Windows Server 2003**

For all domain controllers that are running Windows Server 2003, the **msDS-HasDomainNCs** attribute of the NTDS Settings object contains the name of the domain directory partition that is hosted by the domain controller.

In forests that have the forest functional level of at least Windows Server 2003 or Windows Server 2003 interim, the following additional information is used by the KCC to evaluate the topology for application directory partitions and to generate the needed connections:

- The linked multivalued attribute **msDS-NC-Replica-Locations** on cross-reference objects stores the distinguished names of NTDS Settings objects for all domain controllers that are configured to host a replica of the corresponding application directory partition.

  **Note**

  - When you remove Active Directory from a server that hosts an application directory partition, its corresponding entry in this multivalued attribute is automatically dropped because **msDS-NC-Replica-Locations** is a linked attribute.

- Application directory partition replica locations are determined by matching the values of the **hasMasterNCs** attribute with the values of the **msDS-NC-Replica-Locations** linked multivalued attribute of cross-reference objects. The **msDS-NC-Replica-Locations** attribute holds distinguished name references to the NTDS Settings objects for domain controllers that have been configured to store replicas of the application directory partition. The **msDS-NC-Replica-Locations** attribute facilitates the enumeration of *existing* replicas for a given application directory partition. Connection objects can then be created between the domain controllers that hold matching replicas.

Be aware that due to replication latency, the configuration of replicas in attribute values does not guarantee the existence of the replica on a given server. For example, you can designate a domain controller as a global catalog server by clicking the **Global Catalog** check box on the NTDS Settings object properties in Active Directory Sites and Services. However, until all of the partial domain directory partitions have replicated to that domain controller and global-catalog-specific SRV records are registered in DNS, it is not a functioning global catalog server (does not advertise as a global catalog server in DNS). Similarly, observing the NTDS Settings name for a server in the **msDS-NC-Replica-Locations** attribute on the cross-reference object does not indicate that the replica has necessarily been fully replicated to that server.

**Connection Translation**

All KCCs process their connection objects and translate them into connection agreements, also called "replica links," between pairs of domain controllers. At specified intervals, Active Directory replicates data from the source domain controller to the destination for directory partitions that they have in common. These replication agreements do not appear in the administrative tools; the replication engine uses them internally to track the directory partitions that are to be replicated from specified servers.

For each directory partition that two domain controllers have in common and that matches the full and partial characteristics of a replication source, the KCC creates (or updates) a replication agreement on the destination domain controller. Replication agreements take the form of entries for each source domain controller in the **repsFrom** attribute on the topmost object of each directory partition replica. This value is stored and updated locally on the domain controller and is not replicated. The KCC updates this attribute each time it runs.

For example, suppose a connection object is created between two domain controllers from different domains. Assuming that neither of these domain controllers is a global catalog server and neither stores an application directory partition, the KCC identifies the only two directory partitions that the domain controllers have in common — the schema directory partition and the configuration directory partition. If a connection object links domain controllers in the same domain, at least three directory partitions are replicated: the schema directory partition, the configuration directory partition, and the domain directory partition.

In contrast, if the connection object that is created establishes replication between two domain controllers that are global catalog servers, then in addition to the directory partitions the domain controllers have in common, a partial replica of each additional domain directory partition in the forest is also replicated between the two domain controllers over the same connection.

For more information about replication agreements, see "How the Active Directory Replication Model Works."

**Read-only and Writable Replicas**
When computing the replication topology, the KCC must consider whether a replica is writable or read-only. For each potential set of replication partners in the topology, the considerations are as follows:

- A writable replica can receive updates from a corresponding writable replica.
- A read-only replica can receive updates from a corresponding writable replica.
- A read-only replica can receive updates from a corresponding read-only replica.
- A writable replica *cannot* receive updates from a corresponding read-only replica.

In Windows 2000 forests, for any one domain directory partition, the KCC calculates two topologies: one for the writable replicas and one for the read-only replicas. This calculation allows redundant connections for read-only replicas under certain conditions.

The improved KCC spanning tree algorithm eliminates redundancy that can occur in Windows 2000. The algorithm computes only one topology with slightly different behavior for replicating the global catalog. The KCC on a domain controller that is not a global catalog server does not consider global catalog servers in its calculations for read-only domain replicas because it never replicates read-only data *from* a global catalog server.

**Automated Intrasite Topology Generation**
For replication within a site, a topology is generated and then optimized to minimize the number of hops to three. The means by which the three-hop minimum is achieved varies according to the number of domain controllers that are hosted in the site as well as the presence of global catalog servers. Generally, the intrasite topology is formed in a ring. The topology becomes more complex as the number of servers increases. However, the KCC can accommodate thousands of domain controllers in a site.

**Simplified Ring Topology Generation**
A simplified process for creating the topology for replication within a site begins as follows:

- The KCC generates a list of all servers in the site that hold that directory partition.
- These servers are connected in a ring.
- For each neighboring server in the ring from which the current domain controller is to replicate, the KCC creates a connection object if one does not already exist.

This simple approach guarantees a topology that tolerates a single failure. If a domain controller is not available, it is not included in the ring that is generated by the list of servers. However, this topology, with no other adjustments, accommodates only seven servers. Beyond this number, the ring would require more than three hops for some servers.

The simplest case scenario — seven or fewer domain controllers, all in the same domain and site — would result in the replication topology shown in the following diagram. The only directory partitions to replicate are a single domain directory partition, the schema directory partition, and the configuration directory partition. Those topologies are generated first, and at that point, sufficient connections to replicate each directory partition have already been created.

In the next series of diagrams, the arrows indicate one-way or two-way replication of the type of directory partitions indicated in the Legend.

### Simple Ring Topology that Requires No Optimization

Because a ring topology is created for each directory partition, the topology might look different if domain controllers from a second domain were present in the site. The next diagram illustrates the topology for domain controllers from two domains in the same site with no global catalog servers defined in the site.

**Ring Topology for Two Domains in a Site that Has No Global Catalog Server**

The next diagram illustrates replication between a global catalog server and three domains to which the global catalog server does not belong. When a global catalog server is added to the site in DomainA, additional connections are required to replicate updates of the other domain directory partitions to the global catalog server. The KCC on the global catalog server creates connection objects to replicate from domain controllers for each of the other domain directory partitions within the site, or from another global catalog server, to update the read-only partitions. Wherever a domain directory partition is replicated, the KCC also uses the connection to replicate the schema and configuration directory partitions.

**Note**

- Connection objects are generated independently for the configuration and schema directory partitions (one connection) and for the separate domain and application directory partitions, unless a connection from the same source to destination domain controllers already exists for one directory partition. In that case, the same connection is used for all (duplicate connections are not created).

**Intrasite Topology for Site with Four Domains and a Global Catalog Server**

**Expanded Ring Topology Within a Site**

When the number of servers in a site grows beyond seven, the KCC estimates the number of connections that are needed so that if a change occurs at any one domain controller, there are as many replication partners as needed to ensure that no domain controller is more than three replication hops from another domain controller (that is, a change takes no more than three hops before it reaches another domain controller that has not already received the change by another path). These optimizing connections are created at random and are not necessarily created on every third domain controller.

The KCC adds connections automatically to optimize a ring topology within a site, as follows:

- Given a set of nodes in a ring, create the minimum number of connections, *n*, that each server must have to ensure a path of no more than three hops to another server.

Given *n*, topology generation proceeds as follows.

- If the local server does not have *n* extra connections, the KCC does the following:
    - Chooses *n* other servers randomly in the site as source servers.
    - For each of those servers, creates a connection object.

This approach approximates the minimum-hop goal of three servers. In addition, it grows well, because as the site grows in server count, old optimizing connections are still useful and are not removed. Also, every time an additional 9 to 11 servers are added, a connection object is deleted at random; then a new one is created, ideally having one of the new servers as its source. This process ensures that, over time, the additional connections are distributed well over the entire site.

The following diagram shows an intrasite ring topology with optimizing connections in a site that has eight domain controllers in the same domain. Without optimizing connections, the hop count from DC1 to DC2 is more than three hops. The KCC creates optimizing connections to limit the hop count to three hops. The two one-way inbound optimizing connections accommodate all directory partitions that are replicated between the two domain controllers.

**Intrasite Topology with Optimizing Connections**

**Excluded Nonresponding Servers**

The KCC automatically rebuilds the replication topology when it recognizes that a domain controller has failed or is unresponsive.

The criteria that the KCC uses to determine when a domain controller is not responsive depend upon whether the server computer is within the site or not. Two thresholds must be reached before a domain controller is declared "unavailable" by the KCC:

- The requesting domain controller must have made *n* attempts to replicate from the target domain controller.
    - For replication between sites, the default value of *n* is 1 attempt.
    - For replication within a site, the following distinctions are made between the two immediate neighbors (in the ring) and the optimizing connections:

      For immediate neighbors, the default value of *n* is 0 failed attempts. Thus, as soon as an attempt fails, a new server is tried.

      For optimizing connections, the default value of *n* is 1 failed attempt. Thus, as soon as a second failed attempt occurs, a new server is tried.
- A certain amount of time must have passed since the last successful replication attempt.
    - For replication between sites, the default time is 2 hours.
    - For replication within a site, a distinction is made between the two immediate neighbors (in the ring) and the optimizing connections:

      For immediate neighbors, the default time is 2 hours.

      For optimizing connections, the default value is 12 hours.

You can edit the registry to modify the thresholds for excluding nonresponding servers.

**Note**

- If you must edit the registry, use extreme caution. Registry information is provided here as a reference for use by only highly skilled directory service administrators. It is recommended that you do not directly edit the registry unless, as in this case, there is no Group Policy or other Windows tools to accomplish the task. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. Storage of incorrect values can result in unrecoverable errors in the system.

Modifying the thresholds for excluding nonresponding servers requires editing the following registry entries in HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters, with the data type REG_DWORD. You can modify these values to any desired value as follows:

For replication between sites, use the following entries:

- **IntersiteFailuresAllowed**

  Value: Number of failed attempts

  Default: 1

- **MaxFailureTimeForIntersiteLink (sec)**

  Value: Time that must elapse before being considered unavailable, in seconds

  Default: 7200 (2 hours)

For optimizing connections within a site, use the following entries:

- **NonCriticalLinkFailuresAllowed**

  Value: Number of failed attempts

  Default: 1

- **MaxFailureTimeForNonCriticalLink**

  Value: Time that must elapse before considered unavailable, in seconds

  Default: 43200 (12 hours)

For immediate neighbor connections within a site, use the following entries:

- **CriticalLinkFailuresAllowed**

  Value: Number of failed attempts

  Default: 0

- **MaxFailureTimeForCriticalLink**

  Value: Time that must elapse before considered unavailable, in seconds

  Default: 7200 (2 hours)

When the original domain controller begins responding again, the KCC automatically restores the replication topology to its pre-failure condition the next time that the KCC runs.

#### Fully Optimized Ring Topology Generation

Taking the addition of extra connections, management of nonresponding servers, and growth-management mechanisms into account, the KCC proceeds to fully optimize intrasite topology generation. The appropriate connection objects are created and deleted according to the available criteria.

**Note**

- Connection objects from nonresponding servers are not deleted because the condition is expected to be transient.

#### Automated Intersite Topology Generation

To produce a replication topology for hundreds of domains and thousands of sites in a timely manner and without compromising domain controller performance, the KCC must make the best possible decision when confronted with the question of which network link to use to replicate a given directory partition between sites. Ideally, connections occur only

between servers that contain the same directory partition(s), but when necessary, the KCC can also use network paths that pass through servers that do not store the directory partition.

Intersite topology generation and associated processes are improved in Windows Server 2003 in the following ways:

- Improved scalability: A new spanning tree algorithm achieves greater efficiency and scalability when the forest has a functional level of Windows Server 2003. For more information about this new algorithm, see "Improved KCC Scalability in Windows Server 2003 Forests" later in this section.

- Less network traffic: A new method of communicating the identity of the ISTG reduces the amount of network traffic that is produced by this process. For more information about this method, see "Intersite Topology Generator" later in this section.

- Multiple bridgehead servers per site and domain, and initial bridgehead server load balancing: An improved algorithm provides random selection of multiple bridgehead servers per domain and transport (the Windows 2000 algorithm allows selection of only one). The load among bridgehead servers is balanced the first time connections are generated. For more information about bridgehead server load balancing, see "Windows Server 2003 Multiple Bridgehead Selection" later in this section.

**Factors Considered by the KCC**

The spanning tree algorithm used by the KCC that is running as the ISTG to create the intersite replication topology determines how to connect all the sites that need to be connected with the minimum number of connections and the least cost. The algorithm must also consider the fact that each domain controller has at least three directory partitions that potentially require synchronization with other sites, not all domain controllers store the same partitions, and not all sites host the same domains.

The ISTG considers the following factors to arrive at the intersite replication topology:

- Location of domain directory partitions (calculate a replication topology for each domain).

- Bridgehead server availability in each site (at least one is available).

- All explicit site links.

- With automatic site link bridging in effect, consider all implicit paths as a single path with a combined cost.

- With manual site link bridging in effect, consider the implicit combined paths of only those site links included in the explicit site link bridges.

- With no site link bridging in effect, where the site links represent hops between domain controllers in the same domain, replication flows in a store-and-forward manner through sites.

**Improved KCC Scalability in Windows Server 2003 Forests**

KCC scalability is greatly improved in Windows Server 2003 forests over its capacity in Windows 2000 forests. Windows 2000 forests scale safely to support 300 sites, whereas Windows Server 2003 forests have been tested to 3,000 sites. This level of scaling is achieved when the forest functional level is Windows Server 2003. At this forest functional level, the method for determining the least-cost path from each site to every other site for each directory partition is significantly more efficient than the method that is used in a Windows 2000 forest or in a Windows Server 2003 forest that has a forest functional level of Windows 2000.

**Windows 2000 Spanning Tree Algorithm**

The ability of the KCC to generate the intersite topology in Windows 2000 forests is limited by the amount of CPU time and memory that is consumed when the KCC computes the replication topology in large environments that use transitive (bridged) site links. In a Windows 2000 forest, a potential disadvantage of bridging all site links affects only very large networks (generally, greater than 100 sites) where periods of high CPU activity occur every 15 minutes when the KCC runs. By default, the KCC creates a single bridge for the entire network, which generates more routes that must be processed than if automatic site link bridging is not used and manual site link bridges are applied selectively.

In a Windows 2000 forest, or in a Windows Server 2003 forest that has a forest functional level of Windows 2000, the KCC reviews the comparison of multiple paths to and from every destination and computes the spanning tree of the least-cost path. The spanning tree algorithm works as follows:

- Computes a cost matrix by identifying each site pair (that is, each pair of bridgehead servers in different sites that store the directory partition) and the cost on the site link connecting each pair.

  **Note**

  - This matrix is actually computed by Intersite Messaging and used by the KCC.

- By using the costs computed in the matrix, builds a spanning tree between sites that store the directory partition.

This method becomes inefficient when there are a large number of sites.

**Note**

- CPU time and memory is not an issue in a Windows 2000 forest as long as the following criteria apply:
- D is the number of domains in your network
- S is the number of sites in your network
- (1 + D) * S^2 <= 100,000

**Windows Server 2003 Spanning Tree Algorithm**

A more efficient spanning tree algorithm improves efficiency and scalability of replication topology generation in Windows Server 2003 forests. When the forest functional level is either Windows Server 2003 or Windows Server 2003 interim, the improved algorithm takes effect and computes a minimum-cost spanning tree of connections between the sites that host a particular directory partition, but eliminates the inefficient cost matrix. Thus, the KCC directly determines the lowest-cost spanning tree for each directory partition, considering the schema and configuration directory partitions as a single tree. Where the spanning trees overlap, the KCC generates a single connection between domain controllers for replication of all common directory partitions.

In a Windows Server 2003 forest, both versions of the KCC spanning tree algorithms are available. The algorithm for Windows 2000 forests is retained for backwards compatibility with the Windows 2000 KCC. It is not possible for the two algorithms to run simultaneously in the same enterprise.

**DFS Site Costing and Windows Server 2003 SP1 Site Options**

When the forest functional level is Windows Server 2003 or Windows Server 2003 interim and the ISTG does not use Intersite Messaging to calculate the intersite cost matrix, DFS can still use Intersite Messaging to compute the cost matrix for its site-costing functionality, provided that the **Bridge all site links** option is enabled. In branch office deployments, where the large number of sites and site links makes automatic site link bridging too costly in terms of the replication connections that are generated, the **Bridge all site links** option is usually disabled on the IP container (CN=IP,CN=Inter-Site Transports,CN=Sites,CN=Configuration,DC=*ForestRootDomain*). If the **Bridge all site links** option is disabled, DFS is unable to use Intersite Messaging to calculate site costs.

When the forest functional level is Windows Server 2003 or Windows Server 2003 interim and the ISTG in a site is running Windows Server 2003 with SP1, you can have the **Bridge all site links** option enabled, and then use a site option to turn off automatic site link bridging for KCC operation without hampering the ability of DFS to use Intersite Messaging to calculate the cost matrix. This site option is set by running the command **repadmin /siteoptions W2K3_BRIDGES_REQUIRED**. This option is applied to the NTDS Site Settings object (CN=NTDS Site Settings,CN=*SiteName*,CN=Sites,CN=Configuration,DC=*ForestRootDomain*). When this method is used to disable automatic site link bridging (as opposed to disabling **Bridge all site links**), default Intersite Messaging options enable the site-costing calculation to occur for DFS.

| **Note** |
| --- |
| The site option on the NTDS Site Settings object can be set on any domain controller, but it does not take effect until replication of the change reaches the ISTG role holder for the site. |

**Intersite Topology Generator**

The KCC on the domain controller that has the ISTG role creates the inbound connections on all domain controllers in its site that require replication with domain controllers in other sites. The sum of these connections for all sites in the forest forms the

intersite replication topology.

A fundamental concept in the generation of the topology within a site is that each server does its part to create a site-wide topology. In a similar manner, the generation of the topology between sites depends on each site doing its part to create a forest-wide topology between sites.

**ISTG Role Ownership and Viability**

The owner of the ISTG role is communicated through normal Active Directory replication. Initially, the first domain controller in the site is the ISTG role owner. It communicates its role ownership to other domain controllers in the site by writing the distinguished name of its child NTDS Settings object to the **interSiteTopologyGenerator** attribute of the NTDS Site Settings object for the site. As a change to the configuration directory partition, this value is replicated to all domain controllers in the forest.

The ISTG role owner is selected automatically. The role ownership does not change unless:

- The current ISTG role owner becomes unavailable.
- All domain controllers in the site are running Windows 2000 and one of them is upgraded to Windows Server 2003.

If at least one domain controller in a site is running Windows Server 2003, the ISTG role is assumed by a domain controller that is running Windows Server 2003.

The viability of the current ISTG is assessed by all other domain controllers in the site. The need for a new ISTG in a site is established differently, depending on the forest functional level that is in effect.

- Windows 2000 functional level: At 30-minute intervals, the current ISTG notifies every other domain controller of its existence and availability by writing the **interSiteTopologyGenerator** attribute of the NTDS Site Settings object for the site. The change replicates to every domain controller in the forest. The KCC on each domain controller monitors this attribute for its site to verify that it has been written. If a period of 60 minutes elapses without a modification to the attribute, a new ISTG declares itself.
- Windows Server 2003 or Windows Server 2003 interim functional level: Each domain controller maintains an up-to-dateness vector, which contains an entry for each domain controller that holds a full replica of any directory partition that the domain controller replicates. On domain controllers that are running Windows Server 2003, this up-to-dateness vector contains a timestamp that indicates the times that it was last contacted by its replication partners, including both direct and indirect partners (that is, every domain controller that replicates a directory partition that is stored by this domain controller). The timestamp is recorded whether or not the local domain controller actually received any changes from the partner. Because all domain controllers store the schema and configuration directory partitions, every domain controller is guaranteed to have the ISTG for its site among the domain controllers in its up-to-dateness vector.

  This timestamp eliminates the need to receive periodic replication of the updated **interSiteTopologyGenerator** attribute from the current ISTG. When the timestamp indicates that the current ISTG has not contacted the domain controller in the last 120 minutes, a new ISTG declares itself.

The Windows Server 2003 method eliminates the network traffic that is generated by periodically replicating the **interSiteTopologyGenerator** attribute update to every domain controller in the forest.

**ISTG Eligibility**

When at least one domain controller in a site is running Windows Server 2003, the eligibility for the ISTG role depends on the operating system of the domain controllers. When a new ISTG is required, each domain controller computes a list of domain controllers in the site. All domain controllers in the site arrive at the same ordered list. Eligibility is established as follows:

- If no domain controllers in the site are running Windows Server 2003, all domain controllers that are running Windows 2000 Server are eligible. The list of eligible servers is ordered by GUID.
- If at least one domain controller in the site is running Windows Server 2003, all domain controllers that are running Windows Server 2003 are eligible. In this case, the entries in the list are sorted first by operating system and then by GUID. In a site in which some domain controllers are running Windows 2000 Server, domain controllers that are running Windows Server 2003 remain at the top of the list and use the GUID in the same manner to maintain the order.

The domain controller that is next in the list of servers after the current owner declares itself the new ISTG by writing the **interSiteTopologyGenerator** attribute on the NTDS Site Settings object.

If the current ISTG is temporarily disconnected from the topology, as opposed to being shut down, and a new ISTG declares itself in the interim, then two domain controllers can temporarily assume the ISTG role. When the original ISTG resumes replication, it initially considers itself to be the current ISTG and creates inbound replication connection objects, which results in duplicate intersite connections. However, as soon as the two ISTGs replicate with each other, the last domain controller to write the **intersiteTopologyGenerator** attribute continues as the single ISTG and removes the duplicate connections.

**Bridgehead Server Selection**

Bridgehead servers can be selected in the following ways:

- Automatically by the ISTG from all domain controllers in the site.
- Automatically by the ISTG from all domain controllers that are identified as preferred bridgehead servers, if any preferred bridgehead servers are assigned. Preferred bridgehead servers must be assigned manually.
- Manually by creating a connection object on a domain controller in one site from a domain controller in a different site.

By default, when at least one domain controller in a site is running Windows Server 2003 (regardless of forest functional level), any domain controller that hosts a domain in the site is a candidate to be an ISTG-selected bridgehead server. If preferred bridgehead servers are selected, candidates are limited to this list. The connections from remote servers are distributed among the available candidate bridgehead servers in each site. The selection of multiple bridgehead servers per domain and transport is new in Windows Server 2003. The ISTG uses an algorithm to evaluate the list of domain controllers in the site that can replicate each directory partition. This algorithm is improved in Windows Server 2003 to randomly select multiple bridgehead servers per directory partition and transport. In sites containing only domain controllers that are running Windows 2000 Server, the ISTG selects only one bridgehead server per directory partition and transport.

When bridgehead servers are selected by the ISTG, the ISTG ensures that each directory partition in the site that has a replica in any other site can be replicated to and from that site or sites. Therefore, if a single domain controller hosts the only replica of a domain in a specific site and the domain has domain controllers in another site or sites, that domain controller must be a bridgehead server in its site. In addition, that domain controller must be able to connect to a bridgehead server in the other site that also hosts the same domain directory partition.

### Note

- If a site has a global catalog server but does not contain at least one domain controller of every domain in the forest, then at least one bridgehead server must be a global catalog server.

**Preferred Bridgehead Servers**

Because bridgehead servers must be able to accommodate more replication traffic than non-bridgehead servers, you might want to control which servers have this responsibility. To specify servers that the ISTG can designate as bridgeheads, you can select domain controllers in the site that you want the ISTG to always consider as preferred bridgehead servers for the specified transport. These servers are used exclusively to replicate changes collected from the site to any other site over that transport. Designating preferred bridgehead servers also serves to exclude those domain controllers that, for reasons of capability, you do *not* want to be used as bridgehead servers.

Depending on the available transports, the directory partitions that must be replicated, and the availability of global catalog servers, multiple bridgehead servers might be required to replicate full and partial copies of directory data from one site to another.

The ISTG recognizes preferred bridgehead servers by reading the **bridgeheadTransportList** attribute of the server object. When this attribute has a value that is the distinguished name of the transport container that the server uses for intersite replication (IP or SMTP), the KCC treats the server as a preferred bridgehead server. For example, the value for the IP transport is CN=IP,CN=Inter-Site Transports,CN=Sites,CN=Configuration,DC=*ForestRootDomainName*. You can use Active Directory Sites and Services to designate a preferred bridgehead server by opening the server object properties and placing either the IP or SMTP transport into the preferred list, which adds the respective transport distinguished name to the **bridgeheadTransportList** attribute of the server.

The **bridgeheadServerListBl** attribute of the transport container object is a backlink attribute of the **bridgeheadTransportList** attribute of the server object. If the **bridgeheadServerListBl** attribute contains the distinguished name of at least one server in a site, then the KCC uses only preferred bridgehead servers to replicate changes for that site,

according to the following rules:

- If at least one server is designated as a preferred bridgehead server, updates to the domain directory partition hosted by that server can be replicated only from a preferred bridgehead server. If at the time of replication no preferred bridgehead server is available for that directory partition, replication of that directory partition does not occur.

- If any bridgehead servers are designated but no domain controller is designated as a preferred bridgehead server for a specific directory partition that has replicas in another site or sites, the KCC selects a domain controller to act as the bridgehead server, if one is available that can replicate the directory partition to the other site or sites.

Therefore, to use preferred bridgehead servers effectively, be sure to:

- Assign at least two or more bridgehead servers for each of the following:

    - Any domain directory partition that has a replica in any other site.

    - Any application directory partition that has a replica in another site.

    - The schema and configuration directory partitions (one bridgehead server replicates both) if no domains in the site have replicas in other sites.

- If the site has a global catalog server, select the global catalog server as one of the preferred bridgehead servers.

**Windows 2000 Single Bridgehead Selection**
In a Windows 2000 forest or in a Windows Server 2003 forest that has a forest functional level of Windows 2000, the ISTG selects a single bridgehead server per directory partition and transport. The selection changes only when the bridgehead server becomes unavailable. The following diagram shows the automatic bridgehead server (BH) selection that occurs in the hub site where all domain controllers host the same domain directory partition and multiple sites have domain controllers that host that domain directory partition.

**Windows 2000 Single Bridgehead Server in a Hub Site that Serves Multiple Branch Sites**

**Windows Server 2003 Multiple Bridgehead Selection**
When at least one domain controller in a site is running Windows Server 2003 (and thereby becomes the ISTG), the ISTG begins performing random load balancing of new connections. This load balancing occurs by default, although it can be disabled.

When creating a new connection, the KCC must choose endpoints from the set of eligible bridgeheads in the two endpoint sites. Whereas in Windows 2000 the ISTG always picks the same bridgehead for all connections, in Windows Server 2003 it picks one randomly from the set of possible bridgeheads.

Assuming two out of three of the domain controllers have been added to the site since the ISTG was upgraded to Windows Server 2003, the following diagram shows the connections that might exist on domain controllers in the hub site to

accommodate the four branch sites that have domain controllers for the same domain.

**Random Bridgehead Server Selection in a Hub Site in which the ISTG Runs Windows Server 2003**

If one or more new domain controllers are added to the hub site, the inbound connections on the existing bridgehead servers are not automatically re-balanced. The next time it runs, the ISTG considers the newly added server(s) as follows:

- If preferred bridgehead servers are not selected in the site, the ISTG considers the newly added servers as candidate bridgehead servers and creates new connections randomly if new connections are needed. It does not remove or replace the existing connections.

- If preferred bridgehead servers are selected in the site, the ISTG does not consider the newly added servers as candidate bridgehead servers unless they are designated as preferred bridgehead servers.

The initial connections remain in place until a bridgehead server becomes unavailable, at which point the KCC randomly replaces the connection on any available bridgehead server. That is, the endpoints do not change automatically for the existing bridgehead servers. In the following diagram, two new domain controllers are added to the hub site, but the existing connections are not redistributed.

**New Domain Controllers with No New Connections Created**

Although the ISTG does not rebalance the load among the existing bridgehead servers in the hub site after the initial connections are created, it does consider the added domain controllers as candidate bridgehead servers under either of the following conditions:

- A new site is added that requires a bridgehead server connection to the hub site.

- An existing connection to the hub site becomes unavailable.

The following diagram illustrates the inbound connection that is possible on a new domain controller in the hub site to accommodate a failed connection on one of the existing hub site bridgehead servers. In addition, a new branch site is added and a new inbound connection can potentially be created on the new domain controller in the hub site. However, because the selection is random, there is no guarantee that the ISTG creates the connections on the newly added domain controllers.

**Possible New Connections for Added Site and Failed Connection**

**Using ADLB to Balance Hub Site Bridgehead Server Load**

In large hub-and-spoke topologies, you can implement the redistribution of existing bridgehead server connections by using the Active Directory Load Balancing (ADLB) tool (Adlb.exe), which is included with the "Windows Server 2003 Active Directory Branch Office Deployment Guide." ADLB makes it possible to dynamically redistribute the connections on bridgehead servers. This application works independently of the KCC, but uses the connections that are created by the KCC. Connections that are manually created are not moved by ADLB. However, manual connections are factored into the load-balancing equations that ADLB uses.

The ISTG is limited to making modifications in its site, but ADLB modifies both inbound and outbound connections on eligible bridgehead servers and offers schedule staggering for outbound connections.

For more information about how bridgehead server load balancing and schedule staggering work with ADLB, see the "Windows Server 2003 Active Directory Branch Office Planning and Deployment Guide" on the Web at http://go.microsoft.com/fwlink/?linkID=28523.

**Network Ports Used by Replication Topology**

By default, RPC-based replication uses dynamic port mapping. When connecting to an RPC endpoint during Active Directory replication, the RPC run time on the client contacts the RPC endpoint mapper on the server at a well-known port (port 135). The server queries the RPC endpoint mapper on this port to determine what port has been assigned for Active Directory replication on the server. This query occurs whether the port assignment is dynamic (the default) or fixed. The client never needs to know which port to use for Active Directory replication.

**Note**

- An endpoint comprises the protocol, local address, and port address.

In addition to the dynamic port 135, other ports that are required for replication to occur are listed in the following table.

**Port Assignments for Active Directory Replication**

| Service Name | UDP | TCP |
|---|---|---|

| | | |
|---|---|---|
| LDAP | 389 | 389 |
| LDAP | | 636 (Secure Sockets Layer [SSL]) |
| LDAP | | 3268 (global catalog) |
| Kerberos | 88 | 88 |
| DNS | 53 | 53 |
| SMB over IP | 445 | 445 |

Replication within a domain also requires FRS using a dynamic RPC port.

**Setting Fixed Replication Ports Across a Firewall**

For each service that needs to communicate across a firewall, there is a fixed port and protocol. Normally, the directory service and FRS use dynamically allocated ports that require a firewall to have a wide range of ports open. Although FRS cannot be restricted to a fixed port, you can edit the registry to restrict the directory service to communicate on a static port.

### Note

- If you must edit the registry, use extreme caution. Registry information is provided here as a reference for use by only highly skilled directory service administrators. It is recommended that you do not directly edit the registry unless, as in this case, there is no Group Policy or other Windows tools to accomplish the task. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. Storage of incorrect values can result in unrecoverable errors in the system.

Restricting the directory service to using a fixed port requires editing the **TCP/IP Port** registry entry (REG_DWORD), located in:

HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

Changing this registry entry on a domain controller and restarting it causes the directory service to use the TCP port named in the registry entry. For example, port 49152 is DWORD=0000c000 (hexadecimal).

# Active Directory Replication Tools and Settings

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**Active Directory Replication Tools and Settings**

**In this section**

- Active Directory Replication Tools
- Active Directory Replication Registry Entries
- Active Directory Replication Group Policy Settings
- Active Directory Replication WMI Classes
- Network Ports Used by Active Directory Replication
- Related Information

**Active Directory Replication Tools**

The following tools are associated with Active Directory replication.

| Note |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

**Dssite.msc: Active Directory Sites and Services**

**Category**

Active Directory Administrative Tools Microsoft Management Console (MMC) snap-in. This tool is installed automatically when you install Active Directory, and is available on the Start menu under Programs\Administrative Tools. This tool also ships with the Administration Tools Pack (Adminpak.msi).

**Version compatibility**

Active Directory Sites and Services provides a view into the Sites container of the configuration directory partition. Use Active Directory Sites and Services to manage Active Directory replication topology. The following objects and their properties can be managed by using this tool:

- Sites container: Add new sites.
- Site objects: Add new servers to a site.
- NTDS Site Settings object: For each site, view the connection object schedule and enable Universal group membership caching.
- Server object: View the NTDS Settings object and designate the server as a bridgehead server.
- NTDS Settings object: View inbound connections for the server. View the connection object schedule and change the source server for the connection.
- Inter-Site Transports container: Manage IP and SMTP site links.
- Site link objects: Manage the site link properties for a set of sites.

- Subnets container: Add, remove, and configure subnets with IP addresses. Associate subnets with sites.

**Repadmin.exe: Repadmin**

**Category**
Command-line tool.

**Version compatibility**
Repadmin is used to view the replication information on domain controllers. You can determine the last successful replication of all directory partitions, identify inbound and outbound replication partners, identify the current bridgehead servers, view object metadata, and generally manage Active Directory replication topology. You can use Repadmin to force replication of an entire directory partition or of a single object. You can also list domain controllers in a site.

Repadmin is extended to enable commands to target sets of domain controllers. For example, you can target all domain controllers in a site or domain, or all domain controllers that are global catalog servers.

Repadmin also includes the **RemoveLingeringObjects** command, which removes objects that are outdated (do not exist in a replica of the same directory partition on the source domain controller).

For more information about removing lingering objects, see "Fixing Replication Lingering Object Problems (Event IDs 1388, 1988, 2042)" in the Windows Server 2003 Operations Guide at http://go.microsoft.com/fwlink/?LinkId=44131. For more information about Repadmin, see Repadmin Overview.

**Ntdsutil.exe: Ntdsutil**

**Category**
Command-line tool.

**Version compatibility**
Ntdsutil.exe provides management capabilities for Active Directory. You can use Ntdsutil.exe to perform Active Directory database maintenance, manage and control single-master operations, and remove replication metadata left behind by domain controllers that are removed from the network without uninstalling Active Directory. The version of Ntdsutil that is included with Windows Server 2003 SP1 removes File Replication service (FRS) metadata in addition to Active Directory replication metadata. You can also use Ntdsutil to create application directory partitions and perform authoritative restore operations. This tool is intended for use by experienced administrators.

**Active Directory Replication Registry Entries**
The information here is provided as a reference for use in troubleshooting or verifying that the required settings are applied. It is recommended that you do not directly edit the registry unless there is no other alternative. Modifications to the registry are not validated by the registry editor or by Windows before they are applied, and as a result, incorrect values can be stored. This can result in unrecoverable errors in the system. When possible, use Group Policy or other Windows tools, such as Microsoft Management Console (MMC), to accomplish tasks rather than editing the registry directly. If you must edit the registry, use extreme caution.

The following registry settings cannot be modified by using Group Policy or other Windows tools.

**NTDS Parameters Registry Settings**
The following registry entries are associated with Active Directory replication.

**Replicator notify pause after modify (secs)**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows 2000 Server.

**Default value**
Windows 2000 Server: 300 seconds.

The value for the delay between an originating update on a domain controller and the first change notification. On domain controllers running Windows Server 2003 or higher, the value for initial change notification delay is stored in the **msDSReplicationNotifyFirstDSADelay** attribute on the cross-reference object for each directory partition in the Configuration container. The default value in Windows Server 2003 and higher operating systems is decreased to 15 seconds

when the forest functional level is Windows Server 2003 or higher.

**Replicator notify pause between DSAs (secs)**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows 2000 Server.

**Default value**
Windows 2000 Server: 30 seconds

The value for the delay before each subsequent change notification. On domain controllers running Windows Server 2003, the value for subsequent notification delay is stored in the **msDSReplicationNotifySubsequentDSADelay** attribute on the cross-reference object for each directory partition in the Configuration container. The default value in Windows Server 2003 is decreased to 3 seconds when the forest functional level is Windows Server 2003.

**RPC Replication Timeout (mins)**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
Windows 2000 Server: 45 minutes; Windows Server 2003 and higher server operating systems: 5 minutes.

The number of minutes between initiation of Active Directory replication and the RPC timeout. The domain controller must be restarted before the change takes effect.

**Strict replication consistency**

**Registry path**
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008 R2, Windows Server 2003, Windows 2000 Server with SP3.

**Default value**
Windows 2000 Server with SP3: off (0); Windows Server 2003 and higher server operating systems: on (1)

The value that determines the treatment of replication of outdated objects that exist on reconnected domain controllers that have not replicated in longer than a tombstone lifetime. If the destination domain controller has strict replication consistency enabled, inbound replication of an outdated object is blocked. If the destination domain controller has strict replication disabled, inbound replication of the full object occurs.

**Replicator intra site packet size (objects)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
1/1,000,000th the size of RAM, with a minimum of 100 objects and a maximum of 1,000 objects.

The maximum number of objects per packet for RPC replication within a site.

**Replicator intra site packet size (bytes)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
1/100th the size of RAM, with a minimum of 1 megabyte (MB) and a maximum of 10 MB.

The maximum size of objects per packet for RPC replication within a site.

**Replicator inter site packet size (objects)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008 R2, Windows Server 2003, Windows 2000 Server.

**Default value**
1/1,000,000th the size of RAM, with a minimum of 100 objects and a maximum of 1,000 objects.

The maximum number of objects per packet for RPC replication between sites.

**Replicator inter site packet size (bytes)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

The maximum size of objects per packet for RPC replication between sites.

**Default value**
1/100th the size of RAM, with a minimum of 1 MB and a maximum of 10 MB.

**Replicator async inter site packet size (objects)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008, Windows Server 2008 R2, Windows Server 2003, Windows 2000 Server.

**Default value**
1/1,000,000th the size of RAM, with a minimum of 100 objects and a maximum of 1,000 objects.

The maximum number of objects per packet for SMTP replication between sites.

**Replicator async inter site packet size (bytes)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
1 MB.

The maximum size of objects per packet for SMTP replication between sites.

**Replicator compression algorithm**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003.

**Default value**
For Windows 2000 Server compression, change the value to 2.

Determines the compression algorithm that is used on a site link

**Repl topology update delay (secs)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
300 seconds.

Number of seconds to wait between the time Active Directory starts and the KCC performs the first topology check.

To find more information about **Repl topology update delay (secs)**, see "Registry Reference" in Tools and Settings Collection.

**Repl topology update period (secs)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008, Windows Server 2008 R2, Windows Server 2003, Windows 2000 Server.

**Default value**
900 seconds.

Interval between KCC replication topology checks.

To find more information about **Repl topology update period (secs)**, see "Registry Reference" in Tools and Settings Collection.

**IntersiteFailuresAllowed**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
1.

Number of failed replication attempts prior to excluding nonresponding servers from the intersite topology.

**MaxFailureTimeForIntersiteLink (sec)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
7200 seconds (2 hours).

Time in seconds that must elapse prior to excluding nonresponding servers from the intersite topology.

**NonCriticalLinkFailuresAllowed**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
1.

Number of failed replication attempts prior to excluding nonresponding servers from the intrasite topology.

**MaxFailureTimeForNonCriticalLink (sec)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008, Windows Server 2008 R2, Windows Server 2003, Windows 2000 Server.

**Default value**
43200 seconds (12 hours).

Time in seconds that must elapse prior to excluding nonresponding servers from the intrasite topology.

**CriticalLinkFailuresAllowed**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
0.

Number of failed replication attempts prior to excluding nonresponding servers for immediate neighbor connections within a site.

**MaxFailureTimeForCriticalLink (sec)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
7200 seconds (2 hours).

Time in seconds that must elapse prior to excluding nonresponding servers for immediate neighbor connections within a site.

**TCP/IP Port**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003, Windows 2000 Server.

**Default value**
135.

TCP port that the directory service uses instead of using dynamic port 135. The domain controller must be restarted before the change takes effect.

**Backup Latency Threshold (days)**

**Registry path**
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NTDS\Parameters

**Version**
Windows Server 2008 R2, Windows Server 2008, Windows Server 2003 with SP 1

**Default value**
Half the value of the tombstone lifetime of the forest.

When the value is reached, logs event ID 2089 in the Directory Service event log, warning administrators and monitoring applications to make sure that domain controllers are backed up before the tombstone lifetime expires.

**Active Directory Replication Group Policy Settings**

The following table lists and describes the Group Policy settings that are associated with Active Directory replication updates.

**Group Policy Settings Associated with Active Directory Replication**

| Group Policy Setting | Description |
|---|---|
| Account Lockout Policy:<br>• Account lockout duration<br>• Account lockout threshold<br>• Reset account lockout counter after | Changes to these settings in the Domain Security Policy trigger urgent replication. |
| Password Policy:<br>• Enforce password history<br>• Maximum password age<br>• Minimum password age<br>• Minimum password length<br>• Password must meet complexity requirements<br>• Store passwords using reversible encryption | Changes to these settings in the Domain Security Policy trigger urgent replication. |
| Contact PDC on logon failure | Account lockout and domain password changes rely on contacting the primary domain controller (PDC) emulator urgently to update the PDC emulator with the change. If Contact PDC on logon failure is disabled, replication of password changes to the PDC emulator occurs non-urgently. |

To find more information about these Group Policy settings, see “Group Policy Settings Reference” in Tools and Settings

Collection.

**Active Directory Replication WMI Classes**

The following table lists and describes the WMI classes that are associated with Active Directory replication. These classes are shipped with Windows Server 2003 or later server operating systems, but are also compatible with Windows 2000 Server.

**WMI Classes Associated with Active Directory Replication**

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| MSAD_DomainController | \\root\MicrosoftActiveDirectory | Windows Server 2008 R2<br>Windows Server 2008<br>Windows Server 2003<br>Windows 2000 Server |
| MSAD_NamingContext | \\root\MicrosoftActiveDirectory | Windows Server 2008 R2<br>Windows Server 2008<br>Windows Server 2003<br>Windows 2000 Server |
| MSAD_ReplNeighbor | \\root\MicrosoftActiveDirectory | Windows Server 2008 R2<br>Windows Server 2008<br>Windows Server 2003<br>Windows 2000 Server |
| MSAD_ReplCursor | \\root\MicrosoftActiveDirectory | Windows Server 2008 R2<br>Windows Server 2008<br>Windows Server 2003<br>Windows 2000 Server |
| MSAD_ReplPendingOp | \\root\MicrosoftActiveDirectory | Windows Server 2008 R2<br>Windows Server 2008<br>Windows Server 2003<br>Windows 2000 Server |

For more information about these WMI classes, see the WMI SDK documentation on MSDN.

**Network Ports Used by Active Directory Replication**

By default, RPC-based replication uses dynamic port mapping. When connecting to an RPC endpoint during Active Directory replication, the RPC run time on the client contacts the RPC endpoint mapper on the server at a well-known port (port 135). The server queries the RPC endpoint mapper on this port to determine what port has been assigned for Active Directory replication on the server. This query occurs whether the port assignment is dynamic (the default) or fixed. The client never needs to know which port to use for Active Directory replication.

**Note**

- An endpoint comprises the protocol, local address, and port address.

In addition to the dynamic port 135, other ports that are required for replication to occur are listed in the following table.

**Port Assignments for Active Directory Replication**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | 389 | 389 |
| LDAP | | 636 (Secure Sockets Layer [SSL]) |
| LDAP | | 3268 (global catalog) |
| Kerberos | 88 | 88 |
| DNS | 53 | 53 |
| SMB over IP | 445 | 445 |

Replication within a domain also requires FRS using a dynamic RPC port.

# Active Directory Search and Publication Technologies

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

Active Directory exists so that users, services, and applications can search for and publish useful information in the directory. The operations that users, services and applications perform against the directory include the following:

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

- Performing searches against the data
- Finding (or in the case of services, publishing) information related to services that are available on the network

**Active Directory Search and Publication Architecture**

The Active Directory architecture that supports search and service publication can be divided into two functional areas:

- Search
- Service publication

The following table describes these Active Directory functional areas.

**Active Directory Search and Service Publication**

| Functional Area | Description |
| --- | --- |
| Active Directory search | Directory clients and services need a way to find data that is stored in the directory. Requests for directory objects are carried out either through the Active Directory Service Interfaces (ADSI) Lightweight Directory Access Protocol (LDAP) provider or through the LDAP application programming interface (API). |
| Active Directory service publication | Service publication in Active Directory enables services to provide information about themselves in the directory, and it enables directory clients to search for available services on the network. In addition, Active Directory supports service principal names (SPNs) as the means by which client applications can authenticate the services that they use. |

**Active Directory Search**

The primary components of the architecture for the Active Directory search function include the directory client applications that search the directory; LDAP, which is used for searching and retrieving directory information; and the Active Directory database against which the directory client applications search.

The following table describes the Active Directory search components.

**Active Directory Search Components**

| Search Component | Description |
| --- | --- |
| Directory client application | A directory client application is any application that is capable of searching for information that is stored in Active Directory. |

| | |
|---|---|
| LDAP | LDAP is a directory service protocol that specifies directory communications. It runs directly over TCP/IP, and it can also run over user datagram protocol (UDP) connectionless transports. LDAP enables clients to query, create, update, and delete information that is stored in a directory service over a TCP connection. LDAP is the preferred and most common means of interacting with Active Directory. |
| Active Directory database | The Active Directory database is the structured data store that Active Directory uses to store information about objects on the network, including users, user groups, computers, services, applications, application data, shared files, and distribution lists. A copy (or replica) of the Active Directory database resides on every domain controller in an Active Directory forest. |

**Active Directory Service Publication**

The primary components of the architecture for Active Directory service publication are the services that publish information about themselves and the client applications that search the directory to find and authenticate services. Active Directory provides the storage and distribution mechanism for published service information and for the SPN attributes that are used in mutual authentication. The Key Distribution Center (KDC) provides the mechanism for authenticating services, using SPNs that are constructed by the client applications.

The following table describes the Active Directory service publication and SPN components.

**Active Directory Service Publication and SPN Components**

| Service Publication Component | Description |
|---|---|
| Service | An application that makes data or operations available to client applications. |
| Client application | An application, which runs on a workstation (or on a server), that makes use of a service. |
| KDC | A service, which runs on every domain controller, that provides authentication services for clients as well as for servers and services. |
| Connection point object | An object in Active Directory that contains information about a service. |
| Service account object | An object in Active Directory that represents the account in whose security context a service runs and on which an SPN attribute resides. |
| SPN attribute | An attribute that contains a unique name that identifies an instance of a service and that is associated with the logon account under which the instance of the service runs. |

**Active Directory Search and Publication Scenarios**

Scenarios that rely on Active Directory search and publication include performing directory searches, advertising available services, finding available services, and authenticating services.

**Performing Directory Searches**

Searching the directory is a common Active Directory scenario in which directory clients use LDAP to query the directory and find information. Clients search the directory for a wide variety of information, including address book information, information about shared resources, and information related to a specific directory-enabled application. This scenario requires directory clients, LDAP, and the Active Directory database.

**Advertising Available Services**

A service that has services to offer client applications can use Active Directory as a way of advertising its services. In this scenario, a network service (at the time when it is installed) publishes a special object in the directory, called a connection point object. The connection point object holds information about the service, including binding information that a client application can use to connect to the service.

**Finding Available Services**

In large, distributed networks, directory clients must be able to find the network services that they need, regardless of where those services reside on the network. In this scenario, client applications search the directory for connection point objects that contain information about specific services that are available on the network. Client applications can then use this information to connect to the services that they need.

**Authenticating Services**

In large, distributed networks, a client application must be able to authenticate a service before the client application uses the

service. The process of authenticating a service protects client applications from malicious or accidental damage or breaches of security that can be caused by an unauthorized, or rogue, service. In this scenario, a client application requests authentication of an SPN representing the service that the client application wants to use. If the service can authenticate against a domain controller by using the SPN, the client application can safely use that service.

# Active Directory Searches Technical Reference

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

In the Active Directory directory service, directory clients use Lightweight Directory Access Protocol (LDAP) to perform searches against the directory. LDAP is defined by Request for Comments (RFC) 3377, "Lightweight Directory Access Protocol (v3): Technical Specification." LDAP is a standards-based protocol that makes it possible for users to query and update information in an LDAP-based directory service, such as Active Directory.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

# What Are Active Directory Searches?

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**What Are Active Directory Searches?**

**In this section**

- The Business Need
- The Active Directory Searches Solution
- LDAP and Security
- Related Information

In Active Directory, directory clients use Lightweight Directory Access Protocol (LDAP) to perform searches against the directory. LDAP is defined by Request for Comments (RFC) 3377, "Lightweight Directory Access Protocol (v3): Technical Specification." LDAP is a standards-based protocol that makes it possible for users to query and update information in an LDAP-based directory service, such as Active Directory. To perform Active Directory searches, LDAP-compliant directory clients compose a search query using LDAP syntax and then submit the query to Active Directory for processing.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

Active Directory searches are an important part of many directory activities. Active Directory searches are commonly used by:

- Directory clients to find a domain controller.
- Directory clients to find network resources, such as printers and shared folders.
- Directory clients to find address book information, such as user names, e-mail addresses, and phone numbers.
- Non-Microsoft applications, such as Web portal, e-commerce, and white pages applications, to find and modify application-specific data that is stored in Active Directory.

**The Business Need**

Active Directory can be used to store all kinds of information, including identity, resource, infrastructure, and application-specific information. For this information to be useful, directory clients must be able to query and retrieve the information from Active Directory with a commonly understood protocol. This protocol must interact with a variety of directory client applications — and with a variety of client operating systems, because many organizations deploy more than one client operating system.

**The Active Directory Searches Solution**

The Active Directory searches solution consists of the following:

- Directory clients that submit LDAP search requests
- Domain controllers (or computers running Active Directory Application Mode (ADAM)) that accept and respond to the LDAP search requests

Any directory client that supports LDAP v2 (RFC 1777, "Lightweight Directory Access Protocol") or LDAP v3 (RFC 3377) can submit LDAP queries to Active Directory. The following figure illustrates the Active Directory searches solution.

**Active Directory Searches**

**Note**

- In the Windows Server 2003 family, a server running Windows Server 2003, Web Edition cannot be a domain controller.

Windows operating systems that can be used as a directory client include the following:

- Windows 95 (requires Active Directory Client Extensions)
- Windows 98 (requires Active Directory Client Extensions)
- Windows NT 4.0 (requires Active Directory Client Extensions)
- Windows 2000 Professional, Windows 2000 Server family
- Windows XP Home Edition, Windows XP Professional
- Windows Server 2003 family

For more information about Active Directory Client Extensions, see "ADSI WinNT Provider" in the Microsoft Platform SDK on MSDN.

Active Directory supports both LDAP v2 and LDAP v3. For more information about LDAP v2, see RFC 1777 in the IETF RFC Database. For more information about LDAP v3, see RFC 3377 in the IETF RFC Database.

**LDAP and Security**

Active Directory is designed to be secure by default, which means that directory clients must authenticate themselves before they can search Active Directory. Directory clients authenticate themselves against Active Directory by using the security mechanisms that are built into Windows Server 2003, including the Simple Authentication and Security Layer (SASL) protocol, the Kerberos version 5 (V5) authentication protocol, and NTLM. If necessary, Active Directory can also be configured to accept search requests from anonymous (unauthenticated) directory clients. For more information about search requests from anonymous directory clients, see "Anonymous queries" in "How Active Directory Searches Work." For more information about authentication methods, see "Logon and Authentication Technologies."

# How Active Directory Searches Work

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**How Active Directory Searches Work**

**In this section**

- Active Directory Searches Architecture
- Active Directory Searches Protocols
- Active Directory Searches Interfaces
- The LDAP Standard
- Active Directory Searches Processes and Interactions
- Network Ports Used by Active Directory Searches
- Related Information

In Active Directory, directory clients use Lightweight Directory Access Protocol (LDAP) to perform searches against the directory. LDAP is defined by Request for Comments (RFC) 3377, "Lightweight Directory Access Protocol (v3): Technical Specification." LDAP is a standards-based protocol that makes it possible for users to query and update information in an LDAP-based directory service, such as Active Directory. To perform Active Directory searches, LDAP-compliant directory clients compose a search query using LDAP syntax and then submit the query to Active Directory for processing.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

The ideal environment for Active Directory searches includes network connections between directory clients and Active Directory that are available and working properly, domain controllers that are running and replicating without errors, and directory clients that support LDAP v2 or LDAP v3. This section describes the elements of Active Directory searches, including architecture, protocols, interfaces, LDAP, processes and interactions, and network ports.

**Active Directory Searches Architecture**

The architecture for Active Directory searches includes both client and server components. On the client side, a directory client application constructs LDAP requests to be sent to Active Directory. These requests can be one of several types, including connect, bind (authentication), modify, and unbind. Depending on how a directory client application is written, one of three different application programming interfaces (APIs) is used to submit requests. The LDAP requests are received and processed by the Directory System Agent (DSA), which is represented by Ntdsa.dll on a domain controller. Ntdsa.dll runs as a part of the local security authority (LSA), which runs as Lsass.exe. The architecture for Active Directory searches is shown in the following figure.

**Active Directory Searches Architecture**

The components of the architecture for Active Directory searches are described in the following table.

**Active Directory Searches Components**

| Component | Description |
|---|---|
| Directory client application | Any application that is used to send LDAP messages to an LDAP directory service |
| LDAP APIs | Interfaces through which a directory client application can submit an LDAP request. For directory clients running a Windows operating system, one of three LDAP APIs can be used. For more information, see "Active Directory Searches Interfaces" later in this section. |
| DSA (Ntdsa.dll) | The DSA, which runs on each domain controller, accepts LDAP requests through its LDAP protocol head and issues LDAP responses based on those requests. |
| LDAP protocol head | The LDAP interface on the DSA through which LDAP requests are accepted |
| LDAP request | A message that is constructed with LDAP syntax and sent by a directory client application to an LDAP directory service, such as Active Directory |
| LDAP response | A message that is constructed with LDAP syntax and sent by an LDAP directory service, such as Active Directory, to a directory client application |

**Active Directory Searches Protocols**

LDAP is the standards-based protocol that directory client applications use to submit LDAP directory requests (for example, bind, search, modify, and unbind) to Active Directory. Active Directory supports both LDAP v2, which is defined in RFC 1777, "Lightweight Directory Access Protocol," and LDAP v3, which is defined in RFC 3377. LDAP is designed to be connection oriented, and it uses Transmission Control Protocol (TCP) as its transport layer protocol. LDAP uses Internet Protocol (IP) as its network layer protocol. The Secure Sockets Layer (SSL) protocol can be used for encrypting LDAP communications.

The protocols that are used by Active Directory searches — and their relationship to the International Organization for Standardization (ISO) Open Systems Interconnection (OSI) 7-layered network protocol model — are shown in the following figure.

**Note**

- The ISO OSI model is a layered architecture that standardizes levels of service and types of interaction for computers that exchange information through a communications network. The ISO OSI model separates computer-to-computer communications into seven layers, or levels, with each level building on the standards that are contained in the levels below it.

**Active Directory Searches Protocols**

The following table describes the protocols that are used in Active Directory searches.

**Protocols Used in Active Directory Searches**

| Component | Description |
|---|---|
| LDAP | A standards-based protocol that is used for communication between directory clients and a directory service. LDAP is the primary directory access protocol for Active Directory. |
| SSL | A standards-based protocol for encrypting private communications on the Internet. When a Certificate Services infrastructure is in place (that is, when you have installed a certification authority (CA)), specifying server port 636 in an LDAP bind call results in an attempt to establish an SSL session. The CA serves as the security authority for the secure channel (Schannel) authentication protocol, which includes SSL. For this reason, some form of certificate services must be in place to use LDAP over SSL. For more information about Certificate Services, see "Certificate Services Technical Reference." |
| TCP | The connection-oriented session protocol on which LDAP runs |
| IP | A routable protocol that is responsible for the addressing, routing, and fragmenting of packets by the sending node. IP is required for Active Directory replication. |

**Active Directory Searches Interfaces**

On computers running a Windows operating system, directory client applications can use one of three different LDAP APIs. As shown in the following figure, all LDAP requests from a directory client application ultimately go through the native LDAP C API, which runs as Wldap32.dll.

**Active Directory Searches Interfaces**

The following table describes the Windows LDAP APIs that are available for Active Directory searches.

**Active Directory Searches APIs**

| API | Description |
|---|---|

| | |
|---|---|
| System.DirectoryServices<br><br>(ADSI for .NET Framework) | A namespace in the Microsoft .NET Framework that provides simple programming access to LDAP directories, such as Active Directory. This API requires the Microsoft .NET Framework to be installed. |
| Active Directory Service Interfaces (ADSI) (Ads*.dll) | A set of Component Object Model (COM) interfaces that abstracts the capabilities of directory services from different network providers (such as LDAP) in a distributed computing environment to present a single set of directory service interfaces for managing network resources. |
| Native LDAP API (Wldap32.dll) | Provides functions that enable directory client applications to search for and retrieve information from an LDAP directory service, as well as functions for modifying directory entries where such modifications are permitted. There are also functions that provide access control for servers by allowing clients to authenticate themselves. |

**The LDAP Standard**
To understand how Active Directory searches work, it is important to understand the LDAP standard. Active Directory structure is based on LDAP v3 requirements, which are defined in a series of Internet Engineering Task Force (IETF) RFCs, as summarized in RFC 3377.

LDAP features and functionality are described in four models:

- The information model, or schema, which describes the structure of information in a directory information tree
- The naming model, which describes how information is organized and referenced
- The functional model, which describes what can be done with the information
- The security model, which describes how information is protected in the directory information tree

Standardization of LDAP behavior through these models makes LDAP the preferred access protocol for all directory services.

**Differences Between LDAP v2 and LDAP v3**
Two versions of the LDAP specification exist: LDAP v2 and LDAP v3. LDAP v3 includes the following features that are not supported in LDAP v2:

- The use of UCS Transformation Format (UTF)-8 for all text string attributes to support extended character sets. Active Directory sends all responses in UTF-8-encoded form.
- Operational attributes that the directory maintains for its own use, for example, to log the date and time when another attribute is modified.
- Referrals, which enable a server to direct a client to another server. An LDAP server can return a referral to an LDAP client when the operation that is presented by the client cannot be serviced locally but the LDAP server has information about other LDAP servers that can handle the operation.
- Schema publishing with the directory, so that a client can discover what object classes and attributes a server supports.
- Extended search operations that facilitate paging and sorting of results and client-defined searching and sorting controls.
- Stronger security through the Simple Authentication Security Layer (SASL) authentication mechanism.
- Extended operations, which provide additional functionality without changing the protocol version.

**Note**

- LDAP v3 is backward compatible with LDAP v2. One requirement of an LDAP v3 server is that an LDAP v2 client should be able to connect to the server. Active Directory is compliant with both LDAP v3 and LDAP v2 standards.

**LDAP Information Model**
The LDAP information model describes the structure of information in a directory. The LDAP information model is based on the entry, which contains information about some object, for example, a person or computer. In Active Directory, an LDAP entry is referred to as an object. Entries are composed of attributes, which have a type and one or more values.

The LDAP information model organizes objects into a hierarchical tree structure. The implementation of the model is called the schema, which is a set of objects that defines the structure and content of every object that can be created in a directory service.

A default (base) schema is installed with Active Directory. The Active Directory schema is stored in the schema directory partition, and the schema is replicated to every domain controller in the Active Directory forest.

For more information about the Active Directory schema, see "Active Directory Schema Technical Reference."

**Classes and Attributes**
Classes and attributes are defined in the schema by classSchema objects (object classes) and attributeSchema objects (object attributes), as follows:

- Object classes are categories of objects that can be created in the directory. For example, users, computers, and printers are classes of objects. Every object in the directory is created as an instance of some class according to the definition that is stored in the classSchema object for the respective class.

- Object attributes are the characteristics of the object. (These characteristics are also called properties). An attribute can hold a value or values that represent some property of the object. For example, given name, surname, and e-mail address are attributes of every object of the user class, and their values can be created only as character strings. The schema specifies the attributes that are required to have values and the attributes that can have values as an option. In Active Directory, only attributes that have values assigned to them actually use storage space in the database.

- Each attribute has a syntax that is specified in the schema that determines the kind of values that are allowed in the attribute. Examples of attribute syntaxes are Unicode string, binary, and integer.

New object classes and attributes can be added to the schema, and existing objects can be modified by adding or modifying classSchema and attributeSchema objects.

Child classes inherit attributes from their parent classes. Therefore, each class builds on the attribute set of its parent class. The position in the directory tree of one object relative to another is also defined in the schema.

**Categories of Object Classes**
Different categories of object classes make it possible to define structure in the directory. The 1993 X.500 specification requires that object classes be assigned to one of three categories:

- Structural

- Abstract

- Auxiliary

**Structural classes**
Structural classes are the only classes that can have instances in the directory. That is, you can create directory objects whose class is one of the structural classes. A structural class:

- Can be used in defining the structure of the directory.

- Is derived from either an abstract class or another structural class.

- Can include any number of auxiliary classes in its definition.

**Abstract classes**
Abstract classes are templates that are used to derive new structural classes. Abstract classes cannot be instantiated in the directory. This means that no object can belong only to an abstract class; each object of an abstract class also belongs to some

structural subclass of that class. A new abstract class can be derived from an existing abstract class. Abstract classes only provide attributes for subordinate classes, which are called subclasses. A subclass contains all mandatory and optional attributes of the class from which it is derived (its superclass) in addition to those attributes that are specific to the class itself. Likewise, the subclass of that class contains all attributes of both superclasses, and so forth.

**Auxiliary classes**

Auxiliary classes are like include files; they contain a list of attributes. Adding an auxiliary class to the definition of a structural class or an abstract class adds the auxiliary class's attributes to the definition of the structural class or the abstract class. An auxiliary class cannot be instantiated in the directory, but new auxiliary classes can be derived from existing auxiliary classes. For example, the **securityPrincipal** class is an auxiliary class, and it derives its attributes from the parent abstract class called **Top**. Although you cannot create a security principal object in the directory (because auxiliary classes cannot have instances), you can create an object of the structural class user, which has the **securityPrincipal** class as an auxiliary class. The attributes of the **securityPrincipal** class help the system recognize the user object as a security account. Similarly, the **group** class has **securityPrincipal** as an auxiliary class.

**Windows 2000 Server vs. Windows Server 2003 auxiliary classes**

The behavior of auxiliary classes has changed in Windows Server 2003. In Windows 2000 Server, changes that are made to an auxiliary class affect its parent class as well as all instances of the parent object. For example, adding an auxiliary class called **pager** to the structural class **user** affects all instances of **user**, which are all of the user accounts that are created with the **user** class.

In Windows Server 2003, auxiliary classes can be assigned dynamically to individual instances of classes, rather than being applied automatically to all instances. For example, you can assign the **pager** auxiliary class to only those users who need it.

**Object Identifiers**

Object identifiers (also known as OIDs) are hierarchical, dotted-decimal numeric values that uniquely identify entries in a data model. Object identifiers are found in OSI applications, X.500 directories, Simple Network Management Protocol (SNMP), and other applications in which uniqueness is required. Object identifiers are based on a tree structure in which a designated issuing authority (such as the ISO) allocates a branch of the tree to a subauthority, which in turn can allocate subbranches. The Active Directory schema identifies the object identifier for each class, attribute, and syntax.

**Schema Versions**

The schema directory partition has an attribute called **objectVersion** that stores the schema version number for a forest. To facilitate upgrading your forest from Windows 2000 Server to Windows Server 2003, Windows Server 2003 includes a tool (Adprep.exe) that automatically upgrades the schema to the version that is required by Windows Server 2003. Before you upgrade the first domain controller, you must use this tool to prepare the domain and the forest so that the schema is upgraded before the operating system is upgraded. Running Adprep.exe prepares the forest and the domain for the Active Directory upgrade by making certain data changes, including an extension of the schema. This schema extension merges existing schema information with new schema information that is supplied by Adprep.exe. This merging of schema information does not affect any schema modifications that you may have already made in your existing environment.

**Leaf Objects and Container Objects**

Objects in Active Directory are either leaf objects or container objects. A leaf object is an object that has no child objects. The term "container" refers to one of two things:

- An object of the **container** structural class
- An object that has child objects

In the schema, a structural class defines objects that can be created as instances of the class in Active Directory. To have child objects, an object must be an instance of a class that is defined by the schema as being a possible superior of those child objects.

### Note

- A new attribute in the Windows Server 2003 schema, **msDsApproxImmedSubordinates**, stores the approximate count of immediate children of a container. You can use the ADSI Edit snap-in in Microsoft Management Console (MMC) to view the value of this attribute for any container object. Windows 2000 Server containers do not have this attribute.

**Directory Tree**

The directory tree represents the hierarchy of Active Directory objects for a given forest. The structure of the hierarchy is derived from the schema, and the directory service implements the hierarchy. The hierarchy provides the basis both for using names for navigation and for defining the scope of search requests.

Every object in Active Directory has exactly one parent, and a reference to the parent object is stored with the object. By virtue of these parent references, the hierarchy of objects that are managed by Active Directory forms a tree structure. The objects that populate the directory create this tree structure according to the rules of the schema. For example, the schema might dictate that a given class of object can be the child of one class but not the child of another class.

The following are architectural restrictions and requirements in the directory tree:

- Domain objects, which are containers, can be children only of other domain objects. For example, a domain cannot be the child of an organizational unit (OU).

- The root of the directory tree is a DSA-Specific Entry (DSE) called the rootDSE, or the directory root. The rootDSE is an object that has no hierarchical name or schema class, but it does have a set of attributes that identify the contents of a given domain controller. Therefore, the rootDSE constitutes the root of the directory tree from the perspective of the domain controller to which you are connected.

- Below the rootDSE, every directory has a root domain, which is the first domain that is created in a forest. This domain always has a child container called the Configuration container, which contains configuration data for the forest.

**rootDSE**
An LDAP directory service is also referred to as a DSA. In Active Directory, servers that host DSAs are domain controllers.

At the root of an LDAP directory tree is a DSE (the rootDSE), which is not part of any directory partition. TherootDSE represents the top of the logical namespace for one domain controller. The rootDSE attributes contain information about the directory server, including its capabilities and configuration.

There is only one root for a given DSA, but the information that is stored in the root is specific to the domain controller to which you are connected. Among other things, the attributes of the rootDSE identify the following key information:

- The directory partitions (the domain, schema, and configuration directory partitions) that are specific to one domain controller

- The forest root domain directory partition

In this way, the rootDSE provides a "table of contents" for a given domain controller. For more information about rootDSE attributes, see "Data Store Technical Reference."

**LDAP Naming Model**
The LDAP naming model describes how information is organized and referenced in an LDAP directory. LDAP requires that names of directory objects be formed according to RFC 1779, "A String Representation of Distinguished Names," and RFC 2247, "Using Domains in LDAP/X.500 Distinguished Names."

For more information about the LDAP naming model, see RFC 1779 and RFC 2247 in the IETF RFC Database.

**Distinguished Name**
Every object in Active Directory has a distinguished name (also known as DN). A distinguished name uniquely identifies an object by using the name of the object, plus the names of the container objects and domains that contain the object. Therefore, the distinguished name identifies the object as well as its location in a tree. The distinguished name is unambiguous (that is, it identifies one object only) and unique (that is, no other object in the directory has this name). It contains enough information for an LDAP client to retrieve the object's information from the directory.

For example, a user named Jeff Smith works in the marketing department of a company as a promotions coordinator. His user account is created in an OU that stores the accounts for marketing department employees who are engaged in promotion activities. The root domain of the company is proseware.com, and the local domain is noam.proseware.com. The distinguished name for this user object is:

cn=Jeff Smith,ou=promotions,ou=marketing,dc=noam,dc=proseware,dc=com

**Relative Distinguished Name**
The relative distinguished name (also known as the RDN) of an object is the part of the distinguished name that is an attribute of the object itself — the part of the object name that identifies this object as unique within a container. For the example in the previous paragraph, the relative distinguished name of the user object:

cn=Jeff Smith,ou=promotions,ou=marketing,dc=noam,dc=proseware,dc=com

is cn=Jeff Smith.

The following figure illustrates the relative distinguished names that make up the distinguished name of the user object Jeff Smith.

**Relative Distinguished Names That Make Up a Distinguished Name**

The maximum length that is allowed for a relative distinguished name is 255 characters, but attributes have specific limits that are imposed by the directory schema. For example, in the case of the common name (cn), which is the attribute type that is often used for naming the relative distinguished name, the maximum number of characters that is allowed is 64.

Active Directory relative distinguished names are unique within a container; that is, Active Directory does not permit two objects with the same relative distinguished name under the same parent container. However, two objects can have identical relative distinguished names but still be unique in the directory because, within their respective parent containers, their distinguished names are not the same. For example, the object cn=Jeff Smith,cn=users,dc=noam,dc=proseware,dc=com is recognized by LDAP as being different from cn=Jeff Smith,ou=marketing,dc=noam,dc=proseware,dc=com.

The relative distinguished name for each object is stored in the Active Directory database. Each object in the directory contains a reference to the parent of the object. An LDAP operation can construct the entire distinguished name by following these references to the root.

**Naming Attributes**

Each portion of the distinguished name is expressed as attribute_type=value. The attribute type that is used to describe the object's relative distinguished name (in the Jeff Smith example, cn) is called the naming attribute. In Active Directory, instances of classes have a default mandatory naming attribute that is defined in the schema. For example, part of the definition of the class **user** is the attribute **cn** (**Common-Name**) as the naming attribute. Therefore, the relative distinguished name for user Jeff Smith is expressed as cn=Jeff Smith.

Classes that do not define a naming attribute inherit the naming attribute from their parent class. If you create a new class in the Active Directory schema (that is, if you create a new classSchemaobject), you can use the optional **rDNAttID** attribute to specify the naming attribute for the class.

The following table shows the naming attributes that are used in Active Directory.

**Default Active Directory Naming Attributes**

| Object Class | Naming Attribute Display Name | Naming Attribute LDAP Name |
|---|---|---|
| **user** | **Common-Name** | cn |
| **organizationalUnit** | **Organizational-Unit-Name** | ou |
| **domain** | **Domain-Component** | dc |

Other naming attributes that are described in RFC 2253, "Lightweight Directory Access Protocol (v3): UTF-8 String Representation of Distinguished Names," such as o= for organization name and c= for country/region name, are not used in Active Directory.

The use of distinguished names, relative distinguished names, and naming attributes is required when you are programming

for LDAP and using ADSI or other scripting or programming languages. Active Directory tools, such as Active Directory Users and Computers, do not require you to enter such values, nor do they display these values. However, LDAP editors, such as ADSI Edit in Support Tools, require input and display output in the LDAP distinguished name format.

**Using different naming attributes for users to avoid naming collisions**

To ensure data integrity, Active Directory requires that relative distinguished names be unique in a container. By default, the **user** class uses **Common-Name** (**cn**) as the naming attribute, which ties the test for uniqueness to the user name. The combination of these two restrictions can result in naming collision problems in large deployments. For example, a very large company might want to create user accounts in the same OU where, as a result of the high incidence of certain common names, many user objects have identical first and last names and, therefore, identical relative distinguished names. In this scenario, it is helpful to be able to use a different naming attribute that guarantees uniqueness, such as an employee ID that is created by the human resources department.

The **inetOrgPerson** object class is a general-purpose object class that holds attributes about people, and it is defined in RFC 2798, Definition of the inetOrgPerson LDAP Object Class. A solution is provided in the Windows Server 2003 schema so that administrators can delete **inetOrgPerson** (which uses **cn** as the naming attribute in the default schema) and re-create it using any attribute as the naming attribute. For example, instead of **cn**, the attribute **emplID** can be used as the naming attribute. You can choose the attribute and select one that will guarantee that there are no naming collisions.

For more information about **inetOrgPerson**, see Active Directory Schema Technical Reference.

**Object identity**

In addition to its distinguished name, every object in Active Directory has an identifier that is unique. This identifier is called the globally unique identifier (GUID). A GUID is a unique 128-bit number that is assigned by the DSA when the object is created. Objects might be moved or renamed within a forest, but their GUID never changes. The GUID is stored in an attribute, **objectGUID**, which is present on every object. The **objectGUID** attribute is protected so that it cannot be altered or removed. When you store a reference to an Active Directory object in an external store (for example, in a database, such as Microsoft SQL Server), you should use the **objectGUID** value to represent the object uniquely.

**Active Directory Name Formats**

In addition to distinguished names, other formats for providing object names are supported by Active Directory. These formats accommodate the different forms that a name can take, depending on its application of origin.

The LDAP distinguished name in the example earlier in this section can be used to illustrate the other Active Directory name formats. This example distinguished name identifies the account of user Jeff Smith in the OU Promotions, in the OU Marketing, in the domain noam.proseware.com:

cn=Jeff Smith,ou=promotions,ou=marketing,dc=noam,dc=proseware,dc=com

The following formats are supported by Active Directory, and the format examples are based on the LDAP distinguished name of Jeff Smith:

- LDAP Uniform Resource Locator (URL). Active Directory supports access through the LDAP protocol from any LDAP-enabled client. LDAP URLs are used in scripting. An LDAP URL names the server that holds Active Directory and the attributed name of the object (the distinguished name), for example:

  ldap://server1.proseware.com/cn=Jeff Smith,ou=promotions,ou=marketing,dc=noam,dc=proseware,dc=com

- Active Directory canonical name. By default, the user interface (UI) for certain Active Directory administrative tools displays object names as canonical names. When you view the properties of objects in Active Directory Users and Computers and Active Directory Sites and Services, the **Object** tab shows the canonical name of the selected object. The canonical name lists the relative distinguished names from the root downward, without the naming attribute descriptors, and it uses the Domain Name System (DNS) domain name, as follows:

  noam.proseware.com/marketing/promotions/Jeff Smith

### Note

- If the name of a container includes a forward slash character (/), the system requires an escape character in the form of a backslash (\) to distinguish between forward slashes that separate elements of the canonical name and the forward slash that is part of the container name. For example, if the name of an OU is Promotions/Northeast and the name of the domain is proseware.com, the canonical name is displayed as proseware.com/Promotions\/Northeast.

**DNS-to-LDAP Distinguished Name Mapping**
Although DNS domain names match Active Directory domain names, they are not the same thing. Active Directory names have a different format, which is required by LDAP to identify directory objects. Therefore, DNS domain names are mapped to Active Directory domain names (and back again) as described in RFC 2247.

All access to Active Directory is carried out through LDAP, and every object in Active Directory has an LDAP distinguished name. An algorithm automatically provides an LDAP distinguished name for each DNS domain name.

The algorithm provides a domain component (dc) attribute-type label for each DNS label in the DNS domain name. Each DNS label corresponds to the relative distinguished name of a DNS domain. For example, the DNS domain noam.proseware.com is translated to the LDAP distinguished name that has the form dc=noam,dc=proseware,dc=com.

**LDAP Functional Model**
The LDAP functional model describes what can be done with directory information. The functional model consists of nine operations in the following three areas:

- *Authentication* provides a method for the client to prove its identity to the DSA.
- *Interrogation* provides a method for the client to interrogate the directory information tree.
- *Update* provides a method for the client to add or modify information in the directory information tree.

The following table shows the nine basic LDAP operations according to their functional areas.

**LDAP Functional Model Operations**

| Functional Area | Operations |
|---|---|
| Authentication | 1. Bind<br>2. Unbind<br>3. Abandon |
| Interrogation | 1. Search<br>2. Compare |
| Update | 1. Add<br>2. Modify<br>3. Modify RDN<br>4. Delete |

**Authentication**
LDAP authentication consists of the following operations:

- Bind. Initiates a protocol session to the DSA. After a session is established, a method of authentication is negotiated between the DSA and the client. When the client is authenticated by the DSA, the DSA returns a bind response to the client.
- Unbind. Terminates an LDAP session between the client and the DSA.
- Abandon. Issued by the client to stop obtaining the results of a previously initiated operation.

**Interrogation**
LDAP interrogation consists of the following operations:

- Search. Used to select entries from a specific region of the directory information tree based on customized criteria called a search filter. The search operation includes several arguments, which are described in "Performing an LDAP Search" later in this section.

- Compare. Returns a Boolean response based on a comparison of an entry's attribute value with a user-supplied value.

**Update**
LDAP update consists of the following operations:

- Add. Creates an object in the directory information tree based on information that is provided by the client to the DSA. The information that is passed to the DSA must meet the conditions that are imposed on entry creation through the classes that are defined in the schema.

- Modify. Allows the client to modify an entry's attributes. Modification of attributes includes creating, modifying, and deleting the attributes.

- Modify RDN. Provides a mechanism for an entry to be moved in the directory. Modifying the relative distinguished name components of an entry effectively moves the entry to a new container in the directory.

- Delete. Provides a method for a client to remove an entry from the directory. The success of an entry modification depends on the schema's constraints and the access permission of the client.

**Extended LDAP Controls**
Active Directory supports several LDAP controls that extend the functionality of LDAP v3 beyond the standard set of nine LDAP operations. Microsoft has defined these LDAP controls to provide functionality in Active Directory that is not provided by current IETF RFCs. The rootDSE indicates all controls that are in effect for the contacted server through the object identifier values in the **supportedControl** attribute.

Extended LDAP control functionality is useful to programmers who are using LDAP to perform directory operations. Some of the operations that can be implemented by using extended controls are deleting trees, paging and sorting search results, and showing deleted objects. For more information about these operations, see "Optimizing Searches" later in this section.

**LDAP Security Model**
The LDAP security model specifies how to access information in the directory in a secure manner. RFC 2251, "Lightweight Directory Access Protocol (v3)," states that SASL mechanisms may be used with LDAP to provide security services. RFC 2222, "Simple Authentication and Security Layer (SASL)," defines SASL.

The rootDSE includes an attribute called **supportedSASLMechanisms** that lists the supported SASL security features.

RFC 2222 describes a method for providing authentication support in connection-based protocols. To use this specification, protocols have to include a command to identify and authenticate users to a server and, optionally, to negotiate protection of subsequent protocol interactions. If protection is negotiated, a security layer is inserted between the protocol and the connection. RFC 2222 explains how a protocol specifies such a command, and it defines several mechanisms for use by the command, as well as by the protocol, that carry a negotiated security layer over the connection.

Active Directory supports SASL mechanisms, including Kerberos V5 and NTLM. To view the supported SASL mechanisms, you can query the rootDSE. When you perform the query, Active Directory returns the **supportedSASLMechanisms** attribute and other attributes. The **rootDSE** attribute value is **supportedSASLMechanisms: GSSAPI; GSS-SPNEGO**, where GSSAPI = Kerberos and GSS-SPNEGO = NT Negotiate (Kerberos, NTLM, and so on).

The Generic Security Service Application Program Interface (GSS-API), which is defined in RFC 2078, Generic Security Service Application Program Interface, Version 2, provides security services to callers in a generic manner that can be supported with a range of underlying mechanisms and technologies. This enables applications (at the source level) to be ported to different environments. RFC 2078 defines GSS-API services at a level that is independent of the underlying mechanism and programming language environment.

RFC 1510, "The Kerberos Network Authentication Service (V5)," defines an authentication process that provides a method for verifying the identities of principals, such as workstation users and network servers, on an open network. For authentication purposes, clients use Kerberos tickets, which represent the clients' network credentials. Clients obtain the tickets from the

Kerberos Key Distribution Center (KDC), and they present these tickets when a network connection is established. Kerberos represents the identity of a client by using its domain name, user name, and password.

The Active Directory security infrastructure also supports the following primary security protocols:

- The NTLM authentication protocol is provided to support Windows NT version 4.0 and earlier. NTLM will continue to be supported and used for pass-through network authentication, remote file access, and authenticated Remote Procedure Call (RPC) connections to previous versions of Windows NT.

- Distributed Password Authentication (DPA) is the authentication protocol that is used by many Internet membership organizations, such as MSN and CompuServe. This authentication protocol is part of Microsoft Commercial Internet System (MCIS) services, and it is designed specifically to enable users to use the same Internet membership password to connect to various Internet sites that are part of the same membership organization. The Internet content servers use MCIS as an authentication service, and users can connect to multiple sites without reentering their passwords.

The following table lists the LDAP authentication methods that are supported by Active Directory.

**LDAP Authentication Methods**

| **LDAP Authentication Method** | **Description** | **Credential** |
|---|---|---|
| SIMPLE | Authentication with a simple plaintext password | A string containing the user's password |
| NTLM | An authentication protocol that is used on stand-alone systems and on networks that include systems running the Windows NT 4.0 operating system | An array of strings containing the domain name, user name, and encrypted password |
| DPA | Distributed password authentication, which is used by the Microsoft Membership System component of the MCIS | Encrypted password |
| NEGOTIATE (GSS-API) | Does not provide any authentication services; instead, it chooses the most appropriate authentication method from a list of available services and passes all authentication information on to that service. | To log on as the current user, set the *dn* and *cred* parameters to NULL. To log on as another user, pass a pointer to a SEC_WINNT_AUTH_IDENTITY structure with the appropriate user name and password. |
| SSPI | This constant (Security Support Provider Interface (SSPI)) is obsolete, and it is included for backward compatibility only. Using this constant selects GSS-API. | Same as NEGOTIATE |

**Note**

- If a directory client attempts to bind to a directory server without specifying credentials, an anonymous bind is attempted. Active Directory does not accept anonymous binds by default. However, Active Directory can be configured to accept anonymous binds. For more information, see "Anonymous queries" later in this section.

Although the LDAP security model does not include mechanisms for access control, Active Directory provides access control in the form of access control lists (ACLs) on directory objects.

**LDAP Encoding**

In accordance with RFC 2251, LDAP protocol elements are encoded on the wire using the Basic Encoding Rules (BER) of Abstract Syntax Notation One (ASN.1).

**Active Directory Searches Processes and Interactions**

Performing an Active Directory search involves several processes, including finding a server, establishing a connection, authenticating, and actually performing the search. In addition, performing an Active Directory search may involve the use of an LDAP referral, which is a reference pointing to a location where data that is searched for might be found. When a search is performed, several features may be used to optimize the search, including indexing, LDAP query policy, the global catalog, query limits, and paging.

**Searching Active Directory**
Searching is the most common directory activity. To complete an LDAP search, a directory client must complete a series of steps, as follows:

- Find an LDAP directory server
- Establish a connection
- Authenticate against (bind to) the LDAP directory server
- Perform a search

Windows Server 2003 provides several directory client tools for searching Active Directory, including the following:

- Active Directory Users and Computers (a Microsoft Management Console (MMC) snap-in that is installed by default on domain controllers)
- ADSI Edit (an MMC snap-in that is installed with Windows Support Tools)
- Dsquery (a command-line tool that is installed by default on Windows Server 2003)
- Ldp (an LDAP graphical user interface (GUI) tool that is installed with Windows Support Tools)
- Search Companion (which appears on the **Start** menu as the **Search** command)

In addition to these tools, many non-Microsoft applications are available for searching Active Directory as well as other LDAP directory servers. The information that you provide the search tool to complete the steps that are described in the following sections depends on the tool that you are using. For example, some directory client tools and applications find an LDAP directory server and establish a connection automatically.

**Finding a Server**
The first step that a directory client must take in conducting an Active Directory search is to find an LDAP directory server (in other words, a domain controller) to search against. To find a domain controller, directory clients rely on DNS. When a domain controller starts up, it registers service (SRV) records in DNS that indicate that the domain controller provides LDAP directory services. To locate a domain controller, a directory client performs a DNS query for SRV records of hosts that provide LDAP directory services. For more information about how DNS is used to locate domain controllers, see "DNS Support for Active Directory Technical Reference."

**Establishing a Connection**
After it finds a directory server, a directory client must next connect to the server. A directory client can connect to an LDAP directory server by opening a session on a TCP port number on which the LDAP directory server is listening. The string that is used to establish the connection includes the fully qualified domain name (FQDN) of the LDAP directory server, along with the TCP port number of the directory server. For standard LDAP searches, directory clients connect to TCP port 389. To search the Active Directory global catalog, directory clients must instead connect to TCP port 3268.

For more information about the global catalog, see "Global Catalog Searches" later in this section. For information about TCP ports that are used by LDAP directory servers and clients, see "Network Ports Used by Active Directory Searches" later in this section.

**Authenticating (Binding)**
After a directory client establishes a communications path to the domain controller, it must bind to the domain controller to establish the logon and authentication credentials and, if necessary for Windows-based computers, set up a secure channel. (A client can also attempt to bind to a domain controller without first establishing a connection.) The bind operation identifies the connecting person, device, or application to the server by providing a distinguished name and some type of authentication credential, such as a password. The exact credentials depend on the authentication method that is being used.

LDAP v3 enables the client to negotiate with the LDAP server to determine the best available security package. If no security package is available, the bind is a simple bind that uses a plaintext password. The Microsoft implementation of the LDAP API uses the NEGOTIATE flag so that the client can discover the best security package that is available. For example, a SASL mechanism, such as Kerberos V5 or NTLM, might be used. A domain controller can be also be configured to accept anonymous connections.

**LDAP bind request**
The **bind** command initiates a protocol session to the domain controller. After a session is established, a method of authentication is negotiated between the domain controller and the client. By default, Kerberos is used, but other methods can also be used. Finally, the domain controller returns a bind response to the client when the client is authenticated.

According to RFC 2251, the LDAP bind request has the following parameters:

- *Version*. A version number that indicates the version of the protocol to be used in this protocol session. Note that there is no version negotiation, and the client sets this parameter to the appropriate version.

- *Name*. The name of the directory object to which the client wants to bind. This field can take on a null value (a zero-length string) for the purposes of anonymous binds, when authentication has been performed at a lower layer, or when the client is using credentials that are established through a SASL mechanism.

- *Authentication*. Information that is used to authenticate the name, if any, that is provided in the bind request.

When a server receives a bind request, it authenticates the requesting client, if necessary. The server then returns a bind response to the client indicating the status of the authentication.

In the following Network Monitor example of an LDAP bind request, the LDAP version is 3, the Name is null, and the authentication type is SASL:

```
LDAP: ProtocolOp: BindRequest (0)
  LDAP: MessageID = 11 (0xB)
  LDAP: ProtocolOp = BindRequest
    LDAP: Version = 3 (0x3)
    LDAP: Name =
    LDAP: Authentication Type = Sasl
      LDAP: Sasl Mechanism = GSS-SPNEGO
      LDAP: Sasl Credentials
```

**LDAP authentication methods**
The Windows Server 2003 and Windows 2000 Server implementations of LDAP include support for the authentication methods that are described in "LDAP Security Model" earlier in this section.

### Note

- Authentication within and between Windows Server 2003 and Windows 2000 Server domains is performed by using either the Kerberos V5 authentication protocol (the default method) or NTLM (for Windows NT 40 and earlier). Other methods are available to other clients and external users who connect over the Internet. For more information about authentication, see "Logon and Authentication Technologies."

**LDAP bind response**
An LDAP bind response is an indication from the server regarding the status of a request for authentication of the client. If the bind is successful, the result code is "success." Otherwise, an error is reported in accordance with RFC 2251.

The following is a Network Monitor example of a successful LDAP bind response:

```
LDAP: ProtocolOp: BindResponse (1)
  LDAP: MessageID = 18 (0x12)
  LDAP: ProtocolOp = BindResponse
    LDAP: Result Code = Success
    LDAP: Matched DN =
    LDAP: Error Message =
    LDAP: Sasl Mechanism = GSSAPI
    LDAP: Sasl Credentials
```

The following is a Network Monitor example of an unsuccessful LDAP bind response:

```
  LDAP: ProtocolOp: BindResponse (1)
  LDAP: MessageID = 8 (0x8)
  LDAP: ProtocolOp = BindResponse
    LDAP: Result Code = Invalid Credentials
    LDAP: Matched DN =
```

```
LDAP: Error Message =
```

**SPNEGO**
The client and server can use simple protected negotiation (SPNEGO) to negotiate either through Kerberos V5 or NTLM, depending on the authentication mechanisms that are available to the particular client and server. With SPNEGO, both the client and server negotiate on a common secure authentication mechanism (Kerberos V5 or NTLM). For more information about SPNEGO, see "Logon and Authentication Technologies.

**Concurrent bind for Web site logons**
Internet service providers (ISPs) can use LDAP authentication for Active Directory user accounts. In this case, users do not actually have (or need) direct access to Active Directory objects. An application on the Web server uses LDAP to request user name and password verification of credentials that are presented by the site user. The application then passes the user information to Active Directory, which authenticates the user.

Domain controllers running Windows Server 2003 can perform concurrent binds. Unlike normal binds that are serialized on a single connection, concurrent binds enable applications to request multiple binds over a single LDAP connection. Concurrent binds are faster than normal binds, which require construction of a full security token for later use in access checks. In the Web site case, the user has no need for the security token.

Unlike a normal LDAP bind, a concurrent bind does not determine a user's group association or build a token. The concurrent bind determines only whether the user has a valid user name and password and that the account is enabled. Eliminating the construction of the access token permits the concurrent bind to complete in a fraction of the time that it takes a normal bind to complete.

**Determining if concurrent bind exists**
To determine if your version of Active Directory supports concurrent binds, view the values in the **supportedExtension** attribute of the rootDSE. If concurrent binds are supported, the returned attribute includes the value 1.2.840.113556.1.4.1781.

For information about concurrent binding, see "Using Concurrent Binding" in the Microsoft Platform SDK on MSDN.

**Anonymous queries**
By default, anonymous LDAP operations to Active Directory, other than rootDSE searches and binds, are not permitted in Windows Server 2003. (Active Directory in Windows 2000 Server accepts anonymous requests; a successful result depends on objects having correct user permissions in Active Directory.)

To enable anonymous binding to Active Directory in Windows Server 2003, you must change the seventh character of the **dsHeuristics** attribute on the following directory object:

CN=Directory Service,CN=Windows NT,CN=Services,CN=Configuration,Root *domain in forest*

Valid values for the **dsHeuristics** attribute are **0** and **2**. By default, the **dsHeuristics** attribute does not exist, but its internal default is **0**. If you set the seventh character to **2**, anonymous clients can perform any operation that is permitted by the access control list (ACL). If the attribute is already set, do not modify any bits in the **dsHeuristics** string other than the seventh bit. If the value is not set, make sure that you provide the leading zeros up to the seventh bit. You can use Adsiedit.msc to make the change to the **dsHeuristics** attribute.

After you set the **dsHeuristics** attribute, if you want anonymous users to be able to query Active Directory, you can enable anonymous access to specific directory objects. Users gain anonymous access to Active Directory objects through Anonymous Logon, which is a special security identifier (SID) that is used to represent anonymous network callers that perform an LDAP bind with NULL credentials.

**Performing an LDAP Search**
LDAP searches are the most common LDAP operations that are performed against an Active Directory domain controller. An LDAP search retrieves information about all objects within a specific scope that have certain characteristics, for example, the telephone number of every person in a department.

The following parameters are used in LDAP to accomplish an LDAP search:

- *Search base* (the distinguished name of the search base object). Defines the location in the directory from which the LDAP search begins.

- *Search scope*. Defines how deep to search within the search base:

    - *Base* (or *zero level*). Indicates a search of the base object only.

- *One level*. Indicates a search of objects immediately subordinate to the base object but not the base object itself.
- *Subtree*. Indicates a search of the base object and the entire subtree of which the base-object distinguished name is the topmost object.

- *Filter*. Allows certain entries in the subtree and excludes others.
- *Selection*. Indicates what attributes to return from objects that match the filter criteria.
- Optional controls that affect how the search is processed.

The following figure shows the base distinguished name and the possible search scopes of an LDAP search.

**LDAP Search Base and Three Search Scopes**

The following figure shows the base distinguished name for a container object that is the search base for a search of an OU structure in Active Directory. The entire distinguished name is constructed from the relative distinguished name of an OU named Sales.

**Base Distinguished Name for an LDAP Search**

**Search filters**

By using search filters, you can define search criteria to achieve more effective and efficient searches. For example, you might be interested in all the user's whose surname is Smith, or you might want to find all the team members who report to a manager named Jeff Smith. ADSI supports LDAP search filters as defined in RFC 2254, "The String Representation of LDAP Search Filters." These search filters are represented by UTF-8 strings. The following table lists some commonly used LDAP search filters.

**Common LDAP Search Filters**

| Filter | Description |
|---|---|
| (objectCategory=*) | All objects |
| (&(objectClass=user)(!(cn=susan))) | All user objects except susan |
| (sn=sm*) | All objects with a surname that starts with sm |
| (&(objectClass=contact)(\|(sn=Smith) (sn=Johnson))) | All contacts with a surname equal to Smith or Johnson |

The search filters in the previous table use one of the following formats:

(*attribute operator value*)

or

(*operator* (*filter1*) (*filter2*))

The following table lists some of the most frequently used LDAP search filter operators.

**Commonly Used LDAP Search Filter Operators**

| Operator | Description |
|---|---|
| = | Equal to |
| ~= | Approximately equal to |
| <= | Lexicographically less than or equal to |
| >= | Lexicographically greater than or equal to |
| & | AND |
| \| | OR |
| ! | NOT |

For more information about LDAP search filter syntax, see "Search Filter Syntax" in the Microsoft Platform SDK on MSDN.

**objectClass vs. objectCategory in a search filter**

Sometimes, you might want to search Active Directory for objects of a particular type. For example, you might want to search for Active Directory objects that represent users. You can do this by searching for objects of a particular object class, using the **objectClass** attribute (objectClass=user). Or, you can search for objects of a particular category, using the **objectCategory** attribute (objectCategory=user). Because of the class inheritance hierarchy in the schema, every object in Active Directory is in fact a member of many classes — four or five, on average. For this reason, searches that use **objectClass** can be less accurate than searches that use **objectCategory**.

For example, a search filter of objectClass=user returns both user and computer objects. On the other hand, **objectCategory** usually refers to the most specific class in the object's class hierarchy. Every Active Directory object has an **objectCategory** attribute whose value is a classSchema object. For example, a search filter of objectCategory=user returns only user objects. Although **objectClass** can have multiple values, the attribute **objectCategory** has only one value.

**Note**

- Every classSchema object has an attribute called **defaultObjectCategory**, which is the object category of an instance of the class if no object category is specified by the user. For most classes, the **defaultObjectCategory** value is the class itself. In the search filter, you can specify objectCategory=X, where X is the **ldapDisplayName** of a class and LDAP automatically expands the filter to objectCategory=*defaultObjectCategory of class X*. The **objectCategory** attribute has a syntax of distinguished name, and LDAP automatically converts the value for **objectCategory** to the distinguished name format. For example, if you use objectCategory=contact in the filter, the filter changes to objectCategory=cn=Person,cn=Schema,cn=Configuration,dc=*ForestRootDomain*. (**Person** is the **defaultObjectCategory** for the class **Contact**).

For more information about class inheritance, see "Active Directory Schema Technical Reference."

**LDAP Referrals**

When a requested object exists in the directory but is not present on the contacted domain controller, resolution of the object name depends on information that is stored on that domain controller about how the directory is partitioned. In a partitioned directory, by definition, the entire directory is not always available on any one domain controller.

In its Configuration container, every domain controller has information about the other domains in the forest. The objects in cn=Partitions,cn=Configuration,dc=*ForestRootDomain* are cross-reference objects that contain information that Active Directory uses to construct the directory tree hierarchy. When an operation in Active Directory requires action on objects that might exist in the forest but that are not located in the particular domain that is stored on a domain controller, that domain controller must send the client a message that describes where to continue this action — that is, the client is "referred" to a domain controller that is presumed to hold the requested object.

An LDAP referral is a domain controller's way of indicating to a client application that the domain controller does not have a copy of a requested object (or, more precisely, that the domain controller does not hold the section of the directory tree where that object would be if, in fact, it exists) and of providing the client with a name of a server that is more likely to hold the object. The client uses the name of the server that is provided in the LDAP referral as the basis for a DNS search for a domain

controller. Ideally, referrals always reference a domain controller that does indeed hold the object. However, it is possible for the referred-to domain controller to generate yet another referral, although it usually does not take long to discover that the object does not exist and to inform the client that the object does not exist. Active Directory returns referrals in accordance with RFC 2251.

Clients do not have to know the name or location of a child domain to contact a domain controller in that domain. They can query the root domain and reach the appropriate domain controller by being referred there. Two situations generate this type of domain controller response:

- An external referral, in which the base distinguished name of the requested object is not in this directory, but the domain controller holds information about another LDAP directory where the requested object might be found.

- A subordinate referral, in which the base distinguished name of the requested object is in this directory, but the directory partition that contains the requested object is not stored locally.

Every domain controller contains information about how the directory is partitioned, and this information can be used in conjunction with DNS to find the Active Directory domain that contains a particular object.

**Knowledge References**
Active Directory stores information about the existence and location of directory partitions in a forest, including the names of the directory partitions and the names of domain controllers that hold replicas of those directory partitions. Active Directory uses this information (known as knowledge references) to generate referrals to other domain controllers.

Active Directory uses three kinds of knowledge references to generate referrals to other domain controllers:

- A subordinate reference, which is knowledge of a directory partition (or partitions) directly adjacent in the naming hierarchy to a directory partition that is held by the domain controller.

- A cross-reference, which is knowledge of one directory partition and which is stored in a cross-reference object in the Partitions container. On a specific domain controller, the combination of all cross-references provides knowledge of all directory partitions in the forest, regardless of the locations of those directory partitions in the directory tree.

  **Note**

  - The state of cross-reference knowledge at any specific time is subject to the effects of directory replication latency.

- A superior reference, which is knowledge of a specifically designated location that is used whenever the domain controller has no knowledge of the search base that is used in a search.

Knowledge references are the glue that holds the pieces of the distributed directory together. Because Active Directory is logically partitioned and directory partitions are the discrete components of the directory that replicate between domain controllers, either all objects in a directory partition are present on a particular domain controller or no objects in the directory partition are present on the domain controller. References have the effect of linking directory partitions together, which enables operations such as searches to span multiple domain directory partitions.

In Active Directory, referrals are generated when a client requests that the directory locate an object where, based on the position at which the search begins, no copy exists in a local directory partition. When Active Directory can determine definitively from the information it holds that no such object exists in the directory — rather than that it might exist somewhere else, even though no copy exists locally — instead of sending a referral, the directory returns an error message to the client that no such object exists in the forest.

For information about replication of directory partitions, see "Active Directory Replication Model Technical Reference."

**Subordinate References**
When a client requests a search, the domain controller searches all objects at or below the search base in the directory partition that the domain controller holds. If a subtree search has a search base that includes child partitions, the domain controller uses information that is provided by subordinate references to return referrals (called subordinate referrals) to these partitions on other domain controllers.

Subordinate referrals are returned as part of the data that is returned from the distinguished name of the directory partition

that is named in the search base. The referral contains the distinguished name of the subordinate directory partition and the access point to which queries can be referred. An access point consists of a DNS name and a port number, which is the information that is required to contact a specific LDAP server. Access points are generated from information that is contained in the cross-reference object.

**Cross-References**

Cross-references are stored as directory objects of the class **crossRef** that identify the existence and location of all directory partitions, irrespective of their location in the directory tree. Cross-reference objects are used to generate referrals to other directory partitions in the forest and to external directories.

Cross-references enable every domain controller to be aware of all directory partitions in a forest, rather than only the directory partitions that a particular domain controller holds. Because cross-reference objects are stored in the Configuration container, they are replicated to every domain controller in the forest.

Cross-reference objects store the following information:

- **nCName** . The distinguished name of the directory partition that the crossRef object references. ("nC" stands for "naming context," which is a synonym for "directory partition.") The combination of all of the **nCName** properties in the forest defines the entire directory tree, including the subordinate and superior relationships between directory partitions.

- **dNSRoot**. The DNS name of the domain where servers that store the particular directory partition can be reached. This value can also be a DNS host name.

Cross-reference objects are created in two ways:

- Internally, by the system, to refer to known locations that are within the forest.

- Externally, by administrators, to refer to locations that are external to the forest.

**Internal cross-references**

An internal cross-reference is a cross-reference object that is created by the system. For every directory partition in a forest, there is an internal cross-reference object in the Partitions container (cn=Partitions,cn=Configuration,dc=*ForestRootDomain*). When you create a new forest, the Active Directory Installation Wizard creates the following three directory partitions:

- First domain directory partition

- Configuration directory partition

- Schema directory partition

### Note

- On a domain controller running Windows Server 2003, one or more application directory partitions might be created in addition to the domain, configuration, and schema directory partitions.

For each of these partitions, a cross-reference object is created automatically. Thereafter, when a new domain or application directory partition is created in the forest, another directory partition is created and the respective cross-reference object is created.

### Note

- Whenever you create a new domain or application directory partition, the appropriate cross-reference objects are created automatically.

Because these cross-reference objects are located in the Configuration container, they are replicated to every domain controller in the forest, and therefore every domain controller has knowledge of the name of every partition in the forest (as well as their superior and subordinate relationships to each other). By virtue of this knowledge, any domain controller can generate referrals to any other domain in the forest, as well as to the schema and configuration directory partitions.

**External cross-references**
An external cross-reference is a cross-reference object that you create manually to provide the location of an object that is not stored in the forest. If your LDAP clients submit operations for an external LDAP namespace against servers in your forest and you want your forest's servers to always refer these clients to the correct location, you can create a cross-reference object for that directory in the Partitions container.

There are two ways that external cross-references are used:

- To reference external directories by their disjoint directory name, that is, a name that is not contiguous with the name of the local directory tree. In this case, when you create the cross-reference, you create a reference to a location that is not a child of any object in the local directory.

- To reference external directories by a name that is within the Active Directory namespace, that is, a name that is contiguous with the name of this directory tree. In this case, when you create the cross-reference, you create a referenceto a location that is a child of an existing directory object.

### Note

- An external directory that is stored on a domain controller running Windows Server 2003 or Windows 2000 Server does not require an explicit cross-reference object. Because the domain component (dc=) portions of the distinguished names of all Windows Server 2003 domains match their DNS addresses and because DNS is the worldwide namespace, all domain controllers running Windows Server 2003 or Windows 2000 Server can generate external referrals to each other automatically, assuming that the appropriate credentials and trust relationships exist.

**Creating External Cross-References**
The only time that you have to create a cross-reference object is when you want to extend a search to a directory outside the forest that is a non-Windows LDAP directory service. In this case, you can use an LDAP editor such as ADSI Edit to create objects of the class **crossRef** (in the Partitions container) that reference external directories.

When you create a cross-reference object, you must provide the values for three attributes:

**cn**
The name that describes the directory. For example, for the domain noam.proseware.com, your **cn** value might be noam or something else that describes that domain, such as NorthAmerica. This value is for administrative convenience; it has no impact on the system.

**nCName**
The distinguished name of the domain directory partition to which your cross-reference refers. If the domain name is noam.reskit.com, the value of **nCName** is dc=noam,dc=proseware,dc=com.

**dnsRoot**
The DNS host name of an LDAP server in the domain that is identified by **nCName** (for example, server1.noam.proseware.com). The value of **dnsRoot** can also be the domain name if you do not want to specify a server.

### Note

- You must be able to resolve (use the **ping** command to test) the name in **dnsRoot**, which does not necessarily name another system running Windows Server 2003; it might be the DNS address of an LDAP server instead of a domain controller. If the directory partition is a Windows Server 2003 domain in another forest, automatically generated knowledge is usually sufficient and no external cross-reference is required.

ADSI Edit, an MMC snap-in and Active Directory administrative tool, provides a convenient GUI for creating cross-reference objects.

To make use of cross-references, clients must be able to follow ("chase") referrals that are returned. Windows Address Book chases referrals by default. When you are using ADSI programmatically (for example, by using Active Data Objects (ADO) to search), you must specify whether to chase referrals.

### Note

- When you set the LDAP referral chasing option (**LDAP_OPT_REFERRALS**) to **ON**, the LDAP client (Wldap32) ensures that plaintext passwords are not sent over the network and that the same level of security that is required of the originating

query server is achievable from the referral server. If the referral server does not support the security package that was used to bind to the query server or if the referral server does not support the same level of integrity or privacy as the query server, Wldap32 does not chase the referral.

- If no bind is performed on the originating query server, or if a simple (plaintext) bind is performed on the originating server without the use of SSL encryption to protect the passwords, the LDAP client performs an anonymous bind to the referral server. The latter behavior protects passwords from being sent inadvertently over the network in plaintext as the result of chasing a referral.

**Creating an external cross-reference for an external location**
To create a cross-reference to an external directory by referencing an external location, give the **nCName** attribute a value that is the name of the actual external directory. For example, an external LDAP directory might use X.500 naming (such as o=*Organization Name*,c=*Country/Region*), which can be used for the value of the **nCName** attribute. Queries for this directory must specify the external object by name in the search base distinguished name. A request for a referral to such a location might come in the form of an LDAP URL that is embedded in an e-mail message or from an application that specifically names the directory distinguished name.

**Creating an external cross-reference for an internal location**
If you want a subtree search of a portion of your directory to always include an external LDAP directory that is not a Windows Server 2003 or Windows 2000 Server directory service, you can create a cross-reference to the external directory for an internal location. To create an internal location that references an external directory, give the **nCName** attribute of the cross-reference object a value that is an immediate child object of an existing directory object and that also matches the distinguished name of the external directory. Choose the location according to where you want the external directory to be locatable in Active Directory.

This type of cross-reference is especially useful for integrating dynamic directories smoothly. For example, you might use an instant messaging application such as Microsoft NetMeeting conferencing software to publish a list of current or planned conference calls. LDAP is an effective protocol for querying such a published list. However, short-lived, highly volatile data is inappropriate for Active Directory storage. Therefore, you might use an in-memory, nonreplicated LDAP server (one that can store volatile data) at an arbitrary point in the namespace. This "volatile" directory service can then be configured to inhabit a name inside your organization's Active Directory namespace, and it can be made available to users through a cross-reference for an internal location in Active Directory. For example, users can use this location to find the list of instant messaging conversations by directory tree navigation.

**Note**

- On Windows Server 2003 domain controllers, application directory partitions can be used to provide directory storage for dynamic data. For more information about application directory partitions, see "Data Store Technical Reference."

Suppose your domain name is proseware.com and you install your messaging application on an LDAP server that does not use Active Directory, which is named vds.it.proseware.com. On that server, you create a directory for your volatile data, such as cn=conversations,dc=proseware,dc=com. Then, on your Active Directory domain controller, you create a cross-reference object and use the following attribute values:

- cn=conversation server
- nCName=cn=conversations,dc=proseware,dc=com
- dnsRoot=vdserver.it.proseware.com

When a user performs a subtree search of dc=proseware,dc=com, the client receives results from the domain controllers running Windows 2000 Server or Windows Server 2003 and also a subordinate referral to the volatile directory service server at vdserver.it.proseware.com, which instructs the client to continue the LDAP search from cn=conversations,dc=proseware,dc=com and below on that server.

**Superior References**
A superior reference is the fully qualified DNS name of a directory partition that is stored in the **superiorDNSRoot** attribute on the crossRef object for the forest root domain (the first domain that is created in the forest). A domain controller uses its superior reference to construct a referral only when a search base does not match any directory partition that is defined by the cross-reference objects. A superior reference contains no directory tree information; it consists of only an access point to which

otherwise unanswerable queries can be referred.

By default, **superiorDNSRoot** does not store a value, but the directory uses the dc= components of the search base distinguished name to construct the equivalent of a superior referral. You can use the **superiorDNSRoot** attribute to define a location to which all queries that cannot be resolved are sent.

**Optimizing Searches**

Because searches against Active Directory require CPU and memory resources, searches should be performed in ways that minimize their performance impact on domain controllers. You can use several techniques to reduce the impact of directory searches on domain controllers running Windows Server 2003.

Extensions to the base LDAP API, in the form of LDAP v3 controls, make it possible to sort results and set various limits on search operations. You can process search results by paging and by sorting. Paging and sorting are supported in Windows Server 2003 as new LDAP v3 control extensions.

**Effects of Indexing on Search Behavior**

You can improve search behavior by indexing the attributes that are most likely to be searched. The **searchFlags** attribute of an attributeSchema object indicates whether the attribute is indexed and the nature of the indexing.

The **searchFlags** attribute is an integer value whose least significant bits indicate whether the attribute is indexed and in what way. Use the OR operator to combine the bit values to achieve the appropriate indexing behavior.

Values in the **searchFlags** attribute have the following effects:

- 1 = Index over attribute only. Bit 0 must be set (0001). You can use the Active Directory Schema MMC snap-in to set this flag.
- 2 = Index the attribute in each container (this value is used in conjunction with 1). Bit 0 and bit 1 must be set (0011). You can use Active Directory Schema to set this flag.
- 4 = Add this attribute to the ANR set (this value is used in conjunction with 1). Bit 0 and bit 2 must be set (0101).
- 8 = Preserve this attribute on logical deletion (that is, make this attribute available on tombstones). Bit 3 must be set (1000).
- 16 = Copy the value for this attribute when the user object is copied. You can use this value to set up a user object template so that you can create multiple users by making copies of an original and providing values for only those attributes that are unique to each user. Bit 4 must be set (10000). For example, set this flag for attributes, such as **company** and **department**, that you want to copy, but do not set attributes that must be unique, such as **objectSid** and **sAMAccountName**.
- 32 = Index this attribute for medial-string search (this value is used in conjunction with 1). Bit 5 and bit 0 must be set (100001). This indexing capability is provided on domain controllers running Windows Server 2003 when the schema has been updated for Windows Server 2003 functionality.

**Optimizing container searches**

An attribute can be indexed for the attribute only or for both the attribute and the containers that are on the same search level. The value of the **searchFlags** attribute on the attributeSchema object indicates how the attribute is indexed.

One-level searches are confined to the immediate children of the base object of the search. An index on containers, as well as the attribute, optimizes the search where values are expected to be common across containers. For example, suppose you store phone book data for the United States in Active Directory, organized by state and then by region. If you want to search for a Jeff Dulong in northern Idaho, you go to the Northern Idaho container and do a one-level search for (&(givenName=Jeff)(sn=Dulong)). If the **givenName** or **sn** attributes are indexed on the attribute only (flag 1 on the **searchFlags** attribute), the search must examine all the Dulongs in the United States, all the Jeffs in the United States, or all the people in northern Idaho. With the **searchFlags** value of 2 set (index the container and the attribute), the search examines only the Dulongs or only the Jeffs in northern Idaho, which results in a substantial improvement in the time that the search takes to complete.

**Note**

- Active Directory Schema provides an option to index an attribute for container searches.

**ANR**
Ambiguous name resolution (ANR) is the process of searching for a string value in a set of attributes by using one filter of the form (ANR=*string*).

**ANR attribute set**
Attributes are designated as members of the ANR attribute set according to the value of the **searchFlags** attribute on the attributeSchema object that defines the attribute.

By default, the following attributes are members of the ANR attribute set, and they are evaluated when you enter an ANR search string in an LDAP filter:

- **givenName** (first name)
- **sn** (surname, or last name)
- **displayName** (the name that is given to the object when it is created)
- **RDN** (the relative distinguished name of the object)
- **legacyExchangeDN** (for enterprises that have upgraded a Microsoft Exchange installation to a later version of Exchange that is synchronized with Active Directory, the distinguished name of the old Exchange mailbox that corresponds to the user in Active Directory)
- **physicalDeliveryOfficeName** (for example, Building A, Suite 1234)
- **proxyAddresses** (the collection of e-mail addresses over all e-mail address spaces that the Exchange server knows about)

When the (ANR=*string*) filter is encountered by Active Directory, the filter is expanded to include a search of every attribute in the ANR set. For example, an ANR search is implemented when you use the **Check Names** option in Microsoft Outlook that searches against a Microsoft Exchange mail server. Because **physicalDeliveryOfficeName** is in the default ANR attribute set, you can type the building number and room number as it appears in the attribute value into the **To** line of a mail message, click **Check Names**, and the Address Book responds with the user name of any account that contains that value in the **physicalDeliveryOfficeName** attribute of a user object.

In Active Directory Users and Computers, you can use the **Filter** or **Find** options on the toolbar and select the **Custom** and **Advanced** options to enter an ANR filter. You can also use ADSI Edit to perform filtered LDAP searches.

**ANR matching of an embedded space**
For the **givenName** and **sn** attributes, if a space is embedded in the string that is presented in an ANR filter, the string is split at the first such space, and each piece of the string is evaluated separately. You can use this feature to search for a user object by providing the first few characters of the first name (**givenName**) and the first few characters of the last name (**sn**). For example, the filter (ANR=mar ha) finds all objects that have a **givenName** attribute value that begins with "mar" and an **sn** attribute value that begins with "ha". In this example, the filter returns a user who has a **givenName** attribute of Mark and an **sn** attribute of Hanson, as well as a user who has a **givenName** attribute of Mark and an **sn** attribute of Harrington.

**First/last and last/first functionality**
For the **givenName** and **sn** attributes, if a space is embedded in the string that is presented in an ANR filter, the filter is expanded to find the values in both respective positions. For example, the filter (ANR=c d) finds both the user David Campbell and the user Craig Dewer.

**Expanded ANR filter**
When an ANR filter is encountered by Active Directory in an LDAP search, the filter is expanded to construct an OR operation on the string for every attribute in the ANR set. For the **givenName** and **sn** attributes, the first/last and last/first matching are also applied.

The ANR filter of the form (anr= *xxxyyy*) is expanded in the following manner:

```
(| (displayName=xxx yyy*)
(givenName=xxx yyy*)
(physicalDeliveryOfficeName=xxx yyy*)
(proxyAddresses=xxx yyy*)...
(sn=xxx yyy*)
```

```
(& (givenName=xxx*)(sn=yyy*))
(& (givenName=yyy*)(sn=xxx*)))
```

The last three lines of the expanded filter are the portion of the filter that evaluates first name and last name.

**Suppressing first/last and last/first functionality**
You can turn off first/last and last/first functionality if you do not need this type of evaluation and you do not want CPU cycles to be used for it. For example, in the filter (ANR=c d), which finds both the user David Campbell and the user Craig Dewer, you can specify that ANR will always find only Craig Dewer, perhaps because names in your database never occur in any order other than first name/last name and no searches are likely to be looking for anything other than first name/last name. Likewise, if names are always represented in last/first format, you can turn off the first/last functionality. If you do not have values that apply to the first names and last names of people, you can disable both first/last and last/first functionality.

The **dsHeuristics** attribute on the Directory Service object (cn=Directory Service,cn=Windows NT,cn=Services,cn=Configuration,dc=*ForestRootDomain*) contains a string value that governs the use of first/last and last/first functionality in the first two character positions. The default value of **dsHeuristics** is 00, which indicates that both functions are enabled. (For all positions, 0 means "perform the default behavior.") The first character in the string governs first/last functionality; the second character in the string governs last/first functionality.

You can modify the first two characters of the string to suppress either one or both functionalities as follows:

- 10 = Suppress first/last functionality. (This value can also be written 1 or 10000 because both mean that only the first character's behavior must be something other than the default.)
- 01 = Suppress last/first functionality.
- 11 = Suppress last/first and first/last functionality.

**Adding attributes to the ANR set**
You can add attributes to the default ANR set by setting a flag on the attributeSchema object. By using ADSI Edit, connect to the schema, and then open the properties on the attribute that you want to add. Set the **searchFlags** attribute value to a value that represents a bitwise OR operation of 4 and 1 to the existing value. The value 4 adds the attribute to the ANR set; the value 1 indexes the attribute.

### Note

- Limit the number of attributes that you add to the ANR set as much as possible, because adding an attribute to the ANR set affects the performance of any search that is performed against that attribute on any domain controller.

**Searching for deleted objects**
When an Active Directory object is deleted, it is stored as a tombstone in the Deleted Objects container of the respective directory partition, with the exception of some objects from the configuration partition, which remain in their original location, even after they are deleted. When an object is marked as a tombstone, the attributes are stripped from the object, with the exception of **objectGuid**, **objectSid**, **distinguishedName**, **nTSecurityDescriptor**, and **usnChanged**, and any additional attributes that are marked in the schema as "preserve on delete." For more information about tombstones, see "Active Directory Replication Model Technical Reference."

Tombstones are stored for a configurable period of time to allow replication of the deletion to occur. All domain directory partitions, as well as the configuration directory partition, have a hidden Deleted Objects container that stores tombstones until they are permanently removed from the directory by garbage collection. By using the **Show Deleted Object** control (controlType = 1.2.840.113556.1.4.417) in conjunction with search commands, you can view Active Directory objects that have been deleted but not yet garbage collected.

To retrieve tombstone objects, use Ldp.exe to list the contents of the Deleted Objects container for a directory partition.

**Medial-string searches**
In Windows 2000 Active Directory, efficient substring searches are supported for query filters with initial strings (for example, cn=abc*). However, medial-string searches (for example, cn=*def*) and final-string searches (for example, cn=*ghi), although supported, are slow as a result of the lack of appropriate indexing. Active Directory in Windows Server 2003 provides support for selectively indexing attributes that have **DirectoryString** syntax for efficient medial-string and final-string searching. For example, if you index the surname (**sn**) attribute for medial-string searching, you can find all users named McLaughlin, MacLaughlin, and McLaughlan by using the search string cn=*claughl*. You can use the **searchFlags** attribute with a value

of 33 (1 AND 32) to implement both attribute-level and medial-string indexing.

**Note**

- The **searchFlags** value of 32 makes only medial-string searching efficient. To ensure efficiency for initial-string searches as well, use the value 33.

This new type of indexing, called Tuple indexing, is available only on domain controllers running Windows Server 2003, and it is available at any forest functional level. With Tuple indexing, you can see improved performance of medial-string searches on strings that are *at least 3 characters* in length. For example, assuming that the attribute **cn** has been indexed for medial-string search, the performance of searches by filters such as cn=*mic* or cn=*mich* is substantially faster than searches that are run without indexing for medial-string search. However, searches on medial strings that have a shorter length, such as cn=*m* or cn=*mi*, might not see any improvement in performance compared to searches that are not indexed for medial search.

Database indexes are generated separately on each domain controller. Therefore, Tuple indexing only affects domain controllers running Windows Server 2003, and it does not affect any Windows 2000 Server–based domain controllers that are present in the domain or forest. Because searches of the type cn=*def* are possible on Windows 2000 Server–based domain controllers, there are no backward compatibility issues with Tuple indexing and Windows 2000 Server domain controllers. You can perform medial-string searches on both domain controllers running Windows 2000 Server (without the benefit of Tuple indexing) and domain controllers running Windows Server 2003 (with the benefit of Tuple indexing).

**Performance considerations**

Tuple indexing is a resource-intensive operation for the Active Directory database, which means that updating an attribute that has Tuple indexing applied takes longer than normal. For this reason, by default, no attributes are indexed for this type of search in the Windows Server 2003 schema.

**Note**

- Only attributes that are often used to perform medial-string searches should be marked as indexed for medial-string search. Unnecessary indexing, especially of this type, can cause update performance to decrease.

**Deleted objects exception to medial-string search**

Because Tuple indexes can become quite large, values of Tuple-indexed attributes on deleted objects (called tombstones) are not included in the index. Therefore, if the special LDAP control to *show deleted objects* is specified in the search operation, the search cannot use Tuple indexes to speed up the search.

**Indexing an attribute for medial-string search**

You can use ADSI Edit to mark an attribute for Tuple indexing. To use ADSI Edit, you must have Windows Support Tools installed.

The process for marking an attribute for Tuple indexing involves changing the value of the **searchFlags** attribute on the corresponding attributeSchema object that defines the attribute that you want to index.

**Efficient listing of large search results in Windows Server 2003**

New LDAP v3 controls are introduced in Windows Server 2003 that improve the ability of applications to display large lists of search results. Two new controls extend the LDAP protocol to provide a scalable solution for managing large directory deployments by improving the paging and sorting of search lists, as follows:

- Virtual list view (VLV). Allows only the viewed portion of the list to be required in memory.

- Attribute scoped query (ASQ). Applies VLV functionality to the listing of search results on large, multivalue attributes.

These two controls enable a client to browse large lists of objects without a negative impact to the client. VLV and ASQ lower network traffic and ease the client's burden of holding a large set of unneeded data in memory.

VLV and ASQ can also be used to extend other applications that retrieve information from Active Directory. For more information about programming applications that implement VLV and ASQ, see "Extended Controls" in the Microsoft Platform SDK on MSDN.

**VLV**

A virtual list is a GUI technique that is employed when ordered lists containing a large number of entries need to be displayed. When the LDAP protocol is extended to use VLV, a window that contains a small number of visible list entries is drawn. The

visible portion of the list can be relocated to different points in the list by means of scrolling, slider bars, and cursor keys as well as PAGE UP and PAGE DOWN keys. The user experience is that the full list can be browsed at will, even though it might contain millions of entries. In fact, the complete list contents are never required at any one time. Rather than retrieve the complete list from wherever it is stored (typically, from disk or a remote server), the server retrieves only the information that is required to display the part of the list that is currently in view on the client.

When you have indexed appropriate attributes to use VLV, you can use Ldp (or other VLV-enabled applications) to retrieve large lists from Active Directory without requiring the server to return the entire contents of the results set (improving response speed) and without requiring the search client to store the results set in memory (improving the speed at which results are listed).

**Configuring VLV**
For the directory service to efficiently browse a container that is sorted on a particular attribute, special indexes have to exist in the directory. These indexes are available in all the languages that are installed on the particular server.

You can define the views that the directory supports by modifying the attributeSchema object for the particular attribute on which you want to search. More specifically, you can modify the **searchFlags** attribute on the attributeSchema object to set it for VLV indexing.

To index an attribute for VLV, set the **searchFlags** value as follows:

*current value* OR 2

For example, if you want to add support for VLV container browsing using the **name** attribute, modify the attributeSchema object cn=RDN,cn=Schema,cn=Configuration,dc=*DomainName*.

The default value of **searchFlags** for this object is 13 (1101); therefore, in this case it becomes 15 (1111). If the attribute has a different value, simply perform an OR operation on that value with 2 (0010).

Active Directory does not implement any specific restrictions on the use of the VLV control. However, if a search operation cannot be processed by the server before the time-out (to build the required table that is specified by the search filter and sort key), the server returns a time-out.

**ASQ**
The ASQ LDAP control, which is new in Windows Server 2003, makes it possible to apply the query scope to a linked-value attribute instead of to a container. In this way, ASQ extends the VLV feature to apply to large, multivalue attributes with distinguished name values (the type of attributes that can be linked).

With ASQ, the VLV control can be run on an attribute with distinguished name syntax to:

- Receive a sorted list of values in a multivalue attribute that has a large number of distinguished name values, such as the **member** attribute on a group object.

- Perform a nested query on a multivalue attribute that has a large number of distinguished name values and return the values in a single operation.

For example, if an ASQ search is performed on the **member** attribute of a group object, ADSI enumerates the distinguished names in the **member** attribute and searches each of the members of the group for the specified search criteria.

**LDAP Query Policy**
LDAP v3 supports the definition of client query policy. By default, limits are placed on the server resources that are available to clients requesting LDAP queries, paged result sets, and sorted result sets. These limits constitute the LDAP query policy.

The query policy is stored as a multivalue attribute (**lDAPAdminLimits**) of the Default Query Policy object in the configuration directory partition (cn=Default Query Policy,cn=Query-Policies,cn=Directory Service,cn=Windows NT,cn=Services,cn=Configuration,dc=*Forest RootDomain*).

**Note**

- LDAP query policy is not related to, and is not a subset of, Group Policy.

Because the workload and resources of a given server can vary, the LDAP query policy is configurable at the server level.

LDAP query policy applies to the following LDAP query–related operations:

- Search. The basic query operation. An LDAP search might cover a small part of a single domain, or it might span every directory partition in the forest. A search can generate a significant amount of disk activity, take a long time, and return a large volume of data.

- Search with Paged Results. Because a search can return a large volume of data, the client can ask the server to hold the result set and return it in "pages" of a specified length. The server must hold the result set until the client releases it or unbinds.

- Search with Sorted Results. A client can request a result set in a particular order. Sorting requires storage and CPU cycles at the server. The resources consumed are directly proportional to the size of the result set.

- Search with Replication. The administrator can specify the maximum number of attribute values that can be returned per request.

- Change Notify. A client can request change notification on particular objects in the directory. The mechanism that is used to post a Change Notify request is the asynchronous LDAP query.

In the absence of any other assigned policy, all domain controllers use the default query policy. If a site policy is assigned, the domain controller uses the site policy. If a specific policy has been assigned to a domain controller, this policy takes precedence over any site policy.

**Administrative query policies: attribute values**
The following table shows the administrative limits for default query policy.

**Default Values for LDAP Administrative Limits**

| LDAP Administrative Limits | Default Value | Description and Search Behavior |
|---|---|---|
| **MaxConnIdleTime** | 900 | Maximum Connection Idle Time. The maximum time (in seconds) that the client is allowed to be idle before the connection is closed. |
| **MaxActiveQueries** | 20 | Maximum Active Queries. The maximum number of concurrent search operations allowed on the server. When the stated limit is reached, the LDAP server returns a busy notification. |
| **MaxNotificationPerConn** | 5 | Maximum Notifications per Connection. The maximum number of concurrent notification requests allowed per connection on the server. When the stated limit is reached, the server returns a busy notification. |
| **MaxPageSize** | 1000 | Maximum Page Size. The largest page size allowed by the server (in number of rows). The server returns the number of rows that are specified by **MaxPageSize**. If paged results are requested, the client can retrieve additional pages until all results are returned. |
| **MaxQueryDuration** | 120 | Maximum Query Duration. The maximum elapsed time (in seconds) that is allowed for a query to complete. If paged results are requested, the client can continue the query if the timer expires before the query completes. When the stated limit is reached, the server returns the **timeLimitExceeded** error. |
| **MaxReceiveBuffer** | 10485760 | Maximum Receive Buffer. The maximum LDAP request size (in bytes) that the server attempts to process. If the server receives a request that is larger than this value, it closes the connection. |
| **MaxTempTableSize** | 10000 | Maximum Temporary Table Size. The upper limit (in candidate objects) on the temporary table. If the temporary table maximum limit is reached by an "OR" query optimization, the optimization is abandoned and replaced with a direct table scan. |
| **MaxResultSetSize** | 262144 | Maximum Result Set Storage. The maximum storage (in kilobytes (KB)) that the server can hold for all paged result sets. If the stated limit is reached, the oldest result sets are discarded. |

| | | |
|---|---|---|
| **MaxPoolThreads** | 4 | Per Processor Asynchronous Thread Queue (ATQ) Threads. The number of threads that are allocated by ATQ per processor. This value is sent as an advisory notification to ATQ. ATQ decides whether to use it or not.<br><br>**Note** If it takes a long time to bind, increase the count to 6 or 8. |
| **MaxDatagramRecv** | 1024 | Maximum Receive Datagram Size. The maximum size of datagrams (in bytes) that can be received by the server. The server preallocates datagram buffers and cannot receive datagrams with a size that is larger than the stated limit. |
| **InitRecvTimeout** | 120 | The maximum time (in seconds) that the server waits for the initial request before the connection is dropped. |
| **MaxConnections** | 5000 | The maximum number of concurrent LDAP connections allowed on the server. User Datagram Protocol (UDP) connections do not count toward this limit. If the limit is reached, the LDAP server sends back an LDAP disconnect notification and closes down the connection. |
| **MaxValRange** | 1500 | Maximum Value Range. Controls the threshold at which the server will start returning the range option for attributes with a large number of values. The minimum value for this policy is 30. |

**Query Limits**

To improve the query response time for searches for Active Directory objects, searches are limited to 1,000 objects by default. However, you may want to increase this limit as your organization grows. You can control the buffer size that is allocated for storing the number of objects that are returned by a query search. To control the buffer size, you can either modify the registry on the search client or use Group Policy to set the buffer size on all computers in a domain, site, or OU.

**Modifying the registry to change the maximum query limit**

You can increase the number of objects that are returned by an Active Directory search on an individual search client by setting the limit in the registry. The **REG_DWORD** value named **QueryLimit** on the registry key **HKEY_CURRENT_USER\Software\Policies\Microsoft\Windows\Directory** controls the maximum query limit on the local computer.

**Using Group Policy to change the maximum query limit**

You can use Group Policy to increase the maximum query limit on objects that are returned in response to a command to browse or search Active Directory when the command is issued from an operating system in the Windows 2000 Server family or the Windows Server 2003 family. In the User Configuration section of Group Policy, the setting is found in \Administrative Templates\Desktop\Active Directory\Maximum size of Active Directory searches. You can edit this setting with Group Policy Management Console (GPMC).

### Note

- Because this query limit policy is a user-based policy, it is not enforced until the user has logged off the system and then logged on again. Also, the policy only applies to default Active Directory tools, such as Active Directory Users and Computers. Any query limits that are set through Group Policy do not apply to LDAP queries that are performed programmatically.

**Paging**

When an LDAP client is accessing a server across a slow connection or if the result set from a given query may be very large, the client can retrieve a result set in small pieces. The Simple Paged Result extended control provides for this type of retrieval. Options for this control enable the client to set the initial page size and reset the page size with each subsequent request to the server.

The Simple Paged Result control is also used to access all of a large results set when there is a server-side administrative limit to the number of items that are returned from a query. For example, domain controllers running Active Directory have a default server-side limit of 1,000 entries as the maximum number of results that are returned in a single request. If the results of a query exceed this limit, the Paged Results control is used, with a page size equal to or less than the server-side limit, to retrieve all of the results of the query.

For more information about paging, see “Paging Search Results” in the Microsoft Platform SDK on MSDN.

**Multivalue Attributes**

Attributes can be single value or multivalue. Single-value and multivalue attributes are defined by the **singleValued** attribute

being set to **TRUE** or **FALSE**. A multivalue attribute can contain multiple values, all of uniform syntax. Note that multivalue attributes hold a set of values with no particular order. There is no guarantee that multivalue properties are ever going to be returned in the order in which they were stored (or in any other order).

Retrieving the contents of a multivalue attribute, such as a distribution list, can often result in a large number of returned values. LDAP servers often place limits on the maximum number of attribute values that can be retrieved in a single query. If an attribute has more members than can be returned by the server in a single call, the only way to enumerate all of the attribute values is through the use of the range option.

Range retrieval involves requesting a limited number of attribute values in a single query. The number of values that are requested must be less than, or equal to, the maximum number of values that are supported by the server. To reduce the number of times that the query must contact the server, the number of requested values should be as close to this maximum as possible.

Active Directory servers set a limit on the maximum number of attribute values that are returned. The version of the operating system for the server that supplies the requested data determines the maximum number of values that can be retrieved in a single query. The following table lists the operating system version and the maximum number of values that can be retrieved in a single query.

**Maximum Query Size for Multivalue Attribute Searches**

| Operating system version | Maximum values returned |
|---|---|
| Domain controllers running Windows 2000 Server | 1,000 |
| Domain controllers running Windows Server 2003 | 1,500 |

**Note**

- In the Windows Server 2003 family, a server running Windows Server 2003, Web Edition cannot be a domain controller.

#### Attribute range option

The range option can be specified as part of an LDAP search to retrieve the values of a multivalue attribute incrementally. An LDAP search on an attribute includes an attribute type (for example, **member**) and a list of options, one of which can be the range option. When it is presented in a **searchRequest** message, the range option specifies a zero-relative range of elements (for example, 0 through 9) to be retrieved. When the range option is specified, followed by a range specifier, only the number of values in that range is retrieved. For more information about the range option, see "Searching Using Range Retrieval" in the Microsoft Platform SDK on MSDN.

**Note**

- You can use the range option in multivalue attribute searches by using Ldp.exe.

#### Linked-value attributes

Linked-value attributes are a new feature in Windows Server 2003. Linked-value attributes are pairs of attributes in which the system calculates the values of one attribute (the back link) based on the values that are set on the other attribute (the forward link) throughout the forest. A back-link value on any object instance consists of the distinguished names of all the object's that have the object's distinguished name set in the corresponding forward link. A back link is always a multivalue attribute. A forward link can be a multivalue attribute or a single-value attribute.

For example, **Manager** and **Reports** are a pair of linked-value attributes, where **Manager** is the forward link and **Reports** is the back link. For example, suppose that Bill is Joe's manager. If you store the distinguished name of Bill's user object in the **Manager** attribute of Joe's user object, the distinguished name of Joe's user object shows up in the **Reports** attribute of Bill's user object.

A forward-link/back-link pair is identified by the **linkID** values of two **attributeSchema** definitions. The **linkID** of the forward link is an even, positive, nonzero value, and the **linkID** of the associated back link is the forward **linkID** plus one. For example, the **linkID** for **Manager** is 42, and the **linkID** for **Reports** is 43.

The following is a list of guidelines for defining a new pair of linked-value attributes:

- The **linkID** values must be unique among all attributeSchema objects. To avoid conflicts, you can obtain values for **linkID** attributes from the Link ID Generator on MSDN.

- A back link must have a corresponding forward link; that is, the forward link must exist before a corresponding back-link attribute can be created.

- The **attributeSchema** value of a forward link must be **2.5.5.1**, **2.5.5.7**, or **2.5.5.14**. These values correspond to syntaxes that contain a distinguished name, such as the Object(DS-DN) syntax.

- The **attributeSchema** value of a back link must be **2.5.5.1**, which is the Object(DS-DN) syntax.

- By convention, back-link attributes are added to the **mayContain** value of the top abstract class. This enables the back-link attribute to be read from objects of any class, because they are not actually stored with the object but calculated based on the forward-link values.

For information about the replication of linked-value attributes, see "How the Active Directory Replication Model Works."

**Global Catalog Searches**
The global catalog enables searches for Active Directory objects in any domain in the forest, without the need for subordinate referrals. Users can find an object of interest quickly without having to know which domain holds the object.

**Global catalog servers**
A global catalog server is a domain controller that stores extra information. The database on the global catalog server stores information about every object in the forest, instead of information for the objects in only one domain. The information about objects that occur in directory partitions for domains other than the local domain includes only a subset of attributes for each object. In this way, the global catalog enables forest-wide searches without requiring replication of the entire contents of Active Directory to every domain controller. The Knowledge Consistency Checker (KCC) process creates a replication topology that ensures delivery of the partial contents of every directory partition to every global catalog server in the forest.

### Note

- A global catalog server stores full copies of the schema and configuration directory partitions, which is the same as for any domain controller.

By default, the server on which you install Active Directory to create the first domain in a new forest is a global catalog server. Thereafter, you must designate additional global catalog servers if you need them.

**Searching the domain vs. searching the global catalog**
The decision whether to search the domain or the global catalog is based on the scope of the search:

- When the scope of a search is the domain or an OU, the query can be resolved in the domain directory partition by using an LDAP search.

- When the scope of a search is the forest and the attributes that are being searched against are part of the global catalog, the query can be resolved in any directory partition by using a global catalog search.

**Searches that use the global catalog by default**
To search the global catalog, instead of the local domain partition, you must specify port 3268 in the search tool that you are using, instead of port 389, the standard LDAP port. Anytime that you specify port 3268, you are searching in the global catalog. In addition, the global catalog is searched by default under the following conditions:

- During the logon process, when a user principal name (UPN) is presented. The global catalog is searched to find the domain and account name on the basis of the UPN.

- During the logon process, to expand universal groups. Universal group membership can span domains. It is possible, therefore, that a user has a membership in a universal group that is not in the logon domain. For this reason, the global catalog is contacted to search the membership of universal groups. If a membership is found, the group is attached to the user's logon credentials.

- When you select **Entire Directory** in a search-scope list in an Active Directory tool, such as Active Directory Users and Computers.

- When you write the distinguished name value for a property, where the distinguished name represents a nonlocal object. For example, if the member that you are adding is from a different domain, the global catalog is used to verify that the user object that is represented by the distinguished name actually exists.

**Global catalog search base**
For an LDAP search, you must supply a valid search base. For a global catalog search, the search base can be any value, including the value NULL ( ). A search base of NULL effectively scopes the search on the search computer to the global catalog. If you use a NULL search base with a scope of one level or subtree and specify port 389 (the default LDAP port), the search fails. Therefore, if you submit a NULL search to the global catalog port and then change the port to the LDAP port, you must change the search base for the search to succeed.

**Characteristics of a global catalog search**
The following additional characteristics differentiate a global catalog search from a standard LDAP search:

- A global catalog search crosses directory partition boundaries. The extent of an LDAP search is the directory partition.

- A global catalog search does not return subordinate referrals. If you use port 3268 to request an attribute that is not in the global catalog, you do not receive a referral to it. Subordinate referrals are an LDAP response. When you query a server over port 3268, you receive global catalog responses, which are based solely on the contents of the global catalog. If you query the same server over port 389, you receive referrals for objects that are in the forest but whose attributes are not referenced in the global catalog.

### Note

- An external referral can be returned by the global catalog if a base-level search for an external directory is submitted and if the distinguished name of the external directory uses the domain component (dc=) naming attribute. This referral is returned according to the ability of Active Directory to construct a DNS name from the domain components of the distinguished name, and it is not based on the presence of any cross-reference object. The same referral is returned by using the LDAP port; it is not specific to the global catalog. For more information about constructing a DNS name from the domain components, see “Superior References” earlier in this section.

When a forest consists of a single domain, there is no need for a global catalog because every domain controller has a full, writable copy of every object in the domain and forest. However, it is important to retain the global catalog on at least one domain controller because many applications use port 3268 for searching. For example, if you do not have any global catalog servers, the **Search** command on the **Start** menu of Windows 2000 Professional, Windows 2000 Server, Windows XP Professional, and Windows Server 2003 cannot locate objects in Active Directory.

**Searching on back links**
Some Active Directory attributes cannot be located specifically in the directory database. A back link is an attribute that can be computed only by referencing another attribute, called a forward link. An example of a back-link attribute is the **memberOf** attribute on a user object, which relies on the group attribute **member** to derive its values. For example, if you request the groups of which a specific user is a member, the forward link **member** — an attribute of the group object — is searched to find values that match the user name that you specify.

When you request the value of a back link on a particular object (for example, “What objects are managed by UserB?”), the system searches for all objects whose corresponding forward link names the original object (that is, " What objects have the distinguished name of UserB as the value in their **managedBy** attribute?"). The results of that search, and therefore the apparent contents of the back-link attribute, depend on the LDAP port to which the client is bound. That is, the results can differ, depending on whether the client binds to the local domain (LDAP port 389) or to the global catalog (LDAP port 3268).

**Effect of the global catalog on searches of back links and forward links**
Because of the way that groups are enumerated by a global catalog server, the results of a back-link search can vary, depending on whether you search the global catalog (port 3268) or the domain (port 389), the kind of groups that the user belongs to (global groups or domain local groups), and whether the user belongs to universal groups outside the local domain.

### Note

- Universal groups are available only in domains where domain controllers are operating in Windows 2000 native mode (in a Windows 2000 domain), in domains that have a Windows 2000 native domain functional level (in a

Windows Server 2003 domain), or in forests that have a Windows Server 2003 forest functional level.

Domain controllers store a full replica of the domain global groups, domain local groups, and any universal groups that are created in that domain. Therefore, if a query occurs over port 389, the global group and domain local group memberships for users in the local domain can be found, as well as memberships in any universal groups that are stored in that domain.

Global catalog servers store a partial replica of every group in the forest. The **member** attribute of a group is replicated to the global catalog for universal group objects but not for global groups or domain local groups. Therefore, if a query occurs over port 3268 and the global catalog server that is contacted is authoritative for the user's domain, that user's domain local memberships and global group memberships can be enumerated because full replicas of those objects exist on the server. Otherwise, only the user's universal group memberships are available.

Connecting to the global catalog always locates the user's membership in universal groups. However, connecting to the global catalog does not locate the users membership in global groups or domain local groups, unless the global catalog server happens to be an authoritative domain controller for the user's domain.

**Network Ports Used by Active Directory Searches**
The network ports that are used by Active Directory searches are listed in the following table.

**Port Assignments for Active Directory Searches**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | None | 389 |
| LDAP SSL | None | 636 |
| Global Catalog LDAP | None | 3268 |
| Global Catalog LDAP SSL | None | 3269 |

# Active Directory Searches Tools and Settings

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**Active Directory Searches Tools and Settings**

**In this section**

- Active Directory Searches Tools
- Active Directory Searches Group Policy Settings
- Active Directory Searches WMI Classes
- Network Ports Used by Active Directory Searches
- Related Information

This section contains information about the tools, Group Policy settings, Windows Management Instrumentation (WMI) classes, and network ports that are associated with Active Directory searches.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

**Active Directory Searches Tools**

The following tools are associated with Active Directory searches.

**Adsiedit.msc: ADSI Edit**

**Category**

This tool ships with Support Tools for Windows Server 2003.

**Version Compatibility**

| Can Be Run From | Can Be Run Against |
| --- | --- |

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br>• Windows Server 2008<br>• Windows Server 2008 R2<br><br>Computers running:<br>• Windows XP Professional<br>• Windows Vista<br>• Windows 7 | Domain controllers running:<br>• Windows Server 2008 R2<br>Windows Server 2008<br>Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server<br>• |

ADSI Edit is a Microsoft Management Console (MMC) tool that you can use to view and modify directory objects.

To find more information about ADSI Edit, see "Support Tools Help" in Tools and Settings Collection.

**Dsquery.exe: Dsquery**

**Category**
This tool ships with Windows Server 2003.

**Version Compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|

| | |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

You can use Dsquery to perform searches against Active Directory according to specified criteria.

To find more information about Dsquery, see "Command-Line References" in Tools and Settings Collection.

**Ldp.exe: Ldp**

**Category**
This tool ships with Support Tools for Windows Server 2003.

**Version Compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br><br>Servers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows Server 2003, Web Edition<br><br>Computers running:<br>• Windows XP Professional | Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

Ldp is a Lightweight Directory Access Protocol (LDAP) graphical user interface (GUI) tool that you can use to perform

operations, such as connect, bind, search, modify, add, and delete, against any LDAP-compatible directory, such as Active Directory.

To find more information about Ldp, see "Support Tools Help" in Tools and Settings Collection.

**Ntdsutil.exe: Ntdsutil**

**Category**
This tool ships with Windows Server 2003.

**Version Compatibility**

| Can Be Run From | Can Be Run Against |
|---|---|
| Domain controllers running:<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition | Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition |

You can use Ntdsutil to perform Active Directory database maintenance, manage and control single master operations, and remove metadata left behind by domain controllers that are removed from the network without being properly uninstalled. This tool is intended for use by experienced administrators.

To find more information about Ntdsutil, see "Command-Line References" in Tools and Settings Collection.

**Active Directory Searches Group Policy Settings**
The following table lists and describes the Group Policy settings that are associated with Active Directory searches.

**Group Policy Settings Associated with Active Directory Searches**

| Group Policy Setting | Description |
|---|---|
| **Maximum size of Active Directory searches** | Specifies the maximum number of objects that the system displays in response to a command to browse or search Active Directory.<br><br>This policy affects all browse displays that are associated with Active Directory, such as those displays in Local Users and Groups, Active Directory Users and Computers, and dialog boxes that are used to set permissions for user or group objects in Active Directory.<br><br>If you enable this policy, you can use it to limit the number of objects that are returned from an Active Directory search.<br><br>If you disable this policy or if you do not configure it, the system displays up to 10,000 objects. |
| **Enable filter in Find dialog box** | Displays the filter bar above the results of an Active Directory search. The filter bar consists of buttons for applying additional filters to search results.<br><br>If you enable this policy, the filter bar appears when the Active Directory **Find** dialog box opens, but users can hide it. |

| | |
|---|---|
| **Hide Active Directory folder** | Hides the Active Directory folder in My Network Places.<br><br>The Active Directory folder displays Active Directory objects in a browse window.<br><br>If you enable this policy, the Active Directory folder does not appear in the My Network Places folder.<br><br>If you disable this policy or if you do not configure it, the Active Directory folder appears in the My Network Places folder. |

To find more information about Group Policy settings, see the "Group Policy Settings Reference" in Tools and Settings Collection.

**Active Directory Searches WMI Classes**

The following table lists and describes the WMI classes that are associated with Active Directory searches.

**WMI Classes Associated with Active Directory Searches**

| Class Name | Namespace | Version Compatibility |
|---|---|---|
| **rootDSE** | root\directory\LDAP | Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |
| **DS_LDAP_Class_Containment** | root\directory\LDAP | Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

| | | |
|---|---|---|
| **DS_LDAP_Instance_Containment** | root\directory\LDAP | Domain controllers running:<br>• Windows Server 2008 R2<br>• Windows Server 2008<br>• Windows Server 2003, Standard Edition<br>• Windows Server 2003, Enterprise Edition<br>• Windows Server 2003, Datacenter Edition<br>• Windows 2000 Server<br>• Windows 2000 Advanced Server<br>• Windows 2000 Datacenter Server |

For more information about these WMI classes, search for "Mapping Active Directory to WMI" in the WMI SDK documentation on MSDN.

**Network Ports Used by Active Directory Searches**

The network ports that are used by Active Directory searches are listed in the following table.

**Port Assignments for Active Directory Searches**

| Service Name | UDP | TCP |
|---|---|---|
| LDAP | None | 389 |
| LDAP SSL | None | 636 |
| Global Catalog LDAP | None | 3268 |
| Global Catalog LDAP SSL | None | 3269 |

**Related Information**

The following resources contain additional information that is relevant to this section:

- "Support Tools Help" in Tools and Settings Collection for information about ADSI Edit and Ldp
- "Command-Line References" in Tools and Settings Collection for information about Dsquery and Ntdsutil
- "Group Policy Settings Reference" in Tools and Settings Collection for more information about Group Policy settings for Active Directory searches
- Microsoft Platform SDK on MSDN for more information about WMI classes for Active Directory searches (in "Mapping Active Directory to WMI")

# Service Publication and Service Principal Names Technical Reference

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

Services use service publication in the Active Directory directory service to provide information about themselves in the directory for easy discovery by client applications and other services. Service publication occurs when the installation program for a service publishes information about the service, including binding and keyword information, to the directory. In addition, Active Directory supports service principal names (SPNs) as a means by which client applications can identify and authenticate the services that they use. Service publication is accomplished through the creation of service objects (also called connection point objects) in Active Directory. Service authentication is accomplished through Kerberos authentication of SPNs.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

# What Are Service Publication and Service Principal Names?

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- The Business Need
- The Service Publication and SPN Solution
- Service Publication and SPN Scenarios
- Related Information

Services use service publication in Active Directory to provide information about themselves in the directory for easy discovery by client applications and other services. Service publication occurs when the installation program for a service publishes information about the service, including binding and keyword information, to the directory. In addition, Active Directory supports service principal names (SPNs) as a means by which client applications can identify and authenticate the services that they use. Service publication is accomplished through the creation of service objects (also called connection point objects) in Active Directory. Service authentication is accomplished through Kerberos authentication of SPNs.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

**The Business Need**

As organizations come to rely more heavily on distributed services for getting work accomplished, service consumers (that is, users and client applications) in those organizations need a way to search for and discover services on the network quickly and easily. At the same time, administrators need to protect service consumers from insecure or unidentified services and to keep track of valid services that are running on their networks.

**The Service Publication and SPN Solution**

Service publication and SPNs are two separate, independently deployable Active Directory technologies that together provide a complete solution for the service discovery and authentication needs in an organization.

Service publication in Active Directory enables users and applications to find services on the network — without having to know on which server the service resides — through the use of connection point objects in the directory. A connection point object is created by a service at the time that the service is installed. The service uses this object to publish information about itself, including binding information and searchable keywords. Clients of the service can search against the data that is stored in connection point objects in the directory to find out about services on the network.

Service consumers can use SPNs in Active Directory to authenticate the identity of services before using the services. An SPN is a unique attribute that resides on the account object in whose security context a given service runs. SPN structures generally follow Internet Engineering Task Force (IETF) naming conventions, and they often include the name of the computer on which the service is running. SPNs may be used to request Kerberos tickets, and they are required for mutual authentication between clients and services. For more information about SPNs, see "How Service Publication and Service Principal Names Work."

Before connecting to a service, a service consumer can construct an SPN string that matches the SPN of the service by using information that is gathered from a connection point object or some other source. The service consumer can then present this SPN string to the Key Distribution Center (KDC) and request that the KDC authenticate the service that is represented by the SPN.

The following figure illustrates the relationship between services, client applications, and Active Directory.

**Service Publication and SPNs in Active Directory**

**Service Publication and SPN Scenarios**
The following sections describe the scenarios to which service publication and SPNs most commonly apply.

**Standardized Service Publication**
Service publication through connection point objects is most commonly used by organizations to establish a single, standard mechanism for publishing service information throughout the organization. This scenario takes advantage of Active Directory as the single, pervasive directory service that is available to all clients throughout the network. This scenario involves services that can write connection point objects to the directory. As an alternative, administrators can create and maintain connection point objects manually.

**Protecting Clients from Unauthorized Services**
In this scenario, organizations that are concerned about protecting clients from unauthorized services use SPNs as a way to enable client authentication of services. This scenario involves client applications that can request authentication of SPNs.

- "Microsoft Platform SDK" on MSDN for more information about service publication (in "Service Publication")
- "Microsoft Platform SDK" on MSDN for more information about service authentication (in "Mutual Authentication Using Kerberos")

# How Service Publication and Service Principal Names Work

Updated: November 19, 2014

Applies To: Windows Server 2003, Windows Server 2003 R2, Windows Server 2003 with SP1, Windows Server 2003 with SP2, Windows Server 2008, Windows Server 2008 R2, Windows Server 2012, Windows Server 2012 R2

**In this section**

- Service Publication and SPN Architecture
- Service Publication and SPN Protocols
- Service Publication and SPN Physical Structure
- Service Publication and SPN Processes and Interactions
- Related Information

Services use service publication in Active Directory to provide information about themselves in the directory for easy discovery by client applications and other services. In addition, Active Directory supports service principal names (SPNs) as a means by which client applications can identify and authenticate the services that the client applications use. Service publication is accomplished through the creation of service objects (also called connection point objects) in Active Directory. Service authentication is accomplished through Kerberos authentication of SPNs.

| **Note** |
| --- |
| In Windows 2000 Server and Windows Server 2003, the directory service is named Active Directory. In Windows Server 2008 and Windows Server 2008 R2, the directory service is named Active Directory Domain Services (AD DS). The rest of this topic refers to Active Directory, but the information is also applicable to AD DS. |

Service publication and SPNs work through special objects and attributes that are stored in Active Directory. These objects and attributes are published to the directory by the respective services that the objects and attributes represent. Service publication and SPNs are optional capabilities of Active Directory, and they are not required for a properly functioning Active Directory infrastructure. However, a properly functioning Active Directory infrastructure is required for service publication and SPNs to work.

In addition to a properly functioning Active Directory infrastructure, an ideal environment for service publication and SPNs requires that the following components be present and functioning properly:

- Kerberos and Key Distribution Center (KDC)
- The services that use Active Directory to publish information about themselves
- The client applications that authenticate and use the published services
- Network connectivity, including Internet Protocol (IP), among all components

This section describes the elements of Active Directory service publication and SPNs, including their architecture, protocols, physical structure, and processes and interactions.

**Service Publication and SPN Architecture**

The primary components of the service publication and SPN architecture are the services that publish information about themselves and the client applications that search the directory to discover the services. In addition, Active Directory plays a key role in the architecture, both as the storage and distribution mechanism for published service information and as a source for the SPN attributes that are used in mutual authentication. Finally, the KDC provides the mechanism for authenticating services by means of the SPNs that are constructed by the client applications. The relationships of these components are shown in the following figure.

**Service Publication and SPN Architecture**

The following table describes the service publication and SPN components.

**Service Publication and SPN Components**

| Component | Description |
|---|---|
| Service | An application that makes data or operations available to network clients. |
| Client application | An application running on a workstation or on a server that makes use of a service. |
| KDC | A service running on every domain controller that provides authentication services for clients, as well as for servers and services. A client application requests the authentication of an SPN through a KDC. |
| Active Directory | The directory that is used to store connection point objects and service account objects. |
| Connection point object | An object in Active Directory that contains information about a service. Client applications search for these objects to find out about services that are available on the network. Typically, connection point objects are created on the computer object of the computer on which a given service is running. |
| SPN attribute | An attribute that contains a unique name that identifies an instance of a service. An SPN attribute resides on the service account object in whose security context a given service instance runs. |

**Service Publication and SPN Protocols**

Service publication and SPNs rely on the IP network protocol as well as on transport protocols, including Transmission Control Protocol (TCP) and User Datagram Protocol (UDP). Client applications perform service discovery against Active Directory by using the standard operations of the Lightweight Directory Access Protocol (LDAP). Client applications request mutual authentication of services by using the Kerberos V5 authentication protocol. The protocols that are used in service publication and authentication are shown in the following figure.

**Service Publication and SPN Protocols**

The following table describes the service publication and SPN protocols.

**Service Publication and SPN Protocols**

| Protocol | Description |
|---|---|
| LDAP | The core protocol that is used to communicate with Active Directory. LDAP is described in RFC 2551 (LDAP v3) and RFC 1777 (LDAP v2). |
| Kerberos | The authentication protocol that is used by clients and services to communicate with the KDC. |
| TCP | The connection-oriented session protocol on which LDAP runs. |
| UDP | The connectionless session protocol on which Kerberos runs. |
| IP | The standard network protocol that is used by Windows Server 2003. |

**Service Publication and SPN Physical Structure**

In Active Directory, the physical structure for service publication consists of connection point objects and the containers in which those objects reside. Typically, connection point objects are created on the computer object of the computer on which a given service is running.

Microsoft SQL Server 2000 is an example of an application that supports the publication of information about itself in Active Directory by using connection point objects. SQL Server 2000 supports the registration of instances of the SQL Server relational database engine, databases, replication publications, and analysis servers in Active Directory.

For example, SQL Server 2000 can be installed on a computer for which the distinguished name in Active Directory is the following:

CN=dbserver,OU=ComputersOU,DC=corp,DC=cohovineyard,DC=com

After installing SQL Server 2000, an administrator can register an instance of the SQL Server relational database engine in Active Directory by using the tools that are provided by SQL Server 2000. After the database engine is registered in Active Directory, an **MS-SQL-SQLServer** connection point object is added to the container. This new connection point object has the following distinguished name:

CN=MS-SQL-SQLServer,CN=dbserver,OU=ComputersOU,DC=corp,DC=cohovineyard,DC=com

For more information about SQL Server 2000 service publication, see “Active Directory Integration” in the “Microsoft Platform SDK” on MSDN.

**Note**

- You can search Active Directory for existing connection point objects, using the **dsquery** command-line tool, by typing the following at a command prompt:
- **dsquery * forestroot -filter (objectclass=serviceconnectionpoint)**
- For more information about **dsquery**, at a command-line prompt, type:
- **dsquery /?**

The physical structure for client authentication of services consists of the service account objects of the services to be authenticated, the SPN attributes that reside on those objects, and the containers in which those objects reside. The service account under which a service runs determines the security identity of the service at run time, that is, it determines the service’s primary security context. The security context determines the service’s ability to access local and network resources. Generally, the service installer specifies the service account when it calls the **CreateService** function to install the service on a host computer. In addition, if the service is to support mutual authentication by means of SPNs, the service installer registers SPNs on the service account object as an attribute. If the service runs under a domain user account, the SPN attribute is created on the domain user account under which the service runs. If the service runs under the Local System account, the service’s logon account is the computer account of the host computer.

**Connection Point Objects**

A connection point object is used in Active Directory to represent a service and to store information about that service. Connection point objects are derived from the **connectionPoint** schema class, which is the base class from which all objects representing connectable resources are derived. The following figure shows some of the object classes that are derived from the **connectionPoint** object class.

**connectionPoint Class and Derived Classes**

The following items are examples of objects that are derived from the **connectionPoint** class and that are used by various services to publish their availability on the network.

**printQueue and volume**

The **printQueue** and **volume** objects are the standard connection points that are used by print services and file services, respectively. These objects are used to help directory clients find available printers and shared volumes on the network.

**rpcEntry**

The **rpcEntry** object class is used by services that publish information about themselves by using the RPC Name Service (RpcNs) application programming interfaces (APIs). Typically, objects of this class can be found in a container in the domain directory partition whose distinguished name is similar to the following:

CN=RpcServices,CN=System,DC=cohovineyard,DC=com

**serviceInstance**

The **serviceInstance** object class is used by Windows Sockets (Winsock) services that publish information about themselves by using registration and resolution (RnR).

Typically, objects of this class can be found in a container in the domain directory partition whose distinguished name is similar to the following:

CN=WinsockServices,CN=System,DC=cohovineyard,DC=com

**serviceConnectionPoint**

The **serviceConnectionPoint** object class is most commonly used by application-oriented (rather than infrastructure) services that publish information about themselves in Active Directory. Examples of services that publish information about themselves by using service connection points (SCPs) include SQL Server 2000, Remote Installation Services (RIS), and Active Directory Application Mode (ADAM).

Active Directory does not define how the attributes of the **serviceConnectionPoin**t class are to be used; therefore, clients of a service that is published as an SCP must be able to interpret and use the data that is published in the SCP. Services that must publish additional data about themselves can extend the Active Directory schema by creating a subclass of the **serviceConnectionPoint** class and giving the subclass a distinct name.

The most important attributes of the **serviceConnectionPoint** class are **keywords**, **serviceDNSName**, **serviceDNSNameType**, **serviceClassName**, and **serviceBindingInformation**. Client applications search the directory for **keywords** values to locate a connection point object. When a connection point object is found, clients can read other attributes to retrieve service data. The most important attributes of the **serviceConnectionPoint** class are described in the following table.

**serviceConnectionPoint Attributes**

| Attribute | Description |
|---|---|

| | |
|---|---|
